- Epistaxis (see p. 357):
  - Inherited or acquired coagulopathies, including platelet and endothelial disorders
  - Infectious diseases:
    - Ehrlichiosis
    - Babesiosis
    - Leishmaniasis
    - Rocky Mountain spotted fever
  - Trauma
- Nasal discharge, obstruction, sneezing or reverse sneezing:
  - Foreign body
  - Granuloma
  - Infectious (fungal, bacterial) rhinitis or sinusitis
  - Tooth root abscess
  - Nasal mites
  - Allergic rhinitis

INITIAL DATABASE

- CBC
  - Inflammatory leukogram possible
  - Mild to moderate anemia that can be nonregenerative or microcytic
  - Erythrocytosis occasionally with fibrosarcoma
- Biochemical profile
  - Hypoproteinemia if severe hemorrhage (uncommon)
- Mandibular lymph node aspiration may show evidence of metastasis (10% of cases at diagnosis).
- Thoracic radiographs usually normal, but evidence of metastasis may be seen.

ADVANCED OR CONFIRMATORY TESTING

- Nasal imaging:
  - Plain radiographs: least sensitive, but dorsoventral intraoral and rostrocaudal frontal sinus views may identify loss of trabecular bone and increased density in the normally air-filled sinuses.
  - CT or MRI best identify and define the full extent of a tumor and can aid in distinguishing a tumor mass from fluid and surrounding tissues.
  - To avoid iatrogenic artifacts, imaging should be performed prior to biopsy whenever possible.
- Rhinoscopy may demonstrate a mass in the nasal cavity.
- Biopsy:
  - Blind transnasal core biopsy, with the location determined by previous imaging, provides the best samples.
  - Samples obtained with rhinoscopic guidance may be too small for accurate diagnosis.
  - Rarely, rhinotomy may be needed to obtain diagnostic samples.

TREATMENT

TREATMENT OVERVIEW

Because cure is usually not possible for nasal malignancies, alleviation of clinical signs becomes the focus of treatment.

ACUTE GENERAL TREATMENT

- Epistaxis:
  - Sedation
  - Packing of the nasal passages with epinephrine-soaked gauze
  - Application of cold compresses to the patient's nose
  - Ligation of the ipsilateral carotid artery (rarely needed)
- Nasal congestion, discharge:
  - Antimicrobials for secondary bacterial infections, based on a culture and sensitivity (C&S) test
  - Antiinflammatory medications (steroidal or nonsteroidal) may help but should be used cautiously.

CHRONIC TREATMENT

- External beam fractionated radiation therapy is considered definitive therapy.
  - Median survival 8-31 months depending on the report cited
  - Coarse-fractionated radiation therapy can be used for palliation.
- Chemotherapy may palliate clinical signs.
  - Carboplatin combined with piroxicam has shown the greatest response.
- Radiation therapy combined with chemotherapy does not increase survival over radiation alone.
  - Feline nasal lymphoma may be the exception.
- Surgery alone is not recommended, as it does not prolong life.
  - Surgery after accelerated radiation therapy had a reported survival of 16 months, but side effects were significant.

POSSIBLE COMPLICATIONS

- Radiation damage to the surrounding tissues will be seen acutely with mucositis, conjunctivitis, and dermatitis lasting about 2 weeks post radiation therapy. Chronic changes (late effects) can also be seen in the eye, brain, and nasal passages but are less common and should not severely affect quality of life.
- Tumor progression can cause central nervous system signs.

RECOMMENDED MONITORING

Primarily clinical signs; imaging (more than 3 months after radiation) may also be helpful.

PROGNOSIS AND OUTCOME

Varies with tumor type (animals with sarcomas generally live longer than those with carcinomas), clinical stage of tumor at time of treatment, and total dose of radiation delivered to the entire tumor. Median survival ranges from 8-31 months. Comparison of data from various reports is difficult, limiting its use to offer accurate prognoses. Feline nasal lymphoma can carry a good prognosis, with median survivals of >3 years.

PEARLS & CONSIDERATIONS

COMMENTS

- Treatment of nasal tumors with definitive curative-intent radiation therapy, with possible survival of as little as 8 months, may seem irrational. Most dogs, however, have survivals of about 1 year. Modern approaches to radiation therapy have led to decreased side effects, and most dogs tolerate therapy and have a good-quality life after therapy.
- Chemotherapy alone can also bring some relief from clinical signs, as can a more abbreviated palliative course of radiation. Even the use of piroxicam (COX-1 and COX-2 inhibitor) alone may give some relief from clinical signs for 4 months or longer (unpublished observations).
- In general, nasal tumors should be considered treatable even though they are not often curable.

PREVENTION

There is no means of preventing the development of nasal tumors.

TECHNICIAN TIPS

- While of low diagnostic yield, cytologic examination of nasal exudate can occasionally lead to a definitive diagnosis of the underlying cause of nasal disease.
- The plastic tubes that cover some IV catheters can be modified to attach a syringe and then used as a nasal biopsy instrument.

CLIENT EDUCATION

- Dogs with persistent nasal discharge may require advanced imaging to diagnose the cause of the problem.
- Acute effects of radiation therapy may not be apparent at the end of radiation therapy but can still develop within 1-2 weeks after the last dose of radiation has been administered. These acute effects often subside within an additional 1-2 weeks. Analgesics, antibiotics, and occasionally glucocorticoids can be used in animals experiencing severe acute effects of radiation therapy.

Nasal Mites

BASIC INFORMATION

DEFINITION

Infection of the nasal cavity with the mite *Pneumonyssoides caninum,* an uncommonly recognized cause of nasal disease in dogs

SYNONYMS

Pneumonyssus caninum, nasal acariasis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Nasal mite infection is primarily a disease of dogs; any age or gender can be affected.

GENETICS & BREED PREDISPOSITION: There are no known breed, sex, or age predilections.

RISK FACTORS: Contact with an infected animal.

CONTAGION & ZOONOSIS: *Pneumonyssoides caninum* has only been reported in dogs and foxes *(Vulpes vulpes).*

GEOGRAPHY AND SEASONALITY: Nasal mites appear to have a worldwide distribution with no seasonality.

ASSOCIATED CONDITIONS & DISORDERS: Nasal mites have been associated with gastric dilatation and volvulus.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- The most commonly reported clinical signs are reverse sneezing and sneezing.
- Other reported clinical signs include nasal discharge (typically serous), facial pruritus, head shaking, and hyposmia.
- Epistaxis and orbital cellulitis are uncommon presenting complaints.
- Many dogs have vague signs (restlessness) or are asymptomatic.

PHYSICAL EXAM FINDINGS

- Mites may or may not be observed on or around the external nares.
- ± Nasal discharge
- Epistaxis (rare)

ETIOLOGY AND PATHOPHYSIOLOGY

- *Pneumonyssoides caninum* are non-sarcoptiform mites found in the nasal and paranasal sinuses of dogs.
- Mode of transmission is currently unknown; however, it is thought to occur by direct transfer of larvae from dog to dog. Transmission has been reported between dogs housed together.
- The complete life cycle is unknown; however, adults and larvae have been identified in dogs.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis requires direct observation of the mites around the external nares or in the nares or nasal cavity.

DIFFERENTIAL DIAGNOSIS

Other causes of nasal cavity disease including foreign body, fungal rhinitis, noninfectious rhinitis, neoplasia, dental disease, coagulopathy and *Eucoleus boehmi* (nasal capillarid)

INITIAL DATABASE

- CBC:
  - Mild eosinophilia (nonspecific)
- Rhinoscopy and/or pharyngoscopy:
  - Direct visualization of nasal mites
- Retrograde nasal flushing:
  - Observation of mites in collected fluid

TREATMENT

TREATMENT OVERVIEW

Administration of drugs with acaricidal activity usually eliminates the infection.

ACUTE GENERAL TREATMENT

- Ivermectin, 300 mcg/kg PO weekly for 3 weeks
  - Ivermectin (or other macrocyclic lactones) should not be used in collies and other breeds with the MDR-1 mutation (see p. 706)
- Ivermectin, 200-400 mcg/kg SQ q 2 weeks for 3 treatments
- Selamectin (Revolution), 6-24 mg/kg applied topically q 2 weeks for 3 treatments.
- Milbemycin (Interceptor), 0.5-1 mg/kg PO q 7 days for 3 treatments. Safe for breeds sensitive to macrocyclic lactones.
- All dogs within the same household should be treated, as transmission is unknown but likely occurs by direct transfer between dogs. Cats do not require treatment, because *P. caninum* has not been reported in cats.

POSSIBLE COMPLICATIONS

Dogs with the MDR-1 mutation (ABCB1 −1Δ polymorphism) treated with macrocyclic lactones may experience ataxia, obtundation, hypersalivation, mydriasis, loss of menace, and possibly death. Alternative treatments such as milbemycin should be used for affected animals.

PROGNOSIS AND OUTCOME

Prognosis is excellent.

PEARLS & CONSIDERATIONS

COMMENTS

Nasal mites should be considered as a differential diagnosis for dogs with vague or nonspecific signs of upper respiratory tract disease in which imaging is unremarkable.

PREVENTION

Preventive measures have not been established.

TECHNICIAN TIP

Testing for the MDR-1 mutation (ABCB −1Δ polymorphism) can be accomplished by a PCR-based assay from a cheek swab. See p. 706.

CLIENT EDUCATION

Nasal mite infection is an annoyance more than a health threat to affected dogs.

AUTHOR: ERICK SPENCER

EDITOR: RANCE K. SELLON

Nasal Discharge

BASIC INFORMATION

DEFINITION

- Fluid discharge from the external nares
- Although usually obvious, the discharge can sometimes be missed due to licking or caudal drainage.
- The underlying etiology of the discharge can be intranasal or extranasal disease.
- The type and duration of the discharge varies with the underlying cause.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Younger cats may have viral upper respiratory infections (see p. 1127) or nasopharyngeal polyps (see p. 751).
- Younger unvaccinated dogs are more likely to have canine viral respiratory infections.
- Younger animals may have congenital deformities, such as a cleft palate.
- Older animals are more likely to have neoplastic or dental-related causes of nasal discharge.
- Hunting and working dogs are more likely to have nasal foreign bodies.

GENETICS & BREED PREDISPOSITION

- Brachycephalic breeds have upper airway problems that may lead to nasal discharge.
- Dolichocephalic breeds may be more prone to nasal neoplasia.
- Several specific breeds can be affected by primary ciliary dyskinesia or cleft palate-cleft lip complex (see pp. 916 and p. 218).

RISK FACTORS

- Lack of adequate immunization against viral respiratory infections
- Exposure to unvaccinated animals and high-density husbandry/housing situations
- Geographic locations where grass awns are ubiquitous
- Dental disease and poor dental care
- Immunosuppression (fungal disease)
- Compromise of nasal mucosa (secondary bacterial infections)
- Outdoor exposure (infection, foreign bodies, trauma)

CONTAGION & ZOONOSIS: Viral upper and lower respiratory tract infections.

GEOGRAPHY AND SEASONALITY: Geographic locations where grass awns are ubiquitous (dogs) or where there is lush green grass (blade of grass foreign bodies in outdoor cats)

ASSOCIATED CONDITIONS & DISORDERS: Sneezing

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Types of nasal discharge:

- Serous: clear and watery (acellular)
- Mucoid: clear and thick (acellular with high protein content)
- Purulent: yellow-tan and thick (neutrophilic with bacteria)
- Sanguineous: red-tinged (blood mixed with another type of discharge)
- Hemorrhagic (epistaxis): frank red blood

HISTORY, CHIEF COMPLAINT: Acute onset of paroxysmal sneezing or nasal discharge may suggest nasal foreign bodies or an early viral disease. Husbandry and management practices predispose animals to certain disorders. Examples: recent boarding or exposure to new animals (viral infections); hunting and geographic location (nasal foreign bodies); pertinent medical history (dental disease, history of neoplasia, immunosuppression); exposure to irritating aerosols (hairspray, paints, etc.); vaccine history (viral respiratory tract infections). A complete history should include:

- Recent exposure to new or young animals (infectious diseases)
- Environmental risk factors such as inhaled irritants, foreign bodies, exposure to rodenticides
- Pertinent medical history such as hypertension, current medications, or a history of neoplasia
- Vaccination status
- Acute versus chronic onset (acute onset more likely to be caused by foreign bodies and early viral infection)

PHYSICAL EXAM FINDINGS

- Serous, mucopurulent, or hemorrhagic discharge that may be unilateral or bilateral
- Concurrently possible, suggesting an intranasal or local problem:
  - Facial deformity
  - Exophthalmos
  - Tooth root abscess, oronasal fistula
  - Ocular discharge (e.g., with local disorders, such as an intranasal mass obstructing the nasolacrimal duct)
  - Pawing at face
- Concurrently possible, suggesting an extranasal or systemic problem:
  - Ocular discharge (e.g., with systemic infections, such as canine distemper)
  - Petechiation, ecchymoses
  - Cough, lethargy, inappetence (pneumonia, pulmonary hemorrhage, other)

ETIOLOGY AND PATHOPHYSIOLOGY

- Serous: due to local irritation, early viral infection, allergic rhinitis, or excessive lacrimation
- Mucoid: due to chronic noninfectious irritation and overproduction of mucus by nasal epithelial cells
- Purulent: usually due to secondary bacterial infection
- Sanguineous: due to compromise of the nasal mucosa
- Hemorrhagic (epistaxis): due to local or systemic causes of bleeding

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Nasal discharge is apparent on physical exam, though its onset and volume may be underestimated, since animals lick it away. The gross appearance of the discharge guides diagnostic testing.

DIFFERENTIAL DIAGNOSIS

- Feline viral upper respiratory tract infections (feline rhinotracheitis, feline calicivirus, *Chlamydia psittaci)*
- Neoplasia (adenocarcinoma, lymphosarcoma, undifferentiated carcinoma, osteosarcoma, chondrosarcoma, fibro-sarcoma, transmissible venereal tumor)
- Foreign bodies
- Tooth root abscess, oronasal fistula
- Nasopharyngeal polyps (cats)
- Canine viral infections (canine distemper virus, canine parainfluenza virus, canine herpesvirus, canine adenovirus, types 1 and 2)
- Mycotic infection *(Aspergillus* spp. in dogs; *Cryptococcus* spp. in cats)
- Parasitic rhinitis *(Cuterebra* spp., *Pneumonyssoides caninum, Linguatula serrata)*
- Bacterial infections (usually secondary)
- Rhinitis (allergic/eosinophilic type I hypersensitivity, lymphoplasmacytic, chronic hyperplastic)
- Congenital defects (cleft palate-cleft lip complex, primary ciliary dyskinesia)
- Trauma
- Inhaled irritants (cat litter dust, aerosols, smoke)
- Epistaxis (local causes: mycotic infections, neoplasia, foreign body, trauma; systemic causes: inherited or acquired coagulopathies, thrombocytopenia, thrombocytopathia, hypertension, vasculitides)

INITIAL DATABASE

- Physical assessment for unilateral versus bilateral nasal disease performed by holding a glass microscope slide close to the external nares while holding the animal's mouth closed. When the animal exhales through the nose, steam will be present asymmetrically or unilaterally (one naris obstructed) or not at all (both nares obstructed). Neoplasia, foreign bodies, and dental disease are often causes of unilateral nasal disease and discharge, whereas other local and systemic conditions often result in bilateral disease.

- Oral examination to look for hard palate masses
- Fundic examination to look for evidence of neoplasia, fungal disease, hypertension, and associated retinal hemorrhage
- Eye globe retropulsion to assess for retrobulbar masses
- Blood pressure measurement to assess for systemic hypertension
- CBC including platelet count to look for evidence of infection, inflammation, or thrombocytopenia
- Serum biochemistry profile
- Feline leukemia and feline immunodeficiency viral testing
- Thoracic radiographs (pneumonia, metastatic disease); pneumonia commonly causes mucopurulent nasal discharge, but the reverse process (primary nasal discharge causing a secondary pneumonia) virtually never occurs.

ADVANCED OR CONFIRMATORY TESTING

Any of the following may be indicated, depending on signalment, history, and preliminary exam findings: Rocky Mountain spotted fever, *Ehrlichia,* and *Bartonella* testing; prothrombin time; partial thromboplastin time; thoracic radiographs; nasal swabs; fungal titer determinations; nasal radiography; CT; MRI; rhinoscopy; biopsy; deep tissue cultures; and exploratory rhinotomy.

TREATMENT

TREATMENT OVERVIEW

- Eliminate underlying etiology of nasal discharge.
- Restore normal nasal function.
- Reduce pain and discomfort.
- Provide supportive care.
- Relieve dyspnea, especially in cats that often will not readily breathe with an open mouth.

ACUTE GENERAL TREATMENT

- If discharge is causing dyspnea, oxygen therapy may be needed.
- Treatment for underlying coagulopathy (e.g., vitamin K1; 0.25–2.5 mg/kg for first-generation rodenticide intoxication or 2.5 mg/kg for second-generation rodenticide intoxication, SQ or PO q 12 h × 7–28 days, and fresh frozen plasma transfusion)
- Correct dehydration and electrolyte abnormalities as necessary.
- Broad-spectrum antibiotics if secondary nasal/dental infection (bacteria are rarely the primary cause of nasal disease, but secondary infection with normal nasal flora is common) or pneumonia (culture and sensitivity [C&S] test for the lower airways is essential if pneumonia is present). *Bartonella* spp. have been recently implicated as a cause of chronic rhinitis and epistaxis; azithromycin appears to be the drug of choice (5–10 mg/kg PO q 24 h; start at 5 mg/kg and, if tolerated, increase by 2.5 mg/kg each day. After 1 week, reduce to q 48 h).
- Analgesics if painful (e.g., opiates such as buprenorphine, 0.006–0.01 mg/kg IV/IM q 6-8 h; nonsteroidal antiinflammatory drugs [NSAIDs] such as deracoxib, 1–2 mg/kg PO q 24 h, can also be used). Use NSAID analgesics with caution if the animal has a history of concurrent renal, liver, gastrointestinal, or hemostatic disorders.
- Clinicians should remove the animal from environmental agents (e.g., smoke, dust); if not possible, the clinician should introduce measures to reduce exposure (e.g., air filtration systems).
- Clinicians should consider recommending surgery for treating dental disease, neoplasia, nasopharyngeal polyps, cleft palate, foreign bodies, or traumatic causes.
- Rhinoscopy for removal of a foreign body
- Radiation and/or chemotherapy for neoplasia as appropriate (based on biopsy results)
- Chemoembolization of nasal tumors may be considered when surgery, radiation, or chemotherapy is associated with excessive morbidity, cost, or a poor outcome.
- Fungal: local or systemic treatment depending on type of mycotic infection
- Parasitic rhinitis: ivermectin, 0.2 mg/kg SQ or PO, twice during a 3-week period
- Decongestants and cleaning of the nares (e.g., topical pseudoephedrine [pediatric Neo-Synephrine, 1 drop in alternating nares once daily])

CHRONIC TREATMENT

- Nutrition: cats especially may not eat if unable to smell food. Consider feeding tube (e.g., esophagostomy; see p. 1267) for nutritional support.
- Analgesics
- Antibiotics for secondary infections
- In animals with chronic rhinitis, anti-histamines, inhaled corticosteroids, and systemic NSAIDs may provide some relief (see pp. 991 and p. 993).

POSSIBLE COMPLICATIONS

- Anorexia (especially in cats with severe nasal congestion)
- Keratitis (feline herpesviral upper respiratory infections)
- Upper airway obstruction following extubation after general anesthesia
- Hemorrhage following surgery or rhinoscopy
- Dehiscence of surgical site (e.g., cleft palate)
- Progression of underlying disease

RECOMMENDED MONITORING

- Respiratory rate and effort; ventilation and oxygenation
- Appetite
- Ongoing hemorrhage
- Volume and nature of discharge
- Monitoring as normal for antimicrobials and NSAIDs
- Appropriate laboratory testing or diagnostic imaging (packed cell volume, total solids, prothrombin time/partial thromboplastin time, etc.), depending on underlying disease

PROGNOSIS AND OUTCOME 

- Dependent on etiology
- Good if the underlying problem is canine viral upper respiratory tract infection or foreign body or if the animal has undergone a successful surgery or tooth extraction
- Guarded for feline chronic viral upper respiratory tract infections; low-grade nasal congestion and discharge, with periodic flare-ups, may become persistent or lifelong.
- Guarded to good for fungal rhinitis, depending on response to therapy
- Poor if neoplasia is not amenable to surgery and radiation therapy

PEARLS & CONSIDERATIONS 

COMMENTS

Determining whether nasal discharge is unilateral or bilateral is a simple but critical first step in diagnosis. Neoplasia, foreign bodies, dental disease, and other conditions are common causes of unilateral nasal disease and discharge; other local and systemic causes often result in bilateral disease.

PREVENTION

- Isolation of cats with viral infections
- Appropriate vaccination regime and retroviral testing
- Good dental care
- Limited exposure to irritating aerosols or materials

EDITOR: RANCE K. SELLON

Nasal Cutaneous Disorders

BASIC INFORMATION

DEFINITION

Dermatoses affecting the bridge of the nose (haired) or the nasal planum (hairless). This distribution of lesions is relatively common in dogs and cats, and lesions can be restricted to the nasal area or be part of a more generalized condition.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Affects dogs and cats
- Diseases more likely to appear in dogs <1 year of age: demodicosis, dermatophytosis, dermatomyositis, hereditary nasal parakeratosis, juvenile cellulitis
- Epitheliotropic (cutaneous) lymphoma is more commonly seen in older dogs.

GENETICS & BREED PREDISPOSITION

- Nasal parakeratosis: Labrador retrievers
- Zinc-responsive dermatosis: Alaskan malamutes, Siberian huskies
- Dermatomyositis: collies, Shetland sheepdogs, Beauceron shepherds
- Uveodermatologic syndrome: Akitas, Samoyeds, Siberian huskies, chow chows
- Systemic lupus erythematosus (SLE) and cutaneous (discoid) lupus erythematosus (DLE): collies, Shetland sheepdogs, German shepherds
- Nasal arteritis: Saint Bernards
- Alopecia and melanoderma: Yorkshire terriers
- Familial vasculopathy: German shepherds, Scottish terriers
- Acrodermatitis: bull terriers
- Lentigo simplex: orange cats
- Ulcerative nasal dermatitis: Bengal cat

RISK FACTORS

- Sun exposure can cause or aggravate canine and feline solar dermatitis, DLE, SLE, and pemphigus erythematosus.
    - Lack of skin pigmentation can predispose the patient to sun damage.
- Immunosuppression may predispose the patient to infectious diseases.
- Susceptible dogs fed diets high in phytates (high-cereal) or in minerals such as calcium can develop zinc-responsive dermatosis.
- Outdoor animals are more susceptible to contagious diseases.

CONTAGION & ZOONOSIS

- Dermatophytosis is contagious to other animals and is a zoonotic disease.
- Sporotrichosis (especially feline) has a zoonotic potential.
- Accidental inoculation of *Blastomyces dermatitidis* has been reported in people handling specimens from affected animals.

GEOGRAPHY AND SEASONALITY

- Animals living in sunny climates more commonly develop photoaggravated dermatitis.
- Animals living in areas endemic for leishmaniasis are susceptible to the disease.

ASSOCIATED CONDITIONS & DISORDERS

- Granulomatous uveitis in uveodermatologic syndrome
- Systemic disease in SLE
- Hepatopathy or glucagon-producing pancreatic tumor in superficial necrolytic dermatitis

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Presentation depends on the underlying disease:

- Nonpruritic hair loss confined to the bridge of the nose (e.g., localized demodicosis, localized dermatophytosis) or with a generalized dermatopathy (e.g., generalized demodicosis, dermatophytosis, endocrinopathies)
- Pruritus and facial rubbing, with secondary nasal alopecia in cases of allergic disease or intranasal foreign bodies (usually accompanied by sneezing and/or nasal discharge)
- Erosions and ulcers in cases of immune-mediated diseases or nodules and plaques (e.g., neoplastic, cutaneous histiocytosis, fungal diseases)
- Signs of systemic illness may be reported concurrently with generalized disorders (e.g., systemic mycoses, SLE, systemic histiocytosis).

PHYSICAL EXAM FINDINGS: Any of the following are possible, depending on etiology and severity:

- Nasal depigmentation or hyperpigmentation
- Alopecia
- Erythema
- Papules/pustules/vesicles
- Erosions/ulcers
- Crusts
- Hyperkeratosis
- Nodules/plaques

ETIOLOGY AND PATHOPHYSIOLOGY

Nasal lesions arise following various pathomechanisms, including:

- Infectious agents, which induce an immune response from the host, resulting in tissue inflammatory cell infiltrates (folliculitis, furunculosis, granulomatous lesions, etc.)
- Altered cornification process (proliferation, differentiation, or desquamation), resulting in hyperkeratosis
- Development of antibodies or activated lymphocytes against normal body constituents (autoimmune diseases) or against inciting antigens (drugs, bacteria, viruses), which leads to tissue damage
- Defective melanin production or destruction of melanocytes, leading to pigment disorders; a disturbance at the basal epidermal cell level can cause hypopigmentation.
- Solar exposure of poorly pigmented nasal skin, resulting in a phototoxic reaction (sunburn); immune-mediated diseases, such as pemphigus erythematosus, SLE, and DLE can also be photoaggravated.

DIAGNOSIS 

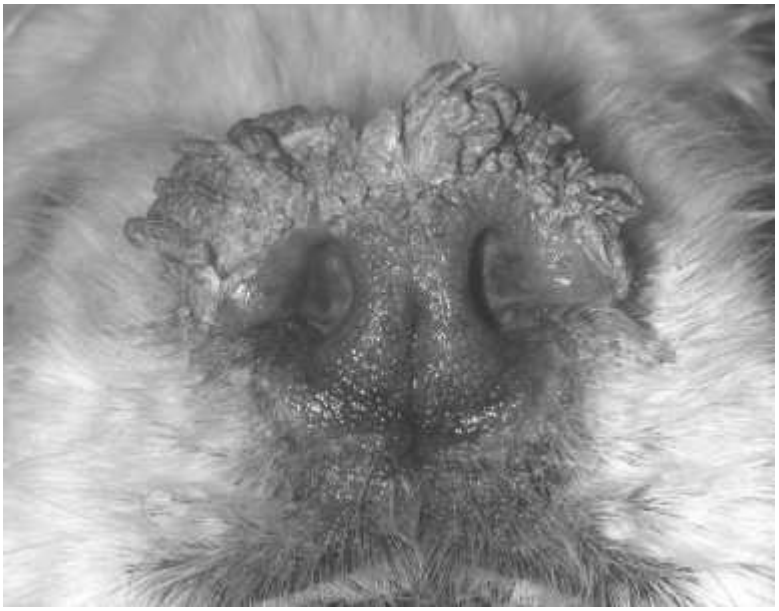
DIAGNOSTIC OVERVIEW

The presenting complaint of nasal cutaneous abnormalities warrants a dermatologic examination. Complementary testing then varies depending on the results of the dermatologic exam and resultant list of possible differential diagnoses.

DIFFERENTIAL DIAGNOSIS

- Infectious
  - Bacterial: mucocutaneous pyoderma, nasal pyoderma, feline leprosy
  - Fungal: dermatophytosis, sporotrichosis, cryptococcosis, blastomycosis, aspergillosis
  - Parasitic: demodicosis (bridge of the nose)
  - Protozoal: leishmaniasis
  - Rickettsial: canine Rocky Mountain spotted fever, canine ehrlichiosis
  - Viral: canine distemper, facial dermatitis associated with herpesvirus infection in cats
- Immune-mediated: pemphigus foliaceus and erythematosus, SLE, DLE, uveodermatologic syndrome, nasal arteritis, canine eosinophilic furunculosis of the face, feline mosquito bite hypersensitivity
- Hereditary (see Genetics and Breed Predisposition above).
- Pigmentary: nasal depigmentation (“Dudley nose”), seasonal nasal hypopigmentation (“snow nose”), vitiligo, alopecia and melanoderma, lentigo simplex
- Metabolic/endocrine: superficial necrolytic dermatitis (hepatocutaneous syndrome), canine hypothyroidism
- Nutritional: zinc-responsive dermatosis
- Environmental/traumatic: canine and feline solar dermatitis, contact dermatitis, local trauma

- Drug eruption: from topical or systemic administration
- Neoplastic: squamous cell carcinoma (SCC), basal cell carcinoma, epitheliotropic lymphoma, fibroma, feline “sarcoid,” and other such conditions
- Miscellaneous: idiopathic sterile granulomas and pyogranulomas, cutaneous and systemic histiocytosis, idiopathic nasal hyperkeratosis



NASAL CUTANEOUS DISORDERS Idiopathic nasal hyperkeratosis in a 14-year-old female cocker spaniel. Excessive keratin forms projections over the dorsal aspect of the nasal planum.

(Courtesy Dr. Nadia Pagé.)

INITIAL DATABASE

- Selection of diagnostic tests is based on history and physical examination.
- Wood's lamp (cats > dogs): dermatophytosis (fluorescent strains of *Microsporum canis)*
- Skin cytologic examination: phagocytized bacteria, inflammatory cells, acantholytic keratinocytes (pemphigus), fungal organisms
- Skin scrapings: *Demodex* spp.
- CBC/serum biochemistry profile/urinalysis (if concurrent systemic disease is suspected): results depend on underlying cause and are often normal or with nonspecific changes when cause is not systemic.
- Ocular examination (if vision loss or visible ocular lesions): uveitis (uveodermatologic syndrome). See p. 1313.
- Thoracic and abdominal imaging, if relevant, to confirm systemic disease or stage tumors

ADVANCED OR CONFIRMATORY TESTING

- Skin biopsies for histopathologic evaluation and possible immunofluorescence or irnmunohistochemical staining. Indicated when initial database is inconclusive and nasal lesions persist. Using general anesthesia, nasal planum lesions can be biopsied with a 3- or 4-mm biopsy punch. The lesion should be centered in the specimen. If possible, multiple specimens should be taken of primary lesions (e.g., pustules, papules, bullae). Crusted lesions or depigmented lesions can also be useful.
- Culture: bacterial, fungal (if evidence of bacterial/fungal infection, and if resistance to prior treatment)
- Antinuclear antibody (ANA) test: if SLE is suspected (see p. 1070)
- Endocrine or serologic testing if relevant

TREATMENT

TREATMENT OVERVIEW

- The goal of treatment is to achieve permanent cure or control of the disease. Topical treatment may be sufficient for localized and/or superficial skin disorders, whereas systemic therapy (ranging from simple to ongoing and intensive) may be needed when nasal cutaneous disorders are the first expression of a serious medical condition.

ACUTE AND CHRONIC GENERAL TREATMENT

- Treatment depends on the etiology of the lesions. Specific treatment is selected based on results of tests described above.
- If the animal has undergone prior recent treatment and a drug reaction is suspected, the animal should avoid contact with the offending medication.
- Infectious diseases may be cured with appropriate treatment. Other diseases may need chronic maintenance treatment.

PROGNOSIS AND OUTCOME

Variable, depending on the underlying disease

PEARLS & CONSIDERATIONS

COMMENTS

Skin biopsies are often needed for diagnosis of nasal cutaneous disorders.

TECHNICIAN TIP

Some nasal cutaneous disorders worsen substantially with sunlight. Be sure to take proper precautions (short walk, sunscreen, etc.) with patients with this type of problem.

PREVENTION

- Prevent sun exposure and use of sunscreens on poorly pigmented animals and/or with photoaggravated diseases.
- Discourage breeding of animals with hereditary diseases.

AUTHOR: NADIA PAGÉ

EDITOR: MANON PARADIS

Narcolepsy

BASIC INFORMATION

DEFINITION

- A syndrome in which abnormalities in the sleep/wake cycle are manifested as excessive sleepiness and cataplexy.
- Excessive sleepiness is characterized by waxing and waning drowsiness and abrupt onsets of falling asleep.
- Cataplexy is a brief episode of flaccid paralysis without altered consciousness, usually elicited by excitement or emotion.
- Cataplexy is the clinical sign most commonly seen in narcoleptic domestic animals, whereas excessive sleepiness is the more common sign in humans.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Narcolepsy has been reported in more than 17 canine breeds, cats, cattle, and horses.
- Age of onset of clinical signs is typically between 4 and 24 weeks of age in genetically narcoleptic dogs and between 7 weeks and 7 years in sporadically narcoleptic dogs.
- There is no apparent sex predisposition.

GENETICS & BREED PREDISPOSITION: Narcolepsy is inherited with autosomal recessive transmission in the Doberman pinscher, Labrador retriever, and dachshund and occurs sporadically in other breeds of dogs. Clinical signs are often most severe in small dog breeds.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Cataplexy is the most common clinical sign and is manifested by partial to complete paralysis that may involve all muscles or may be restricted to certain limbs or the head and trunk.
    - Consciousness is maintained at the onset of the attack; however, prolonged episodes may lead to rapid eye movement (REM) sleep.
    - The episodes typically occur spontaneously and are usually elicited by excitement, food, or play.
    - There is an abrupt onset as well as termination of the attack, and the attack may be disrupted by a loud noise or stimulation of the animal.
    - Episodes may last a few seconds to more than 30 minutes.
- Excessive sleepiness is characterized by prolonged periods of sleep, difficulty arousing the dog during sleep, and apparent drowsiness throughout the day.

PHYSICAL EXAM FINDINGS: Physical examination and neurologic examination are typically within normal limits.

ETIOLOGY AND PATHOPHYSIOLOGY

- The narcolepsy syndrome is associated with a deficit in hypocretin (orexin) neurotransmission.
- Hypocretin is an excitatory peptide neurotransmitter produced in the hypothalamus.
- Canine narcoleptics have normal amounts of hypocretin but lack the receptor to which it binds.
- Mutations in hypocretin-receptor-2 gene were found in the familial form (canarc-1), and losses of hypocretin ligand have been associated with sporadic canine narcolepsy.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is achieved by observing the cataplectic attack. The food-elicited cataplexy test and pharmacologic testing are helpful tools in eliciting the attacks.

DIFFERENTIAL DIAGNOSIS

Narcolepsy must be distinguished from other paroxysmal disorders such as epilepsy, syncope, myasthenia gravis, and metabolic disorders (hypoglycemia, hypocalcemia, etc.).

INITIAL DATABASE

Basic clinical pathologic and imaging studies are typically within normal limits.

ADVANCED OR CONFIRMATORY TESTING

- Cerebrospinal fluid may contain a decreased hypocretin-1 concentration (<80 pg/mL; the normal range is 250-350 pg/mL).
- The food-elicited cataplexy test (FECT) is performed by placing pieces of food at set intervals apart and timing the animal while it consumes the food.
    - A normal animal should be able to consume the food in a short period of time (<45 sec).
    - Narcoleptic animals may need more time (more than 2 min) to consume the food because of partial to complete cataplexy, which is evident on observation of the test.
- Mildly affected animals may need pharmacologic testing to confirm a cataplectic attack.
    - Physostigmine salicylate, a cholinesterase inhibitor that crosses the blood-brain barrier, is given (0.025-0.1 mg/kg IV). Physostigmine increases the chances of spontaneous or elicited cataplectic attacks within 5-15 min in susceptible animals. The side effects of this drug are excessive salivation and diarrhea.

TREATMENT

TREATMENT OVERVIEW

The goal of treatment is controlling cataplexy, because the impact of excessive sleepiness is less in dogs than it is in humans. This is achieved through the use of tricyclic antidepressants.

CHRONIC TREATMENT

- Cataplexy is treated with tricyclic antidepressants that act by blocking cellular norepinephrine reuptake in the central nervous system (CNS).
    - Imipramine (1 mg/kg PO q 8 h) has been used successfully in the long-term treatment of cataplexy. Imipramine also blocks serotonin reuptake.
    - Other tricyclic antidepressants used include amitriptyline (2.2-4.4 mg/kg PO q 24 h), desipramine, and protriptyline.
- Excessive sleepiness is treated with stimulant sympathomimetics such as methylphenidate (0.1 mg/kg PO q 24 h) or dextroamphetamine.
- Selegiline (2 mg/kg PO q 24 h) is a monoamine oxidase B inhibitor that has been an effective anticataplectic drug through its metabolism to amphetamine and methamphetamine and by increasing dopamine levels in the CNS.

RECOMMENDED MONITORING

Routine blood screening and cardiovascular evaluation prior to and periodically after the initiation of therapy with tricyclic antidepressants.

PROGNOSIS AND OUTCOME

- Cataplectic attacks are generally not life threatening, and although there is no cure, the clinical signs are usually successfully minimized with treatment.
- Some animals may improve with no treatment.

PEARLS & CONSIDERATIONS

COMMENTS

Abrupt withdrawal of medication can lead to increased cataplexy, so clinicians should warn clients not to discontinue medications quickly.

Ovarian Tumors

BASIC INFORMATION

DEFINITION

Ovarian tumors are uncommon, benign or malignant neoplasms arising from specific tissue in the female gonad. Tumor classification includes epithelial (adenoma, adenocarcinoma, carcinoma, cyst adenoma, cyst adenocarcinoma), germ cell (dysgerminoma, teratoma, teratocarcinoma), and sex cord (granulosa cell tumor, Sertoli, Sertoli-Leydig).

EPIDEMIOLOGY

SPECIES, AGE, SEX: Canine, intact females:

- Epithelial tumors: median age 9.6 years (adenomas, 10.5 years; adenocarcinomas, 9.3 years)
- Sex cord tumors: median age 8 years (granulosa cell tumor, 7 years; Sertoli, 5 years; Sertoli-Leydig, 12 years)
- Germ cell tumors: median age *6.4* years (dysgerminoma, 9 years; teratoma, 5 years; teratocarcinoma, 5 years)

Feline, intact females:

- Epithelial tumors: median age 10 years (cystadenoma, 10 years)
- Germ cell tumors: median age 6 years (dysgerminoma, 6 years; teratoma, 8 years)
- Sex cord tumors: median age 9 years (granulosa, 10 years)
- Epithelial tumors: 5% of all pathologic examination reports, no case reports
- Germ cell tumors: 15% of all pathologic examination reports, 50% of case reports
- Sex cord tumors: 31% of all pathologic examination reports, 50% of case reports

RISK FACTORS

- Intact reproductive status (presence of ovaries)
- Age

ASSOCIATED CONDITIONS & DISORDERS: Persistent estrus, hyperestrogenism (anemia and thrombocytopenia), pyometra and/or cystic endometrial hyperplasia are sometimes seen in association with epithelial and sex cord tumors.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Epithelial tumors (adenoma, adenocarcinoma, carcinoma, cystadenoma, cystadenocarcinoma)
- Sex cord tumors (granulosa cell tumor, Sertoli, Sertoli-Leydig)
- Germ cell tumors (dysgerminoma, teratoma, teratocarcinoma)

HISTORY, CHIEF COMPLAINT: Dog:

- Abdominal enlargement (adenomas, adenocarcinoma, granulosa cell tumor, dysgerminoma, teratoma, teratocarcinoma)
- Depression (dysgerminoma, teratocarcinoma)
- Estrous cycle abnormalities such as prolonged estrus (adenocarcinoma, granulosa cell tumor)
- Vaginal discharge and vulvar enlargement (adenocarcinoma, granulosa cell tumor)
- Incidental finding during ovariohysterectomy or necropsy (adenomas, teratoma)
- No common findings (Sertoli and Sertoli-Leydig cell tumors)
- Fever, pallor, weakness, and heart murmurs if pancytopenia secondary to estrogen myelotoxicity

Cat:

- Estrous cycle abnormalities such as persistent estrus (granulosa cell tumor)
- Depression (granulosa cell tumor)
- Incidental finding during ovariohysterectomy or necropsy (cystadenoma, dysgerminoma, teratoma)
- Fever, pallor, weakness, and heart murmurs if pancytopenia secondary to estrogen myelotoxicity

PHYSICAL EXAM FINDINGS

- Estrus (vaginal smear for cytologic examination)
- Vaginal discharge
- Abdominal enlargement/effusion
- Fever, pallor, weakness, and heart murmurs if pancytopenia secondary to estrogen myelotoxicity

ETIOLOGY AND PATHOPHYSIOLOGY

Clinical signs can be related to hormone production by sex cord tumors; the signs can also be related to organ impingement by space-occupying masses or metastasis for other types. Abdominal distension can occur secondary to carcinomatosis (abdominal effusion).

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

The diagnosis is expected if an older intact animal has persistent estrus, vaginal discharge, or abdominal enlargement. The diagnosis is aided by diagnostic imaging and is confirmed via surgery.

DIFFERENTIAL DIAGNOSIS

- Estrus
- Pyometra
- Gastrointestinal or other intraabdominal disease

INITIAL DATABASE

- Routine lab tests (CBC including platelet count, urinalysis, serum chemistry panel): generally unremarkable unless estrogen toxicity is present
- Vaginal cytologic examination
    - Confirmation of estrus
    - Assessment for pyometra or other infection

ADVANCED OR CONFIRMATORY TESTING

- Abdominal radiographs
- Abdominal ultrasound
- Abdominocentesis and fluid analysis
- Thoracic radiography for metastasis
- Exploratory surgery
- Histopathologic examination of tissue

TREATMENT 

TREATMENT OVERVIEW

Surgical excision is the most common treatment; however, chemotherapy has been used in some patients.

ACUTE GENERAL TREATMENT

Ovariohysterectomy. A unilateral ovariectomy has been reported, with a subsequent small litter resulting.

CHRONIC TREATMENT

- Chemotherapy should be considered if there is histologic evidence of vascular or lymphatic invasion or evidence of metastasis in the peritoneal cavity during surgery (carcinomatosis).
    - Cisplatin (not in cats) or cyclophosphamide and chlorambucil and nitrosourea have been used for treating metastatic carcinomas in a few dogs, resulting in a median 9-month survival.
    - Additional chemotherapeutics that can be considered include doxorubicin, carboplatin, and 5-fluorouracil. If effusions

are present, intracavitary chemotherapy may be indicated.

POSSIBLE COMPLICATIONS

- Metastasis
- Canine:
  - Epithelial tumors: adenomas and adenocarcinoma in 50% of cases according to pathologic examination reports
  - Germ cell tumors: dysgerminoma is rare; teratoma resulted at a rate of 50% in one study; teratocarcinoma is common
  - Sex cord tumors: granulosa in 30% of case reports
- Feline sex cord: granulosa, lung, liver, and spleen reported

RECOMMENDED MONITORING

- In dogs, enlargement of the abdomen and estrous cycle abnormalities (e.g., prolonged estrus, vaginal discharge, vulvar enlargement) should be monitored. The presence of fever, pallor, weakness, or heart murmurs may indicate pancytopenia secondary to estrogen myelotoxicity.
- In cats, estrous cycle abnormalities (e.g., persistent estrus) should be monitored. The presence of fever, pallor, weakness, or heart murmurs may indicate pancytopenia secondary to estrogen myelotoxicity.

PROGNOSIS AND OUTCOME

- Excellent if benign and no metastasis has occurred
- Unknown, but likely poor if distant metastasis or carcinomatosis is present at the time of diagnosis

PEARLS & CONSIDERATIONS

COMMENTS

May be unilateral or bilateral

PREVENTION

Ovariectomy or ovariohysterectomy

CLIENT EDUCATION

Ovariohysterectomy will eliminate risks of ovarian as well as uterine tumors.

AUTHOR: BRUCE E. EILTS

EDITOR: MICHELLE KUTZLER

Otodectic Mange

BASIC INFORMATION

DEFINITION

A contagious, primarily aural infestation caused by the mite, *Otodectes cynotis*

SYNONYMS

Otodectic acariasis, otoacariasis, ear mite infestation

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Very common in cats. Common in dogs.
- More commonly seen in puppies and kittens. May occur at any age.

RISK FACTORS: Contact with stray animals, shelter, boarding or grooming facility

CONTAGION & ZOONOSIS: Very contagious disease. Transmission by direct contact and via fomites. Very low zoonotic risk.

GEOGRAPHY AND SEASONALITY: Worldwide, nonseasonal

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Aural/periaural pruritus evidenced by head shaking and ear scratching. Asymptomatic carriage occurs.

PHYSICAL EXAM FINDINGS

- Otitis externa characterized by erythema and dark brown, ceruminous otic exudate (“coffee grounds”)
- Erosions, ulcers, crusts found on the inner pinna and the entrance of the external ear canal
- Occasional “ectopic” infestations evidenced by alopecia, erythema, papules and crusts of the periaural region, head, neck, feet and tail occur when mites escape from the ears.
- Cats may present with one or a combination of cutaneous patterns: erosive and crusting dermatosis of the head and neck, miliary dermatitis, symmetric alopecia, eosinophilic granuloma complex.
- Positive ear-pedal reflex is possible, particularly in cats: the animal scratches with ipsilateral hindlimb when ear canal is swabbed.
- Ear mites can be visualized by otoscopic examination, appearing as moving white specks.

OTODECTIC MANGE Gross appearance of a young cat with otoacariasis (otodectic mange) demonstrating the specs of characteristic exudate (“coffee grounds”) in the external ear canal.

OTODECTIC MANGE Microscopic appearance of ear mites from a cat *(Otodectes cynotis).*

ETIOLOGY AND PATHOPHYSIOLOGY

These psoroptiform, non-host-specific, nonburrowing mites can cause a hyper-sensitivity reaction by feeding on epidermal debris and tissue fluids on the surface of the external ear canal lining.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is established through historical and physical examination findings AND the visualization of mites and/or eggs on direct otoscopic or microscopic examination. If mites/eggs cannot be found, a positive response to treatment can be used for tentatively confirming the diagnosis.

DIFFERENTIAL DIAGNOSIS

- Hypersensitivities (atopic dermatitis, flea bite allergy, food allergy, contact allergic dermatitis, adverse drug reaction)
- Ectoparasites *(Sarcoptes,* fleas, lice)
- Otodemodicosis
- Bacterial and fungal otitis externa
- Neoplasia, polyps

INITIAL DATABASE

Microscopic examination of ear swab samples placed in mineral oil is the most effective method for identifying ear mites and eggs. Adult stages have four pairs of long legs. Males have suckers on short pedicles on all legs. Females have them only on the first and second pairs of legs. If the skin is involved, collect a minimum of three broad, superficial skin scrapings as well. Crusts and papules represent the best areas to scrape but mites may be hard to find.

TREATMENT

TREATMENT OVERVIEW

Treatment is achieved by cleaning the external ear canal with a ceruminolytic ear cleanser followed by the application of traditional topical (otic) products or more convenient systemic acaricidal products to the affected animal(s) as well as to all in-contact dog, cats, and ferrets.

ACUTE AND CHRONIC TREATMENT

- Topical (otic) acaricidal products
  - Thiabendazole (Tresaderm [Merial]) applied in affected ears q 12 h for up to 7 days. Off-label use (7 days on, 7 days off, and 7 days on) is more likely to effectively eradicate the mite infestation.
  - Ivermectin (Acarexx [Boehringer Ingelheim Vetmedica]) applied in affected ears in cats as young as 4 weeks of age. Single application as labeled may be suboptimal *(labeled in cat only).*
  - Milbemycin oxime (MilbeMite [Novartis]) applied in affected ears in cats as young as 4 weeks of age. Single application as label may be suboptimal *(labeled in cat only).*
  - Fipronil (Frontline Spot-on [Merial]): 2 drops applied in affected ears once or twice, 1 month apart (off-label)
- Any of the above topical otic treatments should be used in conjunction with an appropriate whole-body acaricide to eliminate ectopic mites.
- Systemic acaricidal treatment
  - Selamectin (Revolution/Stronghold [Pfizer]) and moxidectin (Advantage Multi/Advocate [Bayer]) are approved as topical (spot-on) products for ear mite treatment and prevention in dogs and cats; 2-3 doses administered 15-30 days apart may be necessary for optimal control.
  - Ivermectin (Ivomec [Merial]) or moxidectin (Cydectin [Wyeth]): 200-300 mcg/kg PO or SQ every 1-2 weeks for up to 4 treatments can be used (off label).
  - Whole-body acaricide treatments are not required when spot-on, PO, or SQ macrocyclic lactones (selamectin, ivermectin, moxidectin) are used.

DRUG INTERACTIONS

Off-label doses of ivermectin or moxidectin should not be used in sensitive canine breeds unless the MDR1 mutation is confirmed to be absent (seep. 706).

POSSIBLE COMPLICATIONS

Otitis media

RECOMMENDED MONITORING

Repeat ear swab and physical examination 1 month after first treatment if clinical signs persist.

PROGNOSIS AND OUTCOME

Excellent

PEARLS & CONSIDERATIONS

COMMENTS

- Other household pets such as ferrets can become infested.
- Ear mites can only be eradicated if all animals in contact are treated simultaneously.

PREVENTION

- Ear mites have a 3-week life cycle, a 2-month life span, and can live off the host for weeks. The environment may require thorough cleaning and treatment in cattery or kennel situations.
- When Revolution/Stronghold or Advantage Multi/Advocate is/are used as flea control, they have the added benefit of ongoing ear mite prevention.

TECHNICIAN TIPS

- The diagnosis may be falsely based on the typical appearance of the otic exudate alone, without visualization of parasites on microscopy. This is often misleading. It is important to distinguish an ear infected with yeast or bacteria from one infested with mites by performing a cytologic examination of swabbed ear exudate.
- Tresaderm should be refrigerated in the veterinary office for efficacy. Once given to owner, it can remain at room temperature for up to 7 days (cold drops are uncomfortable in a pet's ears). If treatment is prescribed for more than 7 days, dispense two bottles. Tell owners to keep one bottle out for 7 days, with the other bottle refrigerated until the first is discarded after 7 days.

CLIENT EDUCATION

Most pet owners have heard of ear mites and know they are common parasites. There is a tendency in the general public to see inflamed ears with discharge and assume it is an ear mite infestation, often leading to weeks of inappropriate treatment with over-the-counter treatments. These treatments have largely been replaced by far simpler veterinary products.

EDITOR: MANON PARADIS

Otitis Media/Interna

BASIC INFORMATION

DEFINITION

- Otitis media: inflammation of the middle ear
- Otitis interna: inflammation of the inner ear
- Otitis media/interna may be acute or chronic, may be unilateral or bilateral

SYNONYM

Glue ear = primary secretory otitis media

EPIDEMIOLOGY

SPECIES, AGE, SEX

- More common in dogs than cats
- Any age or breed, either sex

GENETICS & BREED PREDISPOSITION

- Breeds of dogs predisposed to developing otitis externa (e.g., cocker spaniels) may be predisposed to developing otitis media/interna.
- Cavalier King Charles spaniels: presumed inherited primary secretory otitis media

RISK FACTORS

- Dogs, otitis media/interna with otitis externa; three general categories of contributing factors for developing otitis externa: (1) morphologic and environmental (e.g., external ear conformation and high humidity); (2) primary causes (e.g., atopic dermatitis, disorders of keratinization, aural neoplasia, parasitic infection); (3) perpetuating factors (e.g., secondary infections, endocrinopathies)
- Cats, parasitic otitis externa (e.g., *Otodectes* sp.); feline immunodeficiency virus (FIV) infection (predisposes to dermatologic disease); feline leukemia virus (FeLV) infection (predisposes to neoplasia); nasopharyngeal polyps, upper respiratory tract disease

ASSOCIATED CONDITIONS & DISORDERS

- Facial nerve paresis/paralysis: common, otitis media
- Horner's syndrome: common, otitis media
- Peripheral vestibular disease: common, otitis interna
- Keratoconjunctivitis sicca: uncommon, otitis media
- Otitis externa: common in dogs, uncommon in cats
- Deafness or hearing impairment (see p. 280)
- Hypersensitivity disorders
- Neoplasia
- Sinonasal disease: more common than originally believed
- Nasopharyngeal polyps (dogs and especially cats): common in cats, rare in dogs
- Aural cholesteatoma: uncommon
- Meningitis/meningoencephalitis: uncommon
- Congenital palatine anomalies: rare

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: One or more may be present:

- Signs of otitis externa if concurrent otitis externa present (see p. 804)
- Vestibular signs: up to two-thirds of peripheral vestibular disorders can be attributed to otitis media/interna

- Deafness
- History and/or signs of upper respiratory disease (e.g., ocular and nasal discharge)
- Scratching of the head and upper neck region
- Head shaking
- Pain when opening mouth/reluctance to eat

PHYSICAL EXAM FINDINGS: One or combination of several:

- Distant examination:
  - General physical signs of systemic disease (e.g., lethargy, inappropriate body condition, etc.) if underlying systemic disease (e.g., lymphoma)
  - Focal aural or generalized dermatologic signs
  - Horner's syndrome if otitis media
  - Signs of vestibular disease if otitis interna
  - Facial asymmetry (otitis media)
- Otoscopic examination: see p. 804 and p. 1316
  - Abnormalities of the external ear canal if concurrent otitis externa
  - Abnormalities of the tympanic membrane on otoscopic examination (e.g., tympanic membrane rupture (many do not have obvious ruptured membrane), inward or outward bulging of the tympanic membrane, opaque and thickened tympanic membrane
- Neurologic and electrophysiologic examination:
  - Findings consistent with peripheral vestibular disease, facial nerve paralysis, and/or Horner's syndrome
  - Deafness (absent startle response [Preyer response]) unilaterally or bilaterally; abnormalities of the brainstem auditory evoked response (see p. 1216) (otitis media and/or interna)

ETIOLOGY AND PATHOPHYSIOLOGY

- Otitis media and interna often, though not always, occur together.
- Otitis media may develop through one of three different mechanisms:
  - Extension from otitis externa via the tympanic membrane: common (16% of acute otitis externa cases; up to 80% of chronic otitis externa cases)
  - Retrograde migration of infectious agents via the auditory (eustachian) tube
  - Hematogenous origin
- Otitis interna develops principally from extension of otitis externa/media

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A thorough history and clinical and neurologic examinations are important for differentiating otitis media/interna from other causes of peripheral vestibular disease, Horner's syndrome, and facial nerve paresis/paralysis. Confirmation is obtained with diagnostic imaging and during surgical intervention.

DIFFERENTIAL DIAGNOSIS

- Peripheral vestibular disease:
  - Strongly consider idiopathic vestibular disease if no signs of concurrent facial nerve paresis/paralysis and Horner's syndrome.
  - Nasopharyngeal polyps (cats ≫ dogs)
  - Ototoxicosis (to inner ear): when history of ototoxic drug exposure
  - Neoplasia (generalized with metastasis to middle/inner ear or focal within middle/inner ear)
  - Trauma
  - Syringomyelia may result in head shaking, neck and ear itching as only presenting sign and has been observed concurrently with secretory otitis media in Cavalier King Charles spaniels (seep. 184).
- Horner's syndrome (see p. 543)
- Facial nerve paresis/paralysis (see p. 376)

INITIAL DATABASE

- Distant and proximal, otoscopic, and neurologic examinations
- CBC, serum biochemistry, urinalysis (initial screen for systemic disease and for preanesthetic workup)

ADVANCED OR CONFIRMATORY TESTING

- Skin scrapings and ear swabs for determining if concurrent otitis externa present
- Myringotomy (tympanum puncture) with middle ear aspirates/swabs for Cytologie examination and bacterial and fungal culture and antimicrobial sensitivities
- Bulla radiography
- CT (seep. 1233) and/or MRI (seep. 1302) of the middle and inner ear

TREATMENT

TREATMENT OVERVIEW

Treatment should be aimed at treating the underlying cause of the disease (e.g., surgical removal of polyp or neoplasia).

ACUTE GENERAL TREATMENT

- In cases of acute otitis media/interna: identify inciting cause (e.g., migrating foreign body), and then treat the primary cause appropriately.
- If fluid/material present within the middle ear:
  - Medical:
    - Appropriate systemic, nonototoxic, antimicrobial therapy
    - Myringotomy will help relieve pressure and associated pain.
    - +/− Flushing the otic bulla (otitis media) with sterile saline solution to remove material, then instillation of appropriate nontoxic antimicrobials, and repeated weekly until ear canal and bulla is non-exudative on otoscopic examination
    - Appropriate systemic or topical nontoxic corticosteroids (reduce inflammation)
  - Surgical:
    - Ventral or lateral bulla osteotomy + appropriate antimicrobial therapy (cases where bulla effusion and/or masses are present)
    - +/− Total ear canal ablation when otitis media/interna concurrent chronic otitis externa

POSSIBLE COMPLICATIONS

- If underlying/concurrent disease not treated appropriately, chronic relapsing otitis media/interna may result.
- Extension of otitis media/interna may extend to involve the central nervous system.

RECOMMENDED MONITORING

Frequent reexamination to tailor therapy appropriately

PROGNOSIS AND OUTCOME

- Good to poor depending upon the cause and chronicity of the disease process before instituting treatment
- Hearing loss and neurologic signs may be permanent.

PEARLS & CONSIDERATIONS

COMMENTS

- Ensure patient is examined for underlying systemic disease.
- Treatment will only be successful after identifying and appropriately treating underlying cause.
- For patients that are deaf: these patients should not be off leash and may pose risk for biting unsuspecting person (i.e., from being afraid, startled, etc.).
- Dogs and cats with otitis media/interna may resent being handled around the head, especially with long-standing aural treatments; consider sedation or anesthesia for aural examinations.

PREVENTION

- Selective breeding
- Aural hygiene

CLIENT EDUCATION

- Clients should be informed that hearing loss and neurologic signs may be permanent.
- For deaf animals, ensure client knows animal should not be allowed to roam freely (hit by car) and that they may bite/injure unsuspecting people or dogs that startle them.

SUGGESTED READING

AUTHOR: AUBREY A. WEBB

EDITOR: CURTIS DEWEY

Otitis Externa

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

An acute or chronic inflammatory condition affecting the external ear canal

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Common in dogs, uncommon in cats
- Dogs: no sex or age predisposition

GENETICS & BREED PREDISPOSITION

- Idiopathic glandular hyperplasia: cocker spaniels, springer spaniels
- Hair within ear canal: poodles
- Pendulous pinnae: cocker spaniels, springer spaniels, Brittany spaniels, basset hounds, beagles
- Stenotic ear canals: English bulldogs, chow chows, shar-peis
- Cats: young cats may have ear mites, nasopharyngeal polyps; elderly cats may have neoplasia.

RISK FACTORS

- Frequent swimming
- Excessive ear care (including plucking hair)

CONTAGION AND ZOONOSIS

- Ear mites *(Otodectes cynotis* [see page 808]): primary cause of 50% feline otitis cases, 5%-10% in dogs. Commonly contagious between animals.
- Ear mites are rarely zoonotic, although close contact may cause pruritus on the arms or signs of otic discomfort.

GEOGRAPHY AND SEASONALITY

- May be more common in humid environments
- More common in summer months when associated with seasonal environmental allergies (atopic dermatitis), swimming, humidity.

ASSOCIATED CONDITIONS & DISORDERS

- Pyotraumatic dermatitis (seep. 30).
- Aural hematoma (seep. 120).
- Allergic disorders (see p. 106).
- Otitis media may be present in 16% and 82%, respectively, of acute and chronic otitis externa cases in dogs. The tympanum appears intact in about 70% of dogs with proven otitis media.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Head rubbing, ear scratching, or headshaking: common
- Unilateral otitis should raise suspicion for foreign object, polyp, or neoplasm.
- Owners may report odor or discharge from one or both ear canals.
- Head tilt if severe or if otitis media
- Hearing deficit
- Evidence of generalized skin disease possible. Foot chewing, face rubbing, or an obvious seasonality may suggest an underlying environmental or food allergy.

PHYSICAL EXAM FINDINGS

- Otic pruritus or headshaking
- Erythema and edema of the ear canal wall
- Otic discharge: brown-black coffee grounds (ear mites), brown or gray (complicated by *Malassezia),* white-yellow (ceruminous), yellow-green (complicated by bacterial infection)
- Abnormal otic odor
- Erosions and ulcers (most commonly associated with *Pseudomonas* infection, inappropriate cleaning/sampling, or reaction to topicals)
- Alopecia and excoriations on the pinna
- Chronicity: hyperplasia of the ear canal wall, and ceruminous and sebaceous glands leading to stenosis; thickened, nonpliable ear canals indicating mineralization, fibrosis, and stenosis
- Hearing deficits
- Pain when opening the mouth, facial nerve paralysis, hemifacial spasm, head tilt, nystagmus, and/or Horner's syndrome: suggest otitis media
- ± Mass within the ear canal
- ± Signs of generalized skin disease

ETIOLOGY AND PATHOPHYSIOLOGY

Otitis externa is a multifactorial problem. Its severity depends on the interaction of predisposing, primary, and perpetuating factors:

- Predisposing factors: increase the risk of developing otitis externa, such as conformation (congenital stenosis: shar-pei; excessive hair: poodles), lifestyle (grooming, swimming, excessive ear care), obstructive lesions (neoplasms, polyps), and systemic disease (fever, immune suppression, viruses, debilitation).
- Primary factors: incite the condition, such as foreign bodies, allergic disorders (atopic dermatitis, adverse cutaneous food or drug reaction), immune-mediated factors (pemphigus complex), parasites *(Otodectes,* chiggers, ticks), cornification disorders (idiopathic primary seborrhea), and glandular disorders (excessive cerumen/sebum accumulation, sebaceous adenitis).
- Perpetuating factors: prevent the resolution of the problem, such as organism overgrowth (bacteria, yeast), pathologic change (epidermal/glandular hyperplasia, stenosis, mineralization, otitis media), and overtreatment with topical ear medications.
- Pathologic changes permanently alter the microclimate within the canal, promoting colonization by opportunistic microorganisms that may produce further inflammation. As the inflammation progresses, dermal fibrosis followed by mineralization of the auditory cartilages and osseous metaplasia may be noted, leading to decreased flexibility, progressive stenosis, and finally obstructive ear disease.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

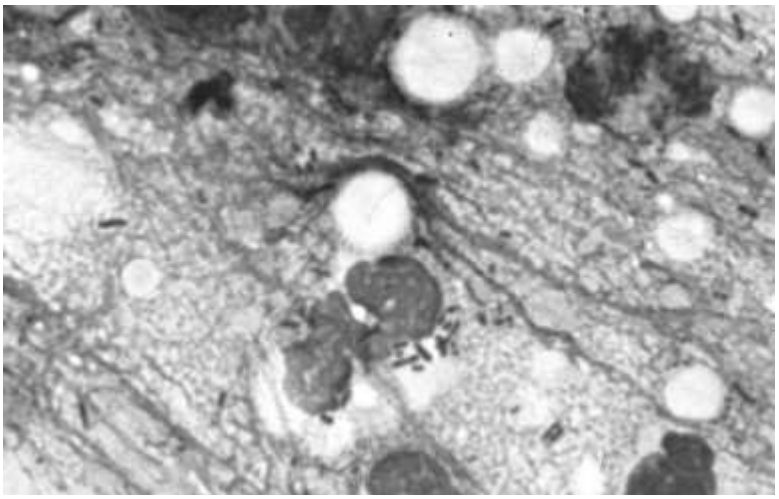
The diagnosis of otitis externa and assessment of severity are based on a thorough history, clinical examination findings, cytologic examination, and if indicated, the results of bacterial culture and susceptibility testing. Advanced diagnostic tests are selected for individual cases with evidence of otitis media, hearing loss, a mass lesion, systemic manifestations of allergic disease, or other complicating factor(s).

INITIAL DATABASE

- History and clinical examination of the ear canals and skin. A history of otic pruritus that precedes odor and discharge is suggestive of allergy. Examination of the vertical and horizontal canal for evidence of ulceration, hyperplasia, thickening, nonpliability, or discharge/debris. Examination of the tympanic membrane if possible (may require sedation/analgesia or general anesthesia).
- Ear canal cytologic examination (vertical canal/horizontal canal junction) for bacteria, yeast, inflammatory cells, and epithelial cells (acantholytic keratinocytes in pemphigus). Inflammatory cells are an important prognostic indicator and should be assessed at each recheck; considered abnormal, per high-power dry microscopic field (400x magnification): >5 *Malassezia* yeast and/or >25 bacteria (dogs), >12 yeast, and/or >15 bacteria (cats). In fall and winter (low humidity) in the northeastern United States, median numbers of cocci and yeast/HPF were <1 in normal dogs and cats. Rods were not seen.
- Bacteria or yeast in the cerumen or on epithelial cells with no inflammatory cells present indicates colonization, not infection, and specific antibiotic or antifungal treatment may not be appropriate.
- Bacterial culture, susceptibility, and minimum inhibitory concentrations (MIC): if bacterial rods are noted on a Cytologie examination or if antimicrobial resistance is suspected.
- The significance of culture and susceptibility testing results are difficult to assess without concurrent cytology.

OTITIS EXTERNA Pinna in a 9-year-old dog, showing the effects of otitis externa due to food allergy. The dog had a 5-year history of bilaterally symmetrical erythematous otitis externa and pinnitis.

(Courtesy Dr. D.W. Scott.)



OTITIS EXTERNA Cytologie examination of the ear canal in a 7-year-old American cocker spaniel with severe, suppurative otitis externa. Note nuclear streaming, degenerative neutrophils, and phagocytosed rods. *Pseudomonas aeruginosa* was isolated in culture.

(Courtesy Dr. D.W. Scott.)

ADVANCED OR CONFIRMATORY TESTING

- Video otoscopy (seep. 1310 : facilitates examination of the horizontal canal and tympanic membrane.
- Biopsy of the ear canal for histopathologic examination: rarely done and of minimal diagnostic value in chronic cases unless a neoplasm is suspected (e.g., visible mass)
- Radiography: fails to diagnose otitis media in 25% of proven cases
- CT (seep. 1233) and MRI (see p. 1302) are both superior to radiography for detecting polyps and neoplasms, distinguishing between fluid and tissue in the middle ear, and detecting otitis interna.
- Neurologic examination
- Brainstem auditory-evoked response (BAER) testing (hearing examination) (see p. 1216)
- Allergy testing: elimination diet trial: intradermal or serum allergy testing

TREATMENT

TREATMENT OVERVIEW

- The primary goal is reduction of ear canal inflammation (provides comfort for the patient, may help eliminate secondary organism involvement, and allows owner to clean and treat effectively). Treatment should be sufficiently thorough to avoid the development of chronic pathologic change. Clinicians should identify and treat all predisposing and perpetuating factors.

ACUTE GENERAL TREATMENT

- Inflammation, ulceration, and ear canal stenosis may preclude a thorough otoscopic examination even under general anesthesia. In such cases, supportive topical and/or systemic therapy is rendered on the basis of cytological findings. Otoscopic examination may then be accomplished on the recheck visit in 2 weeks.
- Polypharmaceutical products (antibacterial, antifungal, glucocorticoid combinations) are very useful in acute, uncomplicated cases: e.g., Animax, Otomax, Surolan.
- When strict antibacterial topical therapy is desired, chlorhexidine (Chlorhexiderm flush), gentamicin (Gentamicin Ophthalmic drops), and enrofloxacin-silver sulfadiazine (Baytril Otic) are useful: 5-20 drops, q 24 h to q 12 h, depending on patient size and disease severity.
- When strict antifungal topical therapy is desired, miconazole (Conofite) and chlorhexidine-miconazole (Malaseb flush) are useful options: 5-20 drops; q 24 h to q 12 h, depending on patient size and disease severity.
- Systemic antibacterial or antifungal therapy is indicated when marked inflammation, ulceration, stenosis, and/or pain are present. Systemic antibiotics are best chosen on the basis of culture and susceptibility testing. Systemic antifungals most often used are ketoconazole (10 mg/kg PO q 24 h with food) or fluconazole (10 mg/kg PO q 24 h with food).
- Antimicrobial therapy is continued for 1-2 weeks beyond cytological cure. In general, clinical cure precedes cytological cure by 1 to 2 weeks. Cytological examination every 2 weeks is a key to successful therapy.
    - Tris-EDTA (T8 solution) may increase the susceptibility of *Pseudomonas* and other gram-negative rods to topical antibacterials. The Tris-EDTA is typically instilled into the ear canal 15 minutes prior to the topical antibiotic.
- Glucocorticoids:
    - Systemic glucocorticoids (e.g., prednisone or prednisolone, 1 mg/kg q 24 h PO [dog] or prednisolone, 2 mg/kg q 24 h PO [cat]) may be necessary for the first 10-14 days of treatment when severe pain/pruritus are welfare issues or create pet/client compliance difficulties, or stenosis is preventing appropriate therapy or otoscopic examination.
    - Topical glucocorticoids are useful in the chronic management of otic allergies and ceruminous otitis: examples are HydroB 1020 (hydro-cortisone and aluminium acetate) or Synotic (fluocinolone and DMSO). Topical glucocorticoids must be administered no more frequently than q 48 h.
- Ear cleaning:
    - Flushing debris from the ear canal can be of great benefit. It should not be attempted in the face of severe inflammation, as it may lead to increased discomfort, erosion, and ulceration.
    - Ear cleansers can be detergent and ceruminolytic (Epi-Otic, Oti-Clens, Alo-Cetic, Routeen) or antimicrobial (Chlorhexiderm, Malaseb).
    - In general, ear cleaning is performed once or twice daily until no more debris is visible (typically 3-7 days). Cleaning is then performed once or twice weekly until terminated.
    - Excessive cleaning is a common *cause* of ear disease! All cleansers are liquids and keep the ear canal moist, macerated, and prone to microbial overgrowth and infection.
- Discouraging recurrent bacterial/yeast infections:
    - Recurrent bacterial (especially *Pseudomonas)* and yeast infections can be frustrating. In some instances, these are triggered by swimming (“swimmer's ear”).
    - The use of an astringent, acidifying, and antimicrobial topical such as acetic acid (1 part vinegar to 2-3 parts water) can be very useful. This solution can be applied after a day of swimming or once/twice weekly as needed. Do not use if erosions/ulcers present.

CHRONIC TREATMENT

- Once an ear has reached the obstructive or “end” stage, with palpable mineralization and complete occlusion of the external ear canal by hyperplastic tissue, surgical intervention and a total ear canal ablation (TECA) and bulla osteotomy may be indicated.
- In patients with medically resistant otitis externa, lateral ear resection may be useful if the horizontal canal is normal.

OTITIS EXTERNA Pinna in an American cocker spaniel showing end-stage otitis externa. Note the nodular proliferation of inflammatory tissue obliterating the ear canal.

(Courtesy Dr. D.W. Scott.)

POSSIBLE COMPLICATIONS

Paraaural abscesses and draining tracts, otitis media, and otitis interna may develop if otitis externa is not resolved.

RECOMMENDED MONITORING

Clinicians should reevaluate the patient every 2 weeks; the purpose is to assess response to therapy by noting improvement in clinical findings and performing ear cytologic examination.

PEARLS & CONSIDERATIONS

COMMENTS

- Since many ear problems are part of a generalized dermatologic disease, a full dermatologic examination is indicated as part of the evaluation.
- Complete resolution of ear problems is very unlikely unless predisposing, primary, and perpetuating factors are identified.
- Dogs and cats with atopic dermatitis or food allergy may present with signs of otitis externa only.
- Response to therapy should be based on degree of clinical improvement and cytologic examination results.

TECHNICIAN TIPS

- Samples for analysis (e.g., swabs for cytologic exam, bacterial culture) should be obtained prior to ear cleaning/medication, which otherwise dilutes and washes away the material of interest.
- Severe inflammation and signs of pain are contraindications to ear cleaning and should be brought to the veterinarian's attention first if ear cleaning was prescribed. Ear cleaning should not hurt.

Osteosarcoma

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Osteosarcoma (OSA) is a primary malignant tumor of mesenchymal tissue that always includes the production of bone (osteoid) by malignant osteoblasts. Appendicular OSA involves the limbs; axial OSA involves the remainder of the skeleton.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- In dogs, OSA accounts for up to 85% of all primary bone tumors:
  - Median age is 7-9 years, with a smaller peak incidence at 1.5-2 years of age.
  - There is no obvious gender predilection.
- In cats, primary bone tumors are uncommon, but OSA accounts for 70%-80% of those seen. OSA also rarely can occur in the soft tissues at sites of previous vaccinations.

GENETICS & BREED PREDISPOSITION

- Large- and giant-breed dogs are predisposed.
- Body size (height and weight) is a more important predictor than breed.
- Compared to small-breed dogs (weighing <10 kg [22 lbs]), the risk of OSA is 60 times higher in dogs weighing > 30 kg *[66* lbs], and 8 times higher in dogs weighing 20-30 kg (44-66 lbs).
- Appendicular OSA accounts for almost 95% of all cases in dogs weighing >40 kg but only 40%-50% of all cases in dogs weighing <15 kg.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Approximately 75% of OSA arises from the appendicular skeleton and 25% from the axial skeleton. Rarely, OSA can arise in the soft tissues (called *extraskeletal OSA).*
- Appendicular: in the forelimb, the distal radius and proximal humerus are most commonly affected. In the hind limb, lesions are evenly distributed between the distal femur, proximal tibia, and distal tibia.
- Axial: in the axial skeleton, the mandible, maxilla, vertebra, and ribs are most commonly affected.

HISTORY, CHIEF COMPLAINT

- Appendicular OSA usually is associated with progressive lameness. Lameness is less commonly acute and severe due to a pathologic fracture. A palpable swelling may or may not be present.
- Axial OSA can present with a variety of signs. Localized swelling with or without pain is common. Tumors arising from the mandible or maxilla can be associated with halitosis, dysphagia, pain on opening the mouth, or nasal discharge. Vertebral tumors may induce neurologic deficits. Rarely, rib tumors are associated with respiratory signs.
- If pulmonary metastasis is present, the first clinical signs usually are vague, including lethargy and anorexia. The animal may cough, but overt respiratory distress is uncommon. Rarely, lameness develops in one or more limbs secondary to hypertrophic osteopathy.

PHYSICAL EXAM FINDINGS

- Dogs with appendicular OSA exhibit lameness of variable severity, ranging from minimal to non-weight-bearing. A palpable swelling may or may not be present.
- Dogs with axial OSA can have variable physical examination findings (see History above). Signs of pain or discomfort are not as consistent as with appendicular tumors. Depending on the size and location of the tumor, a mass may or may not be visible or palpable.

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology is largely unknown, but it is often hypothesized that minor traumatic events incurred by weight-bearing bones induce mitogenic signals, increasing the probability of mutation and malignant transformation.
- OSA has also been associated with fractures, metallic orthopedic implants, chronic osteomyelitis, bone infarction, osteochondromatosis, and ionizing radiation.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is strongly suspected based on patient signalment, history, physical examination findings, and radiographic evidence of an aggressive bone lesion. Cytology can help further support the diagnosis, but confirmation requires histopathologic examination.

DIFFERENTIAL DIAGNOSIS

- Other primary bone tumors (chondrosarcoma, fibrosarcoma, hemangiosarcoma)
- Metastatic bone tumors (transitional cell, prostatic, mammary, thyroid, anal sac carcinomas)
- Tumors that locally invade adjacent bone (synovial cell sarcoma; histiocytic sarcoma; oral squamous cell carcinoma [SCC], melanoma, fibrosarcoma, ameloblastoma; digital SCC, melanoma)
- Hematopoietic tumors (myeloma, lymphoma). Radiographic lesions typically are purely lytic.
- Bacterial or fungal osteomyelitis

INITIAL DATABASE

- Radiographic imaging of OSA:
  - Aggressive bone lesions are associated with neoplasia and infection, and they are characterized by one or more of the following radiographic signs:
    - Presence of bone disruption, particularly involving the cortex
    - Bone lysis; permeative and moth-eaten patterns always are aggressive; geographic lysis can be aggressive or benign.
    - Nonhomogeneous, interrupted periosteal bone formation, or amorphous new bone deposited haphazardly in the soft tissues surrounding the bone
    - Ill-defined or indistinct transition zone between normal and abnormal bone
  - Appendicular OSA is usually located in the metaphyseal region of long bones. Extension across joints is uncommon.
- Following a radiographic or histologic diagnosis, animals should be completely staged.
  - CBC, serum biochemistry panel, urinalysis
  - Three-view thoracic radiographs:
    - <10% of animals will have visible pulmonary metastatic lesions at initial diagnosis.
    - Most dogs with OSA ultimately develop visible metastatic disease, even if the primary tumor is surgically removed, indicating metastasis has occurred prior to initial presentation.
  - <5% of dogs will have lymph node metastasis. Any enlarged regional lymph nodes should be evaluated with cytologic examination and/or histopathologic examination.

ADVANCED OR CONFIRMATORY TESTING

- Fine-needle aspiration (FNA) and cytologic analysis is a minimally invasive diagnostic that can help support a diagnosis of OSA.
  - FNA can be considered for lesions with associated cortical destruction. Ultrasound guidance can be used to aid sample collection.
  - cytologic analysis can distinguish between malignant and nonmalignant lesions with an accuracy of 70%-85%. In samples diagnostic for cancer, staining for alkaline phosphatase can help distinguish OSA from other bone tumors.
- Histopathologic examination is required to confirm the diagnosis of OSA.
  - An incisional biopsy can be performed using a Jamshidi bone marrow biopsy needle. Tumors are distinguished from benign lesions with an accuracy of 90%; the specific tumor type is diagnosed with an overall accuracy of 80%.
    - Based on radiographic images, biopsy core(s) should be taken from the lesion's center. Samples taken from the periphery are likely to be nondiagnostic, containing only reactive bone.
  - If signalment, history, and initial database all support a diagnosis of OSA, and if the owners are willing to treat aggressively, it is reasonable to surgically remove the local disease (limb spare or amputation), with biopsy submission following surgery.
- CT imaging is recommended for axial tumors to more accurately stage local disease and help with planning surgery and/or radiation therapy. If a patient is undergoing CT, concurrent imaging of the lungs is recommended as a more sensitive way to screen for pulmonary metastasis.
- Whole-body bone survey radiography and nuclear scintigraphy (i.e., bone scan) are not routinely recommended; however,

any suspicious lesions or painful areas should be imaged.

TREATMENT

TREATMENT OVERVIEW

Definitive treatment includes surgical removal of the primary tumor followed by adjuvant chemotherapy to help delay the onset of visible metastasis. Palliative therapy, which focuses primarily on pain control, is indicated when patients present with metastatic disease or when owners decline definitive therapy.

ACUTE GENERAL TREATMENT

- Surgical removal of the primary tumor:
  - Amputation is the standard treatment for appendicular OSA. Most animals function well after surgery; osteoarthritis is rarely a contraindication.
  - Several limb-salvage techniques exist, where the neoplastic portion of the affected bone is excised while sparing the remainder of the limb. Candidates should have tumors arising from the distal radius, distal ulna, or proximal femur, and the tumor should involve <50% of the bone, with minimal extension into the surrounding soft tissues.
    - Compared to amputation, limb-salvage techniques result in similar survival times but have much higher complication rates (infection, implant failure, local tumor recurrence).
  - For animals with axial OSA, wide surgical excision is recommended whenever possible. Complete excision is often more difficult because of the tumor's proximity to vital structures. When excision is incomplete, adjuvant radiation therapy may help improve local control.
- In the adjuvant setting, IV treatment with cisplatin (50-70 mg/m^2 every 3 weeks along with saline diuresis), carboplatin (250-300 mg/m^2 every 3 weeks), and/or doxorubicin (30 mg/m^2 every 2 weeks) extends disease-free interval and survival. Special handling requirements and potentially severe or life-threatening adverse effects for animals exist with all chemotherapeutic drugs; these concerns and rapid evolution of protocols warrant consultation with/referral to an oncologist.
  - Platinum drugs are more efficacious than doxorubicin.
  - Combinations of cisplatin/doxorubicin and carboplatin/doxorubicin have also been evaluated. There is no clear evidence that combination chemotherapy is superior to single-agent platinum therapy.
- A variety of palliative treatments can be used to help control the pain associated with the primary tumor. In general, multimodality therapy is more effective. Also, pain is easier to prevent than it is to reverse.
  - Nonsteroidal antiinflammatory (NSAID) choices include: aspirin (10-25 mg/kg PO q 8-24 h), carprofen (2 mg/kg PO q 12 h), deracoxib (1-2 mg/kg PO q 24 h; may use 3-4 mg/kg PO q 24 h for first 7 days only), meloxicam (0.1 mg/kg PO q 24 h), firocoxib (5 mg/kg PO q 24 h)
  - Other oral analgesic drugs include acetaminophen with codeine (Tylenol #4 [300 mg acetaminophen, 60 mg codeine]).
  - Pamidronate (1-2 mg/kg IV in saline over 2 h, q 3-4 weeks) decreases bone resorption, increases bone mineral density, and in 30% of dogs, decreases pain.
  - Palliative radiation therapy very effectively controls the pain associated with bone tumors. For animals with appendicular OSA, 75%-90% of animals have a noticeable improvement in lameness, with analgesia persisting for a median of 2-3 months.
  - Animals with pulmonary metastasis often benefit from oral glucocorticoids at antiinflammatory doses, such as prednisone, 0.5-1 mg/kg PO q 24 h (do not combine with NSAIDs).

RECOMMENDED MONITORING

Clinicians should evaluate animals every 2-3 months for evidence of local recurrence and metastatic disease. At a minimum, this includes a thorough physical examination and three-view thoracic radiographs. Imaging of the site of the primary tumor may be indicated as well, depending on location, completeness of excision, and clinical signs.

PROGNOSIS AND OUTCOME

- Most animals with OSA ultimately succumb to the effects of the primary tumor and/or metastatic disease.
- The lungs are the most common site for metastasis, followed by other bones and then various soft tissues.
- For animals with appendicular OSA:
  - With amputation alone, median survival is 4-5 months; the 1-year survival rate is 10%, and the 2-year survival rate is 2%.
  - When amputation or limb salvage is combined with adjuvant platinum-based chemotherapy, median survival improves to 10-12 months, and the 2-year survival rate improves to 15%-25%. When surgery is combined with single-agent doxorubicin, median survival is 8 months; the 1-year survival rate is 35%, and the 2-year survival rate is 17%.

        - Elevated serum alkaline phosphatase is associated with a poor prognosis. In addition, the prognosis may be even more guarded if alkaline phosphatase remains elevated in the postoperative period.
    - With palliative care alone, survival times are up to 4-5 months, depending on how well the pain associated with the primary tumor can be controlled.
    - Once metastatic disease is visible, survival times typically are <2-3 months regardless of therapy (palliative or aggressive).
- For most animals with axial OSA, prognosis is similar or more guarded depending on whether the primary tumor can be completely removed surgically.
- Mandibular OSA carries a better prognosis. With mandibulectomy alone, metastatic rate is around 30%, and median survival is around 17 months. There is no evidence that chemotherapy improves outcome.
- Nasal and digital OSA may also have a lower metastatic rate, but information is limited.

PEARLS & CONSIDERATIONS

COMMENTS

- Animals who are non-weight-bearing lame on a limb affected by OSA have already demonstrated the degree to which they will be able to ambulate after amputation.

Osteomyelitis

BASIC INFORMATION

DEFINITION

An acute or chronic inflammatory process of bone secondary to hematogenous or traumatic infection with pyogenic organisms

SYNONYM

Bone infection

EPIDEMIOLOGY

SPECIES, AGE, SEX: Young male dogs for traumatic osteomyelitis

GENETICS & BREED PREDISPOSITION: German shepherds for *Aspergillus*

RISK FACTORS

- Open fractures secondary to trauma, bite wounds, gunshot wounds
- Closed fractures or elective orthopedic procedures with direct or hematogenous contamination
- Extension of soft-tissue infections
- Immune system is compromised, allowing hematogenous dissemination

GEOGRAPHY AND SEASONALITY

- Blastomycosis and histoplasmosis: mid-Atlantic states, south of the Ohio River and east of the Mississippi
- Coccidioidomycosis in the southwestern United States and Central and South Americas
- Actinomycosis associated with migrating grass awns in summer in California and Florida

ASSOCIATED CONDITIONS & DISORDERS: Periodontitis, bulla osteitis, disco-spondylitis, and paronychia, depending on location of infected bone

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Orthopedic surgery, trauma, or travel (systemic fungal infection) may be in the recent history.
- Owner may have noted lethargy, anorexia, lameness, swelling, signs of pain, and cutaneous draining tracts.

PHYSICAL EXAM FINDINGS

- Acute osteomyelitis: fever, lethargy, anorexia, limb or joint swelling/pain, lameness
- Chronic osteomyelitis: draining tracts or fistulas, normothermia, disuse muscle atrophy, lameness, limb deformity

ETIOLOGY AND PATHOPHYSIOLOGY

- Neonatal osteomyelitis may originate from the umbilicus.
- Acute postoperative osteomyelitis presents with clinical signs 2-7 days after the surgery.
- Radiographic changes evident 2 weeks after trauma or surgery.
- Glycocalyx (biofilm) is formed on surgical implants after combining with bacteria. This produces a barrier that protects bacteria from antibodies and drugs.
- Between 50% and 60% of cases are monomicrobial, with *Staphylococcus* spp. most common (50%).
- Between 40% and 50% of cases are polymicrobial, with a mixture of aerobes and anaerobes.
- Up to 70% of cases are positive for anaerobes, including *Actinomyces, Clostridium, Bacteroides, Fusobacterium,* and *Peptostreptococcus* spp.
- Other common isolates are *Streptococcus, Escherichia colt, Pasteurella, Pseudomonas, Proteus,* and *Klebstella* spp.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- Diagnosis is suspected based on history, clinical and radiographic findings, and is confirmed with direct bacterial or fungal cultures.

DIFFERENTIAL DIAGNOSIS

- Bone infarct, neoplasia, cellulitis

INITIAL DATABASE

- CBC, serum biochemistry panel
- Craniocaudal and mediolateral radiographs of affected bone
- Thorax and abdominal radiographs if fungal etiology suspected
- Arthrocentesis (seep.1199) with cytologic examination; culture and sensitivity (C&S) test if joint involvement
- Aerobic and anaerobic C&S tests of deep fine-needle aspirates of tissues
- Fungal titers

ADVANCED OR CONFIRMATORY TESTING

- Ultrasound may reveal soft-tissue abscess or periosteal elevation
- Contrast fistulogram to localize source or sequestrum
- CT and/or MRI
- Radionuclide bone scan with technetium-99m will detect inflammatory lesions; more specific if performed with leukocytes labeled with gallium-67 or indium-lll, and best if animal has a confirmed leukocytosis
- Blood and/or urine cultures if systemic infection suspected

TREATMENT

TREATMENT OVERVIEW

- Treatment is based on identification and elimination of the source of infection. Infected fractures must be stabilized for healing to occur, and removal of infected bone may be necessary.

ACUTE GENERAL TREATMENT

- Acute osteomyelitis requires 4-6 weeks of antimicrobials based on C&S results.
- Initial antibiotics may be given IV.
- Since *Staphylococcus* spp. are most common, initial therapy can involve:
  - Clavulanic acid/amoxicillin: 10-20 mg/kg PO q 12h, *or*
  - Cefazolin: 10-30 mg/kg SQ, IM, or IV q 8 h; *or*
  - Clindamycin: 5-10 mg/kg PO q 12 h; *or*
  - Cloxacillin: 20-40 mg/kg PO q 8 h
- Definitive (medium- and long-term) antibiotic selection will depend on results of bacterial C&S.
- Choices for fungal osteomyelitis include itraconazole, ketoconazole, amphotericin B, and fluconazole

CHRONIC TREATMENT

- May require surgical exploration and removal of sequestrum (dead bone) with curettage of surrounding bone.
- Removal of loose implants, retention of stable implants, and possibly external fixation if additional stability is needed.
  - Fracture-associated infection will not clear unless fracture is stable.
- A cancellous bone graft may be indicated once the infection has subsided.
- Open drainage with lavage or closed drainage with ingress/egress
- Antibiotic-impregnated polymethylmethacrylate beads
- Animals should continue antibiotics for minimum of 6-8 weeks.

DRUG INTERACTIONS

- Clinicians should avoid administering aminoglycosides to animals with renal disease.
- Clinicians should avoid administering quinolones to skeletally immature dogs (risk of cartilage defects).
- Monitor renal values if on amphotericin B.
- Monitor hepatic values if on itraconazole or ketoconazole.

POSSIBLE COMPLICATIONS

- Bone abscess
- Bacteremia
- Fracture/limb deformity
- Implant failure(s)
- Cellulitis
- Draining tracts
- Delayed/nonunion
- Sequestra formation

RECOMMENDED MONITORING

- Radiographs at 4-6 week intervals to evaluate healing
- Clinicians can aspirate and reculture if animal shows signs of recurrence.

PROGNOSIS AND OUTCOME

- Acute osteomyelitis can be eradicated with early aggressive treatment.
- Chronic osteomyelitis can recur within weeks to years after the initial treatment.
- Fungal osteomyelitis may require several months of treatment, and outcome is guarded to poor.
- Involvement of joints may result in osteoarthrosis and limb disuse.

PEARLS & CONSIDERATIONS

COMMENTS

- Obtaining a culture only from the drainage tract can be confusing because contaminants (skin organisms and gram-negative bacteria) are common.
- Leukocytosis is common with acute disease; typically it is absent with chronic conditions.
- Antibiotic-coated implants are being used for prevention and treatment.

PREVENTION

- Aseptic surgical technique
- Appropriate antimicrobial prophylaxis and therapy

CLIENT EDUCATION

- Treatment of chronic osteomyelitis can be costly and lengthy.

TECHNICIAN TIPS

- Animals with active draining infections should be isolated to reduce possibility of cross-contamination of other surgical patients.

AUTHOR: MARY E. SOMERVILLE

EDITOR: JOSEPH HARARI

Osteochondrosis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Osteochondrosis is an abnormality of endochondral ossification, producing thickened cartilage that is susceptible to injury.
- Osteochondrosis produces a nonpainful thickening of cartilage, which may tear and loosen and thus develop into the painful and clinically overt osteochondritis dissecans (OCD).
- In turn, OCD may lead to osteoarthritis (see p. 796; also called *degenerative joint disease* [DJD]), a deterioration of articular cartilage and joint capsule tissues that leads to decreased joint function.
- It is a common heritable/developmental disorder in canines.

SYNONYMS

Osteochondritis, osteochondritis dissecans (OCD)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Fast-growing large-and giant-breed dogs
- More frequent in males
- First signs may appear at maximum growth rate (4-8 months of age)

GENETICS & BREED PREDISPOSITION: Predisposition within these breeds is seen in certain blood lines, but the mode of inheritance is unknown:

- Border collie, German shepherd, golden retriever, Great Danes, Irish wolfhound, Labrador retriever, Newfoundland, rottweiler, Saint Bernard, Bernese Mountain dogs, others

RISK FACTORS

- Genetic
- Rapid growth rate
- Excessive intake of calcium (Ca) with or without excess of phosphorus (P) and vitamin D and/or excessive intake of food
- Hormonal effects (i.e., male dogs, calcitonin)
- Increased joint loading and trauma from intense exercise

ASSOCIATED CONDITIONS & DISORDERS

- Hip dysplasia also occurs in dogs that eat an excessive amount of food.
- Disturbances in endochondral ossification also are seen in the radius curvus syndrome (elbow incongruity) and ununited bone protuberances (anconeal, coronoid, and supraglenoid processes, ununited medial epicondyle).

HISTORY, CHIEF COMPLAINT

- Young dogs with good general health (typically)
- Chief complaint is lameness:
  - Can be unilateral or bilateral
  - Variable degree of lameness
  - Variable duration of lameness
  - May become clinically overt after skeletal maturity
- History may include use of homemade diet or supplemented commercial dog food during the preweaning or postweaning period.

PHYSICAL EXAM FINDINGS

- Lameness as previously described; may manifest as a short-stepping gait if bilateral

- Joint pain, swelling, crepitus, decreased range of motion during flexion and extension
- Muscle atrophy of the affected limb(s).

ETIOLOGY AND PATHOPHYSIOLOGY

- Excessive intake of food with normal content of Ca, P, and vitamin D, increased Ca intake (with or without increased P intake with normal Ca:P ratio), or increased intake of vitamin D with normal Ca and P intake causes disturbed endochondral ossification in fast-growing (not miniature) dogs.
    - Increased protein intake (as in puppy food) does not disturb endochondral ossification.
- Disturbed endochondral ossification leads to cartilage thickening and retention of cartilage in the physis and articular epiphysis.
- The thickened cartilage impedes the diffusion of nutrients from the synovium.
- Tissue malnutrition, ischemia, and chondrocyte necrosis occur.
- Clefts develop at the junction of viable and nonviable layers.
- During normal joint motion and loading, vertical fissures develop in the articular cartilage and result in the formation of a cartilage flap.
- The flap may remain attached to the remaining cartilage tissue or may completely detach (“joint mouse”).
- Inflammatory mediators are released into the synovium, and DJD results.
- Osteochondrosis most commonly affects:
    - Shoulder: caudal humeral head
    - Elbow: medial humeral condyle
    - Hock (tibiotarsal joint): medial or lateral trochlear ridges of the talus
    - Stifle: lateral or medial femoral condyle
    - Also identified in the vertebral articular processes

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on the age (juvenile), breed (large/giant), history, diet, unilateral or bilateral lameness, and radiographic signs of subchondral bone erosion in typical locations.

DIFFERENTIAL DIAGNOSIS

- Shoulder joint: humeral or scapular fracture; biceps tenosynovitis, scapulohumeral luxation
- Elbow joint: fragmented coronoid process, ununited anconeal process, ununited medial epicondyle, incongruity, collateral ligament injury
- Stifle joint: cranial cruciate ligament rupture or avulsion, meniscal injury, collateral ligament injury, extensor tendon avulsion, patella luxation, femoral or tibial fracture
- Hock joint: collateral ligament rupture, fracture
- Radius curvus syndrome: shortening of antebrachium as in chondrodystrophy, curvature due to physeal (Salter type V) fracture

INITIAL DATABASE

- Radiographs of the affected and contralateral joints:
    - Indentation (flattening or saucer shape of the subchondral bone) at the lesion
    - Mineralized density within the joint may be present.
    - Varying degrees of osteoarthrosis
    - Subchondral sclerosis in advanced cases
    - Multiple orthogonal views may be required for accurate visualization.
- Dietary history including food intake and body condition score
- Blood Ca, P, and vitamin D concentrations at the time of clinical signs are not diagnostic.

ADVANCED OR CONFIRMATORY TESTING

- Contrast radiography or CT imaging may be necessary. Scintigraphy and MRI are uncommonly indicated.
- Arthrocentesis for synovial fluid analysis when joint swelling or effusion is present may be indicated. Mild increase in mononuclear cell counts with OCD and DJD.
- Arthroscopy (see p. 1200) can be used for direct visualization of lesion if radiography inconclusive; can also be used for treatment.

TREATMENT

TREATMENT OVERVIEW

- Treatment mainly consists of surgery (arthroscopy or arthrotomy) to débride the devitalized cartilage and stimulate new cartilage formation at the subchondral bone defect. Recent reports have described successful use of autogenous osteochondral grafts (plugs) in treating elbow and stifle joint lesions.
- Restoration of joint health
- Elimination of discomfort and lameness
- Education of clients to provide satisfactory nutrient intake in growing animals to prevent other joints from developing OCD
- Modify excessive activity in large juvenile breeds.

ACUTE GENERAL TREATMENT

- Conservative management:
  - Exercise restriction for 6 weeks
  - Clinicians can choose from the following NSAIDs (never give more than one at a time):
    - Aspirin: 10-25 mg/kg PO q 12 h
    - Carprofen: 2 mg/kg PO q 12 h
    - Etodolac: 10-15 mg/kg PO q 24 h
    - Deracoxib: 1-2 mg/kg PO q 24 h
    - Firocoxib: 5 mg/kg PO q 24 h
    - Ketoprofen 0.25 mg/kg PO q 24 h
    - Meloxicam: 0.1 mg/kg PO q 24 h
    - Tepoxalin: 10 mg/kg PO q 24 h (new product, objective data pending)
- Arthrotomy or arthroscopy to remove loose, discolored, thickened, or devitalized cartilage, cartilage flaps, and intraarticular osteochondral fragments
  - The ridge of the talus is NOT curetted, to avoid creating further joint instability.
  - Curettage and forage (drilling) of the subchondral bone lesion to optimize healing through stimulation of fibro-cartilage formation.

CHRONIC TREATMENT

- DJD (also degenerative osteoarthrosis) may occur at a later age; clinicians can treat the condition by preventing overload of the joint (by limiting activity and body weight gain) and administering NSAIDs as listed above.
- Nutraceutical agents:
  - Glucosamine hydrochloride, chondroitin sulphate, manganese ascorbate, and avocado/soybean unsaponifiables (Dasuquin [Nutramax Laboratories, Edgewood, Md]).
  - Glucosamine (clinicians should follow label instructions for oral dosing).
  - Chondroitin sulfate (clinicians should follow label instructions for oral dosing).
- Chondroprotective agents:
  - Polysulfated glycosaminoglycans (PSGAG): 4.4 mg/kg IM, twice a week for up to 4 weeks (maximum of 8 injections)
  - Pentosan polysulfate: intraarticular (5-10 mg/joint weekly); IM or SQ (3 mg/kg once weekly for 4 weeks); or oral (10 mg/kg weekly for 4 weeks, repeated every 3 months)
  - Hyaluronan: 3-5 mg intraarticular, once a week
- Nutraceutical agents, chondroprotective agents, and intraarticular hyaluronic acid should be considered because they help relieve discomfort, reduce degradative and inflammatory enzyme levels, and stimulate production of synovial fluid, proteoglycan, and collagen.
- Limitation/control activity to low impact.

NUTRITION/DIET

- Animals should avoid excessive intake of food, calcium (bones, bone meal, milk, tablets, powder), or vitamin D (drops, tablets, fish diets).
- Owners should avoid ad libitum feeding:
  - Volume of food should be based on the animal's body condition score.
- During growth, owners should feed their pets a commercially available dog food with a calcium content of <3.5 g/1000 kcal and energy density <4 kcal/g (<17% fat).
- Optimal calcium levels are found in purpose-made large-/giant-breed puppy foods; owners should not feed adult dog food to puppies.
  - Owners should not add supplements.
  - These feeding guidelines are especially important in the preweaning and postweaning periods.

- The lowest risk of diet-induced disease is found in animals whose body condition score is maintained at 2/5 during the period of growth.
- Owners should only use calculated energy requirements and manufacturer's recommendations as initial starting points for feeding, with amounts adjusted to maintain the desired body condition score.

DRUG INTERACTIONS

Intraarticular corticosteroid injections increase lesion severity and are contraindicated.

POSSIBLE COMPLICATIONS

- Untreated cartilage flaps irritate the joint and thus cause more DJD. In OCD of the shoulder joint, the flap can loosen and migrate into the biceps tendon sheath.
- Perioperative and postoperative:
  - Seroma formation due to excessive postoperative physical activity occurs commonly after arthrotomy.
  - Swelling from irrigating fluid leaking into the periarticular soft tissue may occur after arthroscopy.
  - Infection (uncommon)
  - Failure to remove all the osteochondral fragments
  - Tibiotarsal joint instability, not only due to aggressive curettage

RECOMMENDED MONITORING

- Multiple joints, including contralateral, may be affected and should be clinically and radiographically evaluated.
- If lameness persists, synovial fluid analysis, radiographs, arthroscopy, CT, or MRI may be indicated.

PROGNOSIS AND OUTCOME 

- Shoulder: good after treatment, even in cases with DJD. Most dogs become sound 4-8 weeks after surgery.
- Elbow: fair to good when cartilage damage is small in young animals and DJD is minimal. Fair to poor when combined with fragmented coronoid process and/or severe cartilage damage.
- Stifle: variable; a large lesion in a young animal may have a poor prognosis.
- Hock: fair; joint capsule thickening helps stabilize the joint, although residual instability will remain, and DJD should be anticipated.

PEARLS & CONSIDERATIONS 

COMMENTS

- Although the lameness may be unilateral, osteochondrosis often occurs bilaterally. Radiographs of the contralateral joint are indicated.
- Clinicians should make sure surgical curettage of the tibiotarsal joint is kept to a minimum to prevent further joint instability.

PREVENTION

- Owners should only breed animals screened for OCD (and other hereditary diseases); affected dogs and their relatives (parents and siblings) should not be bred.
- Diet management (see above)

TECHNICIAN TIPS

- Application of cold compress immediately after surgery and continued for the first 2-3 days will minimize swelling and inflammation.
- Application of heat compress is recommended after swelling and inflammation have subsided.
- Massage, physical, and hydrotherapy should be considered.

CLIENT EDUCATION

- Before purchasing a puppy, owners should become familiar with the weaker points of the breed in question.
- When a veterinarian knows that an animal's OCD occurs in high incidence, the veterinarian should inform the owner to buy a puppy of screened parents and preferably from a family with previously screened puppies that do not have any hereditary

bone diseases.
- Dietary management (see Nutrition/Diet above)
- Owners should give the puppy the time to grow and should not train their dog too heavily or too early.

Osteoarthritis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Progressive, noninflammatory, irreversible deterioration of articular cartilage

SYNONYMS

Degenerative joint disease, osteoarthrosis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Increasing prevalence with age

GENETICS & BREED PREDISPOSITION: Secondary to:

- Elbow osteochondrosis and dysplasia (rottweilers, Labrador retrievers, Bernese mountain dogs)
- Hip dysplasia (many breeds)
- Cranial cruciate ligament rupture (many breeds)
- Patellar luxation (toy breed dogs)
- Arthropathy in Scottish fold cats

RISK FACTORS

- Joint instability (hip dysplasia, cranial cruciate ligament rupture, trauma)
- Joint incongruity (elbow dysplasia, trauma)
- Obesity
- Work duty (dogs)
- Athletics (dogs)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Primary (idiopathic) osteoarthritis: unknown cause; not common in animals
- Secondary osteoarthritis: commonly results from trauma, joint instability, incongruity, immobilization, or osteochondrosis

HISTORY, CHIEF COMPLAINT

- Reluctance to ambulate
- Lameness and stiffness after excessive exercise or prolonged rest
- Irritable behavior when approached or touched

PHYSICAL EXAM FINDINGS

- Stiff or altered gait (e.g., bunny hopping)
- Lameness
- Abnormalities during joint manipulation (flexion and extension): joint pain, crepitus, instability, and/or decreased range of motion
- Joint effusion
- Joint thickening
- Muscle atrophy

ETIOLOGY AND PATHOPHYSIOLOGY

- Joint homeostasis is disrupted by abnormal cartilage and membrane cell functions, nutrition, or joint biomechanics.
- A catabolic imbalance results, with chondrocytes unable to replace degraded extracellular matrix (degradation via cytokines

and other inflammatory mediators).
- This cycle progresses irreversibly as the weakened biomechanical integrity of articular cartilage potentiates further dysfunction and disease.
- Periarticular fibrosis is a secondary process directed toward stabilizing the joint.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on signalment, history, and especially physical examination (lameness; thickened, painful joint); confirmation requires imaging, primarily radiographs.

DIFFERENTIAL DIAGNOSIS

- Infectious arthritis (bacterial, spirochetal, bacterial L-forms, mycoplasmal, rickettsial and ehrlichial, viral, fungal, and protozoal)
- Immune-mediated arthritis (erosive arthritis, nonerosive arthritis)
- Neoplasia (synovial cell sarcoma, osteosarcoma)

INITIAL DATABASE

- Clinical examination localizing joint pain
- Radiography: subchondral sclerosis, joint space narrowing, osteophytosis, enthesiophytosis, joint capsule thickening, subchondral bone attrition, intraarticular calcified bodies, soft-tissue calcification or subchondral cysts, bone remodeling, joint effusion

ADVANCED OR CONFIRMATORY TESTING

- Arthrocentesis and synovial fluid analysis:
  - Total cell count <5000 nucleated cells/mcL; mononuclear cells/macrophages predominate, <10% polymorphonuclear cells; fluid is clear, hazy, or pale yellow with normal to decreased viscosity.
- Arthroscopy to visualize articular cartilage
- CT may confirm joint incongruity.
- MRI may identify morphologic cartilage changes.
- Nuclear scintigraphy may help localize osteoarthritis.

TREATMENT

TREATMENT OVERVIEW

- The goal of treatment is to alleviate pain, improve function, limit disease progression, and facilitate joint reparative processes. Treatment is aimed at surgical correction of primary cause of osteoarthritis (CCLR, FCP, OCD); non-surgical management includes pain medication, exercise modification, and weight management.

ACUTE GENERAL TREATMENT

- Surgical treatment for cause of joint degeneration: repair of an articular fracture, removal of osteochondral lesion, stabilization of joint
- A nonsteroidal antiinflammatory drug (NSAID) to reduce inflammatory mediators and pain; one of the following NSAIDs (dogs):
  - Carprofen: 2 mg/kg PO, q 12 h
  - Deracoxib: 1-2 mg/kg PO, q 24 h (may use 3-4 mg/kg PO, q 24 h for first 7 days only)
  - Firocoxib: 5 mg/kg PO, q 24 h
  - Meloxicam: 0.1 mg/kg PO, q 24 h
  - Etodolac: 10-15 mg/kg PO, q 24 h
  - Aspirin: 10-25 mg/kg PO, q 8-24 h
  - Tepoxalin: 10 mg/kg PO, q 24 h
  - Meclofenamic acid: 1.1 mg/kg PO, q 24 h after eating, for 5 days maximum
- A chondroprotective agent:
  - Polysulfated glycosaminoglycan: 5 mg/kg IM once weekly for 4-6 weeks (dogs)
  - Pentosan polysulfate (from beech-wood hemicellulose): 3 mg/kg SQ once weekly (dogs)
  - Oral formulations (glucosamine, chondroitin sulphate, hyaluronan): according to formulation/labeled instructions

- Opioids (e.g., butorphanol, 0.5-1 mg/kg PO q 6-8 h) or synthetic opiate agonist (e.g., tramadol, 1-4 mg/kg PO q 8-12 h) if necessary to decrease pain
- NMDA receptor antagonist: amantadine, 3-5 mg/kg PO q 24 h given along with an NSAID

CHRONIC TREATMENT

- NSAIDs
- Cartilage modifiers
- Joint arthroplasty in severely affected hips, knees, and elbows
- Joint arthrodesis in severely affected joints
- Acupuncture

NUTRITION/DIET

Weight control to maintain a thin or non-obese body condition score

BEHAVIOR/EXERCISE

Exercise modification including low-impact activity such as leash walks and swimming, rather than unrestricted off-leash activity

DRUG INTERACTIONS

- Gastrointestinal irritation, hemorrhage, gastric ulceration, and perforation with NSAIDs
- NSAID-induced nephrotoxicity possible with hypovolemia or preexisting renal disease
- Hepatotoxicity with carprofen
- Decreased platelet aggregation with aspirin therapy

POSSIBLE COMPLICATIONS

Polysulfated glycosaminoglycan is a heparin analog; caution if given with NSAIDs to an animal with a bleeding disorder.

RECOMMENDED MONITORING

Clinicians should:

- Quantify muscle mass with palpation and tape measure.
- Measure range of motion with a goniometer during examination.
- Palpate joint effusion and for periarticular fibrosis.
- Monitor joint pain and gait during examination or with force plate analysis.
- Assess serial radiographs.
- Assess animal's attitude, appetite, body condition score, body weight, and activity level.

PROGNOSIS AND OUTCOME 

- Osteoarthritis is typically an irreversible, slowly progressive disease.
- Medical and/or surgical treatment may permit a good quality of life.

PEARLS & CONSIDERATIONS 

COMMENTS

- Radiographic signs of osteoarthritis may not correlate with clinical signs. Treatment decisions cannot be made on the basis of radiographic findings alone.
- Efficacy of cartilage modifiers is not as well documented as NSAIDs.
- Comparative efficacy of NSAIDs is debatable.
- Use of corticosteroids in place of NSAIDs is controversial; using both together is contraindicated because of severe, potentially life-threatening gastrointestinal ulceration.
- In cats, low-dosing regimens of mono-therapy with ketoprofen, meloxicam, or butorphanol have been described.

PREVENTION

Prompt recognition and early intervention may delay progression of disease.

TECHNICIAN TIPS

Slow leash walks with slings to support body weight (especially during rising) may improve dogs' comfort.

CLIENT EDUCATION

- Treatment is palliative (no “magic bullet”); disease will likely progress.
- Client participation is necessary for long-term management.

Oronasal Fistula

BASIC INFORMATION

DEFINITION

A connection between the oral and nasal cavities, usually resulting from severe periodontal disease. In dogs, this condition is almost invariably the result of oral disease extending dorsally and is virtually never caused by nasal disease extending ventrally.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Older small dogs, typically with narrow muzzles. Either sex.

GENETICS & BREED PREDISPOSITION

- Conformation of skull and predisposition to development of periodontal disease
- Breeds: miniature poodles, Chihuahuas, Yorkshire terriers, miniature schnauzers, dachshunds

RISK FACTORS: See Periodontal disease, p. 860.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Area of the maxillary canine tooth is most often affected. Oronasal fistulas are occasionally seen in the premolar area. A fistula may be present even though the tooth is still in place.

HISTORY, CHIEF COMPLAINT

- Acute: epistaxis after tooth extraction
- Chronic: nasal discharge, sneezing, halitosis

PHYSICAL EXAM FINDINGS

- Mucopurulent nasal discharge
- Typically, the canine tooth has been lost or was previously extracted.
- A defect is seen at the junction of the palate and mucosa of the lip, with oral epithelium connected to the nasal epithelium.
- In the occasional case in which the tooth is still present, the tooth typically is mobile and has severe plaque as well as calculus accumulation and deep pockets on periodontal probing.

ETIOLOGY AND PATHOPHYSIOLOGY

Periodontitis results in alveolar bone loss and loss of nasal epithelium separating the oral and nasal cavities.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is purely visual on physical examination. If uncertainty exists, oronasal communication can be demonstrated with injection of water into the fistula while the patient is intubated and under general anesthesia.

ORONASAL FISTULA Upper lip retracted to show a chronic oronasal fistula in the area of a missing right maxillary canine tooth in a dog *(arrow).* The maxillary incisors and most other maxillary teeth also are missing in this dog.

(Copyright Dr. Alexander M. Reiter.)

DIFFERENTIAL DIAGNOSIS

Other causes of chronic nasal discharge. Clinicians should ALWAYS remember to thoroughly examine the mouth and teeth of animals with nasal discharge.

INITIAL DATABASE

- CBC, serum chemistry profile, urinalysis (preanesthetic): generally unremarkable
- Thoracic radiographs: if the chief complaint, history, and physical examination findings raise the possibility of metastatic disease or of pneumonia

ADVANCED OR CONFIRMATORY TESTING

- Periodontal probing and dental radiographs (seep. 1246) will demonstrate the severity of alveolar bone loss.
- If the diagnosis of an oronasal fistula is uncertain, clinicians can inject water (via a syringe nozzle, not by needle) into the questionable area in the mouth while the dog is anesthetized (and while the nose is lower than the cranium) to look for flow of water from the naris.
- Clinicians should check other areas of the mouth, because periodontal disease is likely to be generalized and severe.

TREATMENT

TREATMENT OVERVIEW

Treatment consists of closing the oronasal fistula to prevent continued entry of food or fluid into the nasal cavity.

ACUTE GENERAL TREATMENT

- Under general anesthesia (and after tooth extraction in the area of the oronasal fistula if the tooth is still present), the first step is gentle irrigation of the tissue lining of the fistula to remove debris.
- Single buccal-based flap technique: creation of a flap of buccal mucosa sutured over the defect. The edges of the flap must be gently apposed to freshly incised edges of epithelium and be under no tension following closure. This requires dissection of the labial mucosa (epithelium and supporting connective tissue) from its maxillary attachments and also requires resection of the epithelium lining the oronasal fistula on the palatal side.
- Double flap technique: initially, a full-thickness mucoperiosteal palatal flap is raised but remains hinged at the medial margin of the defect. The flap should be transposed to cover the defect (palatine epithelium becomes “nasal” epithelium). Then a labial-based flap is raised, advanced, and sutured over the connective tissue side of the first flap.
- Treatment of periodontal disease in other areas of the mouth is important. This will often require extraction of other maxillary teeth on the same side; closure of these extraction sites can be combined with closure of the flap covering the oronasal fistula.

POSSIBLE COMPLICATIONS

Dehiscence: avoid tension as previously described.

PROGNOSIS AND OUTCOME

Excellent

PEARLS & CONSIDERATIONS

COMMENTS

- Clinicians should always examine the mouth and teeth of animals with nasal discharge.
- Gentle tissue handling will improve healing chances.

PREVENTION

See Periodontal Disease, p. 860.

CLIENT EDUCATION

See Periodontal Disease, p. 860.

Organophosphate and Carbamate Insecticide Toxicosis

BASIC INFORMATION

DEFINITION

Organophosphate (OP) and carbamate insecticides are used for controlling insects in agriculture, around the home, and on or around animals (e.g., for controlling fleas and ticks). Toxicosis results from dermal or oral exposure and is characterized by any combination of increased salivation, lacrimation, urinary incontinence, diarrhea, dyspnea, emesis (SLUDDE), bradycardia, tremors, shaking, ataxia, and seizures, and may be fatal.

SYNONYM

Acetylcholinesterase = cholinesterase

EPIDEMIOLOGY

SPECIES, AGE, SEX

- All breeds and both sexes susceptible
- Very young, elderly, or debilitated animals are more susceptible than healthy adult animals.
- Cats are particularly sensitive to chlorpyrifos; the onset of clinical signs is usually delayed (1-5 days) after exposure, and signs can last 2 to 4 weeks.

RISK FACTORS: Exposure to other acetylcholinesterase inhibitors

GEOGRAPHY AND SEASONALITY: Toxicosis more common in summer months (insecticide use); can occur year-round in areas where insects flourish throughout the year

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Known dermal or oral exposure to an OP or carbamate
- Recent history (usually within 24 hours prior to onset of clinical signs) of using an OP or carbamate insecticide in the yard or in the house
- Rapid onset of clinical signs (minutes to hours after exposure)
- Salivation, vomiting, diarrhea, lacrimation, dyspnea
- Tremors, muscle weakness, ataxia, seizures; acute death possible
- Cats may not show typical OP toxicosis signs from chlorpyrifos intoxication. Clinical signs, which begin 1-5 days after exposure, can consist of anorexia, depression, vomiting, tremors, salivation, ataxia, seizures, and ventroflexion of the neck.

PHYSICAL EXAM FINDINGS

- Muscarinic signs: SLUDDE, miosis, and bradycardia
- Nicotinic signs: muscle tremors, weakness, and paresis progressing to paralysis
- Central nervous system (CNS) signs: hyperactivity, depressed respiration, and seizures
- Note that muscarinic signs may be overridden by sympathetic stimulation, resulting in opposite effects (mydriasis, tachycardia, etc.).

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

- Organophosphates (OPs) are aliphatic carbon, cyclic, or heterocyclic phosphate esters. Carbamates are cyclic or aliphatic derivatives of carbamic acid.
    - Commonly used carbamates are aldicarb, carbofuran, methomyl, propoxur, and carbaryl (Sevin).
    - Commonly used OPs are disulfoton, acephate, terbufos, phorate, parathion, chlorpyrifos (Dursban), fenthion (Spotton), diazinon, and malathion

Mechanism of Toxicosis:

- OPs and carbamates competitively inhibit AChE by binding to its esteric site. Acetylcholine (ACh) then accumulates in the synapse and causes excessive synaptic neurotransmitter activity, leading to muscarinic, nicotinic, or CNS effects. Competitive inhibition of AChE explains the result of confirmatory testing with OP or carbamate toxicosis (low blood AChE level).
- Some OPs undergo "aging," rendering the phosphorylated (inactivated) cholinesterase enzyme very stable so that recovery of AChE activity occurs only through the synthesis of new enzyme. In general, inhibition of AChE by the OPs tends to be irreversible, while inhibition by the carbamates is reversible, which allows a spontaneous regeneration of the enzyme. Therefore, both carbamates and OPs respond initially to atropine, but only carbamates continue to do so. OPs become refractory to atropine treatment when they age.
- Atropine blocks the effects of the excess ACh at the neuromuscular junction. Atropine can only control the muscarinic signs (not the nicotinic signs).
- Death from either OPs or carbamates occurs secondary to respiratory failure from excessive bronchial secretions, bronchiolar constriction, paralysis of intercostal muscles or diaphragm, or respiratory paralysis (CNS effects).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A tentative diagnosis is based on history of exposure (recent use of pesticide on the animal or in the environment) and presence of one or several SLUDDE signs. Serum AChE levels are the clinical confirmatory test of choice, but treatment generally needs to be initiated prior to availability of results.

DIFFERENTIAL DIAGNOSIS

- Some *Solanaceae* family plants; anatoxin-a(s) found in some blue-green algae
- Muscarinic signs: muscarinic mushrooms, tremorgenic mycotoxins
- Nicotinic signs: nicotine, pyrethrins/pyrethroids, organochlorine-type pesticides, caffeine, strychnine, fluoroacetate (1080), 4-aminopyridine, metaldehyde, zinc phosphide, lead
- CNS signs: any disorder that can cause seizures (see p. 1009)

INITIAL DATABASE

- CBC, urinalysis (usually within normal range)
- Serum biochemistry profile: possible increase in liver and pancreatic enzymes with exposure to some OPs (disulfoton)

ADVANCED OR CONFIRMATORY TESTING

- AChE levels: serum, plasma, whole blood (preferred), brain, or retina:
  - An AChE result that is <50% of normal indicates significant exposure likely, whereas an AChE activity <25% of normal indicates toxicosis.
  - AChE activity can remain depressed for 6-8 weeks (with OPs).
  - Since carbamates are reversible inhibitors of AChE, the results may be normal even in the face of carbamate toxicosis. In such cases, the diagnosis rests on history of exposure and physical exam findings, although carbamate levels also may be measured.
- AChE insecticide screen: liver, kidney, gastrointestinal tract contents, and source material to look for specific insecticide.

TREATMENT

TREATMENT OVERVIEW

Triage identifies cases with life-threatening clinical effects on presentation, which are treated with atropine and pralidoxime (for OPs), ventilator support if hypoventilation, seizure control if needed, and supportive care. Decontamination (bathing, emesis, charcoal, gastric lavage) and other treatment measures are then carried out after the animal has been stabilized.

ACUTE GENERAL TREATMENT

- Clinicians should treat life-threatening signs if present:
  - Atropine sulfate (dogs/cats): 0.1-0.2 mg/kg; one-fourth dose IV and rest of dose IM or SQ to reduce muscarinic signs. The dose can be repeated as needed to control bradycardia and bronchial secretions.

    - Pralidoxime chloride (2-PAM; Protopam) (dogs/cats): 20 mg/kg IM, SQ, or very slow IV q 12 h is used for controlling the nicotinic signs, although some benefit also may be seen with controlling muscarinic and CNS signs. 2-PAM should not be used with carbamates, since it would not be beneficial; oximes reverse binding of toxin to AChE, but carbamate binding to AChE is inherently reversible. If the animal shows no response after 3 doses, the clinician should discontinue treatment with 2-PAM. Oximes such as pralidoxime are ineffective once OP "aging" has occurred. However, the time of aging varies with the compound, so pralidoxime may be effective even days after exposure.
- Seizure control:
    - Diazepam: 1-2 mg/kg IV, repeat as needed; *or*
    - Phenobarbital: 2-5 mg/kg IV bolus, repeated in 20 minutes up to two times. Clinicians can consider pentobarbital if this is ineffective.
    - Pentobarbital to reach desired effect; repeat as needed.
    - Controlling tremors: methocarbamol, 50-100 mg/kg IV. Clinicians can repeat as needed without exceeding more than 330 mg/kg/d.
- Oxygen supplementation and ventilatory support as needed for animals in respiratory distress.
- Decontamination of the animal: indicated once any potentially life-threatening hemodynamic, neurologic, and respiratory abnormalities have been addressed.
    - Dermal exposure: Consists of bathing the animal with a mild dishwashing liquid, then rinsing the coat thoroughly, and drying and keeping the patient warm.
- Emesis only in patients not showing clinical signs; usually effective within a few hours of ingestion (see p. 1364):
    - Apomorphine (0.03-0.04 mg/kg IV or IM; clinicians can instead administer a crushed tablet portion with water, instill into conjunctival sac, and rinse following emesis).
    - Hydrogen peroxide 3% (2 mL/kg, max 45 mL PO; repeat in 10-15 minutes if no vomiting).
- Gastric lavage:
    - Should be considered where a large amount of poison has been ingested or when emesis is contraindicated (comatose) and emesis has not occurred. Clinicians can anesthetize with a short-acting barbiturate and use a cuffed endotracheal tube to protect airway (see p. 1281).
- Activated charcoal:
    - 1-4 g/kg PO or labeled dosage of commercial product. In animals showing overt clinical signs, repeat in 8 hours (half the original dose).
- Supportive care: IV fluids as needed

NUTRITION/DIET

Tube feeding (see p. 1267) or other nutritional support may be necessary for cats who may be anorectic for days to weeks after being exposed to chlorpyrifos.

DRUG INTERACTIONS

Clinicians should avoid:

- Enhancing toxicity: phenothiazine tranquilizers (e.g., acepramazine), opiates, aminoglycoside antibiotics, theophylline
- Administering neuromuscular blocking agents: levamaisole, succinylcholine, nicotine, and curare can enhance the nicotinic effects of OPs.

POSSIBLE COMPLICATIONS

- Pancreatitis and hepatic disease have occurred in some animals after OP toxicosis.
- Certain OPs can cause a delayed neuropathy 2-3 weeks after acute poisoning. This complication is characterized by hind limb ataxia, hypermetria, and proprioceptive deficits. Chlorpyrifos (experimentally at high doses) is possibly associated with this neuropathy in cats.
- There are usually no long-term effects in animals that recover from acute OP or carbamate toxicosis unless there have been prolonged seizures.

RECOMMENDED MONITORING

- Heart rate
- Respiratory rate and effort, and lung sounds
- CNS signs

PROGNOSIS AND OUTCOME 

- Prognosis good unless the animal suffers from respiratory distress (excessive bronchial secretions, aspiration pneumonia) or

seizures
- Duration of signs depends on treatment, dose, compound, and species of animal

PEARLS & CONSIDERATIONS

COMMENTS

- The main difference of clinical importance between carbamates and OPs is that AChE inhibition is generally irreversible in cases of OP toxicity but reversible in cases of carbamate toxicity:
  - Pralidoxime (2-PAM, protopam) is indicated for treatment of OP toxicosis but not carbamate toxicosis (ineffective).
  - Carbamates are generally short-acting.
- SLUDDE signs can occur from several causes. If history of exposure to an anticholinesterase insecticide is not known, a test dose of atropine can be given to determine whether the signs are caused by an anticholinesterase (OP or carbamate) insecticide:
  - Record baseline heart rate.
  - Administer preanesthetic-level dose of atropine (i.e., 0.02 mg/kg IV for dogs and cats), and monitor the animal's response for 15 to 30 minutes.
  - If the heart rate increases and mydriasis occurs, then the muscarinic signs are not due to OP or carbamate toxicosis (it takes approximately 10 times the preanesthetic dose of atropine to resolve signs caused by cholinesterase inhibitor insecticides).
- For dead animals, the clinician can submit half the brain (sagittal section, frozen) to the lab (put the other half in formalin for histopathologic examination) but only if rabies is definitively ruled out (otherwise, the material could be hazardous to personnel during opening of skull and handling of tissue).
- With the availability of safer insecticides for controlling insects, the incidence of OP and carbamate toxicoses in animals has decreased
- See table for toxicity ratings:

LD50: dose that is lethal to 50% of exposed individuals.

Toxicity Ratings

Toxicity Rating	LD50	Substances
Highly toxic	<50 mg/kg	Disulfoton, coumaphos, famphur, phorate, terbufos, methomyl, aldicarb
Moderately toxic	50-1000 mg/kg	Acephate, chlorpyrifos, diazinon, carbaryl, phosmet, propoxur
Lower toxicity	>1000 mg/kg	Malathion, tetrachlorvinphos

CLIENT EDUCATION

Pet owners should use insecticides according to label directions and keep all insecticides away from pets.

Orbital Diseases

BASIC INFORMATION

DEFINITION

Orbital diseases encompass several conditions that frequently lead to an abnormal position of the eye within the orbit. These abnormal positions include exophthalmos (a forward displacement of the eye), enophthalmos (a caudal displacement of the eye), and strabismus (a deviation of axis of the resting eye position). Orbital diseases can be congenital or acquired.

SYNONYMS

Exophthalmia, enophthalmia, retrobulbar disease, orbital or retrobulbar abscess and/or cellulitis, orbital or retrobulbar neoplasia

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats
- Orbital abscess and/or cellulitis are more common in younger animals.
- Orbital neoplasia is more common in older animals.

GENETICS & BREED PREDISPOSITION

- Ocular proptosis (see p. 918) is more common in brachycephalic breeds.
- Myositis is more common in German shepherds, weimaraners, golden retrievers, and Labrador retrievers (masticatory myositis); extraocular polymyositis is more common in golden retrievers (seep. 704).
- Craniomandibular osteopathy is more common in West Highland white terriers.
- Congenital strabismus may be seen in shar-pei dogs as well as in Siamese and some shorthair cats.

RISK FACTORS: Chewing on sticks or other foreign material (orbital abscess)

ASSOCIATED CONDITIONS & DISORDERS

- Pharyngeal abscess (see p. 14)
- Masticatory myositis (seep. 704)
- Systemic mycoses (seep. 138)
- Nasal neoplasms (exophthalmia and/or strabismus) (see p. 749)
- Emaciation (enophthalmos)
- Dehydration (enophthalmos)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Sudden, progressive, or congenital change in position of the eye

PHYSICAL EXAM FINDINGS: Bilateral or unilateral:

- Exophthalmos with any or all of the following:
  - Reduced ability or inability to retropulse the globe within the orbit
  - Lagophthalmos (incomplete closure of the eyelids) with or without corneal ulceration (seep. 250)
  - Third eyelid protrusion (see p. 1089)
  - Conjunctival hyperemia, chemosis
  - Periocular swelling
  - Pain on opening the mouth (orbital abscess/cellulitis; myositis)
- Enophthalmos with any or all of the following:
  - Third eyelid protrusion (see p. 1089)
  - Ptosis (drooping upper eyelid)
  - Extraocular and/or masticatory muscle atrophy
  - Entropion
  - Emaciation may be noted, a component of which (the loss of orbital fat) may be the cause of enophthalmos.

- Strabismus:
  - Deviation of the eye(s): dorsal, ventral, medial, lateral, or a combination of these eye positions
  - ± Exophthalmos or enophthalmos
- Variable systemic signs depending on underlying cause
- Inflamed oral mucosa or draining fistula behind the last upper molar with orbital abscess

ETIOLOGY AND PATHOPHYSIOLOGY

- Exophthalmos: caused by space-occupying orbital lesion caudal to the eye:
  - Congenital:
    - Orbital varix, arterial to venous shunts: rare
    - Orbital cysts and dermoids: uncommon
  - Acquired:
    - Ocular proptosis: usually unilateral, peracute, trauma-associated (seep. 918)
    - Orbital abscess/cellulitis: usually unilateral, peracute to acute, painful resistance to ocular retropulsion and mouth manipulation
    - Orbital hemorrhage: secondary to coagulopathy or head trauma.
    - Orbital neoplasia: usually unilateral, progressive, typically not painful, primary or secondary, predominantly malignant
    - Orbital pseudotumor (cats): rare, progressive, fibrosing disease; restricts eye's mobility; may become bilateral condition
    - Mucocele: unilateral, progressive, arising from zygomatic salivary gland
    - Myositis: bilateral, enophthalmia occurring in late stages
- Enophthalmos: caused by loss of orbital volume or space-occupying lesion rostral to the eye:
  - Congenital: microphthalmos (see p. 778)
  - Acquired:
    - Phthisis bulbi (see p. 778)
    - Loss of orbital fat (older animals with weight loss) or muscle
    - Ocular pain
    - Dehydration
    - Horner's syndrome (seep. 1396)
    - Neoplasia anterior to the eye (e.g., rostral orbit)
- Strabismus; typically caused by lesions restricting extraocular muscle mobility or affecting their innervation:
  - Congenital:
    - Unilateral or bilateral, progressive juvenile fibrosis of the medial rectus muscle seen in Chinese shar-pei dogs
    - Bilateral medial strabismus (esotropia) in Siamese cats
  - Acquired:
    - Trauma-induced extraocular muscle avulsion or scarring
    - Extraocular muscle scarring from previous inflammation
    - Abnormal innervation of extraocular muscle(s) (e.g., cranial nerve [CN] III, IV, and/or VI lesions)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on the time frame of clinical signs, signalment, and clinical appearance of the affected eye. Orbital imaging may be necessary for a definitive diagnosis if the ocular globe is normal.

DIFFERENTIAL DIAGNOSIS

- Exophthalmos:
  - Buphthalmos, which is enlargement of the eye (seep. 448 or 1559)
  - Episcleritis/scleritis (see p. 356)
- Enophthalmos: ruptured globe (see p. 249)

INITIAL DATABASE

- Complete ophthalmic examination (seep. 1313)
- Complete neurologic examination if strabismus (see p. 1311)
- Oral examination if orbital abscess (buccal pain and/or purulent drainage)
- CBC, serum biochemistry profile, urinalysis, skull radiographs, chest radiographs, fine-needle aspirates of submandibular lymph nodes if enlarged, abdominal ultrasound if orbital neoplasia suspected

- CBC may reveal evidence of inflammation (bands, toxic changes in neutrophils) with orbital abscess
- Pharmacologic testing (topical 10% phenylephrine) for Horner's syndrome (see p. 1396)

ADVANCED OR CONFIRMATORY TESTING

- Ocular/orbital ultrasound if exophthalmos (assess for orbital abscesses or masses)
- CT or MRI if orbital masses suspected
- General anesthesia and ultrasound-guided fine-needle aspirates or biopsies of orbital mass, abscess, or mucocele
- Masticatory or extraocular muscle biopsies (see p. 1305) under general anesthesia (e.g., myositis; referable procedure)

TREATMENT

TREATMENT OVERVIEW

Although treatment of orbital abscesses and myositis may not require referral, treatment options for orbital neoplasia are likely to require referral to a veterinary ophthalmologist, surgeon, and oncologist.

- If possible, return the eye to its normal position.
- Alleviate pain.
- Preserve vision (optic neuropathy and/or retinal detachment may occur with space-occupying orbital lesions).

ACUTE AND CHRONIC TREATMENT

Treat underlying cause:

- Ocular proptosis (see p. 918)
- Orbital abscess:
  - Suspected if the oral mucosa caudal to last upper molar is abnormal; in such cases, medical stabilization (e.g., rehydration) is warranted if necessary, followed by surgical drainage via blunt dissection under general anesthesia; samples should be obtained for aerobic & anaerobic culture and sensitivity (C&S).
  - Systemic nonsteroidal antiinflammatory drugs (NSAIDs) for 7 days; may require longer depending on resolution of pain and inflammation.
    - Dogs: carprofen, 2.2 mg/kg PO q 12 h (may use single loading dose of 4 mg/kg SQ once) or meloxicam, 0.1 mg/kg PO q 24 h (may use single loading dose of 0.2 mg/kg SQ or PO once) for 5 days
    - Cats: tolfenamic acid, 4 mg/kg SQ, IM, PO q 24 h for 3-5 days
  - Broad-spectrum oral antibiotics for 14-21 days (amoxicillin-clavulanic acid, 13.5 mg/kg PO q 12 h [dogs] or 62.5 mg PO q 12 h [cats]). Amoxicillin-clavulanic acid is the first-choice antibiotic for this condition.
  - Hospitalization with supportive treatment for first postoperative 24-48 hours (if necessary)
- Orbital neoplasia:
  - Surgical excision (exenteration, orbitotomy, or orbitectomy); may require referral to a veterinary ophthalmologist or surgeon
  - Adjunctive radiation therapy or chemotherapy depending on type of neoplasm (consult veterinary oncologist or ophthalmologist).
  - Orbital pseudotumor:
  - Immunosuppressive therapy (e.g., corticosteroids; azathioprine) or radiation therapy
- Mucocele: surgical excision (typically curative); may require referral to a veterinary ophthalmologist or surgeon
- Myositis: prednisone, 1-2 mg/kg PO q 12 h, tapered gradually once response to treatment is noted (see p. 704). This is long-term therapy that should be tapered every 2-4 weeks pending response to treatment. Additional immunosuppressive drugs may be required if response to treatment is not seen within 1-2 weeks.

POSSIBLE COMPLICATIONS

- Permanent strabismus or third eyelid protrusion
- Blindness
- Loss of the eye
- Systemic complications possible (potentially severe), depending on extent of disease process

RECOMMENDED MONITORING

Weekly or bimonthly reexamination for inflammatory diseases

PROGNOSIS AND OUTCOME

- Favorable with orbital abscess if treated adequately
- Guarded with myositis
- Poor with orbital neoplasia

PEARLS & CONSIDERATIONS

COMMENTS

Orbital disease should be investigated in a timely fashion to alleviate discomfort and potentially preserve vision.

CLIENT EDUCATION

- Consult a veterinarian as soon as an alteration in position of the eye(s) is noted.
- Relapses can occur with myositis or when an orbital foreign body persists.

Oral Tumors, Malignant

Additional Images Available on Website

BASIC INFORMATION

DEFINITION

Neoplastic oral disease that is locally invasive and may metastasize to distant sites. Oral tumors comprise approximately 6% of all tumors in dogs and 10% of all tumors in cats.

SYNONYM

Malignant oral neoplasia

EPIDEMIOLOGY

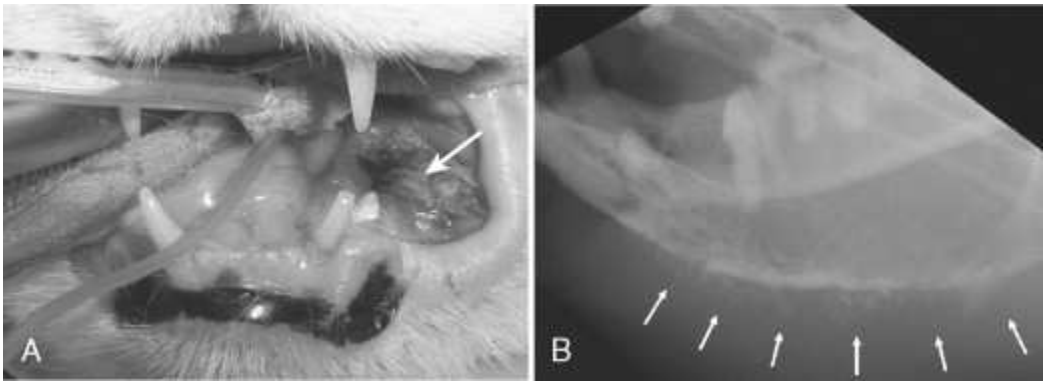
SPECIES, AGE, SEX

- Malignant oral tumors can occur at any age, but middle-aged and geriatric pets are overrepresented.
- Canine papillary squamous cell carcinoma (SCC) occurs most commonly in adolescent and young adult dogs.
- The most common canine malignant oral tumor is malignant melanoma (melanosarcoma;), seen most often in dogs >10 years of age.
- The most common feline malignant oral tumor is SCC (see p. 1045), representing 70% of oral tumors in cats. Average age of onset is 10 years, but cats as young as 5 months have been affected.

GENETICS & BREED PREDISPOSITION: Breeds with pigmented oral mucosa may be predisposed to malignant melanoma.

RISK FACTORS: Factors that increase the risk of feline SCC 3- to 5-fold:

- Exposure to flea collars
- High intake of canned cat food
- Regular ingestion of canned tuna



ORAL TUMORS, MALIGNANT A, Clinical photograph of a cat with squamous cell carcinoma affecting the left lower jaw *(arrow).***B**, Radiograph obtained with dental film of same patient (extraoral lateral oblique technique), showing severe lysis of left mandible and sunburst pattern at ventral mandibular border *(arrows).*

(Copyright Dr. Alexander M. Reiter.)

CONTAGION & ZOONOSIS: Canine transmissible venereal tumor (seep. 1114) can manifest as a primary or metastatic tumor on the lips, buccal mucosa, and tonsils.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Dogs: malignant melanoma, SCC, fibrosarcoma, osteosarcoma, osteochondrosarcoma (multilobular tumor of bone), mast cell

tumor, hemangiosarcoma, peripheral nerve sheath tumor, lymphosarcoma (epitheliotropic lymphoma)
- Cats: SCC, fibrosarcoma, osteosarcoma, hemangiosarcoma, malignant melanoma

HISTORY, CHIEF COMPLAINT

- Swelling of mandible or maxilla
- Oral bleeding, halitosis
- Dysphagia if the mass is large enough to affect masticatory function
- Appetite and activity level are often unaffected

PHYSICAL EXAM FINDINGS

- Specifics may vary with tumor type:
  - Malignant melanoma is pigmented (melanotic) or nonpigmented (amelanotic) and often lobulated, ulcerative, and friable; necrosis may be present when the tumor outgrows its blood supply.
  - Fibrosarcoma is often smooth and firm and may cause generalized disfigurement but rarely bleeds spontaneously.
  - Peripheral nerve sheath tumor tends to grow along larger nerves (e.g., infraorbital nerve into infraorbital canal and inferior alveolar nerve into mandibular canal).
  - SCC is pink, friable, often verrucous (cauliflower-like), and may be either proliferative or ulcerative. Desmoplasia (formation of fibrous tissue) secondary to SCC development may result in a firm tumor on palpation.
  - Osteosarcoma can manifest as a diffuse swelling of the maxilla or mandible but often also exhibits a fleshy, pink or red proliferative component that bleeds easily.
  - Osteochondrosarcoma is locally invasive but slow to metastasize and usually located at mandibular ramus, caudal maxilla, zygomatic arch, or calvarium.
- Halitosis, oral bleeding, facial/oral swelling
- Enlarged mandibular lymph nodes possible
- Maxillary, retroorbital and caudal pharyngeal masses: decreased ability to retropulse the eye globes and decreased range of jaw opening if rostral movement of the mandibular coronoid process is prevented by the tumor or if the tumor involves the temporomandibular joint.

ETIOLOGY AND PATHOPHYSIOLOGY

Etiology is unknown, but genetic predisposition may play a role.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis of malignant oral masses usually requires histopathologic analysis of a biopsy, since many oral masses do not exfoliate well on fine-needle aspirates. Incisional (rather than excisional) biopsy is the preferred initial step for suspected malignancies in order to provide the clinician and client with further information prior to deciding on radical surgery and/or radiation therapy.

DIFFERENTIAL DIAGNOSIS

As for benign oral tumors (see p. 786)

INITIAL DATABASE

CBC, serum biochemistry profile, urinalysis, and thoracic radiographs: to assess for metastases, concurrent illnesses

ADVANCED OR CONFIRMATORY TESTING

- Anesthetized oral examination
- Dental radiography
- CT: particularly helpful for maxillary and caudal mandibular masses
- Cytologic examination of oral masses (fine-needle aspiration, “woodpecker” technique, or scraping from tumor cut surface)
- Cytologic examination of aspirated material or histopathologic examination of resected lymph nodes
- Histopathologic evaluation of incisional or excisional biopsy

TREATMENT

TREATMENT OVERVIEW

- Merely debulking aggressive tumors is rarely helpful. Once a diagnosis is obtained, the mass together with a margin of normal surrounding tissue should be removed comprehensively to prevent local recurrence.
- If complete removal is not an option, radiation or chemotherapy may decrease the rate of growth, depending on tumor type.

ACUTE GENERAL TREATMENT

- Removal of a circumscribed mass to the normal level of the surrounding gingiva will often serve as an adequate biopsy but may not prevent local recurrence. Incisional biopsies of large masses are warranted to provide information prior to performing a radical maxillectomy or mandibulectomy.
- Aspiration and/or removal of head and neck lymph nodes are warranted for staging of animals with malignant oral tumors.

CHRONIC TREATMENT

- Depending on biopsy results and tumor extent, radical surgery and/or radiation therapy may be treatment options. Even when surgery is an option, consult with a medical oncologist and/or radiation oncologist regarding the need for adjuvant or postoperative treatment. Chemotherapy may be used as an adjunctive therapy but is rarely effective by itself against most oral tumors. Immunotherapy of certain tumors shows great promise, and a commercially available melanoma vaccine is available through oncologists (see p. 711).
- Radiation therapy offers good long-term control for treatment of microscopic disease, but bulky tumors rarely respond well.
- Piroxicam, 0.3 mg/kg PO q 24 h in dogs may slow the progression of some carcinomas. Short-term (10 days) use of piroxicam in cats appears to be safe at 0.3 mg/kg PO q 24 h. Further studies are necessary to determine long-term gastrointestinal safety in cats. If prescribed long-term for cancer palliation, the author prescribes 0.3 mg/kg q 48 h.

NUTRITION/DIET

Soft food/esophagostomy tube if necessary because of inability to prehend or chew food

DRUG INTERACTIONS

Piroxicam and other NSAIDs may cause significant gastric ulceration; clinicians should avoid concurrent use of corticosteroids and consider gastric protectants such as misoprostol.

POSSIBLE COMPLICATIONS

- Recurrence of primary tumor. Surgeons should remove at least 1 cm of clinically and radiographically healthy tissue surrounding malignant tumors. Many locally aggressive tumors (fibrosarcoma, peripheral nerve sheath tumor, malignant melanoma) require even wider margins.
- Intraoperative or postoperative bleeding: having blood products available is important with mandibulectomy and maxillectomy procedures.
- Dehiscence of the surgical site: avoid using electrocautery on mucosal edges because it can obscure histologic examination of margins of excised tissue and increases the likelihood of wound dehiscence, which may result in the need for further surgical intervention (such as repair of an oronasal fistula).
- Sublingual or cervical mucoceles may occur if transection of salivary ducts is necessary; these ducts should be ligated if transected.

RECOMMENDED MONITORING

- Oral examination to monitor for local recurrence 1 month after surgery and at a maximum of 6-month intervals thereafter.
- Thoracic radiographs and lymph node palpation should be performed every 6 months.

PROGNOSIS AND OUTCOME

- Median survival time for most malignant oral tumors after surgical excision has been 7-12 months. However, when surgeons obtain clean surgical margins in the absence of microscopic metastasis, patients can be cured.
- Prognosis with SCC is good if found while still surgically resectable.
- Malignant melanomas >8 cm^3 (2 × 2 × 2 cm) have a high incidence of microscopic metastasis at the time of diagnosis.
- Mandibular osteosarcoma has been reported to have a lower metastatic rate and better prognosis than appendicular osteosarcoma.
- Tonsillar SCC in dogs commonly metastisizes to regional lymph nodes, with 85% having regional metastasis at necropsy.

PEARLS & CONSIDERATIONS

COMMENTS

- Incisional biopsy should be performed for larger oral masses. Excisional biopsy may be curative but carries the risk of inadequate tumor removal. When submitting excisional biopsies, clinicians should request that the pathologist evaluate margins for the presence of neoplastic cells. Clean margins according to histologic examination do not rule out the possibility of recurrence, but animals with clean margins have a better long-term prognosis.
- Dental radiography (see p. 1246) is invaluable in providing diagnostic and treatment planning information for oral tumors. Benign tumors tend to displace teeth that often remain firmly seated, whereas more aggressive tumors will cause root and alveolar bone resorption, which may manifest as very mobile (floating) teeth. Benign tumors may have a smooth layer of reactive bone surrounding the neoplastic tissue, whereas a malignant tumor often exhibits destruction of cortical bone, with formation of a classic radiographic "sunburst" appearance (see figure).
- Right or left total mandibulectomy (previously referred to as *hemimandibulectomy)* and maxillectomy surgeries carry with them the potential for profuse bleeding. Blood type and cross matching may be warranted preoperatively.
- Sublingual edema seen within 48 hours after mandibulectomy should not be confused with a sublingual mucocele (ranula). Edema will usually resolve without treatment.
- Pigmentation is not a reliable indicator of tumor type. About 40% of oral malignant melanomas may be amelanotic (unpigmented). Malignant tumors other than melanoma may be partially pigmented if the patient's oral mucosa is normally pigmented.
- Removal of regional lymph nodes may be beneficial at the time of oral surgery. A single surgical approach to parotid, mandibular, and retropharyngeal lymph nodes has been described.
- If the biological behavior of a tumor does not match histopathologic results, clinicians should have the biopsy reread or retaken. A type of fibrosarcoma exists which appears histologically benign but is biologically (clinically) very aggressive.
- Nonhealing dental extraction sites, particularly in cats, may be a clinical manifestation of SCC; clinicians should biopsy any suspicious tissues at the time of extraction.
- Dehiscence and inappropriate healing often occur when oral surgery is performed on irradiated sites.

TECHNICIAN TIPS

- Technicians are on the front line of identifying oral tumors during professional dental cleanings. Do a complete oral examination on each anesthetized patient, including the sublingual area, palate, and tonsils. Bring all identified oral masses to the attention of the clinician for possible biopsy under the same episode of general anesthesia.
- Provide as much information as possible on histopathology forms. Include size (in three dimensions), surface characteristics (ulcerated, smooth, verrucous), complete history, and specific location of tumors. When an excisional biopsy is performed, ask the pathologist to evaluate the specimen for evidence of "clean" or "dirty" margins.

CLIENT EDUCATION

- Complete surgical removal of oral tumors provides the best long-term prognosis. Tumors that are detected early are likely to be operable. Clinicians should advise new pet owners to socialize puppies and kittens and allow them to feel comfortable with periodic examination of the oral cavity.
- Animals adapt remarkably well after radical resection of oral tumors (mandibulectomy or maxillectomy), though one study noted that 12% of cats did not regain the ability to eat on their own. Altered cosmesis is usually well accepted by owners if masticatory function can be restored. Clients should be shown before-and-after pictures of similar surgical cases to ensure their understanding of cosmetic changes (see online version of this chapter).
- Lymph node aspirates and thoracic radiographs are important for preoperative animal staging, but microscopic metastasis cannot be totally ruled out by these tests.

Oral Tumors, Benign

BASIC INFORMATION

DEFINITION

Tumor generally refers to a swollen or distended area. A second definition refers more specifically to a benign or malignant neoplastic disease. Benign and malignant oral tumors are common in dogs, whereas oral tumors in cats tend to be malignant. Benign tumors may be locally invasive but do not metastasize to distant sites.

SYNONYMS

- Benign oral neoplasia
- "Epulis" (plural = "epulides") is a nonspecific clinical descriptive term referring to a local exophytic growth on the gingiva (e.g., focal fibrous hyperplasia, peripheral odontogenic fibroma [fibromatous epulis and ossifying epulis], acanthomatous ameloblastoma [acanthomatous epulis], nonodontogenic tumors). See p. 359 .

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: usually gingival hyperplasia, peripheral odontogenic fibroma, acanthomatous ameloblastoma; occasionally pyogenic granuloma, dentigerous cyst, odontoma, papilloma, osteoma, plasmacytoma; rarely giant cell epulis, amyloid-producing odontogenic tumor
- Cats: usually gingival hyperplasia; occasionally giant cell epulis, osteoma, plasmacytoma; rarely peripheral odontogenic fibroma, acanthomatous ameloblastoma, inductive ameloblastoma (feline inductive odontogenic tumor), amyloid-producing odontogenic tumor, odontoma
- Benign oral tumors can occur at any age.
- Oral papillomas (see p. 830) usually occur in dogs <2 years old.
- Inductive fibroameloblastomas usually occur in cats <2 years old.
- Odontogenic tumors (those arising from tooth-forming tissue) can occur at any age, but tumors in young pets are more likely to be of odontogenic origin.

GENETICS & PREDISPOSITION

- Peripheral odontogenic fibroma: more common in brachycephalic dog breeds
- Oral tumors in cats are rarely benign.

CONTAGION & ZOONOSIS: Oral papillomas in young dogs are caused by species-specific papillomavirus.

ASSOCIATED CONDITIONS & DISORDERS

- Gingival hyperplasia
- Malignant oral tumors

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Gingival hyperplasia: abnormal increase in the number of normal cells in a normal arrangement, resulting in clinical enlargement or thickening of gingiva
- Pyogenic granuloma: usually developing on the gingival margin and consisting of markedly vascular granulation tissue with endothelial proliferation, generally ulcerated and inflamed, commonly with hemosiderin deposits
- Dentigerous (tooth-containing) cyst (follicular cyst): develops around the crown of an unerupted tooth
- Odontoma: not a true tumor, but considered to be a hamartoma (accumulation of normal epithelial and mesenchymal odontogenic cells arranged in an abnormal manner, but allowing for induction of dental hard tissues)
    - Compound odontoma: hard tissues produced in a relatively organized manner, resulting in tooth-like structures
    - Complex odontoma: dental hard tissue bearing no resemblance to a tooth
- Peripheral odontogenic fibroma: historically classified as fibromatous and ossifying epulides (ossifying epulides may contain bone-, dentin- or cementum-like tissue within the soft tissue swelling); minimally invasive
- Giant cell epulis (giant cell tumor, giant cell granuloma): rare; rapid growth with inflammatory and ulcerative changes, osteoid and woven bone formation; multinucleated giant cell is main component in mass; rapid recurrence after incomplete excision; thought to be a variant of the peripheral odontogenic fibroma.
- Ameloblastoma: central (intraosseous) or peripheral (extraosseous); both locally invasive, but central ameloblastoma often exhibiting cystic bony changes; acanthomatous ameloblastoma in dogs historically classified as acanthomatous epulis but probably similar to peripheral ameloblastoma
- Inductive fibroameloblastoma (feline inductive odontogenic tumor): rare; occurs most commonly in the rostral maxilla of cats <2 years of age; may be locally invasive but does not metastasize
- Amyloid-producing odontogenic tumor: rare; previously referred to as *calcifying epithelial odontogenic tumor;* may be locally invasive in both dogs and cats but does not metastasize

- Plasmacytoma (plasma cell tumor): extramedullary variant at nasal, pharyngeal, and oral mucosa that has no apparent primary bone involvement; sessile or polypoid sessile and usually solitary oral masses appear to remain localized.
- Osteoma: slow-growing; composed of well-differentiated, densely sclerotic, compact bone

HISTORY, CHIEF COMPLAINT

- Focal swelling of gingiva and/or alveolar mucosa commonly noted as an incidental finding by the client or the veterinarian during routine physical examination
- Benign oral tumors rarely present with oral bleeding or halitosis unless they are large enough to be traumatized by opposing teeth upon closure of the mouth. Bleeding at the lesion site is a common complaint in dogs with a large acanthomatous ameloblastoma.

PHYSICAL EXAM FINDINGS

- Focal swelling of gingiva and/or alveolar mucosa, often circumscribed and rarely ulcerated
- Benign tumors that are locally invasive (e.g., canine acanthomatous ameloblastoma) may cause disfigurement secondary to invasion of the maxilla or mandible.
- Displaced but often firmly seated teeth
- Mandibular lymph nodes are often within normal limits.
- Appetite and activity level are usually unaffected.

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology is unknown, but genetic predisposition may play a role.
- Some benign masses have been suspected to undergo malignant transformation, though this seems to be rare.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis of benign oral masses usually requires histopathologic examination of an incisional or excisional biopsy specimen, because many oral masses do not exfoliate well upon cytologic sampling.

DIFFERENTIAL DIAGNOSIS

- Normal anatomy (e.g., incisive papilla caudal to maxillary incisors in dogs and cats; lingual molar gland caudolingual to mandibular first molar teeth in cats): if the mass is located directly on the midline or bilateral, consult an anatomy textbook to rule out normal structures before performing a biopsy
- Scar tissue (chewing lesions from traumatizing buccal or sublingual mucosa)
- Eosinophilic granuloma (see p. 351): occurring in dogs and cats on tongue, lips, and palate
- Inflammatory swelling due to foreign body
- Apical abscess (see p. 10)
- Osteomyelitis/bone sequestrum: usually seen in the incisive bone or bilaterally in the caudal mandible or maxilla; often appears as bony swelling with gingival recession, erosion, and ulceration; exposed bone; and fetid odor. Cocker spaniels and dachshunds may be overrepresented.
- Gingival hyperplasia
- Dentigerous cyst: arising in area of a tooth that has not erupted
- Craniomandibular osteopathy (CMO): most commonly seen in West Highland white, Scottish, Cairn terriers; mandibular swellings associated with CMO are often bilateral.
- Malignant oral tumors (see p. 788)

INITIAL DATABASE

- CBC, serum biochemistry profile, and urinalysis: generally unremarkable
- Thoracic radiographs (often unremarkable if oral tumor is benign)

ADVANCED OR CONFIRMATORY TESTING

- Anesthetized oral examination
- Dental radiography: variable bony changes
- CT scan (particularly helpful for maxillary masses)
- Cytologic examination of aspirated oral masses and lymph nodes
- Histopathologic evaluation of incisional or excisional biopsy

TREATMENT

TREATMENT OVERVIEW

- Marginal resection (removal of the mass and a small amount of unaffected surrounding tissue) will usually prevent local recurrence of benign mass lesions. For such tumors as acanthomatous ameloblastoma, wide resection (removal of the mass and 1-2 cm of surrounding tissue) is indicated.

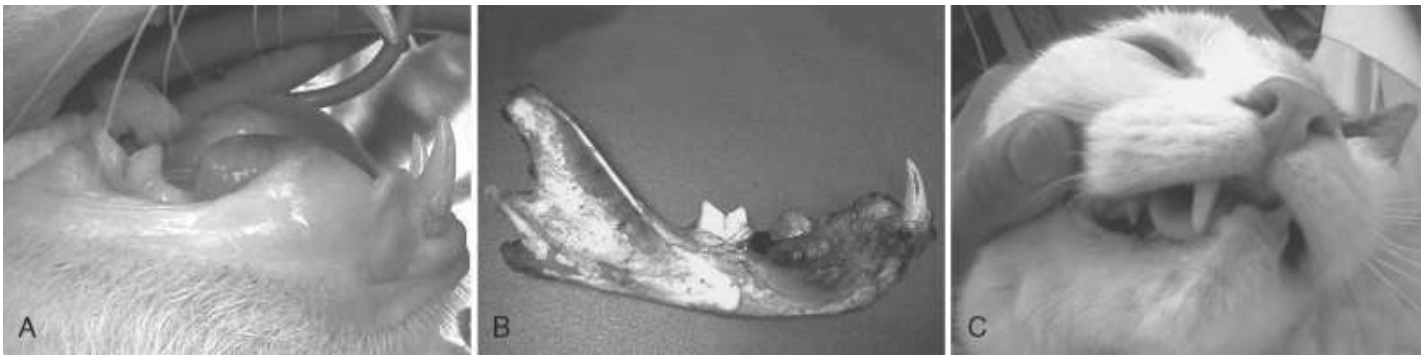
- When surgical excision is not an option, efforts should be made to decrease the rate of growth (such as radiation therapy) and provide relief from discomfort (extraction of teeth impinging on the tumor, administration of pain medications).

ACUTE GENERAL TREATMENT

- Removal of a circumscribed mass to the normal level of the surrounding gingiva will often serve as an adequate biopsy but may not prevent local recurrence. Peripheral odontogenic fibromas will likely recur without removal of the tooth and the periodontal ligament lining the alveolar socket (s).
- Incisional biopsies of large masses are warranted to provide information prior to considering radical surgery.

CHRONIC TREATMENT

- Depending on biopsy result and tumor extent, surgery or radiation therapy may be good long-term options.
- Intralesional chemotherapy has been reported to be successful for treatment of some benign tumors (e.g., acanthomatous ameloblastoma). Systemic chemotherapy may be used as an adjunctive therapy but is rarely effective by itself against most oral tumors.
- Radiation therapy offers excellent long-term control for treatment of acanthomatous ameloblastoma, but malignant tumors may develop in the irradiated area in 3.5%-12.5% of dogs.



ORAL TUMORS, BENIGN A, Total mandibulectomy: preoperative image of a cat with a right mandibular amyloid-producing odontogenic tumor (APOT), which is a benign but locally aggressive neoplasm. **B**, Total mandibulectomy: intraoperative image of resected right mandible from same cat shown in A. **C**, Total mandibulectomy: postoperative image of same cat presenting several months later for a recheck; excellent healing of the surgical site; no tumor recurrence.

(Copyright Dr. Alexander M. Reiter.)

POSSIBLE COMPLICATIONS

- Recurrence of primary tumor
- Intraoperative or postoperative bleeding
- Dehiscence of the surgical site: use of electrocautery may obscure histologic examination of margins of excised tissue and increase the likelihood of wound dehiscence in oral surgery.

RECOMMENDED MONITORING

Repeat oral examination, including head/neck lymph node palpation, to monitor for recurrence at 6-month intervals.

PROGNOSIS AND OUTCOME

- Prognosis is excellent with benign tumors if they are amenable to complete surgical resection or respond to radiation therapy.
- When clients are reluctant to pursue surgery, radiation therapy has been documented to provide a good long-term clinical outcome for treatment of canine acanthomatous ameloblastoma.

PEARLS & CONSIDERATIONS

COMMENTS

- For larger oral masses, start with an incisional biopsy to obtain more information prior to definitive resection; biopsy results will help determine the required extent of definitive surgical resection, and other treatment options. When submitting excisional biopsies, clinicians should request that the pathologist evaluate margins for presence of neoplastic cells. Clean margins according to histologic examination do not rule out the possibility of recurrence, but animals with clean margins do have a better long-term prognosis.
- Dental radiography is invaluable in providing diagnostic and treatment planning information for oral tumors. Benign tumors tend to displace teeth that often remain firmly seated, whereas aggressive tumors will cause root and alveolar bone resorption, which may manifest as very mobile (floating) teeth. Benign tumors may have a smooth layer of reactive bone surrounding the neoplastic tissue, whereas a malignant tumor often exhibits destruction of cortical bone with formation of a classic “sunburst” appearance.
- Right or left total mandibulectomy (previously referred to as *hemimandibulectomy)* and maxillectomy surgeries carry with them the potential for

profuse bleeding. Blood type and cross matching may be warranted preoperatively.

TECHNICIAN TIPS

- Technicians are on the frontline of identifying oral tumors during professional dental cleanings. Do a complete oral examination on each anesthetized patient, including the sublingual area and tonsils. Bring all identified oral masses to the attention of the clinician for possible biopsy during the same anesthetic episode.
- Provide as much information as possible on histopathologic evaluation forms. Include size (in three dimensions), surface characteristics (ulcerated, smooth, verrucous), complete history, and specific location of tumors.

CLIENT EDUCATION

- Complete surgical removal of oral tumors provides the best long-term prognosis. Clinicians should advise new pet owners to socialize puppies and kittens and allow them to feel comfortable with periodic examination of the oral cavity.
- Animals adapt remarkably well after radical resection of oral tumors, and altered cosmesis is usually well accepted by owners if enough function can be restored to allow for independent eating and drinking. Clients should be shown before-and-after pictures of similar surgical cases to ensure their understanding of cosmetic changes.

Optic Neuritis

BASIC INFORMATION

DEFINITION

Inflammation of one or both optic nerves, leading to loss of vision. This is an acquired condition that may be primary or secondary to systemic central nervous system (CNS) disease. The optic nerve is surrounded by dura mater and communicates with the subarachnoid space.

SYNONYM

Papillitis (inflammation of the optic disk)

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats; more commonly seen in middle-aged dogs

ASSOCIATED CONDITIONS & DISORDERS

- Granulomatous meningoencephalitis (GME) (see p. 457)
- Systemic infectious diseases, including:
  - Systemic mycoses in dogs and cats
  - Feline infectious peritonitis (FIP; seep. 383)
  - Canine distemper (see p. 317)
  - Toxoplasmosis in dogs and cats (see p. 1105)
  - Neosporosis in dogs (seep. 1105)
- Neoplasia: primary or secondary

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Intraocular: inflammation of the optic disk; detected with ophthalmic examination
- Orbital: inflammation of the retrobulbar/orbital portion of the optic nerve; not detectable with ophthalmic examination
- Intracranial: inflammation of the portion of the optic nerve following its exit from the orbit at the optic foramen and to the level of the optic chiasm; not detectable with ophthalmic examination but may be associated with neurologic deficits

HISTORY, CHIEF COMPLAINT: Sudden blindness of one or both eyes

PHYSICAL EXAM FINDINGS

- Blindness if bilateral
- Absent unilateral or bilateral menace response(s), pupillary light and dazzle reflexes
- Fixed and dilated pupil (mydriasis; unilateral or bilateral)
- Swollen, edematous, and hyperemic optic disk with possible peripheral retinal edema and/or hemorrhages if intraocular portion of optic nerve (i.e., optic disk) is affected
- Normal-appearing optic disk if the inflammation is limited to the orbital and/or intracranial portions of the optic nerve
- Small, pale optic disk (i.e., optic disk atrophy) in advanced cases
- Depending on the cause (see Etiology, below), systemic abnormalities also may be present.

ETIOLOGY AND PATHOPHYSIOLOGY

- Infectious:
  - Canine: viral (canine distemper [seep. 317]), systemic mycoses (seepp. 138 , 266, and538), protozoal *(Toxoplasma gondii; Neospora caninum.* seep. 1105)
  - Feline: viral (FIP), systemic mycoses (cryptococcosis [seep. 266], histoplasmosis [seep. 538]), protozoal *(Toxoplasma gondii)*
- Neoplastic: feline lymphoma, orbital neoplasia

- Immune-mediated: GME
- Traumatic: leading to orbital cellulitis or abscess
- Nutritional: vitamin A deficiency (rare in dogs and cats)
- Secondary to orbital inflammation, meningitis, scleritis, retinitis, posterior uveitis
- Idiopathic

DIAGNOSIS

DIAGNOSIS OVERVIEW

The diagnosis is suspected with loss of vision, fixed and dilated pupil(s), and abnormal appearance of the optic disk(s). A normal electroretinogram further supports the diagnosis; evidence of sterile inflammation in cerebrospinal fluid is consistent but not required. To confirm orbital/intracranial optic neuritis, advanced imaging such as MRI is required. Since treatment (corticosteroids) may alter the results of advanced diagnostic tests, prompt referral to a veterinary ophthalmologist should be considered for optic neuritis suspects.

DIFFERENTIAL DIAGNOSIS

- Unilateral:
  - Acute primary glaucoma (elevated intraocular pressure [IOP] > 30 mm Hg) and signs of glaucoma (see pp. 448 and 1559)
- Bilateral:
  - Sudden acquired retinal degeneration (SARD) in dogs (seep. 983): normal fundic (i.e., posterior segment) examination early on with flatline electroretinogram (ERG; see p. 1255), meaning no retinal function, versus ERG waveforms confirming retinal function in acute optic neuritis.
  - Immune-mediated retinitis in dogs: uncommon to rare; normal fundic exam possible early on; low retinal function on ERG, vision may return with oral prednisone (1 mg/kg PO q 24 h) in combination with oral doxycycline (5 mg/kg PO q 24 h)
  - Enrofloxacin toxicosis in cats: retinal degeneration noted on fundic examination versus normal-appearing retina with optic neuritis. Exception: if the intraocular portion of optic nerve (i.e., optic disk) is affected with optic neuritis, the clinician may detect peripheral retinal edema and/or hemorrhages.
  - Neoplasm at the optic chiasm (advanced imaging such as MRI to differentiate from bilateral orbital/intracranial optic neuritis)
  - Cortical (central) blindness (normal pupillary light reflexes; normal fundic examination; possibly additional neurologic abnormalities)
  - Papilledema: edema of the optic nerve head (no blindness)

INITIAL DATABASE

- Complete ophthalmic examination (seep. 1313), including:
  - Menace response and dazzle reflex (absent in affected one or both eyes)
  - Pupillary light reflexes (PLRs): if bilateral optic neuritis, pupils typically are fixed and dilated, thus producing negative direct and consensual PLRs; if unilateral, direct PLR absent in affected eye and consensual PLR absent in contralateral eye. NOTE: *Consensual PLR* refers to reaction of contralateral eye. For example, an absent consensual PLR in the right eye describes the lack of constriction of the right pupil in response to light shone into the left eye.
  - Assessment of IOP; rule out acute primary glaucoma (IOP > 30 mm Hg; seepp. 448 and 1559).
  - Examine posterior segment of eye (i.e., fundus) using direct and/or indirect ophthalmoscopy.
- Neurologic examination (seech p. 1311)

ADVANCED OR CONFIRMATORY TESTING

- ERG to assess retinal function; normal in optic neuritis
- MRI (seep. 1302) or CT (seep. 1233):
  - Advanced imaging can help detect neoplastic processes along the optic nerve and optic chiasm. If a mass is detected in the retrobulbar optic nerve, exenteration (removal of the globe and all of the orbital contents) could be curative.
- Cerebrospinal fluid (CSF) analysis (see p. 1228); may be abnormal, depending on the cause of optic neuritis
- Visual-evoked potentials to assess optic nerve function; severely diminished with optic neuritis

TREATMENT

TREATMENT OVERVIEW

Prompt antiinflammatory therapy is warranted with this condition, but prognosis for return of vision remains poor.

ACUTE GENERAL TREATMENT

- Treat the underlying cause if determined.
- Idiopathic or traumatic (i.e., noninfectious) etiology: prednisone, 1-2 mg/kg PO q 12 h for 7-14 days; then 0.5-1 mg/kg PO q 12 h for 7-14 days; then gradual decrease to reach a maintenance dosage

CHRONIC TREATMENT

GME: possible lifelong immunosuppressive therapy (see p. 457)

RECOMMENDED MONITORING

Monitor clinical signs (i.e., vision and optic disk with or without secondary retinal lesions if intraocular optic neuritis) within 24 hours of the animal commencing medical treatment(s) and at least weekly for the first month (reassessment intervals will vary depending on the cause and response to treatments)

PROGNOSIS AND OUTCOME 

- Prognosis depends on underlying cause.
- Prognosis for return of vision is generally poor, and blindness is usually permanent.
- In cases that do respond to treatment, recurrences may occur if medication is decreased too rapidly or if duration of therapy is inadequate.
- If the animal is untreated or unresponsive to treatment, optic disk atrophy and attenuation of retinal blood vessels will occur.

PEARLS & CONSIDERATIONS 

COMMENTS

- Suspicion or confirmation of optic neuritis warrants referral to a veterinary ophthalmologist.
- Early diagnosis and appropriate, aggressive medical therapy are paramount to limit damage to the optic nerve(s).
- GME is the leading cause of optic neuritis in dogs.

CLIENT EDUCATION

Counsel clients on the high probability of living with a blind dog.

EDITOR: CHERYL L. CULLEN

Opiates/Opioids Toxicosis

BASIC INFORMATION

DEFINITION

- Adverse effects including CNS depression, ataxia, weakness, hypersalivation, vocalization, disorientation, coma, hypothermia, hypotension, bradycardia and possible respiratory depression seen at the recommended dose or from acute overdose of medications containing opiates/opioids
- The term *opiate* refers to alkaloids such as morphine or codeine obtained from the sap of poppy plant (natural); *opioids* are synthetic and natural morphine-like medications which work through the opioid receptors.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats of all breeds, ages, and both sexes susceptible. Dogs more likely to get into owner's medications by accident compared to cats.

GENETICS & BREED PREDISPOSITION: Cats and MDR1-deficient dogs are more sensitive to the effects of opioids (see p. 706).

RISK FACTORS: Concurrent administration of other CNS depressants or preexisting hepatic damage may increase the risk of toxicosis.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Toxicosis is generally acute.

HISTORY, CHIEF COMPLAINT

- Evidence of exposure (owner administration, chewed bottle)
- Presence of CNS depression, vocalization, ataxia, weakness within a few hours after exposure

PHYSICAL EXAM FINDINGS

- CNS depression, sedation, ataxia, weakness, vomiting (gastrointestinal [GI] stasis)
- Bradycardia, hypotension
- Idiosyncratic agitation/excitation (cats and young animals)
- Coma, hypothermia, respiratory depression (rare)

ETIOLOGY AND PATHOPHYSIOLOGY

- Opioids are used as analgesics, antidiarrheals, cough suppressants, and as sedatives before surgery.
- Buprenorphine, butorphanol, fentanyl, hydromorphone, tramadol, and loperamide are commonly used opioids in veterinary medicine.
- Opioids work through interaction with opiate receptors (mu, delta, kappa, sigma, epsilon, nociceptin). Opioids act in the central nervous system to elevate the pain threshold and alter the psychological response to pain. The receptors are found in the limbic system, spinal cord, thalamus, hypothalamus, striatum, and midbrain. Opioids may be agonists, mixed agonist-antagonists, or antagonists at these receptors.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Exposure is suspected or certain from history of ingestion and presence of typical clinical signs (depression, ataxia, sedation, weakness). Over-the-counter urine drug tests (illicit drug test kits) may be used for confirming exposure.

DIFFERENTIAL DIAGNOSIS

- Differentiate from other CNS depression-causing toxicoses such as barbiturate overdose, benzodiazepines, phenothiazines,

alcohol, ivermectin, antifreeze, marijuana.
- Nontoxicologic rule outs include hypoglycemia, meningoencephalitis, intracranial neoplasia, and uremic or hepatic encephalopathy.

INITIAL DATABASE

- Heart rate (increased or decreased), respiratory rate (may be depressed)
- Blood pressure
- Blood gas (respiratory acidosis if hypo-ventilation), oxygen saturation
- Body temperature (normal or below normal)

ADVANCED OR CONFIRMATORY TESTING

- Urine drug screen (antemortem)
- Blood, urine, tissues (postmortem)

TREATMENT

TREATMENT OVERVIEW

Severe intoxications affecting respirations and heart rate require stabilization: intubation and positive-pressure ventilation if the patient is apneic and drugs to address cardiac arrhythmias. Naloxone and supportive care are indicated for reversal of opiate effects in all confirmed or strongly suspected cases showing clinical signs. Induction of vomiting and administration of activated charcoal are warranted in exposed patients not showing any clinical signs.

ACUTE GENERAL TREATMENT

- Provide ventilatory support in a comatose animal with respiratory compromise.
- Naloxone (0.002-0.04 mg/kg IV, IM, SQ); repeat as needed depending on the opioid involved.
- Fluid diuresis depending on severity of signs
- Diazepam (0.25-1 mg/kg slow IV) for dysphoric reactions (vocalization, excitation)
- Cyproheptadine (1.1 mg/kg PO or per rectum) can be used for serotonin syndrome-like effects (muscle rigidity, disorientation). See p. 1427 .

BEHAVIOR/EXERCISE

Restrict/confine activity at home until resolution of signs.

DRUG INTERACTIONS

- Erythromycin, cimetidine, ketoconazole, itraconazole, fluconazole, diltiazem will decrease clearance and increase half-life of opioids owing to decreased metabolism.
- Benzodiazepines, barbiturates, centrally acting muscle relaxants, and phenothiazines will increase CNS depression and risk of respiratory depression.

RECOMMENDED MONITORING

- Heart rate, respiration
- Blood pressure,
- Oxygen saturation
- Body temperature
- CBC, and serum biochemistry profile (no significant changes expected)

PROGNOSIS AND OUTCOME

Good for most exposures, because dogs and cats tolerate higher doses of opioids compared to humans. Animals do not seem to develop severe respiratory depression as readily as humans do from opioid overdose.

PEARLS & CONSIDERATIONS

COMMENTS

- Fentanyl lozenges or suckers contain a sucrose and liquid glucose base and are attractive to pets. There is usually enough fentanyl left on the stick of a used sucker or in a used fentanyl patch to cause overt clinical signs if ingested by a pet. The plastic stick or patch can be retained as a foreign body, causing prolonged exposure and intoxication.
- Due to first pass effect, there is low bioavailability of some opioids when given orally. Opioids are metabolized in liver, and some undergo glucuronide conjugation before being excreted. Cats are deficient in glucuronidation process, and therefore half-life of some opioids in cats is prolonged.

PREVENTION

Keep all medications away from pets.

TECHNICIAN TIPS

Owners/clients may not readily admit presence of any opioids/opiates in pet's environment. Therefore, any mention of this information should be relayed to the attending veterinarian for optimal treatment of the patient.

CLIENT EDUCATION

Keep all medications, used patches, and sucker sticks away from pets.

EDITOR: SAFDAR KHAN

Onion or Garlic Toxicosis

BASIC INFORMATION

DEFINITION

Intoxication results from consumption of a plant in the genus *Allium,* which includes garlic, onions, leeks, scallions, shallots, and chives. Most of these plants are perennial, rhizomatous, or bulbous herbs. Most have a distinctive odor.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Cats are more susceptible than dogs.

GENETICS & BREED PREDISPOSITION: Japanese breeds such as the Akita, Shiba Inu, and Tosa are more susceptible to oxidative damage to the red blood cell (RBC).

RISK FACTORS

- Dogs' indiscriminate feeding behavior increases the risk of ingestion.
- Cats are more likely to be exposed from ingesting foods like baby food with onion or garlic powder as a flavoring (chronically), although some cats can be as indiscriminate as dogs.

ASSOCIATED CONDITIONS & DISORDERS: Any cause of oxidative RBC damage, Heinz body anemia (seep. 1487), hemolytic anemia (see), hemoglobinuria, and methemoglobinemia

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of exposure to raw, cooked, dried, or powdered chives, onions, garlic, leeks, shallots, or scallions
- Common physical signs: weakness, lethargy, pale mucous membranes, discolored urine
- Less common: halitosis, hypersalivation, vomiting, and/or diarrhea
- The owner of any dog with hemolytic anemia should be asked about exposure to onions/garlic.

PHYSICAL EXAM FINDINGS

- Lethargy, weakness, and/or ataxia
- Mild hypersalivation, vomiting, and/or diarrhea
- Pale mucous membranes (anemia), tachypnea, tachycardia
- Discolored (red to brown) urine (hemoglobinuria)

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

These plants grow wild and are widely cultivated.

Mechanism of Toxicosis:

- *Allium* spp. contain sulfoxides (which provide the characteristic odor) that are hydrolyzed to thiosulfinates. Thiosulfinates decompose to dipropyl sulfide. Dipropyl sulfides oxidize RBC membranes, resulting in hemolysis, Heinz bodies, anemia, and less commonly methemoglobinemia.
- Poisoning can result from ingesting raw, dried, powdered, or cooked onions and garlic: cooking or drying does not inactivate the toxic principle.
- Dogs fed onion soup equivalent to 30 g of raw onion/kg q 24 h for 3 days developed marked Heinz body anemia. Similarly, a significant increase in Heinz bodies was seen 12 hours after feeding dogs 200 g (½ lb) of boiled onions (approximate dose of 17 g onions/kg).
- Dogs given an extract equivalent to 5 g of whole garlic/kg PO q 24 h for 7 days developed anemia 9-11 days after dosing.
- Generally, most dogs need to eat at least 0.5% (5 g/kg) body weight to develop onion toxicosis, unless the dog is of a sensitive breed (see Genetics & Breed Predisposition above; Suggested Reading below).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on historical evidence of *Allium* species ingestion and the delayed onset (usually 2-5 days) of compatible signs (anemia, pale mucous membrane color, hemoglobinuria, hemolysis).

DIFFERENTIAL DIAGNOSIS

Toxicologic:

- Other agents known to cause hemolysis, anemia, or hemoglobinuria such as zinc, benzocaine and other local anesthetics, acetaminophen, naphthalene mothballs, propylene glycol, methylene blue, phenols

Spontaneous, Nontoxicologic:

- Parasites such as *Mycoplasma (Haemobartonella) felis, Babesia canis, Cytauxzoon felis,* and *Ehrlichia* spp.
- Immune-mediated hemolytic anemia
- Severe hypophosphatemia
- Ruptured hemangiosarcoma
- Hereditary RBC fragility syndromes
- Feline leukemia virus infection, feline immunodeficiency virus infection, feline infectious peritonitis
- Myelophthisic neoplasia
- Severe hookworm infestation

INITIAL DATABASE

- CBC, serum biochemistry profile:
  - Decreased hematocrit, elevated white blood cell count, methemoglobinemia, and Heinz bodies are possible.
  - Smears should be examined for Heinz bodies, evidence of regeneration.
- With methemoglobinemia (see p. 1501), serum may be brown and/or blood may fail to turn red when exposed to air.
- Hematologic changes (e.g., hemolysis, Heinz body anemia, methemoglobinemia) may occur as early as 12 hours post ingestion but generally take 2-5 days to develop.
- Urinalysis:
  - Reddish-brown color suggests hemoglobinuria (rule out hematuria, myoglobinuria).
  - Urine dipstick will be positive for blood with hemoglobinuria or hematuria.
  - Centrifuged urine will remain reddish brown with hemoglobinuria, whereas the supernatant of centrifuged urine will clear with hematuria.
- Specific assay for serum methemoglobin is available in central laboratories.

ADVANCED OR CONFIRMATORY TESTING

Cooximetry (measures percentage of methemoglobin) and methemoglobin assays exist but are not typically useful in the limited time frame of an intoxication.

TREATMENT

TREATMENT OVERVIEW

If no clinical signs are present, treatment consists of immediate decontamination of the patient (induction of vomiting and administration of activated charcoal). If the patient is showing overt signs compatible with toxicosis, care may include improving tissue oxygenation (packed RBC or whole blood transfusion) and general supportive care.

ACUTE GENERAL TREATMENT

- No clinical signs apparent:
  - Induction of vomiting (seep. 1364) with recent ingestion.
  - Activated charcoal 1-2 g/kg PO (dose according to packaging label of product; e.g., 10 mL of activated charcoal suspension PO made from 2 g activated charcoal suspended in 10 mL tap water). Repeat dosing may be indicated with large ingestions (caution: monitor for hypernatremia if repeatedly giving charcoal-cathartic combination, e.g.,

Toxiban).
- Patient showing clinical signs:
  - Packed RBC or whole blood transfusion if necessary (NOTE: new RBCs remain at risk for hemolytic damage if toxicant is still in the blood). See p. 1347.
  - IV fluids to treat shock and promote fluid diuresis; caution regarding hemodilution with anemia
  - Management of vomiting and diarrhea as needed
  - Oxygen supplementation of limited benefit, since oxygen saturation of intact hemoglobin remains high, and methemoglobin binds oxygen poorly even with supplementation.

CHRONIC TREATMENT

Generally not indicated; recovery is expected with appropriate acute treatment.

BEHAVIOR/EXERCISE

Exercise restriction pending resolution of anemia

DRUG INTERACTIONS

Garlic has an antithrombotic effect, and concomitant use of garlic and drugs that alter platelet function (e.g., aspirin, clopidogrel) may produce additive antithrombotic effects.

POSSIBLE COMPLICATIONS

- Hemoglobinuria-associated renal tubular damage possible in severe cases
- Abortions can occur secondary to severe hypoxemia if a pronounced anemia is present.

RECOMMENDED MONITORING

- CBC/hematocrit/blood smear
- Renal function

PROGNOSIS AND OUTCOME

- Generally good with prompt veterinary care of patients showing overt clinical signs
- Guarded with severe anemia or secondary renal damage

PEARLS & CONSIDERATIONS

COMMENTS

- Many commercial garlic or onion powder products will list the conversion for a clove of garlic (e.g., 1 tsp of garlic powder equals one clove of garlic).
- One pearl onion weighs about 14 g, a small onion (2 in/5 cm diameter) weighs about 56-85 g, a medium onion (3 in/7.5 cm diameter) weighs about 226-255 g, and a large onion (4 in/10 cm diameter) weighs about 425-450 g.
- A medium onion yields about 1 cup of coarsely chopped onion.

TECHNICIAN TIP

When recommending baby food to stimulate appetite, it is important to remind clients to avoid products with garlic or onion powder, especially for cats.

PREVENTION

Owners should keep foods with onion or garlic ingredients out of their pets' reach.

CLIENT EDUCATION

Garlic supplementation for the prevention of heartworm disease is unsubstantiated and contraindicated.

1ST EDITION AUTHOR: CHARLOTTE MEANS

Oleander Toxicosis

BASIC INFORMATION

DEFINITION

An acute poisoning that occurs following ingestion of dried or fresh parts of an oleander plant (genus *Nerium* or *Thevitia).* Clinical manifestations are similar to those of digoxin toxicity: gastrointestinal (GI) signs initially, with possible subsequent cardiac arrhythmias.

SYNONYMS

- *Nerium oleander:* oleander
- *Thevitia nerifolia:* yellow oleander

EPIDEMIOLOGY

SPECIES, AGE, SEX: Animals of all ages, breeds, and both sexes susceptible; dogs are more commonly affected.

RISK FACTORS: Availability of oleander plant in pet's environment

GEOGRAPHY AND SEASONALITY: Oleander is an ornamental evergreen shrub widely cultivated all over the world and most of the southern United States, notably California and Florida.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Observed or suspected exposure to plant
- Vomiting, with plant material in the vomitus
- Owners may note lethargy, salivation, signs of abdominal pain, diarrhea, weakness, and tremors.

PHYSICAL EXAM FINDINGS

- See History, Chief Complaint above.
- Cardiac arrhythmias, either tachycardias (premature beats or runs of tachycardia) or bradycardias; a pattern of bradycardia, initially present for 24 hours, followed by tachycardia and ventricular arrhythmia, has been described.
- Central (seizures) and peripheral (tremors, weakness) nervous system effects. Severe intoxications can lead to coma and death.

ETIOLOGY AND PATHOPHYSIOLOGY

- Clinical signs usually appear within 6 hours of ingestion, depending on the amount ingested.
- Oleander contains cardiac glycosides (oleandrin, neriine, etc.) that inhibit the sodium/potassium (Na^+/K^+) ATPase enzyme, which is essential for normal cellular function in multiple body systems, notably the cardiovascular and nervous systems.
- Inhibition of Na^+/K^+ ATPase leads to an abnormal accumulation of potassium outside the cell and sodium inside the cell, producing a cascade of calcium release that results in cardiac arrhythmia and myocardial ischemia or necrosis (in severe cases).
- The toxic effects are indistinguishable from those of digoxin toxicosis in pets receiving digoxin therapeutically.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A functional diagnosis is made when a pet with appropriate clinical signs and possibility of exposure (e.g., unmonitored in garden) is seen in areas where oleanders are accessible, and general decontamination of the patient is warranted based on these findings alone. New cardiac arrhythmias increase the index of suspicion. Diagnosis can be confirmed (generally retrospectively and therefore

for preventative, group health, or medicolegal reasons) by showing presence of oleandrin in body fluids by thin-layer chromatography (TLC) or high-performance liquid chromatography (HPLC).

OLEANDER TOXICOSIS Oleander plant, showing characteristic long, oval, robust leaves and ornamental flowers.

DIFFERENTIAL DIAGNOSIS

- Advanced primary heart disease (cardiomyopathy, valvular heart disease, traumatic myocarditis if hit by car, etc.)
- Primary bradycardias (third-degree atrioventricular block, sick sinus syndrome, atrial standstill/hyperkalemia)
- Systemic causes of ventricular arrhythmias (seep. 1165)
- Exposure to other plants that contain cardiac glycosides (seep. 175)

INITIAL DATABASE

- CBC: no significant changes likely
- Serum chemistry profile: hypokalemia or hyperkalemia possible. Hypokalemia may be particularly detrimental: it fosters ventricular arrhythmia and also makes animals refractory to antiarrhythmics (lidocaine, quinidine, mexiletine, etc.).
- Electrocardiogram (ECG) to determine type of cardiac arrhythmia if present.

ADVANCED OR CONFIRMATORY TESTING

- Confirmation of oleandrin in body fluids, stomach, and intestinal contents by using TLC and HPLC techniques (available in some veterinary diagnostic laboratories).
- Postmortem examination may reveal oleander plant material in the GI tract, pericardial effusion, possibly pulmonary edema, and varying degrees of thrombi and hemorrhages in epicardial surfaces.
- Histologic examination of the heart tissue may reveal evidence of myocardial inflammation, degeneration, and necrosis.

TREATMENT

TREATMENT OVERVIEW

When exposure is known or suspected but no clinical signs are present, induction of vomiting is indicated, followed by administration of activated charcoal. If overt signs are present (or emerge) or physical exam abnormalities lead to identification of consequences of toxicosis (e.g., cardiac arrhythmias), treatment is directed at both decontamination and palliation of consequences (e.g., antiarrhythmic therapy) while also addressing any potentially complicating factors (e.g., hypokalemia, retention of plant material). Antidigitalis antibodies are indicated in critical cases with severe signs when not cost-prohibitive.

ACUTE GENERAL TREATMENT

- These guidelines are appropriate for an average adult dog.
- Decontamination of patient:
    - Induction of emesis if appropriate and within 1-2 hours after ingestion (seep. 1364)

- Activated charcoal: administration of activated charcoal after inducing emesis or if few hours have elapsed after exposure; 1-4 g/kg with a cathartic such as 70% sorbitol (3 ml/kg) PO

- Treating cardiac arrhythmias:
  - Sinus bradycardia (see online chapter: Sinus Bradycardia) that occurs within 24 hours of exposure: clinicians should treat the condition if severe (e.g., heart rate <60-80 beats/min in an awake and standing large- to small-breed dog, respectively) or if the condition is associated with overt signs (e.g., lethargy).
  - Ventricular arrhythmias (see p. 1165)
  - Supraventricular arrhythmias (see p. lll): extremely rapid, persistent supraventricular tachycardias may need to be controlled (e.g., with propranolol, 0.1-0.5 mg IV total dose per bolus; no more frequently than 1 bolus q 1-3 min to 5 mg maximum for large dogs). The goal is to lower heart rate to acceptable level (e.g., by 20%) and not cause an overly rapid suppression.
- Use of specific fluorescent antibodies (FAB, Digibind) in severe cases:
  - IV antidigitalis antibodies; inactivate significant proportion of circulating cardiac glycoside
  - Extremely expensive (several thousand dollars per dose); reserved for cases in which animals are profoundly ill or manifesting severe arrhythmias and in which cost of treatment is unimportant to the owner (for dosage and details, see online chapter: Digitalis Toxicosis)
- For supportive care, clinicians should:
  - Administer IV fluids as needed.
  - Treat diarrhea, severe vomiting, and abdominal pain as needed.
  - Correct electrolytes (potassium) if needed.

RECOMMENDED MONITORING

- ECG
- Serum chemistry profile, especially electrolytes

PROGNOSIS AND OUTCOME

- Poor prognosis with severe cardiac arrhythmias; animals are often found dead.
- Clinical signs of toxicosis may persist for 24 hours or longer in animals that ultimately survive; hospitalization for >24 hours is appropriate, and outcome can be successful.

PEARLS & CONSIDERATIONS

COMMENTS

- Animals that survive may have no permanent sequelae or may have sustained myocardial infarcts, causing some degree of permanent cardiac damage (severe intoxications).
- Oleander leaves can be identified by a characteristic venation pattern and stromata; they have a prominent midrib with parallel veins extending to the periphery.
- All parts of oleander are toxic; ingestion of dry leaves/clippings is the most common cause of poisoning in animals.
- As little as 0.005% of an animal's body weight in oleander leaves (e.g., 10-12 leaves) may be lethal to an animal.
- Intoxication can occur by drinking water in which oleander was soaked.

PREVENTION

Owners should use extreme caution when growing oleander close to animal housing or on premises.

1ST EDITION AUTHOR: MOAZZAM A. KHAN

Ocular Size Abnormalities

BASIC INFORMATION

DEFINITION

- Buphthalmos: a larger than normal globe; may be congenital or acquired and is a result of current or past glaucoma
- Microphthalmos: a smaller than normal globe; a congenital condition sometimes associated with other ocular anomalies
- Phthisis bulbi: a shrunken globe; a condition acquired as a result of chronic ocular inflammation (e.g., uveitis or severe ocular trauma)
- May occur in one or both eyes

SYNONYMS

Buphthalmia (buphthalmos), microphthalmia (microphthalmos)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Buphthalmos may occur, and microphthalmos does occur, congenitally.
- Phthisis bulbi: no age predisposition

GENETICS & BREED PREDISPOSITION

- Buphthalmos secondary to glaucoma (see p. 448) is inherited in several breeds.
- Microphthalmos is inherited in miniature schnauzers, Australian shepherds, collies, Shetland sheepdogs, and Doberman pinschers.

ASSOCIATED CONDITIONS & DISORDERS

- Buphthalmos can be associated with:
  - Lagophthalmos (incomplete closure of the eyelids) with or without secondary corneal ulceration (see p. 250)
  - Lens subluxation/luxation (see p. 644)
  - Intraocular neoplasia (seep. 620)
- Microphthalmos is associated with:
  - Other congenital ocular anomalies, including cataracts (seep. 181) and retinal dysplasia/folds
  - Collie eye anomaly, including choroidal hypoplasia with or without optic nerve coloboma, staphyloma, retinal detachment, and intraocular hemorrhage
- Phthisis bulbi is associated with:
  - Untreated or poorly responsive ocular inflammation (e.g., uveitis or severe ocular trauma)
  - Variable systemic abnormalities depending on cause of uveitis (see p. 1151)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Condition is most likely unilateral but can also occur bilaterally.

- Buphthalmos: enlargement of globe during first few months of life (i.e., congenital glaucoma); progressive enlargement of globe and “red eye” (seep. 448)
- Microphthalmos: small eye from birth
- Phthisis bulbi: progressive shrinkage of globe following a “red eye” (seep. 967)

PHYSICAL EXAM FINDINGS

- Buphthalmos: larger globe and signs of glaucoma, including:
  - Red eye (congested conjunctival and scleral blood vessels)
  - Diffuse corneal edema with possible striae (white streaks in the cornea from breaks in Descemet's membrane)
  - Corneal vascularization if eyelids cannot close over the enlarged globe (i.e., lagophthalmos)
  - Fixed and dilated pupil

    - Lens subluxation/luxation (see p. 644)
    - Blindness
- Microphthalmos: smaller globe and the following:
    - Enophthalmos (caudal displacement of the eye) (see p. 790)
    - Prolapsed third eyelid (seep. 1089)
    - Other intraocular abnormalities (cataracts, retinal folds/dysplasia)
    - ± Small palpebral fissure (i.e., small opening between the eyelids) or entropion and/or conjunctivitis if eyelids are normal length despite small eye
    - Vision may be normal, reduced, or absent.
- Phthisis bulbi: shrunken globe and the following:
    - Enophthalmos (caudal displacement of the eye; see p. 790)
    - Prolapsed third eyelid
    - Corneal edema; deep corneal vascularization
    - ± Entropion, conjunctivitis, posterior synechiae, cataract, iris atrophy
    - Vision typically reduced or absent

ETIOLOGY AND PATHOPHYSIOLOGY

- Buphthalmos: result of untreated or poorly managed glaucoma
- Microphthalmos: congenital deficiency of optic vesicle or failure of normal growth and expansion of optic cup; inherited condition
- Phthisis bulbi: acquired condition that possibly follows chronic intraocular inflammation (see pp. 1151, 448, and 249)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The definitive diagnosis depends on the general appearance of the ocular globe and signalment of the patient.

DIFFERENTIAL DIAGNOSIS

- Buphthalmos: exophthalmos (forward displacement of the globe; see p. 790)
- Microphthalmos, phthisis bulbi: ruptured globe (seep. 249)

INITIAL DATABASE

- Complete ophthalmic examination, including:
    - Measurement of intraocular pressure (IOP): may be elevated (>30 mm Hg, indicating uncontrolled glaucoma), or normal (chronic glaucoma) with buphthalmos; typically low (<10-15 mm Hg) with phthisis bulbi.
    - Fluorescein dye application with buphthalmos (there may be positive dye retention, such as with a corneal ulcer)
    - Neuroophthalmic exam (seep. 1313) to assess vision (e.g., menace response)
- Additional tests vary depending on underlying cause

ADVANCED OR CONFIRMATORY TESTING

- Buphthalmos: ocular ultrasound if corneal or ocular media opacification precludes evaluation of intraocular structures (e.g., assess lens for cataracts and globe for intraocular mass)
- Ocular histopathologic examination if enucleation is performed due to blindness and ocular pain (common with buphthalmos)

TREATMENT

THERAPEUTIC OVERVIEW

The management of ocular pain is paramount, independent of the appearance of the globe. Unfortunately, pain control may require enucleation for several patients. No treatment may be required if ocular size abnormalities are not accompanied by evidence of discomfort, inflammation, or elevated IOP.

ACUTE GENERAL TREATMENT

- For buphthalmos (for treatment options, see Glaucoma,p. 1151); if the animal's globe is blind and if glaucoma remains

medically uncontrolled, options include:
  - Enucleation, evisceration with intraocular prosthesis, or chemical ablation of blind eyes with chronic primary glaucoma (seep. 115); chemical ablation is not recommended in cats
  - Enucleation of eyes with intraocular neoplasia
  - Enucleation of eyes with congenital glaucoma
- For microphthalmos: enucleation is warranted if eye is blind and entropion or chronic conjunctivitis occurs.
- For phthisis bulbi: treatment of underlying uveitis and advise enucleation if eye is blind and entropion or chronic conjunctivitis occurs.

PROGNOSIS AND OUTCOME

- Prognosis for vision is grave in cases of buphthalmos and advanced phthisis bulbi.
- Depending on the degree of microphthalmos and the presence of other ocular anomalies, the prognosis for vision varies for microphthalmos.

PEARLS & CONSIDERATIONS

COMMENTS

- Measure the corneal horizontal diameter of each eye to document buphthalmos or microphthalmos/phthisis bulbi.
- Recommend against breeding animals affected with buphthalmos or microphthalmos if the condition is deemed to be breed-related or inherited in nature.
- Abnormal ocular size requires prompt evaluation and may or may not indicate an immediate need to treat; a proper and complete clinical ophthalmic exam determines the need for intervention (or lack thereof).

CLIENT EDUCATION

Clinicians should advise clients to seek veterinary care for their pets as soon as the eye becomes “red” and/or the eye changes in appearance.

SUGGESTED READING

Moore PA: Examination techniques and interpretation of ophthalmic findings. Clin Tech Small Anim Pract 16:1, 2001.

AUTHOR: CHANTALE L. PINARD

EDITOR: CHERYL L. CULLEN

Ocular Discharge

BASIC INFORMATION

DEFINITION

- Abnormal secretions on or around the eye(s)
- These secretions can be watery (serous), contain mucus (mucoid), or contain white blood cells, mucus, and bacterial/fungal agents (mucopurulent).
- An abnormal overflow of tears down the face is termed *epiphora.*

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats; variable age of onset depending on cause

GENETICS & BREED PREDISPOSITION: Depends on cause; examples:

- Brachycephalic breeds with medial entropion (seep. 348)
- Breeds predisposed to distichia, ectopic cilia, and trichiasis (see p. 319)
- Breeds predisposed to congenital atresia, ectopia, and/or imperforated lacrimal puncta
- Breeds predisposed to entropion and/or ectropion (seep. 348)
- Dolichocephalic breeds of dogs with narrow skull conformation and deep medial canthal areas (i.e., medial canthal pocket syndrome)

RISK FACTORS: Outdoor animals prone to infectious causes of conjunctivitis (see pp. 237and239) and ocular trauma (seep. 249)

CONTAGION & ZOONOSIS: Certain infectious causes of conjunctivitis are contagious (e.g., feline herpesvirus type-1 [FHV-1]) and/or zoonotic (e.g., *Chlamydophila* spp.).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Clear, white, to grey mucoid or green-yellow secretions on the eye(s) or eyelids
- Sudden, progressive, or persistent in nature

PHYSICAL EXAM FINDINGS: Unilateral or bilateral serous, mucoid, or mucopurulent ocular secretions with one or more of the following:

- Blepharitis: inflammation of the eyelids (see p. 966)
- Conjunctivitis (see pp. 237 and239)
- Corneal ulceration (seep. 250)
- Keratoconjunctivitis sicca (KCS; seep. 628)
- Qualitative tear film abnormality (e.g., mucin and/or lipid deficiency; see p. 1076)
- Entropion and/or ectropion
- Distichiasis/ectopic cilia/trichiasis (see p. 319)
- Anterior uveitis (see p. 1151)
- Glaucoma (see p. 448)
- Ocular size abnormalities (see p. 778)
- Orbital disease (see p. 790)
- Congenital anomalies or infection of nasolacrimal system (e.g., dacryocystitis; see online chapter: Dacryocystitis)

ETIOLOGY AND PATHOPHYSIOLOGY

- Serous discharge:
  - Corneal mechanical irritation:
    - Distichiasis/ectopic cilia/trichiasis (see p. 319)
    - Entropion (seep. 348)
    - Eyelid agenesis (partial more common than complete): more common in cats

        - Eyelid neoplasia
    - Blockage of nasolacrimal system, congenital:
        - Imperforate lacrimal punctum (dorsal and/or ventral lacrimal puncta/punctum not open; common)
        - Micropunctum (small ventral lacrimal punctum; common)
        - Nasolacrimal aplasia (lack of opening into nasal cavity; rare)
        - Obstruction of nasolacrimal duct in dogs by dacryops (cysts originating from lacrimal tissue) or nasal cyst (rare)
    - Blockage of nasolacrimal system, acquired:
        - Dacryocystitis (inflammation of the nasolacrimal system; see online chapter: Dacryocystitis)
        - Neoplasia (primary, rare; secondary, more common; e.g., nasal; maxillary sinus)
        - Foreign body
        - Trauma to medial canthus/eyelid, involving lacrimal punctum/puncta and/or canaliculus/canaliculi
    - Ocular pain:
        - Conjunctivitis (see pp. 237, 239)
        - Simple or indolent corneal ulceration (see p. 250)
        - Qualitative tear film abnormality (e.g., mucin and/or lipid deficiency; see)
        - Anterior uveitis (seep. 1151)
        - Glaucoma (seep. 1559)
- Mucoid to mucopurulent discharge:
    - Blepharitis (see p. 966)
    - Conjunctivitis (see pp. 237, 239)
    - KCS (seep. 628)
    - Melting/infected corneal ulceration (see p. 250)
    - Orbital abscess/cellulitis (see p. 790)
    - Dacryocystitis (seep. 280)
    - Nasolacrimal foreign body (e.g., grass awn; parasite)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Ocular discharge is apparent on physical examination. The underlying cause should be investigated with a review of the history and physical examination and an ophthalmic examination initially. If the cause is not elucidated, specific ocular tests (some requiring referral) may be warranted.

DIFFERENTIAL DIAGNOSIS

- Ocular discharge with “red eye(s)” is often associated with overproduction of tears (i.e., linked with causes of corneal mechanical irritation, infection or ocular pain).
- Ocular discharge with “quiet eye(s)” (no evidence of ocular pain or eyelid conditions) is often associated with impaired drainage of tears (e.g., congenital or acquired blockage of nasolacrimal system).

INITIAL DATABASE

- Complete ophthalmic examination (seep. 1313), including:
    - Careful examination with magnification of the eyelids
    - Schirmer tear test (dogs: low with KCS; normal 15-25 mm/min; equivocal if 8-15 mm/min)
    - Fluorescein dye application (corneal dye retention with corneal ulceration; dye exiting nares helps confirm patent nasolacrimal system)
    - Intraocular pressure (IOP) (pressures at >30 mm Hg with glaucoma; may be low at <10-15 mm Hg with uveitis; both painful conditions)
- Conjunctival and/or corneal (if infected corneal ulcer) swabs for:
    - Cytologic examination to determine cell type and possible etiology
    - Culture and sensitivity (C&S): aerobic; if needed, anaerobic and fungal
    - PCR: FHV-I, *Chlamydophila* spp., and *Mycoplasma* spp.

ADVANCED OR CONFIRMATORY TESTING

- Varies depending on underlying cause
- Blockage of nasolacrimal system can be investigated with nasolacrimal system flush (see online chapter: Dacryocystitis), if no fluorescein dye exits, nares and blockage is suspected. If results are unclear, confirmation is possible with nasal radiographs and a contrast study of the nasolacrimal system. Contrast CT scanning can accurately assess the integrity of the

nasolacrimal system.

TREATMENT

TREATMENT OVERVIEW

Treatment is directed at the underlying cause. If discharge persists, referral to a veterinary ophthalmologist should be considered.

ACUTE GENERAL TREATMENT

- Treat the underlying cause (see Etiology and Pathophysiology section above).
- Blockage of nasolacrimal system: treat the primary lesion causing the obstruction (may be difficult to diagnose; if so, consult a veterinary ophthalmologist).

CHRONIC TREATMENT

May be required with certain diseases (e.g., KCS)

POSSIBLE COMPLICATIONS

- Conjunctivitis due to FHV-1 may lead to symblepharon (adhesions of conjunctiva to surrounding tissues), KCS, ulcerative keratitis, and stromal keratitis (seep. 524,).
- Chronic epiphora can lead to localized facial dermatitis at the medial canthus.

RECOMMENDED MONITORING

Varies depending on the underlying

PROGNOSIS AND OUTCOME

Prognosis is guarded to excellent depending on the underlying cause.

PEARLS & CONSIDERATIONS

COMMENTS

- Clinicians should perform routine aerobic bacterial C&S tests and submit them in cases of mucopurulent discharge to identify the implicated bacterium or fungus.
- Fungal infections are rare causes of ocular discharge in cats and dogs.
- Serous ocular discharge in cats is common with FHV-1.
- A thorough examination of the ENTIRE conjunctival sac, including dorsally throughout the dorsal surface of the globe and ventrally on both sides of the third eyelid, is necessary to identify any retained foreign material.

CLIENT EDUCATION

At the first sign of abnormal ocular discharge in their pets, owners should consult their veterinarian.

AUTHOR: CHANTALE L. PINARD EDITOR: CHERYL L. CULLEN

Obsessive-Compulsive Disorder (OCD)

BASIC INFORMATION

DEFINITION

Mood/behavioral disorders characterized by repetitive, invariant, patterned behaviors which are exaggerated in intensity, frequency, and duration given the inciting stimuli (i.e., expressed out of context). The behavior interferes with health and well-being.

SYNONYMS

Compulsive disorders, stereotypies; include star gazing, air or fly snapping, spinning/tail chasing, and self-mutilation

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats of any age

GENETICS & BREED PREDISPOSITION: Dogs: Genetic predisposition is suspected. Anecdotally, certain syndromes are more commonly associated with some breeds:

- Acral lick dermatitis: large and giant dog breeds
- Air/fly snapping, checking (hind quarter area), star gazing: miniature schnauzer
- Flank sucking: Doberman pinscher
- Spinning/tail chasing: German shepherd dog, bull terrier, Parson Russell and Jack Russell terrier

Cats: fabric chewing or ingestion is anecdotally associated with so-called Asian breeds (e.g., Siamese, Tonkanese, Burmese).

RISK FACTORS: Stressful or traumatic event. Lack of a daily routine.

CONTAGION & ZOONOSIS: Characteristically, OCD is not induced in conspecifics (e.g., housemates) by affected individuals.

ASSOCIATED CONDITIONS & DISORDERS: The patient may have multiple diagnoses of other impulsive or anxiety-based disorders.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Repetitive behavior that is out of context (may have exacerbated over time or begun suddenly).
- Inciting triggers may be identifiable, or the behavior may occur spontaneously.
- Earlier in the course, the owners may have been able to stop the behavior, but that may not be the case at the time of presentation, and the pet may not stop until exhausted.
- The pet may hide (to perform the behavior) or become aggressive when the owners try to stop the behavior or may begin avoiding the owners.
- Distress vocalizations (whining, crying, yowling, or growling) may occur before, during, or after performance of the compulsive behavior.
- When owners do not identify the behavior as abnormal, the chief complaint may refer to damage to self (alopecia, granuloma, weight loss, change in voice, recurring gastrointestinal obstruction due to pica), damage to the home, or altered social interactions.
- Chief complaint may suggest partial seizures or dysphoria.
- With chronicity, some owners may not consider the behavior problematic or abnormal.

PHYSICAL EXAM FINDINGS

- Often unremarkable
- Skin lesions possible with overgrooming/self-mutilation
- Weight loss if near-constant

ETIOLOGY AND PATHOPHYSIOLOGY

- A genetic contribution is suspected.
- In humans, the current hypothesis of OCD involves dysfunction in a neuronal circuit traversing from the orbital frontal cortex to the cingulate gyrus, caudate nucleus and putamen (the striatum), the globus pallidus, thalamus, and back to the frontal cortex.
- Dysfunction involving glutamate and/or gamma-aminobutyric acid (GABA) is a new focus for research.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

History is the cornerstone of diagnosis: occurrence of repetitive, invariant behaviors that are spontaneous or triggered are difficult or impossible to interrupt and interfere with normal maintenance and social behaviors.

DIFFERENTIAL DIAGNOSIS

- Attention-seeking (behavior occurs only when the owner is present).
- Separation anxiety (behavior occurs only when the owners are absent).
- Cognitive dysfunction (middle aged/geriatric animals that pace or stare)
- Hyperthyroidism (primarily cats)
- Neuropathic pain disorders (e.g., feline hyperesthesia, neck and shoulder hyperesthesia in syringomyelia in the Cavalier King Charles spaniel)
- Degenerative joint disease, anal sac disease, cystitis (excessive licking or hindquarter checking)
- Circling, spinning, and air snapping patients should be evaluated for peripheral or central vestibular disease, psychomotor seizures, or other central nervous system lesions.

INITIAL DATABASE

- CBC, urinalysis, and serum chemistry profile: usually within normal limits (assess for systemic disorders; prior to initiation of medications).
- Dermatologic diagnostic tests (see p. 1248) if skin lesions are a feature.

TREATMENT

TREATMENT OVERVIEW

- All cases of OCD warrant intervention, which is individualized and based on frequency and severity of clinical signs.
- Treatment usually is a combination of behavioral and environmental modification and psychotropic medication.
- The goal is to minimize—and if possible eliminate—bouts of compulsive behavior and the concomitant anxious states that accompany them.

ACUTE AND CHRONIC TREATMENT

- Owner: identify and eliminate trigger events/situations.
- No punishment should ever be used, since it can heighten anxiety and worsen, not improve, the problem.
- If possible, the pet can be redirected to an alternative and incompatible behavior—such as licking food from a toy instead of licking the skin—if the redirection does not make the pet more anxious.
- The pet should be calmly rewarded for any spontaneous calm behavior.
- Keeping a structured daily routine helps decrease anxiety.
- The most successful medications used in the treatment of OCD in people include a number of selective serotonin reuptake inhibitors (SSRIs) and clornipramine, a tricyclic antidepressant (TCA). In dogs and cats, the most commonly used are:
    - Clornipramine (Clomicalm): dogs, 2-3 mg/kg PO q 12 h for a minimum of 16 weeks; cats, 0.5 mg/kg PO q 24 h for a minimum of 16 weeks
    - SSRI drugs (fluoxetine [Prozac, Reconcile]): dogs, 1 mg/kg PO q 24 h for 16 weeks minimum; cats, 0.5 mg/kg PO q 24 h for 16 weeks minimum. Paroxetine (Paxil); dogs, 1 mg/kg PO q 24 h for 16 weeks minimum; cats, 0.25-0.5 mg/kg PO q 24 h for 16 weeks minimum. Sertraline (Zoloft); dogs, 1 mg/kg PO q 24 h for 16 weeks minimum; cats, 0.5 mg/kg PO q 24 h for 16 weeks minimum.
- Very distressed pets may need concomitant use of benzodiazepines (anxiolytic, faster onset of action).
    - Diazepam or oxazepam (oxazepam for cats, obese patients, liver disease), 0.2-0.4 mg/kg PO q 12-24 h; or alprazolam, 0.01-0.025 mg/kg PO q 8-24 h; or clonazepam (dogs), 0.01-0.05 mg/kg PO q 12-24 h for the first 2-3 weeks of treatment. Adjust to ideal dose based on response and lack of adverse (e.g., hepatic) effects. May also be used

preemptively when stress or change in routine is anticipated.
- *N*-methyl-D-aspartate (NMDA) antagonists hold promise as a potential treatment of OCD as single pharmacologic agents or as an adjunct to SSRIs.
- Typically, TCA or SSRI therapy is necessary for longer periods of time than other anxiety-based disorders (months to years, depending upon severity and how long the disorder has been ongoing). Lifelong medication use is not unusual in severe cases.

BEHAVIOR/EXERCISE

Some patients benefit from activities that serve as a controlled outlet for the compulsive behavior (e.g., retrieving, herding, agility, flyball), although they can be too arousing for others; tailor treatment to the individual.

DRUG INTERACTIONS

- TCAs and SSRIs should not be given with monoamine oxidase inhibitors (MAOIs), which are found in many flea and tick collars and dips and in some medications to treat cognitive dysfunction.
- TCAs: use with caution if cardiac arrhythmias, liver or thyroid disorders.
- Use of SSRIs with tramadol, which has a weak serotonin reuptake inhibiting effect, may increase the risk of serotonin syndrome (see p. 1427). Coadministration of fluoxetine, paroxetine, and possibly sertraline may result in decreased plasma concentrations of tramadol's active demethylated metabolite via inhibition of hepatic P450 enzymes. If their use together is necessary, starting both at reduced doses, titrating each to effect and keeping watch for signs of serotonin syndrome reduces but does not eliminate the risk; the client should be informed and should learn to monitor heart rate for profound increases as one way of assaying an early sign of serotonin syndrome.

POSSIBLE COMPLICATIONS

Paroxetine: avoid in renal disease; anecdotal reports of constipation in cats.

RECOMMENDED MONITORING

- Cats receiving paroxetine: monitor stool consistency (reports of diarrhea)
- Animals that take BZDs require a physical exam every 6 months in most U.S. states. The potential for human abuse of the drugs warrants vigilance regarding refill requests.
- Performing a yearly physical exam, CBC, serum chemistry profile, urinalysis, and thyroid screen (twice yearly in senior and geriatric pets) should be a minimum for animals taking other psychotropic medications.

PROGNOSIS AND OUTCOME

- Prognosis is highly variable from guarded to very good for management of the clinical signs of OCD, and is contingent upon a number of variables:
  - Time at which treatment is first instituted (the earlier, the better the prognosis)
  - Owner compliance with all (and not just portions) of the treatment recommendations
  - Frequent communication and follow-up between the owner and the clinician, as the treatment plan will need adjustment based on the pet's response and changing life circumstances
  - Untreated OCD seldom improves and very commonly worsens over time.

PEARLS & CONSIDERATIONS

COMMENTS

Repetitive behaviors are commonly thought of by clients as entertaining or as “quirks” in their pet's personality and seldom understood to be potential early markers of this disease. Many such pets go through their lives suffering greatly while their owners are ignorant of the distress associated with OCDs. Early intervention is a significant factor in the successful treatment of OCDs, but owners seldom talk about behavior during a veterinary visit unless prompted. It is extremely important to incorporate questions about behavior into all wellness and sick exams. “Any behavior that is new, different or peculiar since the last veterinary exam?” is sufficient to open the door and encourage owners to talk about their pet's behavior.

PREVENTION

- Consider temperament when selecting breeding stock.

- At the onset of any repetitive behaviors, the owners should be instructed to watch for a worsening of signs or any specific triggers that may initiate the behavior. Keeping a diary, written or preferably on video media, is helpful to track onset and progression.

TECHNICIAN TIPS

OCD may create a home situation that is very different and disrupted compared to an owner's expectations. Support from the entire veterinary staff for identifying and treating this disorder correctly can be rewarding for all and lifesaving for the pet.

CLIENT EDUCATION

Treatment of OCD is never static, often lifelong, and subject to adjustment based on changing conditions. Relapses may occur with treatment discontinuation. Planning in advance of added stressors can help minimize their effect on an OCD patient.

SUGGESTED READING

AUTHOR: SONYA JUARBE-DIAZ

EDITOR: KAREN OVERALL

Obesity

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A chronic relapsing disorder associated with excessive accumulation of body fat, resulting in an increase in body weight beyond the limitation of skeletal and physical requirements. Animals with an accumulation of body fat of more than 20% of their moderate body weight for that species and breed are considered obese.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Any species, both sexes, any age (3 months of age until the end of life)

GENETICS & BREED PREDISPOSITION: Between 30% and 70% of the risk for obesity in dogs is attributable to breed; breeds that are reportedly at increased risk include Labrador retrievers, cairn terriers, cocker spaniels, dachshunds, Shetland sheepdogs, basset hounds, beagles, and cavalier King Charles spaniels.

RISK FACTORS: Genetic predisposition, neutering, multiple pet households, indoor housing, overfeeding, sedentary lifestyle, metabolic disorders

ASSOCIATED CONDITIONS & DISORDERS: Some obese animals may be at increased risk for diabetes, joint problems, muscle tears, hip dysplasia, tracheal collapse, skin and heart disorders, complications during anesthesia and surgery, and reduced life expectancy.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- The most common history collected is of a pet that has gradually been gaining weight over a period of years, and the owner has been unaware of the increase.
- Another common history is of acute weight gain over a period of a few months after the animal was switched to a different diet or started on a new medication; the animal could also have gone through a stressful period or could have developed a metabolic disorder.

PHYSICAL EXAM FINDINGS: A body condition score (BCS) of 5/5 is characterized by the following:

- Ribs and other skeletal prominences are difficult to feel under thick fat cover.
- Fat hangs from the abdomen.
- The tail base is thickened.
- The animal does not have an apparent waist when it is viewed from the side or above.
- The animal is markedly broadened when it is viewed from above.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis should include identification of conditions that can predispose to or be mistaken for weight gain.

DIFFERENTIAL DIAGNOSIS

- Hypothalamic disorders, hypothyroidism, hyperadrenocorticism (Cushing's disease), insulinoma, chronic corticosteroid use, and chronic use of some epileptic drugs (phenobarbital) can cause obesity.
- Tumors, edema, and ascites may be confused for obesity.

INITIAL DATABASE

- CBC, serum chemistry panel, urinalysis: clinicians should assess for metabolic diseases that could affect the animal's weight,

such as diabetes mellitus, hyperlipidemia, or hypothyroidism.
- Thyroid function studies (TSH, free T4) are used for evaluating the role of hypothyroidism as a cause of obesity (prevalence of hypothyroidism is less than 1% in dogs; rare in cats).

ADVANCED OR CONFIRMATORY TESTING

Radiographic imaging studies are not specific in the diagnosis of obesity but may provide evidence of the extent of fat accumulation in the periphery and in the abdominal and thoracic compartments.

TREATMENT 

THERAPEUTIC OVERVIEW

The therapeutic goal is to return the animal to a healthy status and resolve complaints. A 10% decrease in body weight reduces the risk of obesity-related diseases in humans and a 1%-2% weight loss per week is a reasonable initial goal for animals.

ACUTE GENERAL TREATMENT

Treatment is aimed at weight reduction and risk-factor modification.

- Clinicians should take an accurate diet history; it provides essential information about the food intake of the pet as well as information about the food itself and the related bond between a pet and owner. An accurate diet history can take 30-60 minutes to collect.
- The clinician should calculate caloric intake from all sources. Caloric content of human foods is available at the U.S. Department of Agriculture's Web site (http://nal.usda.gov).
- Clinicians should determine weight reduction goal and calories. An initial goal of a 10% weight loss usually is reasonable and can be attained by prescribing an energy deficit of 10 kcal per kilogram of body weight per day through a combination of decreased intake (about 8 kcal/kg/d) and increased activity-induced expenditure (about 2 kcal/kg/d).
- The clinician should make sure the animal completes the dietary plan.
    - The clinician should create the plan with the owner to increase compliance for completion of the plan.
    - Once the owner and clinician agree to a plan, a schedule of follow-ups must be established to provide coaching and monitor progress.

NUTRITION/DIET

- Therapeutic and over-the-counter (OTC) diets are available that have been formulated to have a low-caloric density and may aid in restricting calories.
- Cases that require a large amount of weight loss may require a therapeutic diet versus an OTC to attain the protein/calorie ratio needed for success.
- In all cases, it is crucial to determine the protein, mineral, and vitamin intake of the diet to ensure that changes will not result in nutrient depletion.

BEHAVIOR/EXERCISE

- The owner should encourage the animal to be active 30 minutes every day if the animal can tolerate this comfortably. This can be achieved with gradual increased increments of 10 minutes of activity per day. The clinician and owner can adjust the time and intensity of the activity according to weight loss and the animal's enjoyment.
- There are many behavioral solutions that may be presented to the owner and should be a part of every recommendation. See Suggested Reading below.

DRUG INTERACTIONS

Glucocorticoids, phenobarbital

POSSIBLE COMPLICATIONS

Nutrient depletion, increased anesthetic risk, slower wound healing, hepatic lipidosis (cats)

RECOMMENDED MONITORING

The clinician's first contact with the client occurs 1 week after initial recommendations are made, followed by repeat “check-ins” at 6 weeks, 3 months, 6 months, and 1 year. These appointments permit the clinician to monitor the animal's BCS and weight progress,

make adjustments as needed, and continue to support and motivate the client.

PROGNOSIS AND OUTCOME

Very good, depending on compliance of owner

PEARLS & CONSIDERATIONS

COMMENTS

- According to veterinary experience, the critical key to successful obesity therapy is ongoing follow-up and support of the animal and owner's progress.
- Many clinics are opting to create a “clinic within a clinic“ that is run by the staff and entails a weight management program similar to Weight Watchers for their clients' pets.

PREVENTION

Starts with puppies/kittens; clinicians should recommend adjusting feeding after spaying/neutering if needed.

TECHNICIAN TIPS

- Assign a “weight loss consultant” to each client. Each time the client calls or comes in, there is consistency in care.
- Provide measuring cups with a line or marker drawn on the cup for desired amount to help with compliance.
- Create a contest to spread the enthusiasm to keep the clients interested.

CLIENT EDUCATION

- Clients should be able to assess and feed according to their pet's appropriate BCS.
- Every client should know how many kilocalories a pet food cup or can contains.

Pythiosis and Lagenidiosis

BASIC INFORMATION

DEFINITION

Pythiosis and lagenidiosis are oomycotic infections of the gastrointestinal (GI) tract *(Pythium)* or skin *(Pythium* and *Lagenidium)* of dogs and cats caused by *Pythium insidiosum* and *Lagenidium* spp.

SYNONYMS

Phycomycosis, swamp cancer

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs are affected more often than cats. Dogs (young to middle-aged adults); cats (any age but often less than 1 year old).

GENETICS & BREED PREDISPOSITION

Dogs: large breeds, especially outdoor working breeds such as Labrador retriever

RISK FACTORS

Recurrent exposure to warm freshwater lakes, swamps, and ponds that may contain *Pythium* or *Lagenidium* zoospores, but disease in house pets without such exposure has been reported.

CONTAGION & ZOONOSIS

Motile zoospores found in warm freshwater habitats cause infections in mammalian species including humans; no direct contagion or zoonotic potential.

GEOGRAPHY AND SEASONALITY

Endemic in warm, humid regions such as the southern United States and the Gulf Coast of Texas, southeast Asia, and eastern Coastal Australia. Infections are most often diagnosed in fall, winter, and early spring.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Pythiosis: GI disease, cutaneous disease
- Lagenidiosis: cutaneous disease initially, usually progressing to systemic involvement by the time the diagnosis is established; often affecting large vessels

HISTORY, CHIEF COMPLAINT

- GI infection: weight loss with chronic vomiting and/or diarrhea; large-bowel diarrhea seen commonly; dogs usually continue to feel well and have a good appetite despite significant weight loss.
- Cutaneous infection: nonhealing wounds and invasive skin masses containing ulcerated nodules and draining tracts

PHYSICAL EXAM FINDINGS

Dog:

- GI infection: chronic severe weight loss in an otherwise active, alert dog; abdominal mass often palpable
- Cutaneous infection: chronic nonhealing wounds and invasive masses that contain ulcerated nodules and draining tracts, most often involving the extremities, tailhead, ventral neck, or perineum

Cat:

- Nasopharyngeal infection: chronic nasal discharge and upper respiratory signs
- Cutaneous infection: invasive subcutaneous masses (especially in inguinal, tailhead, and periorbital regions) or ulcerated plaquelike lesions on the extremities
- GI infection: occasionally seen

ETIOLOGY AND PATHOPHYSIOLOGY

- Infection follows exposure of the immunocompetent host to motile zoospores in warm freshwater environments.
- Hyphal growth within affected tissues causes massive inflammation resulting in masses, draining lesions, and regional lymphadenopathy. In the GI tract, transmural thickening may result in GI obstruction.
- Dogs with *Pythium* infection may have any portion of the GI tract affected; pylorus, proximal duodenum, and ileocolic junction are affected most often. Mesenteric lymphadenopathy is common. Esophagus is affected less often.
- Dogs with *Lagenidium* spp. infection have progressive cutaneous or subcutaneous lesions (often multifocal) involving the extremities, mammary region, perineum, or trunk.
- In contrast to *Pythium* infection, dogs with lagenidiosis have lesions in distant sites, including great vessels, sublum-bar and inguinal lymph nodes, lung, pulmonary hilus, and cranial mediastinum.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in one of two contexts: chronic diarrhea (where marked intestinal thickening/mass raises the differential diagnosis of neoplasia) or chronic, invasive, often ulcerated subcutaneous masses. Confirmation is either via serum titers or histologic demonstration of the organism on biopsy.

DIFFERENTIAL DIAGNOSIS

- GI neoplasia
- Pyloric outflow obstruction due to hypertrophy, intussusception
- Zygomycosis and other hyphal fungal infections
- Mycobacterial, nocardial, and actino-mycotic infections of skin

INITIAL DATABASE

- CBC: eosinophilia and nonregenerative anemia may be seen.
- Serum biochemistry panel: hyperglobulinemia is common. Hypercalcemia has been reported.
- Abdominal radiographs: abdominal mass effect; evidence of intestinal obstruction
- Abdominal ultrasound: severe segmental thickening of the GI tract, mesenteric lymphadenopathy

ADVANCED OR CONFIRMATORY TESTING

- Histopathologic examination of tissue: eosinophilic pyogranulomatous inflammation; *Pythium* hyphae are difficult to visualize on H&E stained sections, whereas *Lagenidium* hyphae are easier to see.
    - Broad, rarely septate, occasionally branching hyphae seen on silver stains. *Lagenidium* hyphae are much wider than *Pythium* hyphae.
    - Immunohistochemical stains can be used for confirming the diagnosis.
- Culture using fungal media
- Serologic testing: ELISA and immuno-blot assays available from the *Pythium* laboratory at Louisiana State University —sensitive and specific for diagnosis of pythiosis and lagenidiosis and for monitoring response to therapy (titers may decrease to normal in months following successful treatment).

TREATMENT

TREATMENT OVERVIEW

Complete surgical resection is indicated whenever possible; otherwise disease will progress.

ACUTE GENERAL TREATMENT

Complete surgical resection is treatment of choice: segmental GI lesions are occasionally completely resectable, especially in cats or if diagnosed early in dogs; if cutaneous lesions are limited to a single extremity, amputation is recommended. Local postoperative recurrence is common. Resection of *Lagenidium* lesions is less likely to be curative.

CHRONIC TREATMENT

- Medical therapy with itraconazole (10 mg/kg PO q 24 h) and terbinafine (5-10 mg/kg PO q 24 h) is recommended for at least 2-3 months after surgery. Some animals (fewer than 20%) will respond to long-term medical therapy alone. Medical therapy for lagenidiosis is typically ineffective.
- Treatment with a *Pythium* vaccine has been recommended but has not been well evaluated, and inconsistent results have been noted.

POSSIBLE COMPLICATIONS

Sudden death associated with *Pythium* infarction or invasion of mesenteric vessels or rupture of a *Legenidium*-induced aneurysm of the aorta or vena cava

RECOMMENDED MONITORING

ELISA serology should be used for monitoring response to medical therapy or recurrence after surgical resection.

PROGNOSIS AND OUTCOME

- Pythiosis: fair to guarded if lesions appear surgically resectable; guarded to poor if medical therapy alone is used
- Lagenidiosis: grave

PEARLS & CONSIDERATIONS

COMMENTS

- GI pythiosis is often mistaken diffuse neoplasia at surgery.
- Aggressive surgery with wide surgical margins is critical to surgical cure.
- ELISA testing can result in a noninvasive diagnosis and can be used to monitor treatment.

CLIENT EDUCATION

Chronic vomiting and weight loss in a dog that spends time in the water in endemic areas should prompt early evaluation for *Pythium* infection.

Pyrethrins/Pyrethroids Toxicosis

BASIC INFORMATION

DEFINITION

Pyrethrin (natural) and pyrethroid (synthetic) insecticides are used in numerous household and garden insecticide products and many flea-control formulations (aerosols, dusts, granules, sprays, collars, dips, shampoos, and once-a-month spot-on products). Adverse reactions and toxicosis vary in severity depending on the agent involved, animal type, and route of administration. Signs can include hypersalivation and restlessness, behavior changes (hiding), vomiting, ataxia, agitation, tremor, and seizures.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Cats are more sensitive than dogs, especially to concentrated synthetic pyrethroids such as permethrin (present at 45%-65% in many dog topical products).
- No breed or sex predisposition

RISK FACTORS

Very young, aged, anemic, or debilitated animals may be at risk for greater toxic effects.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Route:

- Accidental, inadvertent oral exposure can result in acute-onset hypersalivation and vomiting.
- Dermal application may result in acute-onset dermal paresthesia or tingling effect due to stimulation of sensory nerve endings; some dermal-only exposures result in hypersalivation.

Type:

- Pyrethrins (in concentrated amounts) and type I pyrethroids can cause acute-onset tremor, ataxia, hyperexcit-ability, and hyperthermia.
- Type II pyrethroids can cause acute hypersalivation, tremors, rigidity, seizures, ataxia, and coma.

HISTORY, CHIEF COMPLAINT

- History of product use on the animal or another family animal (relay toxicosis), in the yard, or in the house
- Hypersalivation, vomiting; agitation, constant restless or irritable behavior
- Muscle tremors, twitching, ataxia, or seizures

PHYSICAL EXAM FINDINGS

- Hypersalivation
- Muscle tremors (partial to full body), seizure (primarily in cats exposed to permethrin)
- Hyperthermia (if significant neuromuscular signs) followed by hypothermia

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

- Pyrethrins are obtained naturally from *Chrysanthemum* flowers
  - Examples: pyrethrin I and II, pyrethrum, cinerin I and II, jasmolin I and II
  - Pyrethrins are generally safer than pyrethroids.
- Pyrethroids are synthetic analogs of the pyrethrin base and of two basic types:

- Type I: lacks an alpha-cyano group
- Type II: possesses an alphacyano group. Type II is more toxic than type I.
  - Examples, type I: allethrin, bar-thrin, bifenthrin, bioresmethrin, cismethrin, dimethrin, permethrin, phenothrin, resmethrin, tefluthrin, tetramethrin
  - Examples, type II: acrinathrin, cyfluthrin, cyhalothrin, cyperme-thrin, cyphenothrin, deltamethrin, esfenvalerate, fenpropathrin, fen-valerate, flumethrin, fluvalinate, lamda-cyhalothrin, tralomethrin
  - Agents are sold under numerous trade names.
  - Different formulations may be combined with an insect growth regulator (e.g., methoprene, pyriproxyfen) and one or more synergists (e.g., piperonyl but oxide, MGK-264).

Mechanism of Toxicosis:

- Pyrethrin and pyrethroid agents delay opening and closing of sodium channels, resulting in repetitive nerve discharges.
- Type I pyrethroids and pyrethrins cause repetitive discharges and tend to cause tremors and seizures.
- Type II pyrethroids cause longer duration of the sodium current in the axon than type I pyrethroids and pyrethrins. Type II pyrethroids can cause conduction blockage, typically causing weakness and paralysis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on history (known recent use of a pyrethrin or pyrethroid agent either on the patient or in the patient's environment), physical signs (hypersalivation, tremors, twitching, ataxia), and often both. Widely promoted “plant-based” nature of pyrethrins/pyrethroids may mean clients do not consider exposure, and the diagnosis can depend on the clinician's recognition of signs as a reason for asking the owner specifically about exposure to “natural” insecticides.

DIFFERENTIAL DIAGNOSIS

Toxicologic:

- Tremorgenic mycotoxins (see p. 434)
- Organophosphate/carbamate (see p. 792)
- Metaldehyde toxicosis (see p. 720)
- Caffeine (methylxanthine) toxicosis (seep. 194)
- Nicotine toxicosis (see p. 766)
- Prescription, nonprescription drug (serotonergics, dopaminergics, sympa-thomimetics) overdose
- Strychnine toxicosis (see online chapter: Strychnine Toxicosis)
- Organochlorine toxicosis

Spontaneous, Nontoxicologic:

- Intracranial disorders (neoplasia, encephalitis, trauma, idiopathic epilepsy)
- Metabolic disorders (hypocalcemia, portosystemic shunt, etc.)

INITIAL DATABASE

- Body temperature (elevated initially due to muscle tremors followed by hypothermia)
- Serum renal profile and urinalysis (for myoglobinuria, renal compromise due to pigment nephropathy, if severe tremors are present)
- CBC, serum biochemistry profile: no significant changes are expected in routine cases.
- Neurologic examination

ADVANCED OR CONFIRMATORY TESTING

Pyrethrins/pyrethroids can be detected in hair, stomach contents, fat, liver, brain, serum, and urine. Hair samples can be submitted to a veterinary diagnostic laboratory; presence of insecticide only confirms exposure.

TREATMENT

TREATMENT OVERVIEW

Successful management generally involves treatment and resolution of neuromuscular signs, followed by dermal decontamination (bathing with a dilute dishwashing detergent solution as appropriate for the case) once the patient is stable, to prevent reexposure through grooming/licking. Supportive care is indicated until recovery (typically 1-3 days).

ACUTE GENERAL TREATMENT

- In mild cases (excessive hypersalivation following a labeled application), wipe the patient down with a soft, clean, damp washcloth to remove any excess/residual product from the application site. Clean the muzzle area of saliva, and provide small amount of a tasty treat to dilute any small traces of ingested toxicant.
- In more severe cases (tremor or seizure), treatment requires stabilization of neuromuscular signs:
  - Severe tremor or convulsive activity is best controlled with methocarbamol (consider 100-150 mg/kg IV as loading dose, onset is immediate; labeled dose range is 55-220 mg/kg IV); in this range, methocarbamol is a relatively very safe drug. Can use orally (60-130 mg/kg PO), but has a 30-min onset by this route.
    - Repeat PRN to effect, but do not exceed 330 mg/kg per day (labeled ceiling).
  - Diazepam, 0.5-1 mg/kg IV, for mild tremor or paresthesia. Diazepam is generally not effective for controlling severe tremors.
  - If necessary for refractory seizures, may consider phenobarbital (dog, cat, 2-5 mg/kg slow IV, not more than 60 mg/min to avoid respiratory depression, especially in cats; onset 5 minutes); propofol (dog, cat, 3-6 mg/kg slow IV, avoid respiratory depression/apnea; then IV constant rate infusion 0.1-0.6 mg/kg/min), or isoflurane.
- Decontamination of severely-affected patient:
  - Bathe patient (following stabilization; see Pearls) in a dilute solution of liquid dishwashing detergent in lukewarm tap water for dermal exposures, and repeat if needed. Dry thoroughly to prevent chilling.
  - Induction of vomiting rarely indicated; only in patients not showing any clinical signs following accidental ingestion of large amounts of product (seep. 1364)
- Activated charcoal: as above for induction of vomiting (rarely used, only with large ingestions in the absence of any clinical signs). Dose according to charcoal product labeled instructions.
- Supportive care:
  - IV fluids (e.g., lactated Ringer's solution to correct dehydration or volume loss, plus maintenance to maintain adequate perfusion; forced diuresis not indicated).
  - Atropine can be considered for severe hypersalivation, 0.01-0.02 mg/kg IV/IM. Atropine is not antidotal and provides no beneficial effect for other signs.
  - Regulation of body temperature (cool water bathing if hyperthermia; avoid reducing temperature too rapidly).

DRUG INTERACTIONS

Concurrent exposure to other pesticides may increase risk of toxicosis.

POSSIBLE COMPLICATIONS

- Myoglobinuria and acute renal failure due to severe tremors (uncommon)
- Disseminated intravascular coagulation secondary to prolonged hyperthermia (uncommon)

PROGNOSIS AND OUTCOME

- Generally good; recovery in 1 to 3 days
- Guarded if tremors are not controlled or if seizures are prolonged and/or intractable

PEARLS & CONSIDERATIONS

COMMENTS

- In general, flea products will not cause systemic CNS signs if used according to label.
- Cats are very sensitive to concentrated permethrin-based dog-only topical products.
- Systemic CNS effects unlikely if animals access a sprayed area after it has dried.
- Tremors may last for 3 days. After patient stabilization, oral methocarbamol (50-100 mg/kg PO q 6-8 h) can be started, and the animal can be discharged for home observation.

PREVENTION

- Separate permethrin-treated dogs from dog-friendly family cats for several days to avoid relay toxicosis in the cat.

- Keep pets out of areas being treated with insecticides until the product has dried.

TECHNICIAN TIPS

- Note of caution: attempting to bathe a cat that is already tremoring or convulsing, and prior to stabilizing the patient, may further stress the patient and complicate successful treatment. It is essential to control these severe signs first, then proceed to bathing procedure (common sense, but this error has been made repeatedly by veterinarians and technicians alike).
- Whether in response to a client's question or during in-hospital use, it is important to avoid using pyrethrin/pyrethroid products formulated for dogs on cats, which is a significant risk.

CLIENT EDUCATION

Observation of labeled and veterinary instructions for safe applications to reduce accidents at home; ensure cats in the home are not casually coming into contact with dogs being treated with synthetic pyrethroids.

1ST EDITION AUTHOR: ERIC K. DUNAYER

Pyothorax

BASIC INFORMATION

DEFINITION

Accumulation of purulent exúdate within the pleural space; associated with significant pleural inflammation

SYNONYM

Pleural empyema

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats:

- Medium and large breeds of dogs ovenepresented
- Males of both species ovenepresented
- Median age of occurrence = 4 years

GENETICS & BREED PREDISPOSITION

- Dog: hunting breeds subject to increased risk of inhaled foreign (plant) material
- Cat: higher risk if from multicat household and if young; no difference if indoor versus outdoor

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Slowly progressive onset of dyspnea, inappetence, weight loss
- Acute decompensation with dyspnea/tachypnea/collapse from pleural effusion

PHYSICAL EXAM FINDINGS

- Respiratory: dyspnea, tachypnea; muffled heart and lung sounds on auscultation (unilateral/bilateral)
- Systemic: depression, weight loss, ± pyrexia, ± pale mucous membranes
- Cats: possibly decreased compressibility of cranial thorax on palpation

ETIOLOGY AND PATHOPHYSIOLOGY

- Septic pyothorax (most common): potential causes of infection of the pleural space include:
  - Penetrating/migrating plant material
  - Inhaled plant material
  - Penetrating injury:
    - Bite, stab, gunshot wounds
  - Esophageal perforation:
    - Foreign body
    - *Spirocerca lupi* infection
  - Hematogenous spread
  - Extension from diskospondylitis
  - Pneumonia or lung abscess
  - Pulmonary or intrathoracic neoplasia
- Pleuritis (and nonseptic pyothorax) can be associated with canine hepatitis, leptospirosis, canine distemper, feline infectious peritonitis, or feline upper respiratory tract infection.
- Cats: role of feline immunodeficiency virus (FIV) or feline leukemia virus (FeLV) in development of pyothorax not proven

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on patient signalment, presenting history, and physical examination findings. Confirmation requires demonstration of pleural fluid by diagnostic imaging and appropriate analysis of the fluid. Cytologie examination provides a working clinical diagnosis.

DIFFERENTIAL DIAGNOSIS

- Pulmonary disease:
  - Pneumonia
  - Abscess
- Pleural effusion:
  - Chylothorax
  - Heart failure
  - Hemothorax
  - Idiopathic
- Diaphragmatic hernia
- Intrathoracic neoplasia

INITIAL DATABASE

- CBC:
  - Usually: neutrophilic leukocytosis with or without a left shift
  - Possible: leukopenia, thrombocyto-penia if sepsis
- Serum biochemistry profile:
  - Multiple abnormalities (hepatic and renal parameters, electrolytes, hypo-albuminemia, etc.) can occur secondary to sepsis.
- Pleural fluid evaluation (see p. 1338):
  - Diagnostic: obtain fluid for analysis; typically blood-tinged fluid, which may be opaque and often has a foul odor (anaerobes). Macroscopic yellow clumps (“sulfur granules”) strongly suggest presence of *Actinomyces* (see p. 26).
- Analysis of pleural fluid:
  - Fluid analysis/cytologic examination; exúdate (by definition):
    - Protein >3 g/dL
    - Nucleated cell count >7 10^9/L, often >30 × 10^9/L
    - Degenerate neutrophils predominate, with macrophages and activated mesothelial cells also present. Intraleukocytic bacteria are diagnostic (septic pyothorax).
  - Gram stain:
    - Guides initial empirical antimicrobial therapy:
      - Oropharyngeal bacteria (e.g., *Pasteurella* spp., *Bacteroides* spp., *Fusobacterium* spp.) common in cats; *Escherichia coli* in dogs (both gramnegative rods)
      - *Actinomyces* (anaerobe) and *Nocardia* (aerobe): both grampositive short rods and filaments; important potential pathogens in dogs from regions where grass awn endemic
  - Anaerobic and aerobic bacterial culture and susceptibility (C&S):
    - Test of choice for planning long-term antimicrobial therapy
- Survey thoracic radiographs:
  - Initially to identify pleural effusion
  - After therapeutic thoracocentesis, to evaluate pleural space, mediastinum, and pulmonary parenchyma for potential primary cause of pyothorax
- Thoracic ultrasound examination:
  - Identify masses and evaluate their internal structure.
  - Identify site of greatest pleural effusion for centesis (if overall small volume of effusion).
  - Identify foreign material in the pleural space if possible (may be very challenging).

ADVANCED OR CONFIRMATORY TESTING

CT scan:

- Potentially identify cause of pyothorax.
- Evaluate mass(es) in thoracic cavity and determine if resectable.

TREATMENT

TREATMENT OVERVIEW

Patient stabilization, pleural drainage (thoracostomy tubes for pleural lavage), +/− surgical exploration and débridement of the thoracic cavity and long-term antimicrobial therapy are the standard of care. Long-term antimicrobial therapy is based on results of microbiologic C&S testing.

ACUTE GENERAL TREATMENT

- Stabilization of respiratory compromise:
  - Therapeutic (and diagnostic) thoracocentesis (see p. 1338)
  - Oxygen administration (seep. 1318)
  - Intensive care monitoring
- Correction of fluid and electrolyte deficits
- Antimicrobial therapy:
  - Empirical therapy active against both aerobic and anaerobic bacteria:
    - Gram stain results (as previously described)
    - Amoxicillin/ampicillin, 22 mg/kg IV or PO q 8 h, if *Actinomyces* suspected
    - Trimethoprim-sulfa, 15 mg/kg PO q 12 h, if *Nocardia, E. coli,* or *Pasteurella* suspected
- Medical management:
  - Bilateral thoracostomy tube placement
  - Thoracic lavage every 6-8 hours with body-temperature warmed sterile saline
  - Serial cytologic evaluation of pleural fluid to assess success of lavage therapy:
    - Improvement includes change from degenerate neutrophils with intracellular or extracellular bacteria to nondegenerate neutrophils without bacteria.
- Surgical management:
  - Indicated if:
    - Definitive cause identified and retained in thoracic cavity (foreign body, lung lobe abscess)
    - Fluid loculated within the pleural space (lavage cannot access portions of fluid accumulation)
    - Patient fails to respond to intensive medical therapy (4-5 days of pleural lavage and antibiotics)
    - *Actinomyces* present (in dogs, notoriously poor response to medical management alone)
  - Consists of aggressive débridement of the pleural space, removal of underlying cause if identified, thorough intraoperative lavage, and postoperative intermittent pleural aspiration, lavage, and antimicrobial therapy.

CHRONIC TREATMENT

- Thoracostomy tube removal based on overt clinical and cytologic resolution of infection
- Long-term antibiotic therapy in all cases:
  - Based on accurate identification of organism(s) involved
  - Up to 3 months of therapy may be required.

POSSIBLE COMPLICATIONS

Failure to resolve/recurrence of pyothorax:

- Cause not removed
- Failure of medical management:
  - Ineffective pleural lavage
  - Ineffective/inappropriate antibiotic therapy

RECOMMENDED MONITORING

Survey thoracic radiographs:

- At completion of antibiotic therapy
- Periodically (every 3 months)

PROGNOSIS AND OUTCOME

- Surgical management is associated with a better prognosis than medical management in dogs with pyothorax: disease-free at 1 year: 78% (surgical) versus 25% (medical).
- Development of fibrosing pleuritis is associated with poor outcome.
- Lower heart rate and hypersalivation are both associated with poorer outcomes in cats.
- Overall, *66%* of cats and 80% of dogs can survive if treated appropriately.

PEARLS & CONSIDERATIONS

COMMENTS

- Intensive therapy should start immediately upon diagnosis. Undertreatment is thought to be a major contributor to morbidity/mortality.
- Surgical treatment has been associated with a better outcome than medical treatment alone.
- Bilateral thoracostomy tubes are helpful in aspiration and lavage of the pleural space.
- Antimicrobial therapy should be guided by culture and susceptibility, with attention paid to *Actinomyces* and *Nocardia.*
- Obligate anaerobes are common in pyothorax and are present in combination with aerobes; antimicrobial treatment should be aimed at both types of bacteria until culture results are available.

TECHNICIAN TIPS

Knowledge of and experience in working with thoracostomy tubes is important in the management of patients with pyothorax:

- Used as the primary treatment modality for nonsurgical thoracic drainage and lavage
- Used in the postoperative period for continued thoracic drainage +/− lavage.

AUTHOR: MARYANN G. RADLINSKY

EDITOR: RICHARD WALSHAW

Pyometra

BASIC INFORMATION

DEFINITION

Very common uterine disease of middle-aged to older female dog or cat; characterized by an accumulation of purulent material in the uterine lumen or uterine stump

SYNONYMS

Purulent endometritis, purulent metritis, pyo, pyometritis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Female canine or feline (more common in bitches than queens)
- Any age after puberty (more common after 5-6 years of age)

RISK FACTORS

- In dogs, age, hormonal (estrogen and/or progestin) treatments and estrous cycle irregularities are proposed risk factors.
- In cats, pseudopregnancy and ovarian diseases (e.g., granulosa cell tumor) are risk factors.

ASSOCIATED CONDITIONS & DISORDERS

- Sepsis
- Septic shock
- Systemic inflammatory response syndrome (SIRS)
- Multiple organs dysfunction syndrome (MODS)
- Disseminated intravascular coagulation (DIC)
- Acute renal failure
- Acute hepatic injury
- Vaginitis and UTI
- Peritonitis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Open pyometra: mucoid, purulent, mucopurulent or hemorrhagic vulvar discharge
- Closed pyometra: no (or minimal) vulvar discharge

HISTORY, CHIEF COMPLAINT

- Diestrus or anestrus (from a few weeks following the end of estrus up to a few months)
- Anorexia, vomiting
- Lethargy, depression
- Polyuria and polydipsia (PU/PD)
- Abdominal distension (less common)
- Vulvar discharge may be noted by owner.
- Intact female or history of incomplete ovariohysterectomy
- Previous treatment to induce abortion or parturition
- In the queen, the disease is generally more subacute or chronic and associated with few clinical signs but irregular cycles, vaginal discharge, and/or abdominal distension.

PHYSICAL EXAM FINDINGS

- Purulent vulvar discharge is common and should always prompt the consideration of pyometra:
  - Absence of vulvar discharge does not rule out pyometra.
- Abdominal palpation:
  - Signs of abdominal pain
  - Enlarged uterus (may be difficult to palpate if only a moderate enlargement and/or the abdomen is tense)
  - Abdominal distension
- Dehydration
- Fever (or hypothermia if severe, such as in septic shock)
- Red mucous membranes (hyperdynamic stage of sepsis) or pale mucous membranes (septic shock)
- Normal pulse and cardiac auscultation or tachycardia, weak pulse, and cool extremities possible with septic shock
- Normal respiration or hyperpnea

ETIOLOGY AND PATHOPHYSIOLOGY

Two proposed pathways:

- Chronic degenerative uterine process associated with progesterone and bacterial contamination and proliferation; in older animals, often associated with cystic endometrial hyperplasia (CEH):
  - Excessive diestrous endometrial hyperplasia (progesterone-induced), causing cyst formation, decrease myometrial activity, local immune suppression.
  - Pyometra results when bacteria colonize the uterus via ascension through the cervix, or hematogenously.
  - The bacterium most commonly isolated from pyometra is *Escherichia coli,* but *Staphylococcus* spp., *Streptococcus* spp., *Pseudomonas* spp., and *Proteus* spp. also reported.
  - In the queen, the pathogenesis is most likely associated with prolonged progesterone impregnation during pseudopregnancy.
- Pyometra not associated with CEH; trophoblastic reaction:
  - Subclinical bacterial infection in early to mid-diestrus induces uterine endometrial hypertrophy followed by a trophoblastic like hyperplasia of the endometrium and endometrial glands.
  - Increase in glandular secretions exacerbates the infection. This mechanism may explain the occurrence of pyometra in younger bitches.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Pyometra may be strongly (open pyometra) or weakly (closed pyometra) suspected on physical exam; noting that the patient is an intact female is a critical element of the initial suspicion. Leukocytosis on CBC further supports the diagnosis but is not always present. Clinical confirmation justifying treatment (most commonly ovariohysterectomy) comes from abdominal ultrasound.

DIFFERENTIAL DIAGNOSIS

- Mucometra (uterine lumen filled with mucoid endometrial gland secretions without infection; no systemic signs or leukocytosis expected)
- CEH
- Pregnancy
- Vaginitis and purulent UTI
- Reproductive tract tumors
- Uterine torsion
- Postpartum metritis
- Other systemic diseases resulting in an acute abdomen

INITIAL DATABASE

- CBC:
  - Mild to moderate normocytic, normochromic anemia (packed cell volume 30%-35%)
  - Leukocytosis with left shift and/or toxic changes
  - Approximately 25% of leukograms are within normal range in pyometra cases.
- Serum biochemistry profile: elevated hepatic and renal values possible
- A vaginal swab, particularly if it is collected near the external cervical os, may allow detection of a purulent exudate in closed pyometra.
- Vaginal cytologic exam: presence of numerous degenerate neutrophils
- Urinalysis:

- Cystocentesis is contraindicated in suspected or confirmed pyometra cases.
- Catheterized or free-catch samples may show evidence of infection, either as a real finding (bacterial cystitis is often concurrent with pyometra) or as an artifact of collection.

- Abdominal radiographs:
  - Distended viscus consistent with enlarged, fluid-filled uterus:
    - Note: Abdominal radiographs will not differentiate between pyometra and pregnancy of less than 45 days of gestation or mucometra.
    - Abdominal radiographs may not detect slightly enlarged uterus.
- Ultrasonographic examination:
  - Enlarged fluid-filled uterus:
    - Note: easily differentiates from pregnancy; abdominal ultrasound is the method of choice for establishing a diagnosis of pyometra.

ADVANCED OR CONFIRMATORY TESTING

- Open pyometra: cranial vaginal (near external cervical os) culture and sensitivity (C&S)
- Closed pyometra: transcervical endoscopy with uterine sample for C&S
- Gross and histopathologic examination of the surgically removed uterus

TREATMENT

TREATMENT OVERVIEW

- Supportive care followed by ovariohysterectomy (majority of cases) or medical management (bitches with reproductive value)
- Queens: same approach; more resistant to luteolytic treatments and require higher doses

ACUTE GENERAL TREATMENT

- General systemic treatment:
  - Stabilization and treatment of acute renal failure if identified (seep. 1591)
  - IV fluid therapy: typically to correct dehydration, using replacement fluids such as lactated Ringer's solution or 0.9% NaCl, with or without colloids. Rate is calculated based on dehydration and ongoing fluid losses.
  - Treatment/prophylaxis for disseminated intravascular coagulation (DIC; see p. 315)
  - Broad-spectrum antibiotic therapy: oral route is indicated for stable patients; individuals showing systemic signs of illness should receive antibiotics parenterally:
    - Amoxicillin with clavulanic acid, 20 mg/kg PO q 8-12 h; *or*
    - Enrofloxacin, 5 mg/kg PO or diluted 1:1 with saline and given slowly (over 5 minutes) IV q 6-12 h as needed (maximum 5 mg/kg q 24 h in cats); *or*
    - Cephalexin, 22-30 mg/kg PO q 8 h
  - Pain management (e.g., buprenorphine, 0.01-0.03 mg/kg SQ, IM, or IV q 6-12 h as needed based on pain parameters)
- Surgical pyometra treatment: ovariohysterectomy
- Medical pyometra treatment:
  - Prostaglandin F-2alpha (PGF2α, dino-prost [Lutalyse])
    - When used alone, high doses are required (>0.1 mg/kg SQ), which can be associated with significant, sometimes life-threatening, side effects (hypersalivation, emesis, diarrhea, tremor, ataxia, tachypnea, tachycardia, hypovolemic shock).
    - PGF2α alone cannot be used for treating a closed pyometra because of the potential of uterine rupture.
    - Synthetic PGF2α (e.g., cloprostenol [Estrumate] 0.001-0.005 mg/kg SQ from once a day to every 3 days) will produce similar results but more side effects.
    - Low, increasing doses of $PGF^{2\alpha}$ (0.01-0.05 mg/kg SQ q 5-8 h for 7-10 days or until uterine evacuation is complete as assessed by ultrasonography) are not associated with clinical side effects but must be combined with either a dopamine agonist or a progesterone receptor antagonist.
    - Dopamine agonists are used for hastening luteolysis via prolactin inhibition:
      - Cabergoline (Dostinex), 0.005 mg/kg PO q 24 h for 8-10 days; *or*
      - Bromocriptine (Parlodel), 0.03 mg/kg PO q 8-12 h for 10 days; given orally, adverse effects are uncommon at this dose.
    - Progesterone receptor antagonists are used for mimicking luteolysis through progesterone antagonism:
      - Mifepristone (Mifeprex), 2.5 mg/kg PO q 24 h for 5 days; *or*
      - Aglepristone (Alizine), 10 mg/kg SQ twice at 24 hours apart
  - Closed pyometra can safely be treated with PGF2α, starting at 0.01 mg/kg SQ q 5-8 h on day 1, then 0.025 mg/kg SQ q 5-8 h on day 2, then 0.05 mg/kg q 5-8 h the following days in association with dopamine agonists or progesterone antagonists. This treatment will first induce cervical opening before uterine contractions.

- Queens should receive higher natural prostaglandin (dinoprostum [Dynolytic; Upjohn]) doses (generally ranging from 0.05-0.1 mg/kg SQ q 5-8 h for 7-10 days or until uterine evacuation is complete) associated with dopamine agonists.
- Medical management of dogs with transcervical endoscopic catheterization technique (TECT) hastens uterine emptying time.
- Treatment efficacy is evaluated using transabdominal ultrasonography. At least 50% reduction of the uterine luminal diameter should be observed in less than 5-7 days after treatment initiation; complete by 5-10 days.
- Antimicrobial treatment should be continued for at least 2 weeks after the cessation of PGF2α and other specific treatments.

CHRONIC TREATMENT

If necessary, for chronic kidney disease (antigen/antibody complex-induced glomerulonephritis). Seepp. 205 and 450.

DRUG INTERACTIONS

Antiemetic drugs should not be used, as they stimulate prolactin release which would delay luteolysis and prolong medical pyometra treatment.

POSSIBLE COMPLICATIONS

- Peritonitis (resulting from uterine rupture)
- Stump pyometra (resulting from incomplete ovariohysterectomy)
- Bacterial cystitis (often concurrent with pyometra)
- Abdominal abscesses (resulting from bacteremia)
- DIC, SIRS, MODS
- Septic shock

RECOMMENDED MONITORING

- Intensive/critical care
- Cardiovascular support with IV fluid therapy
- Pain management
- Monitor for DIC (CBC, platelet count, coagulation profile, D-dimer test)
- Monitor for liver and kidney failure with a chemistry profile
- Ultrasonographic examination of the uterus every other day during treatment to monitor response

PROGNOSIS AND OUTCOME 

- Always guarded depending on presence of sepsis and liver or renal failure; otherwise good
- In medically managed dogs, is generally advised to breed during the first subsequent cycle
- No difference in the incidence of recurrent pyometra in medically treated dogs compared to intact dogs of the same age that did not previously have pyometra

PEARLS & CONSIDERATIONS 

COMMENTS

- Clinical signs are not related to the size of the distended uterus.
- Pyometra should always be included as a differential diagnosis in a female dog with clinical signs of an acute abdomen or with nonspecific clinical signs.
- A closed pyometra can be a life-threatening condition. Treatment, particularly general, should not be delayed even if the animal appears to be healthy.

PREVENTION

- Ovariohysterectomy in females that are not going to be bred and in females that have retired from breeding
- Avoid prophylactic antibiotic treatment, as this is often associated with progressive development of bacterial resistance and virulence.

CLIENT EDUCATION

- If the animal is not to be used for reproduction, a complete ovariohysterectomy will prevent the development of pyometra.
- Contact the veterinarian immediately if any of the above clinical signs is observed in a post estrus, intact aging female.

Pyoderma

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Pyoderma is a bacterial infection of the skin. It is one of the most common diseases of dogs.

SYNONYM

Bacterial dermatitis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Common in dogs, rare in cats.
- Impetigo (superficial form of pyoderma, typically in juvenile patients): noted in puppies sometimes in conjunction with immunosuppression, poor nutrition, endoparasitism, or poor hygiene.
- Acne is a type of pyoderma that occurs more commonly in young dogs.
- Feline: deep bacterial infections (cellulitis, abscess) are more common in outdoor animals.

GENETICS & BREED PREDISPOSITION

- Intertrigo (skin fold pyoderma): English bulldogs
- Mucocutaneous pyoderma: German shepherd, Bichon frise, poodle
- Familial idiopathic deep pyoderma: German shepherd
- Acne: short-coated breeds such as boxers, Doberman pinschers, bulldogs, Great Danes, mastiffs, rottweilers, and German short-haired pointers

RISK FACTORS

- Some forms of pyoderma, particularly superficial bacterial folliculitis (SBF) and bacterial overgrowth syndrome (BOGS) are often secondary to underlying etiologies such as hypersensitiv-ity skin disease (atopic dermatitis, food allergy, flea bite hypersensitivity), endocrinopathies (hypothyroidism, hyperadrenocorticism), parasitic skin disease *(Sarcoptes, Demodex* spp.), immune-mediated diseases, or cornification disorders.
- Deep pyoderma may be associated with underlying immunoincompe-tence.

CONTAGION & ZOONOSIS

Staphylococcus pseudintermedius, the cause of 90% of canine pyoderma cases, is considered nonpathogenic to humans.
GEOGRAPHY AND SEASONALITY Warm and humid environments predispose animals to pyoderma.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Surface pyoderma: infection restricted to the surface layer of the epidermis:
  - Dog: intertrigo (skin fold pyoderma), acute moist dermatitis (pyotraumatic dermatitis, hot spots), BOGS
- Superficial pyoderma: infection involving the epidermis and the infundibular portion of the hair follicle:
  - Dog: impetigo, SBF, superficial spreading pyoderma, mucocutaneous pyoderma
- Deep pyoderma: bacterial infection extending beyond the hair follicle to involve the dermis and subcutis, which may lead to cellulitis:
  - Dog: acne, pyotraumatic furunculosis, nasal folliculitis (inflammation of the hair follicle) and furunculosis (simultaneous occurrence of many furuncles, which are inflamed hair follicles that have ruptured, triggering pyogranulomatous dermal inflammation), interdigital furunculosis/pododermatitis, infected aerai lick dermatitis (lick granuloma), callus pyoderma, and postgrooming furunculosis; German shepherd pyoderma
  - Cat: bite wounds, cellulitis, abscess, feline acne

HISTORY, CHIEF COMPLAINT

Animals typically are presented for evaluation of skin changes: pustules, crusts, epidermal collarettes, hair loss and/or pruritus. Animals with deep pyoderma may show signs of pain.

PHYSICAL EXAM FINDINGS

- Impetigo: small nonfollicular pustules and crusts on the ventral abdomen
- BOGS: pruritus, greasy coat, offensive odor, erythema, lichenification, hyper-pigmentation, excoriations and alopecia
- SBF: papules, pustules, and epidermal collarettes with patchy alopecia, producing a “moth-eaten” appearance of the haircoat over the trunk. Resolving lesions may show central hyperpig-mentation (“bull's-eye” lesion).
- Superficial spreading pyoderma: large epidermal collarettes with an erythematous leading edge noted over the trunk; associated exúdate may form crusts.
- Canine acne: deep furunculosis and folliculitis, with crusting and possible scarring on the lips and chin of young dogs
- Mucocutaneous pyoderma: crusts and erosions affecting the lip margin, nasal planum, eyelid margin, vulva, prepuce, and perianal area
- Pyotraumatic folliculitis and furunculosis: may occur anywhere on the body depending on underlying cause; atypical acute moist dermatitis with superficial ulceration but also a component of deep folliculitis and occasional furunculosis. Clinically, this lesion may be thickened and plaque-like and have satellite papules and pustules.
- Nasal folliculitis and furunculosis: initially a papular/pustular eruption on the bridge of the nose that progresses to ulceration, crusting, and hemorrhage
- Interdigital folliculitis/pododermatitis: lesions of the feet; interdigital papulonodules, pustules, and ulceration with draining tracts and fibrosis; alopecia secondary to licking
- Callus pyoderma: develops over pressure points. Skin is thickened, fibrotic, and hyperpigmented with foci of papules, pustules, and ulceration.
- Postgrooming folliculitis/furunculosis: papular/pustular rash, crust formation, self-induced alopecia
- German shepherd pyoderma: lesions include ulcerations and draining tracts on the lateral thighs, trunk, and groin ± lips.
- Infected feline acne: comedones, papules, pustules, and alopecia confined to the mandibular and perilabial areas
- Feline bite wounds/abscess/cellulitis: swelling, pain, and alopecia in the affected area; possible dermal and cutaneous necrosis with ulceration, purulent exudate, and hemorrhage

PYODERMA Epidermal collarettes on ventral abdomen of a dog with pyoderma.

ETIOLOGY AND PATHOPHYSIOLOGY

- Canine skin is characterized by a relatively thin *stratum corneum,* a paucity of intercellular lipids, lack of a follicular plug, and a higher pH than that of humans and other domestic species. This predisposes the dog to overgrowth of commensal flora and colonization by potentially pathogenic bacteria.
- Superficial infection may occur if the integrity of the skin is weakened by trauma or there are changes in surface immunity.
- Deep bacterial infections are generally an extension of a superficial pyoderma. As infection progresses deeper into the hair follicle, rupture of the follicle (furuncles) occurs. This leads to a pyogranulomatous endogenous foreign-body reaction on the part of the host. This reaction occurs initially in the dermis and is an inflammatory response to keratin, bacterial organisms, and cellular debris.

- Approximately 90% of cases in dogs are caused by coagulase-positive *S. pseudintermedius,* a normal component of canine skin flora. A small number of cases are caused by *Staphylococcus aureus,* the most common human pathogen.
  - *Staphylococcus intermedius* was reclassified as *S. pseudintermedius* in 2007.
- The gram-negative organisms, *Proteus* spp., *Escherichia coli,* and *Pseudomonas* spp. may act as secondary invaders. Deep pyoderma is occasionally associated with *Actinomyces, Nocardia,* mycobacteria, and *Actinobacillus* spp.
- In cats, *Pasteurella multocida* and beta-hemolytic *Streptococcus* are routinely involved.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The dermatological exam alone may provide a strong suspicion of pyoderma (see signs listed above). With clinical signs of deep pyoderma, systemic signs, or recurrence despite therapy, additional tests beyond basic dermatologic testing are often indicated to rule out predisposing causes.

DIFFERENTIAL DIAGNOSIS

- Demodicosis
- Dermatophytosis
- Pemphigus foliaceus
- Cutaneous epitheliotropic lymphoma
- Subcutaneous mycoses (deep pyoderma)
- Atypical mycobacterial infections (deep pyoderma)
- Hookworm (deep pedal pyoderma)
- Foreign-body granulomas (deep pyoderma)

INITIAL DATABASE

- Skin scrapings to confirm or rule out *Demodex* and *Sarcoptes*
- Skin cytologic examination: direct smear from pustule reveals bacteria, neutrophils in varying stages of degeneration, and active bacterial phagocytosis.
- Fungal culture (for dermatophytes and possibly for deep mycosis if draining tracts are present)

ADVANCED OR CONFIRMATORY TESTING

- Culture and sensitivity (C&S): not normally employed in superficial pyoderma cases unless there has been a failure to respond to rational antibiotic therapy or bacilli are noted on skin cytologic examination.
- Skin biopsy and histopathologic exam: normally not performed unless cases are not responding to appropriate antibiotic therapy. Findings include intraepidermal neutrophilic pustules, folliculitis, or furunculosis ± underlying cause (e.g., *Demodex,* pemphigus foliaceus, epitheliotrophic lymphoma).
- Endocrine status: thyroid function and adrenal function tests
- Allergy testing: intradermal or serum allergy testing for environmental allergies, and elimination diet trial for food allergy

TREATMENT

TREATMENT OVERVIEW

The main goals are to treat the infection and determine the underlying cause(s).

ACUTE GENERAL TREATMENT

Topical Therapy:

- Most commonly used: mupirocin (Bactroderm) and fusidic acid (Fucidin). Silver sulfadiazine and benzoyl peroxide 5% gels are also available.
- Shampoo therapy very effectively decreases bacterial skin colonization (adjunctive therapy). Shampoo therapy (10-15 minutes contact time) with products containing benzoyl peroxide, chlorhexidine, ethyl lactate, and povidone-iodine may improve the condition.
- Clip the fur off affected areas.
- Deep pyoderma: bathe animal or soak lesion with Epsom salts solution (magnesium sulfate, 2 tablespoons/liter of lukewarm

water) or Burow's solution (magnesium sulfate-aluminum acetate solution) daily.

Systemic Antibiotic Therapy:

- Bactericidal antibiotics are generally recommended for skin infections; however, bacteriostatic drugs may be effective in an immunocompetent animal. The chosen drug should have a narrow spectrum to limit the effects on the normal flora of both the skin and gastrointestinal (GI) tract.
- Cases should be treated for a minimum duration of 3-4 weeks, or 7-14 days beyond clinical cure. Deep pyoderma may take as long as 12 weeks to resolve.
- The most commonly used antibiotics include (generally monotherapy):
  - Cephalexin, 22-30 mg/kg PO q 12 h (most common choice in dogs)
  - Clavulanic acid-potentiated amoxicillin, 12.5-25 mg/kg PO q 12 h
  - Clindamycin, 5.5-11 mg/kg PO q 12 h
  - Cefovecin injectable, 8 mg/kg SQ q 14 days
- Other suggested drugs/dosages include (generally monotherapy; all PO): cefpodoxime, 5-10 mg/kg q 24 h; cefadroxil, 22 mg/kg q 12 h; oxacillin, 22 mg/kg q 8 h; erythromycin, 10-20/ kg q 8 h (vomiting and diarrhea common); lincomycin, 15-25 mg/kg q 12 h; azithromycin, 5 mg/kg q 24 h; tylosin, 10-20 mg/kg q 12 h; trimeth-oprim-sulfa, 15-30 mg/kg q 12 h; difloxacin, 5-10 mg/kg q 12 h (not in immature animals); enrofloxacin, 5-20 mg/kg q 24 h (not in immature animals); marbofloxacin, 2.75-5.5 mg/kg q 24 h (not in immature animals); orbifloxacin, 2.5 mg/kg q 24 h (not in immature animals); doxycycline, 5 mg/kg (day 1), then 2.5 mg/kg q 12 h
- Appropriate pain management

CHRONIC TREATMENT

- In face of an idiopathic recurrent pyoderma (generally SBF) that recurs less than three or four times a year, it is often more economical and reasonable to treat each event with an appropriate course of antibiotics. Moreover, when an antibiotic (e.g., cephalexin) is effective in treating an episode of pyoderma, there is no need to change for another antibiotic when the pyoderma recurs later on.
- In cases of idiopathic recurrent pyoderma where several episodes occur annually and/or when total annual antibiotic administration is more than 12 weeks, adjunctive immunomodulatory therapy or extended antibiotic regimens (both controversial in veterinary dermatology) may be needed to maintain clinical remission.
- Immunomodulatory therapy: Staphage Lysate (SPL [Delmont Laboratories]) may help decrease recurrences of pyoderma in up to 35% of dogs. The dog should initially receive a 4- to 6-week course of oral antibiotic in conjunction with a 20- to 30-week course of SPL (0.5 mL twice weekly SQ). If the pyoderma does not recur during that period of time, the frequency of injections is gradually reduced to once weekly, then every other week.
- Extended regimens of antibiotic therapy (or pulse therapy). Pyoderma has to be eliminated by standard appropriate, safe, bactericidal antibiotic therapy (e.g., cephalexin) before extended regimen is used. Many different treatment regimens have been recommended. Pulse therapy implies using full therapeutic doses on an intermittent basis. One proposed regimen involves 1 week at full recommended daily dose, followed by 1 week off medication, and so on. If recurrence is prevented, the duration of the time off the antibiotic can be extended to up to 3 weeks. Two days per week dosing (at full daily dose) is another popular regimen. A third recommended regimen involves once-daily to once-every-other-day dosing.
- Antimicrobial shampoo or lotions used on a regular basis may assist in the prevention of relapses by limiting the bacterial surface flora.

POSSIBLE COMPLICATIONS

- Many antibiotics occasionally cause vomiting and diarrhea.
- Fluoroquinolones: cartilage damage in growing puppies
- Potentiated sulfonamides: keratoconjunctivitis sicca, arthritis, uveitis, immune-mediated dermatitis, hepatobiliary disease, drug interaction, decreased thyroid function (possible hypothyroidism at high dose)
- Benzoyl peroxide gel has to be used with care because it may be irritating with repeated use and causes fabric and hair discoloration.
- Drug-induced pemphigus foliaceus (cephalosporins)

RECOMMENDED MONITORING

It is important to assess response to therapy before the antibiotic course is completed in order to determine the appropriate duration of antibiotic administration and also to determine if there is residual pruritus, which would suggest underlying allergy or ectoparasite or concurrent *Malassezia* dermatitis.

PROGNOSIS AND OUTCOME 

- Superficial pyoderma: good prognosis as long as underlying factors are addressed adequately
- Deep pyoderma: some cases of deep pyoderma will result in scarring.
- Affected animals are often immuno-suppressed or have other intercurrent diseases.

PEARLS & CONSIDERATIONS

COMMENTS

- Epidermal collarettes are extremely useful secondary skin lesions to look for (clip some hair if needed); they are strongly suggestive of a superficial pyoderma.
- Any therapeutic plan for controlling pyoderma without considering underlying predisposing factors is destined to fail.
- Most dermatologists use cephalexin as their first drug choice because it has been shown to be a very effective drug against *S. pseudintermedius,* with minimal change in resistance pattern over the years.
- Both pemphigus foliaceus and epitheliotrophic lymphoma may present as pyodermas that fail to respond to appropriate antibiotic therapy. Skin biopsy is indicated.
- The use of immunomodulating therapy and extended antibiotic regimen should be limited to veterinary dermatologists.

TECHNICIAN TIPS

- Whenever medicated shampoos are used, it is important to respect the contact time, typically 10-15 minutes. Using a timer will aid in providing sufficient contact time.
- Clipping the hair coat may facilitate topical treatment and accelerate healing. However, one needs the client's permission first.

CLIENT EDUCATION

Counsel clients concerning the potential chronicity of the disease, owing to underlying predisposing factors. The need of long antibiotic therapy regimens, the importance of treating for 1-2 weeks beyond cure, and the need for recheck must be explained thoroughly.

EDITOR: MANON PARADIS

Pyloric Hypertrophy Syndrome

BASIC INFORMATION

DEFINITION

Stenosis of the gastric outflow tract secondary to one of the following: hypertrophy of the circular muscle of the pylorus, hyperplasia of the mucosa of the pyloric antrum, or combination of muscular and mucosal thickening

SYNONYMS

Acquired antral pyloric hypertrophy, chronic hypertrophic pyloric gastropathy, gastric antral mucosal hypertrophy, hypertrophy of the muscular layer of the pylorus, pyloric stenosis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Congenital: dogs and cats, identified sometime after animal starts eating solid food, usually at 4-12 months of age
- Acquired: canine, middle-aged (4-7 years) and older

GENETICS & BREED PREDISPOSITION

- Congenital: brachycephalic breeds including Boston terriers, English bulldogs, boxers, and Siamese cats
- Acquired: small, often Asian-breed dogs including Lhasa apso, shih tzu, Pekingese, and Maltese

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Congenital: selective hypertrophy of the circular pyloric muscle
- Acquired: mucosal hypertrophy or combination of mucosal and muscular hypertrophy; mucosal hypertrophy may be focal (polyp) or more generalized involving entire pyloric antrum

HISTORY, CHIEF COMPLAINT

- Chronic vomiting, usually of food several hours after eating; may be projectile
- In congenital form, vomiting begins after animal starts eating solid foods
- Anorexia
- Mild weight loss
- Regurgitation

PHYSICAL EXAM FINDINGS

- Generally unremarkable
- Thin body condition is possible

ETIOLOGY AND PATHOPHYSIOLOGY

- Cause is unknown, and genetics of congenital form are not described.
- Excessive secretion of gastrin may stimulate growth of gastric smooth muscle and mucosa of gastric body.
- Some cases of “acquired” form may be slow progression of congenital form.
- Regurgitation can develop secondary to reflux esophagitis or persistent vomiting.
- Metabolic alkalosis (hypochloremic, hypokalemic) may develop, although only with severe luminal obstruction as fluid typically passes to the duodenum in most cases. In those cases with hypochloremic, hypokalemia, metabolic alkalosis, paradoxic aciduria is possible, although this is not clinically significant.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Chronic vomiting is the main historical clue to this disorder, particularly if it is projectile in nature and/or in a brachycephalic dog. Suspicion may be increased with characteristic contrast radiographic findings, but confirmation requires direct visualization (endoscopic or via laparotomy).

DIFFERENTIAL DIAGNOSIS

- For clinical presentation: other causes of chronic vomiting such as parasitism or viral, bacterial, fungal, or protozoal infection, inflammatory bowel disease, food allergy or intolerance, neoplasia, obstruction, systemic disease (liver disease, kidney disease), central nervous system disease, and drugs must be ruled out by a systematic evaluation.
- For imaging findings: infiltrative diseases such as neoplasia, pythiosis, or other fungal diseases

INITIAL DATABASE

- CBC, serum biochemistry profile, and urinalysis: often unremarkable but hyponatremic, hypochloremic metabolic alkalosis and paradoxic aciduria may be present due to vomiting of gastric contents only. May have prerenal azotemia without concentrated urine secondary to inability to concentrate urine because of hypokalemia.
- Radiographs: usually unremarkable. Stomach may be distended with fluid, uncommonly with air. Severe pyloric hypertrophy may occasionally be noted on plain films.
- Ultrasound: mucosal or muscular thickening of pylorus

ADVANCED OR CONFIRMATORY TESTING

- Contrast radiographs using barium sulfate: delayed gastric emptying, thickening of the pylorus, abrupt narrowing of the pyloric canal filled with contrast (beaklike appearance), or a narrow band of contrast filling the pylorus.
- Endoscopy (see p. 1284): the mucosa appears normal in color, but abundant antral folds or polyps with or without erosive lesions may be seen. Muscular hypertrophy can be more difficult to appreciate, but the pylorus will not distend with air. Either lesion may create a narrowed pyloric lumen through which it is difficult to pass an endoscope.
- Celiotomy: thickened pylorus and abundant mucosal folds in the antrum and pylorus
- Histopathologic evaluation of tissue: mucosa normal or thickened with erosions, edema, and hyperplasia or cystic changes in gastric glands; increased numbers and prominent branching pattern of surface gastric pits; erosions may have lymphocyte and plasma cell infiltration; *Campylobacter-like* organisms have been reported.

TREATMENT

TREATMENT OVERVIEW

The treatment goal is elimination of pyloric canal obstruction caused by the exuberant tissue, which is achieved surgically.

ACUTE GENERAL TREATMENT

- Surgery is indicated for all forms of pyloric hypertrophy syndrome.
- Y-U pyloroplasty is the most common procedure, allows for resection of hypertrophied mucosa, and is recommended in most cases.
- Gastroduodenal anastomosis (Billroth I) for cases with extensive mucosal involvement, particularly when thickening results in loss of normal pliability
- Pyloromyotomy is often ineffective and is not recommended for any type of pyloric hypertrophy.
- Short-term postoperative compromise of gastrointestinal motility may be treated with metoclopramide (0.2-0.4 mg/kg q 8-12 h PO, SQ; or constant rate infusion IV 1-2 mg/kg/d).

POSSIBLE COMPLICATIONS

- Potential complications of surgery include infection, leakage, and dehiscence. The risk of dehiscence is greater with the Billroth I procedure.
- Gastrointestinal motility may be temporarily compromised after surgery.

PROGNOSIS AND OUTCOME

Prognosis is excellent if no postoperative complications occur.

PEARLS & CONSIDERATIONS

COMMENTS

- Should be suspected in brachycephalic breeds with chronic vomiting
- Some cases of “pyloric stenosis” may be functional defects rather than anatomic defects.
- Surgery may not improve measured gastric transit time.
- Hypertrophic gastritis is distinct from this syndrome in that it typically spares the pylorus despite remarkable mucosal hypertrophy of the body and fundus. Seen primarily as a familial disorder as part of immunoproliferative enteropathy of Basenji dogs and familial stomatocytosis-hypertrophic gastritis of Drentse Patrijshond dogs. Reported in a single Old English sheepdog.
- The author has seen pyloric hypertrophy syndrome present as acute gastric dilatation without volvulus in older (8-10 years old) Labrador retrievers.

EDITOR: DEBRA L. ZORAN

1ST EDITION AUTHOR: AMIE KOENIG

Pyelonephritis

BASIC INFORMATION

DEFINITION

Pyelonephritis describes inflammation of the renal pelvis and interstitium typically associated with or originating from ascending bacterial infection. Acute pyelonephritis is uncommon; chronic pyelonephritis is more common but often clinically inapparent.

SYNONYM

Pyelitis

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats are susceptible, with females predisposed; most common in older animals or in younger animals with predisposing cause (e.g., congenital urinary malformations, uroliths).

RISK FACTORS

Dogs and cats:

- Anatomic abnormalities:
  - Ectopic ureter(s)
  - Urethral/ureteral obstruction
  - Hydroureter/hydronephrosis
  - Perineal urethrostomy
  - Urolithiasis
  - Vulvar conformational abnormalities
- Functional abnormalities:
  - Urine retention (>0.25 mL/kg following complete voiding)
  - Urine reflux due to increased intra-vesicular pressure
  - Isosthenuria or hyposthenuria from any cause
  - Immunocompromise
  - Indwelling urinary catheter or repeated catheterization
- Lower genitourinary tract infection:
  - Dogs and cats: various bacteria; *Escherichia coli* most common isolate in urinary infections o Fungal and yeast pyelonephritis possible, especially in immunocompromised animals
  - Bacterial prostatitis: intact male dogs CONTAGION & ZOONOSIS Rarely, shared clones of bacteria involved in urinary tract infections (UTI) have been found in people and their dogs.

ASSOCIATED CONDITIONS & DISORDERS

- Acute renal failure
- Chronic kidney disease
- Hypokalemia (cats)
- Bacterial cystitis
- Urolithiasis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Ascending pyelonephritis
- Hematogenous pyelonephritis: rare; may be associated with septicemia

HISTORY, CHIEF COMPLAINT

Clinical signs may be absent; chronic pyelonephritis is a common complicating factor in chronic kidney disease. When present, clinical signs may include:

- Polyuria and polydipsia (PU/PD; acute or chronic pyelonephritis)
- Malaise (uncommon)
- Hematuria
- Pollakiuria, stranguria (if concurrent lower urinary tract disorder)
- Abdominal, lumbar, or general discomfort (usually associated with acute pyelonephritis)
- Recurrent lower urinary infections (chronic pyelonephritis)
- History of predisposing cause may be present (e.g., urinary catheterization, uroliths)

PHYSICAL EXAM FINDINGS

Exam may be normal, especially in the more common chronic form of infection. Abnormalities, when present, may include:

- Fever (more often associated with acute pyelonephritis)
- Dehydration
- Renomegaly (acute pyelonephritis)
- Renal asymmetry (chronic pyelonephritis)
- Abdominal/renal/lumbar pain
- Oral ulcerations/halitosis (uremia)
- Debris or secretions in the oral cavity (vomitus, saliva)
- Bladder discomfort (if concurrent lower urinary infection)

ETIOLOGY AND PATHOPHYSIOLOGY

- Infectious agent (bacteria, fungus, yeast) usually ascends to renal pelvis from lower urinary tract. The agent rarely infects the kidneys hematogenously.
- Onset may be acute (less common) or insidious (more common).
- Renal response to injury causes clinical signs:
  - Acute infection results in nephritis (renal inflammation), causing renomegaly and renal pain.
  - Acute or chronic infection causes nephrogenic diabetes insipidus via bacterial toxin actions on antidiuretic hormone receptors.
  - Chronic infection results in renal scarring, resulting in smaller than normal kidneys.
- Infection may result in acute renal failure, overt chronic kidney disease, or exacerbation of preexisting chronic kidney disease.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

The diagnosis of pyelonephritis should be considered in any animal with pyuria and/or bacteriuria (especially in absence of lower urinary tract signs), polyuria/polydipsia, kidney disease, chronic lower urinary tract infection, or immunocom-promise. Although acute pyelonephritis may cause dramatic illness, chronic pyelonephritis with obscure clinical signs occurs more commonly.

DIFFERENTIAL DIAGNOSIS

- PU/PD (see p. 902)
  - PD from psychogenic causes, hyperosmolarity, or alteration of the thirst center (e.g., central nervous system [CNS] neoplasia)
  - Osmotic diuresis (e.g., diabetes mellitus, renal glucosuria, drug or toxin)
  - Nephrogenic diabetes insipidus (e.g., congenital, electrolyte abnormalities, hormonal abnormalities, renal failure)
  - Deficient interstitial concentrating gradient (e.g., medullary washout, hyponatremia, portosystemic shunt)
  - Lack of antidiuretic hormone (i.e., central diabetes insipidus)
- Bacteria (see pp. 276 and)
- Pyelectasia (seep. 547)

INITIAL DATABASE

- CBC: may be normal (chronic pyelonephritis) or may show leukocytosis with left shift (acute pyelonephritis); normocytic, normochromic nonregenerative anemia is possible with concurrent chronic kidney disease.
- Serum biochemical profile: often normal, but when acute or chronic renal disease is present, azotemia (elevated blood urea nitrogen [BUN], creatinine), hyperphosphatemia, hypokalemia, or hyperkalemia, and/or metabolic acidosis are often identified.

- Urinalysis: isosthenuria is common; bacteria is inconsistent and often absent; occasionally leukocyte casts (acute pyelonephritis), pyuria, hematuria, and/or crystalluria.
- Abdominal radiographs: variable renal shadow (normal, large, or small and irregular). Radiopaque urinary (upper or lower) calculi (suspect struvite) are sometimes present.
- Abdominal ultrasound: renal pelvic dilation is common; renomegaly or small and irregular kidneys, alterations in renal parenchymal echogenicity also can be present.
- Urine culture prior to treatment whenever suspicion of pyelonephritis exists (even if urine sediment inactive):
    - In occult pyelonephritis, urine culture can be negative.

ADVANCED OR CONFIRMATORY TESTING

- Pyelocentesis (ultrasound guided) to obtain urine directly from the renal pelvis for culture; this procedure is uncommonly used. Begin with routine cystocentesis instead and choose pyelocentesis if trying to pinpoint source of infection to one kidney (rarely clinically necessary).
- Excretory urogram and/or cystourethrogram to rule out anatomic abnormalities. Abdominal ultrasound is the preferred first choice instead.
- If clinical signs are compatible, rule out hyperadrenocorticism as a predisposing cause.
- Renal cortex biopsy: typically not helpful to diagnose pyelonephritis, owing to localization of disease (renal pelvis and interstitium).

TREATMENT

TREATMENT OVERVIEW

The mainstay of treatment is long-term therapy with appropriate type and dose of antimicrobial drugs. It is often a challenge to obtain a positive urine culture, despite renal infection. Since pyelonephritis often occurs secondary to another disease process, recurrence is common unless the predisposing condition can be addressed. Renal failure is addressed as needed (see pp. 31, , and).

ACUTE GENERAL TREATMENT

- Antimicrobial therapy:
    - Antibiotic selection is based on culture and antimicrobial susceptibility (C&S) results whenever possible.
    - Pending results, or if culture is negative despite clinical suspicion of pyelonephritis, therapy is indicated using an antibiotic with gram-negative spectrum that is renally excreted (fluoroquinolone, augmented penicillin, trimethoprim-sulfa) to reach adequate tissue concentrations. Examples:
        - Fluoroquinolone, such as enrofloxacin, 5-20 mg/kg q 12-24 h (dogs), or 5 mg/kg q 24 h (cats) PO, IM, or diluted 1:1 with sterile saline and given slowly IV (oral therapy instituted when practical)
        - Amoxicillin with clavulanic acid, 22 mg/kg PO q 8-12 h
    - For intact male dogs, it is preferable to select an antimicrobial that will penetrate the blood-prostate barrier (e.g., fluoroquinolone, trimethoprim-sulfa).
    - Due to the sluggish rate of renal medullary blood flow, duration of antibiotic therapy should be greater than that for a simple lower urinary tract infection. Therapy typically lasts 3-6 weeks depending on clinical improvement, underlying disease, and follow-up test results.
    - If initial urine sediment was active, a repeat urinalysis about 1 week after starting antibiotic therapy is recommended to ensure resolution of bacteruria and pyuria.
    - If predisposing cause cannot be resolved, urine cultures should be repeated regularly to address future infections.
    - Fungal pyelonephritis may be more difficult to eradicate than bacterial pyelonephritis (see online chapter: Cystitis, Fungal/Algal).
- Treatment of uremic renal failure starts with isotonic crystalloid fluid therapy (see pp. 31 and).
- Medical therapy for hypokalemia:
    - Occurs commonly in cats with chronic PU/PD
    - Potassium chloride (KCl) supplementation of IV fluids used for diuresis, based on sliding scale (see table):
    - Do not exceed a rate of 0.5 mEq KCl/kg per hour for potassium replacement.
    - Recheck potassium levels are indicated at least daily during fluid therapy.
    - When the patient is eating, oral potassium gluconate replacement can be initiated at a starting dose of 2 mEq per cat q 12 h, adjusted as needed based on serial serum potassium measurements.
- Uremic signs are managed as for acute renal failure and chronic kidney disease (see pp. 31 and 207).
- Maintain fluid balance:
    - Hospitalization is not indicated if the patient is drinking and eating enough to maintain hydration.
    - If the patient is hospitalized for IV fluid therapy, fluids should be tapered slowly over 2-3 days and discontinued once hydration is maintained by oral intake.

Administer as constant rate infusion via infusion pump to minimize risk of overly rapid delivery, and adjust supplementation as needed

based on repeated assessments of serum potassium concentrations. Not for oliguric/anuric patients.

Potassium Supplementation in Intravenous Fluid Therapy

Serum Potassium Concentration	Potassium Supplementation to IV Fluids
Potassium 3.5–5.5 mEq/L	Add 20 mEq KCl/L crystalloid
Potassium 3–3.4 mEq/L	Add 30 mEq KCl/L crystalloid
Potassium 2.5–2.9 mEq/L	Add 40 mEq KCl/L crystalloid
Potassium 2–2.4 mEq/L	Add 60 mEq KCl/L crystalloid
Potassium < 2 mEq/L	Add 80 mEq KCl/L crystalloid

- ○ In cats and small dogs, the ability to maintain hydration might require a period of adaptation. Following hospital discharge, SQ crystalloid fluid therapy might be indicated q 12-48 h (seepp. 31 and).

CHRONIC TREATMENT

- Identification, treatment, or cure of predisposing cause if possible (e.g., hyperadrenocorticism, ectopic ureter, urolithiasis)
- Other treatments for chronic kidney disease as necessary (see pp. 205 and 207)

NUTRITION/DIET

Recommend diets appropriate for management of renal failure if it exists. A diet restricted/optimized in protein and phosphorus is ideal. Regardless, ensure the availability of fresh drinking water at all times.

DRUG INTERACTIONS

Cats should be treated cautiously with enrofloxacin, since acute retinal degeneration can occur. Avoid trimethoprim-sulfa antibiotics in Doberman pinschers or dogs with keratoconjunctivitis sicca.

POSSIBLE COMPLICATIONS

- Failure to resolve infection. Bacterial resistance is common if there is infection secondary to an underlying process or a structural lesion.
- Urolithiasis (nephrolithiasis), ureteral obstruction due to urolithiasis

RECOMMENDED MONITORING

- A repeat urine culture 1-2 weeks after completion of antibiotics and approximately 1 and 2 months later are indicated to ensure negative culture.
- If predisposing cause cannot be resolved (e.g., chronic kidney disease), monitoring should include urinalysis and urine culture every 3-6 months to identify recurrence.
- When initial urine culture is negative despite clinical suspicion of pyelonephritis, monitoring should include water consumption daily before and after initiation of antibiotics to assess efficacy of therapy. If water consumption decreases within 2 weeks of antimicrobial therapy, treatment should be continued for a total of 3-6 weeks.

PROGNOSIS AND OUTCOME

- Guarded to good depending on ability to correct predisposing cause and antimicrobial susceptibility of pathogen
- Prognosis for recurrent pyelonephritis is guarded, since infections can cause chronic or acute renal failure, and recurrent infections tend to develop multiple antimicrobial resistance over time.

PEARLS & CONSIDERATIONS

COMMENTS

- Pyelonephritis is often difficult to confirm, especially after antimicrobial therapy has been initiated.

- Evidence of renal pelvic dilation (pyelectasia) on ultrasound, without other supportive clinical findings, might indicate a past infection with permanent renal injury instead of active infection. Vigorous IV fluid therapy can also cause pyelectasia and should be considered an ultrasonographic differential diagnosis for pyelonephritis.
- Chronic pyelonephritis can occur without producing any overt clinical signs and without changes on CBC, serum biochemical profile, or urine sediment exam.
- A urine C&S is warranted in the management of any chronic renal disorder, because pyelonephritis may be clinically silent and difficult to detect (e.g., diluted urine may give the mistaken appearance of an inactive sediment); however, the condition is treatable, potentially resulting in a reversal of renal tubular damage.

PREVENTION

- Address anatomic or functional abnormalities directly.
- Treatment of infections with the appropriate antimicrobial therapy at the correct dose for at least 3-6 weeks
- Regular follow-up visits to identify recurrent infections as early as possible

TECHNICIAN TIPS

- Urinary catheterization can introduce bacteria; therefore, strict aseptic technique should be used.
- Animals that are hospitalized should be allowed to empty their bladder on a regular basis. Dogs that are particularly well housetrained can retain urine when kenneled, which can predispose to ascending pyelonephritis. Cats may have preferences for the type of cat litter used. Monitoring frequency and volume of urine output in hospitalized animals is vitally important.

CLIENT EDUCATION

- Owner education regarding signs of lower and upper urinary tract infection before pyelonephritis develops
- Treatment of resistant strains of bacteria causing pyelonephritis may be costly and require prolonged therapy.
- Chronic kidney disease may predispose animals (especially cats) to recurrent renal infections.

Pustular and Crusting Skin Disorders

BASIC INFORMATION

DEFINITION

Pustules and crusts are common skin lesions. Pustules are small, circumscribed elevations of the skin filled with pus. Healing or ruptured pustules may form crusts, the dried accumulation of exúdate (blood, pus, serum) over a lost or damaged epidermis.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats
- In dogs, impetigo, demodicosis, juvenile cellulitis and dermatophytosis are typically seen in young animals. Pemphigus is more common in middle-age adults.
- Hereditary mechanobullous disease: epidermolysis bullosa develops shortly after birth.
- Drug eruptions may occur at any age.

GENETICS & BREED PREDISPOSITION

- Juvenile cellulitis (seep. 627): dachshund, golden and Labrador retrievers, Gordon setters, pointers. More than one puppy can be affected in a litter.
- Subcorneal pustular dermatosis and superficial suppurative necrolytic dermatitis: miniature schnauzer
- Pemphigus foliaceus: Akita, chow chow, dachshund
- Drug eruption (especially sulfon-amides): Doberman pinscher
- Canine linear immunoglobulin A (IgA) pustular dermatosis: dachshund

RISK FACTORS

- Pyoderma, the most common cause of pustular and crusting dermatitis in dogs, is often secondary to a predisposing skin disease (atopic dermatitis, food allergy, demodicosis, end ocrinopathies).
- With the exception of abscesses, pyoderma is uncommon in cats.
- Cats affected with feline immunodeficiency virus (FIV) are more susceptible to dermatophytosis.

CONTAGION & ZOONOSIS

Dermatophytosis is contagious to other animals and is zoonotic.

GEOGRAPHY AND SEASONALITY

- Pemphigus foliaceus and pemphigus erythematosus (see p. 850) can be aggravated by exposure to sunlight.
- Pyodermas associated with underlying atopic dermatitis may have a seasonal occunence.

ASSOCIATED CONDITIONS & DISORDERS

Bullous impetigo in adult dogs is often associated with immunosuppression (e.g., hyperadrenocorticism, diabetes mellitus, hypothyroidism).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Pustules are usually short-lived and may go unnoticed. Scaling and crusting are often the dominant presentation.
- Pruritus varies with the skin disorder. It can be a major presenting complaint in pyodermas, with or without underlying allergies or ectoparasitism.
- A variable degree of hair loss may accompany follicular damage.
- Systemic signs of lethargy and anorexia can be part of the presenting picture with pemphigus foliaceus, cutaneous drug eruptions, or superficial suppurative necrolytic dermatitis of the miniature schnauzer.

PHYSICAL EXAM FINDINGS

- Pustules are most commonly yellow. Green pustules may indicate the presence of gram-negative bacteria or marked toxic change. Larger flaccid pustules are more common in the pemphigus complex and bullous impetigo.
- Scales, epidermal collarettes, crusts of various color (brown, honey-colored) and texture (adherent, flaky), alopecia, erythema, and focal areas of hyperpig-mentation or hyperkeratosis may be noted. Depending on the condition and severity, the extent and location of lesions may be variable.

ETIOLOGY AND PATHOPHYSIOLOGY

Pustules result from a loss of epidermal intercellular cohesion (edema, degeneration, inflammation, autoantibody formation, etc.), causing epidermal or subepidermal cavities that eventually fill with inflammatory cells.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The combined presence of crusts and pustules restricts the differential diagnosis, but pustules can be short lived, and the clinician should perform a careful examination before confirming their absence. Cytologic examination of the content of an intact pustule or from the exudates under a crust is an important step to orient the diagnosis. When pustules or crusts are present in dogs, skin scrapings should always be performed to rule out demodicosis. Skin biopsies are recommended in most cases presenting with pustules and crusts once pyoderma, demodicosis, and dermatophytosis have been ruled out.

DIFFERENTIAL DIAGNOSIS

- Infectious: pustules most often have a follicular orientation.
  - Bacterial: pyoderma (bacterial folliculitis*, impetigo*, furunculosis), dermatophilosis
  - Fungal: dermatophytosis
  - Parasitic: demodicosis*, *Pelodera* dermatitis
  - Protozoal: leishmaniasis
- Immune mediated: juvenile cellulitis, pemphigus complex (especially pemphigus foliaceus*), canine eosinophilic folliculitis* and furunculosis, canine sterile eosinophilic pustulosis*, subcorneal pustular dermatosis*, and canine linear IgA pustular dermatosis*
- Drug eruption: superficial suppurative necrolytic dermatitis of schnauzers (associated with shampoo therapy), drug-induced pemphigus foliaceus, and eosinophilic pustulosis (subcorneal to follicular neutrophilic pustulosis)

*Intact pustules are often present

INITIAL DATABASE

- The medical history of the animal is important in determining etiology: age of onset, breed, presence or absence of pruritus, previous medications, other animals affected, progression, chronicity, and seasonality.
- Lesion distribution is important to orient the diagnosis:
  - Face (lips, muzzle, eyelids, ear pinnae): juvenile cellulitis, pemphigus erythematosus, demodicosis, eosinophilic folliculitis and furunculosis, nasal pyoderma, mucocutaneous pyoderma, drug eruption
  - Feet: pyoderma, dermatophytosis, demodicosis, pemphigus foliaceus
  - Trunk: superficial pyoderma, demodicosis, subcorneal pustular dermatosis, pemphigus foliaceus, drug eruption, impetigo (abdomen)
- Cytologic examination of pustular contents:
  - Bacteria: phagocytized bacteria (often cocci, because staphylococcal organisms are the primary isolates from dogs and cats with pyoderma).
  - Neutrophils: pyoderma, pemphigus complex, subcorneal pustular dermatosis, and canine linear IgA pustular dermatosis
  - Eosinophils: abundant eosinophils with eosinophilic folliculitis/furunculosis and sterile eosinophilic pustulosis; eosinophils are also associated with superficial pyodermas with parasitic or allergic disorders, deep pyodermas (furunculosis), drug eruptions, and pemphigus foliaceus.
  - Acantholytic keratinocytes: seen in pemphigus complex in conjunction with numerous intact neutrophils and/or eosinophils
- Skin scrapings: *Demodex* spp.
- Fungal culture: dermatophytosis
- CBC, serum biochemistry profile, and urinalysis if systemic disease is suspected; results often unremarkable besides

mild/moderate neutrophilic or eosinophilic leukocytosis.

ADVANCED OR CONFIRMATORY TESTING

- Skin biopsies for histopathologic evaluation
- Bacterial culture and sensitivity (C&S) indicated if bacilliform bacteria are noted on cytologic examination or if poor response to previous appropriate antibiotic therapy.
- Endocrine tests if history and physical exam suggest underlying endocrinopathy.
- Serologie testing for FIV, feline leukemia virus (FeLV), leishmaniasis, based on history and environment

TREATMENT 

TREATMENT OVERVIEW

Pyoderma is the most common cause of pustules and crust formation in dogs. Most pyodermas are successfully addressed with antibiotic therapy. Because etiologies of crusting and pustular skin diseases are often infectious or parasitic, glucocorticoids should not be used until a final diagnosis has been reached.

ACUTE AND CHRONIC TREATMENT

Depends on etiology of the disorder:

- Antibiotic therapy: common empirical choices include cephalexin, 22-30 mg/kg PO q 12 h; or amoxicillin-clavulanate, 15-20 mg/kg PO q 12 h, usually for 1-2 weeks beyond resolution of lesions. A more specific selection can be made based on results of C&S.
- Antifungal therapy: itraconazole, 5 mg/kg PO q 24 h for 3-6 weeks (pulse or continuous) is a good first-choice therapy in cats with dermatophytosis.
- Antiparasitics: choice depends on the parasite identified.
- Glucocorticoids for immune-mediated disorders such as juvenile cellulitis, pemphigus complex, eosinophilic folliculitis/furunculosis, eosinophilic pustulosis
    - Prednisone/prednisolone is a common first choice in dogs, usually for 10-14 days at high induction dosage (2-4 mg/kg PO q 24 h) then gradually tapered according to clinical response. Prednisolone (specifically) is preferred in cats.

PROGNOSIS AND OUTCOME 

- Varies according to the disease
- Excellent for most parasitic and infectious skin diseases
- Excellent for some immune-mediated skin diseases such as juvenile cellulitis, sterile eosinophilic folliculitis, and furunculosis

PEARLS & CONSIDERATIONS 

COMMENTS

- Crusts alone are noted in certain diseases, such as in cornification disorders or zinc-responsive dermatosis.
- Crusts secondary to excoriations are frequently seen in atopic dermatitis, food intolerance, and flea bite dermatitis.
- Treat and rule out the presence of pyoderma before taking biopsies.

CLIENT EDUCATION

- In lay terms, pustules are “pimples” and crusts are “scabs.”

Pupil Abnormalities

BASIC INFORMATION

DEFINITION

Abnormalities include pupils that are inappropriately dilated or constricted as well as pupils with distorted shape.

SYNONYMS

Anisocoria: unequal or asymmetric pupils

Dyscoria: misshapen/distorted pupil

Miosis: constricted pupil

Mydriasis: dilated pupil

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats
- Iris atrophy is a normal aging change and is therefore seen in older animals.
- Iris coloboma (absence of or defect in iris) is a developmental/heritable condition that is usually noticed initially in young animals, most frequently dogs.

GENETICS & BREED PREDISPOSITION

- Distorted pupil: A distorted pupil, such as iris coloboma, may be breed-related in dogs. Australian shepherds and dal-matians are overrepresented.
- Dilated pupil:
  - Glaucoma, primary (predisposed breeds)
  - Toy and miniature poodles are predisposed to optic nerve hypoplasia.
  - Heritable retinal degeneration in many breeds of dogs (see p. 983)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Conditions that lead to pupil abnormalities can be divided into those that cause:

- Pupillary dilation (mydriasis)
- Pupillary constriction (miosis)
- Abnormal pupil shape (dyscoria)

HISTORY, CHIEF COMPLAINT

The pet's owner may notice abnormalities in pupil size and shape. More likely, veterinarians notice the pupil abnormalities in animals presenting for painful, red, or blind eyes.

PHYSICAL EXAM FINDINGS

- Dilated pupil and the following:
  - Scalloping at pupillary margin:
    - Iris coloboma: focal; young animal
    - Iris atrophy: typically multifocal and/or “moth-eaten” effect in iris stroma; typically age-related change (i.e., older animals)
  - Blindness (negative menace response):
    - See Retinal Degeneration, p. 983; Retinal Detachment, p. 985.

        - Optic nerve lesion (e.g., optic nerve hypoplasia, congenital, glaucoma [seep. 1559], optic neuritis (seep. 784)
        - Optic chiasmal lesion (see p. 784)
    - "Quiet" (i.e., nonred) sighted (visual) eye:
        - Internal ophthalmoplegia (paralysis of the iris and ciliary muscles) caused by:
            - Pharmacologic pupillary dilation (e.g., parasympatholytics such as atropine and topical tropicamide)
            - Iris atrophy
            - Lesions involving the parasympathetic fibers of the oculomotor nerve (cranial nerve [CN] III); relatively rare
        - Fearful animal (i.e., sympathetic stimulation): transient mydriasis; resolves once animal becomes calm
- Constricted pupil and the following:
    - Red eye with or without vision impairment:
        - See Uveitis, .
        - Corneal ulceration (seep. 250) and "axon reflex" miosis through trigeminal and oculomotor nerves (CNs V and III)
        - Pharmacologic pupillary constriction (e.g., parasympathomimetic, such as topical pilocarpine, dem-ecarium, or synthetic prostaglan-dins; such analogs include latanoprost, bimatoprost, and tra-voprost; may cause conjunctival hyperemia).
    - Quiet eye with or without vision impairment:
        - Horner's syndrome (see p. 543): other signs include ptosis (drooping of upper eyelid), enophthal-mos (caudal displacement of the eye), and third eyelid protrusion.
- Distorted pupil and the following:
    - Scalloping at pupillary margin:
        - Iris coloboma: focal; young animal
        - Iris atrophy: typically multifocal and/or "moth-eaten" effect in iris stroma; typically age-related change (i.e., older animals)
    - Red eye with or without vision impairment:
        - Adhesions of iris to lens and/or iris to cornea (posterior and anterior synechiae, respectively) from current or past anterior uveitis (see p. 1151)
        - Iris prolapse through full-thickness corneal lesion (see p. 249)
        - Iridodonesis (tremulousness of the iris on movement of the eye) noted, with loss of iris support subsequent to lens subluxation/luxation (see pp. 644 and)
- Anisocoria:
    - Primary iridal disease (age-related atrophy); heritable or developmental coloboma, active inflammatory process causing miosis; chronic inflammation leading to degeneration and/or posterior synechia
    - Primary neurologic cause (CN III abnormality, Horner's syndrome, fright response)
    - Pharmacologic agents (miotics such as pilocarpine, mydriatics such as atropine and tropicamide)
- Unresponsive pupil(s):
    - Retinal disease (seep. 141)
    - Optic nerve disease
    - Iridal disease (see p. 141)
    - Pharmacologic agents
    - Posterior synechia secondary to anterior uveitis

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis of pupil abnormalities requires consideration of the entire eye as well as the orbit and the brain. Pupil abnormalities are frequently indicative of serious but nonocular problems.

INITIAL DATABASE

Complete ophthalmic examination (seep. 1313), including:

- Neuro-ophthalmic examination (seep. 1311) (i.e., menace response; dazzle, palpebral, pupillary light, and vestibulo-ocular reflexes)
- Fluorescein stain application (miosis commonly occurs in animals with corneal ulceration)
- Intraocular pressures (>30 mm Hg with glaucoma; often low [< 10-15 mm Hg] with uveitis)

ADVANCED OR CONFIRMATORY TESTING

Variable depending on underlying condition:

- Pharmacologic testing (e.g., 10% phen-ylephrine) for Horner's syndrome
- CT scans, MRIs, and other imaging procedures; cerebrospinal fluid tap for diseases of the neurologic system (e.g., optic neuritis; optic chiasmal lesions) or orbital disorders
- Electroretinogram (see p. 1255) to assess retinal function (also see p. 983)

TREATMENT

TREATMENT OVERVIEW

If a specific systemic cause of oculomotor neuropathy, optic neuropathy, anterior uveitis, or Horner's syndrome can be identified, treatment should address the specific cause. Treatment is either not indicated or not available for iris atrophy, iris coloboma, optic nerve hypoplasia, retinal degeneration, and optic nerve atrophy/degeneration.

ACUTE AND CHRONIC TREATMENT

Directed at underlying cause

PROGNOSIS AND OUTCOME

- Prognosis varies widely depending on underlying condition and cause.
- Many causes of pupil abnormalities are completely innocuous, while others may be life threatening.

PEARLS & CONSIDERATIONS

COMMENTS

Many pupil abnormalities can be diagnosed with careful consideration of the signalment and the presence or absence of other ophthalmic signs.

CLIENT EDUCATION

- Pupil abnormalities can be an early sign of serious disease.
- Early detection may improve prognosis

AUTHOR: STEVEN R. HOLLINGSWORTH

EDITOR: CHERYL L. CULLEN

Pulse Abnormalities

BASIC INFORMATION

DEFINITION

The arterial pulse is produced by the fluctuation between diastolic and systolic arterial pressure and can be palpated as an impulse in superficial arteries, such as the femoral artery. *Pulse deficit* refers to a heartbeat that is heard on auscultation or felt on the chest wall but does not generate a palpable arterial pulse.

SYNONYMS

- Hyperkinetic pulse: strong, bounding, or “water-hammer” pulse
- Hypokinetic pulse: weak or “thready” pulse

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats of either sex and any age

ASSOCIATED CONDITIONS & DISORDERS

- Reduced pulse amplitude (hypokinetic pulse):
  - Decreased cardiac output (hypovo-lemia, systolic dysfunction)
  - Left ventricular outflow tract obstruction (aortic stenosis, systolic anterior motion of the mitral valve). The pulse is not transmitted normally to the peripheral arteries; with aortic stenosis, it may be decreased and delayed *(pulsus parvus et tardus).*
- Increased pulse amplitude (hyperkinetic pulse):
  - Increased stroke volume (anemia, pregnancy, increased sympathetic tone, hyperthyroidism, bradyarrhythmias)
  - Decreased diastolic arterial pressure (patent ductus arteriosus, aortic insufficiency). Diastolic runoff through the ductus arteriosus or aortic valve, respectively, causes a greater difference between systolic and diastolic pressures (greater pulse pressure) and a correspondingly stronger pulse.
- Variation in pulse amplitude:
  - Exaggerated effect of respiration: *pulsus paradoxus* (pericardial effusion with cardiac tamponade). The pulse is stronger during expiration and weaker during inspiration.
  - Tachyarrhythmias (atrial fibrillation, ventricular and atrial premature complexes, ventricular tachycardia). Generally, in a given animal with one of these arrhythmias, the pulse becomes weaker with higher heart rates or beats that are more premature.
  - Severe myocardial failure *(pulsus alternans).* The pulse amplitude alternates between a strong pulse and a weak (or absent) pulse.
- Regional variation in pulse amplitude:
  - Arterial thromboembolism (feline myocardial disease, infective endocarditis, hypercoagulable states)
- Variation in pulse rhythm:
  - Tachyarrhythmias (atrial fibrillation, premature atrial and ventricular complexes)
  - Bradyarrhythmias (second-degree atrioventricular block)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Highly variable and dependent on underlying cause

PHYSICAL EXAM FINDINGS

- Systemic or primary cardiac problems may alter the pulse; therefore, a complete physical exam is necessary.
- Femoral pulses are easiest to palpate in cats and dogs.
- The dorsal metatarsal pulse can also be palpated.
- Auscultate heart sounds simultaneously (by definition, a pulse deficit exists when a heart sound does not have a

corresponding palpable peripheral pulse).
- Pulse quality relates mainly to pulse amplitude (also affected by rate of rise of arterial pressure in systole and affected by pulse duration).

ETIOLOGY AND PATHOPHYSIOLOGY

- Pulse pressure: difference between systolic and diastolic blood pressure (BP)
- Variations in left ventricular stroke volume are detected as variation in arterial pulse pressure.
- With premature beats, the weak ventricular contraction may not generate sufficient systolic pressure to open the aortic valve, and no S^2 or pulse is produced (S! is still normally heard).
- Variations in stroke volume will also occur with the phase of respiration with cardiac tamponade, where increased filling of the right heart during inspiration leads to decreased filling of the left heart and a reduced pulse pressure.
- Pulsus alternans is an uncommon finding characterized by alternate pulses that are very weak or even absent despite consistent electrical activation (due to abnormal intracellular calcium cycling in myocardial failure).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A pulse abnormality is inherently a physical exam finding, and its significance may vary from harmless (e.g., seemingly weak pulse in an obese patient) to indicative of systemic or primary cardiac disturbances. An intermittent pulse deficit should be investigated initially with an electrocardiogram; a weak pulse should be assessed with evaluation of the patient's intravascular volume status (hydration) and cardiac function (auscultation, thoracic radiographs, echocardiogram).

DIFFERENTIAL DIAGNOSIS

- Hypokinetic pulse: obesity, arterial disease/disorder. The combination of hypokinetic pulse and a palpably strong or hyperdynamic heartbeat (apex beat) is strongly suggestive of outflow obstruction (e.g., moderate to marked aortic stenosis or, less commonly, pulmonic stenosis).
- Hyperkinetic pulse: thin body condition
- Variation in pulse amplitude: normal variation as occurs with respiratory sinus arrhythmia (pulse is stronger after pause)

INITIAL DATABASE

- The presence of pulse deficit should prompt recording of an electrocardiogram.
- The presence of alternate pulse deficits with normal sinus rhythm (pulsus alternans) should prompt a thoracic radiographic exam and an echocardiographic exam.

TREATMENT

TREATMENT OVERVIEW

Management of underlying cause

PROGNOSIS AND OUTCOME

Highly variable and dependent on underlying cause

PEARLS & CONSIDERATIONS

COMMENTS

- Palpation of the peripheral arterial pulse can give useful information about stroke volume and cardiac output.
- Palpation of the arterial pulse is not a useful way of detecting systemic hypertension.
- Presence of a hyperkinetic pulse may be more obvious than a diastolic murmur with severe aortic insufficiency (as with infective endocarditis of the aortic valve).
- Pulsus paradoxus is a very helpful finding when cardiac tamponade is suspected, but it may be difficult to detect if the dog is

panting.

Pulmonic Stenosis

BASIC INFORMATION

DEFINITION

A fixed or dynamic impediment to the ejection of blood from the right ventricle (RV) due to abnormal narrowing of the right ventricular outflow tract, pulmonic valve orifice, or main pulmonary artery

SYNONYM

Pulmonic valve dysplasia

EPIDEMIOLOGY

SPECIES, AGE, SEX

Pulmonic stenosis (PS) is the third most common congenital heart defect in dogs. It is an uncommon congenital defect in cats, which are more likely to develop acquired, benign dynamic infundibular RV outflow tract obstructions as adults, most often in association with other systemic or cardiac diseases.

GENETICS & BREED PREDISPOSITION

Inherited as a polygenic trait or single gene defect with variable penetrance. English bulldogs, miniature Schnauzers, Chihuahuas, Samoyeds, miniature pinschers, boxers, Labrador retrievers, mastiffs, beagles, fox terriers, Scottish terriers, West Highland white terriers, other terrier breeds are overrepresented.

ASSOCIATED CONDITIONS & DISORDERS

Pulmonic stenosis occurs most often as an isolated defect but may be combined with other defects of the conotruncal septum (e.g., tetralogy of Fallot). The tricuspid valve apparatus is concurrently malformed in about one-third of dogs with pulmonic stenosis.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Four anatomic types of obstruction can occur: supravalvular, valvular, subvalvular, and infundibular. While the functional consequences of these different types of obstruction are similar, their distinction is important if repair is contemplated.

HISTORY, CHIEF COMPLAINT

Affected animals may show no overt clinical manifestations or may exhibit exercise intolerance or syncope. Signs of right heart failure (venous engorgement, hepatomegaly, ascites) or sudden death occur in severely affected animals.

PHYSICAL EXAM FINDINGS

A systolic ejection murmur is typically best heard at the left heart base, specifically over the pulmonic area. It may also radiate loudly cranially along the sternal border. Arterial pulses are unremarkable unless severe heart failure is present. Jugular distension, jugular pulses, hepatosplenomegaly, and ascites develop with the onset of right heart failure. Cyanosis may be observed when PS is complicated by right-to-left shunting across a patent foramen ovale or coexisting atrial or ventricular septal defect.

ETIOLOGY AND PATHOPHYSIOLOGY

- Increased resistance to ejection results in concentric RV hypertrophy (RVH), which develops in proportion to the severity of obstruction.
- The resulting decline in right ventricular diastolic compliance impairs ventricular filling, resulting in elevated right atrial pressure.
- Tricuspid regurgitation from progressive ventricular dilation or concurrent valvular dysplasia further increases right atrial pressure.

- Hypertrophy of the infundibular region of the right ventricular outflow tract may also contribute to outflow tract obstruction, particularly during exercise. This additional mechanism of obstruction can be particularly problematic following surgical valvotomy or balloon valvuloplasty.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in a patient with a systolic heart murmur with point of maximal intensity over the left cardiac base. Signalment, pattern of murmur radiation on the chest and neck, and thoracic radiographic findings can help raise or lower suspicion of pulmonic stenosis (versus subvalvular aortic stenosis or other lesions); confirmation requires echocardiography.

DIFFERENTIAL DIAGNOSIS

Other congenital heart defects causing a systolic murmur, such as subvalvular aortic stenosis, ventricular septal defect, and tetralogy of Fallot

INITIAL DATABASE

- Electrocardiography: RVH is usually evident; right axis deviation, S1; S2, S3 deep S waves in CV6LU (or V4), CV6LL (or V2).
- Thoracic radiography: characteristic findings include right ventricular enlargement and dilation of the main pulmonary artery segment. These changes are usually most evident on the dorsoventral view. Pulmonary vasculature is usually normal, but in severe cases, the lungs may appear hypoperfused.
- Echocardiography: site of obstruction, severity of RVH, and poststenotic dilation of the main pulmonary artery are best demonstrated by a two-dimensional echocardiogram. The pulmonic valve area is best visualized from right parasternal short-axis views, from the left cranial parasternal position, or by transesophageal echocardiography. Color flow and spectral Doppler studies are useful to confirm the diagnosis and determine the severity of obstruction. Estimation of peak blood flow velocity through the stenotic area by Doppler interrogation permits calculation of the pressure gradient using the modified Bernoulli equation, pressure gradient = $4 \times V^2$.

ADVANCED OR CONFIRMATORY TESTING

Angiocardiography is performed as a prelude to balloon valvuloplasty or surgical repair. Such studies are useful for clarifying the anatomic location of the obstruction, identifying leaflet fusion and thickening, identifying the severity of RV hypertrophy, and verifying the presence of other abnormalities such as hypoplasia of the pulmonic annulus, tricuspid regurgitation, or a patent foramen ovale. Left ventricular angiography or coronary arteriography should be performed when abnormalities of the left heart are suspected or when concurrent developmental abnormalities of the coronary arteries are suspected in boxer dogs and English bulldogs. The hemodynamic severity of outflow tract obstructions is determined by measuring the systolic pressure gradient across the lesion and estimating the effective valve orifice area.

TREATMENT

TREATMENT OVERVIEW

Definitive treatment eliminates severe obstructing lesions prior to the development of heart failure

ACUTE GENERAL TREATMENT

- Dogs with mild pulmonic stenosis that is not causing overt manifestations do not require treatment.
- Dogs with such overt manifestations as exercise intolerance, syncope, or signs of right heart failure and dogs with severe fixed anatomic obstructions should be referred for surgical repair or balloon valvuloplasty, depending on the precise anatomy of the defect and/or presence of concurrent defects.
- Balloon valvuloplasty is the preferred method of treatment when the main abnormality is fusion of the pulmonic leaflets. Surgery is often required to effectively remedy complex lesions with annular hypoplasia and fixed or persistent subvalvular obstruction.
- Dynamic obstructions during stress or exercise can often be effectively palliated by beta-receptor blockade (e.g., atenolol 0.25-0.5 mg/kg PO q 12 h). Such therapy is sometimes required following balloon valvuloplasty or surgical repair.
- When balloon valvuloplasty or surgical correction are not possible, treatment with beta-receptor blocking drugs and exercise restriction are thought to minimize the chance of sudden death.

POSSIBLE COMPLICATIONS

Dogs with severe untreated disease frequently develop progressive right heart enlargement, tricuspid regurgitation, right heart failure, and atrial fibrillation. Recurrent syncope is common and sudden death has been reported.

RECOMMENDED MONITORING

Color-flow Doppler echocardiography is the most useful tool for assessing dogs with pulmonic stenosis over time. Some lesions that are modest in severity in juvenile animals can become progressively more severe over time. The short-and long-term success of surgery or balloon valvuloplasty is best determined by periodic echocardiographic evaluation. Chest radiographs and electrocardiography are useful for evaluating overall heart size and cardiac arrhythmias, respectively.

PROGNOSIS AND OUTCOME

- Dogs with mild obstructions have a very good prognosis and often reach old age.
- Dogs with severe obstructions (systolic pressure gradient >100 mm Hg) have a guarded prognosis, as they often develop heart failure or die suddenly.
- Balloon valvuloplasty improves outcome, particularly when the pressure gradients are substantially reduced.
- Restenosis occurs in about 10% of dogs treated by balloon valvuloplasty.

PEARLS & CONSIDERATIONS

PREVENTION

- Conscientiously performed physical examinations with careful cardiac auscultation are key to early recognition.
- Dogs with confirmed pulmonic stenosis should not be bred.

CLIENT EDUCATION

Owners should be advised of the high likelihood of heart failure or sudden death in animals with severe untreated pulmonic stenosis. Balloon valvuloplasty and surgical repair are recommended for patients with severe obstructions.

Pulmonary Thromboembolism

BASIC INFORMATION

DEFINITION

The occlusion of a pulmonary artery or arteriole by a thrombus that forms in the systemic venous system/right heart (i.e., embolism) or in the pulmonary arterial system (i.e., in-situ thrombus). Pulmonary thromboembolism (PTE) is infrequently confirmed by direct visualization; therefore diagnosis can be difficult and incidence may be underestimated.

EPIDEMIOLOGY

SPECIES, SEX, AGE

- Dogs: 10 months to 18 years, median age 11 years
- Cats: 2-14 years, median age 7 years

RISK FACTORS

Numerous predisposing conditions are identified as risk factors for PTE, and treatment of these underlying causes is a cornerstone of case management.

- Neoplasia
- Heartworm disease
- Sepsis
- Hyperadrenocorticism
- Disseminated intravascular coagulation
- Immune-mediated hemolytic anemia
- Protein-losing nephropathy/enteropathy
- Central catheters
- Vasculitis
- Pancreatitis
- Cardiac disease
- Surgical procedures especially total hip replacement
- Trauma

ASSOCIATED CONDITIONS & DISORDERS

Hypoxemia, right-sided congestive heart failure, pulmonary hypertension

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Acute onset dyspnea/tachypnea; may be mild or progressive when PTE is small or gradual
- Signs of the underlying disorder may predominate.
- Occasionally signs of right-sided heart failure (abdominal distension, exercise intolerance)
- Uncommonly, cough or hemoptysis
- Nonspecific signs (lethargy, anorexia/inappetence, weight loss, collapse)

PHYSICAL EXAM FINDINGS

- Dyspnea/tachypnea
- Cyanosis
- Pulmonary crackles/increased bronchovesicular sounds; however, pulmonary auscultation often is normal.
- Tachycardia and weak pulses
- Findings reflecting the predisposing condition
- Occasionally, findings consistent with right-sided congestive heart failure are present (jugular venous distension/pulsation, ascites)

- Right apical murmur or split second heart sound possible with pulmonary hypertension

ETIOLOGY AND PATHOPHYSIOLOGY

- Generally, PTE should be thought of as secondary to an underlying condition which causes venous stasis, endothelial damage, and/or hyperco-agulability (Virchow's triad).
- PTE leads to mechanical obstruction of a pulmonary artery or arteriole and reactive pulmonary vasoconstriction. This results in reduced blood flow to the affected region of lung. Other forms of emboli including parasites, neoplastic cells, fat, or gas may also cause pulmonary vascular obstruction.
- While small PTE are often clinically silent and rapidly lysed endogenously, large or numerous PTE cause ventilation/perfusion mismatch and hypoxemia.
- Since the lung has a dual blood supply with bronchial arteries from the aorta perfusing the lung parenchyma with oxygenated blood, even massive PTE generally does not cause lung infarction.
- Increased pulmonary vascular resistance due to pulmonary vascular obstruction and pulmonary vasoconstriction may cause pulmonary hypertension. This leads to a pressure overload of the right ventricle and if severe, right-sided heart failure.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Clinical diagnosis is challenging, and definitive diagnosis may require advanced imaging. Often a presumptive diagnosis is made based on high clinical suspicion from identifying a predisposing disorder, plus thoracic diagnostic imaging results.

DIFFERENTIAL DIAGNOSIS

- Pulmonary parenchymal disease (bron-chopneumonia, pulmonary edema, neoplasia, parasitism, contusion, hemorrhage)
- Upper or lower airway disease (bronchitis/asthma, acquired or congenital structural abnormalities, neoplasia, obstruction)
- Pleural space disease (pleural effusion, restrictive pleuritis, neoplasia)
- Other causes of pulmonary hypertension (see p. 1422)

INITIAL DATABASE

- Thoracic radiographs; initial test of choice, though minimally specific and sensitive: central pulmonary artery dilation, abrupt distal pulmonary artery attenuation, regional oligemia, interstitial or alveolar pulmonary parenchymal pattern (often with lobar distribution), right heart enlargement, pleural effusion. Radiographs may be normal.
- Coagulation profile: not useful because rapid (abnormally low) coagulation values do not indicate a hypercoagulable state.
- CBC, serum biochemistry panel, and urinalysis: not useful in the diagnosis of PTE but important for diagnosis of predisposing diseases
- Echocardiography: evidence of pulmonary hypertension, right atrial and ventricular enlargement, occasionally visible thrombus

ADVANCED OR CONFIRMATORY TESTING

- Blood gas analysis: hypoxemia/hypocapnia (hypercapnia if severe); metabolic acidosis; elevated alveolar-arterial (A-a) gradient
  - A-a gradient = Fio2 (Pb-Ph2o) -(Paco2/R) − Pao2, where Fio2 is the fraction of inhaled oxygen (e.g., 0.21 for room air; 0.4 for 40% oxygen; etc.), Pb = barometric pressure (627-643 mm Hg; www.weather.com), Ph2o = 47 mm Hg, R = 0.8, and Pao2 and Pco2 are obtained from the arterial blood gas result.
  - Normal: <15 mm Hg
  - 15/15 dogs with necropsy-confirmed PTE had elevated A-a gradient.
- Plasma D-dimer concentration: some problems with specificity, but high concentrations (i.e., >2000 ng/mL) consistent with thromboembolic disease in the dog. Normal D-dimer levels should reduce the suspicion of PTE.
- Nuclear ventilation/perfusion scanning: safe and noninvasive but very limited availability
- Pulmonary angiography: gold standard for definitive diagnosis. Invasive and unstable patient condition may preclude sedation/anesthesia.
- CT and magnetic resonance angiography: noninvasive, but require anesthesia

TREATMENT

TREATMENT OVERVIEW

PTE is often a life-threatening emergency, and initial treatment is focused on respiratory support. If clinical suspicion is high or a definitive diagnosis can be made, specific therapy should be provided.

ACUTE GENERAL TREATMENT

- Oxygen therapy (see p. 1318)
- Ventilation with positive end expiratory pressure if severe (see p. 1362)
- Judicious parenteral fluid therapy to maintain tissue perfusion without exacerbating right heart failure
- Anticoagulant therapy to prevent additional thrombus formation:
  - Unfractionated heparin: 100-300 U/kg IV or SQ q 6-8 h to prolong PTT to 1.5-2 times baseline; *or*
  - Low-molecular-weight heparin (LMWH): dalteparin, 100-150 U/kg SQ q 8-12 h; or enoxaparin, 1 mg/kg SQ q 12 h. Doses not well defined.
- Antiplatelet therapy may be considered:
  - Aspirin, 0.5 mg/kg PO q 12-24 h (dogs); 5-20 mg PO q 3 d (cats); *or*
  - Clopidogrel, 1-2 mg/kg PO q 24 h (dogs); 18.75 mg PO q 24 h (cats)
- Thrombolytic therapy (streptokinase, tissue plasminogen activator) may be useful in acute stage, but experience is limited in veterinary medicine, and proposed dosing regimens vary widely.
- Surgical embolectomy is feasible with central thrombi but associated with significant morbidity/mortality. Percutaneous catheter thrombectomy/thrombolysis may be possible with reduced mortality/morbidity but requires specialized equipment.

CHRONIC TREATMENT

- Treatment of underlying condition
- Anticoagulant therapy:
  - LMWH: dalteparin or enoxaparin as above; *or*
  - Warfarin, 0.05-0.2 mg/kg PO q 24 h, to attain an international normalization ratio of 2-3. Must be overlapped with heparin therapy for 3-5 days owing to initial hypercoagulable phase.
- Antiplatelet therapy:
  - Aspirin or clopidogrel as above

POSSIBLE COMPLICATIONS

- Pulmonary hypertension and right-sided heart failure
- Potentially severe hemorrhage is possible with any anticoagulant or thrombolytic therapy. This limits the use of warfarin and thrombolytics but risk appears low with LMWH.

RECOMMENDED MONITORING

- Respiratory rate, arterial blood gas analysis, and thoracic radiography provide relative indications of response to therapy or deterioration of patient condition.
- Careful monitoring of coagulation times with unfractionated heparin or warfarin therapy. This may not be necessary with LMWH.

PROGNOSIS AND OUTCOME

Variable depending upon size of thrombus and degree of pulmonary vascular occlusion. Large thrombi resulting in occlusion of large portions of the pulmonary vascular bed are associated with a poor prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- PTE should be suspected in any patient with severe dyspnea and/or hypoxemia and normal thoracic radiographs.
- Even with management of an underlying disease, recurrence is possible, and long-term anticoagulant therapy may be necessary.

PREVENTION

Elimination of predisposing conditions is imperative. Prophylactic anticoagulant therapy may be considered when this is not possible.

1ST EDITION AUTHOR: BRUCE KORNREICH

Pulmonary Nodules

BASIC INFORMATION

DEFINITION

Single or multiple masses of varying sizes occurring in the lung parenchyma; usually detected radiographically

SYNONYM

Lung nodules

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: 9-11 years
- Cats: 11-12 years
- Females may be at increased risk.
- The prevalence of pulmonary nodules in dogs and cats is not known. Pulmonary neoplasms have an average reported incidence rate of 5.6/100,000 in dogs and 2.2/100,000 in cats.

RISK FACTORS

Exposure to secondhand smoke may be a risk factor.

ASSOCIATED CONDITIONS & DISORDERS

Paraneoplastic syndromes reported to occur secondary to primary or metastatic lung neoplasms:

- Hypertrophic osteopathy
- Hypercalcemia
- Fever
- Elevated ACTH with associated signs of hyperadrenocorticism

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Most primary lung neoplasms are adenocarcinomas (75%) or carcinomas (20%).

HISTORY, CHIEF COMPLAINT

- Pulmonary nodules or masses may be found incidentally in patients undergoing radiography for other reasons.
- When lung neoplasms cause clinical signs, the most frequent complaints from the owner are cough and dyspnea.
- Sputum with or without blood or hemoptysis is possible.
- Other possible signs: fever, weight loss, dysphagia, vomiting, regurgitation, wheezing
- Cats often manifest signs related to metastatic disease to their digits as opposed to respiratory signs.

PHYSICAL EXAM FINDINGS

- Physical exam: usually normal
- Pulmonary nodules due to metastatic disease: physical abnormalities from the primary tumor may be found in other parts of the body.
- In patients with pulmonary nodules, careful evaluation of the more common sites of origin of tumors that metastasize to the lungs is indicated, including the oral cavity, the area of the thyroid, mammary glands, and toenails (especially in cats).
- A rectal exam is essential in every dog with pulmonary nodules (assess prostate, anal sacs, bladder/urethra, sub-lumbar lymph nodes).
- A fundic exam (seep. 1313) and careful dermatologic evaluation (see) may be helpful in identifying disseminated fungal

disease.

ETIOLOGY AND PATHOPHYSIOLOGY

- The main concern with pulmonary nodules is malignancy; neoplasms from virtually any part of the body, including primary lung tumors, may metastasize to the lungs.
- Metastatic neoplasia may reach the lungs via lymphatics or via the bloodstream; both can produce a nodular pulmonary pattern.
- The development of metastasis is a complex, multistep process, and failure to complete any of the steps will prevent the development of a metastatic focus. It is estimated that less than 1 in 100 neoplastic cells that leaves the primary tumor survives the metastatic cascade. This multistep process includes the induction of neovascularization detachment of the tumor cell from the primary tumor, dissolution of the basement membrane and invasion into the bloodstream, evasion of the host immunity and survival in the bloodstream, margination in a new capillary and attachment to the endothelium, dissolution of the basement membrane and extravasation into the extracellular matrix, survival in the new tissue by evading the host immunity, and finally the induction of neovascularization to support continued growth of the new metastatic focus. This neovascularization begins the process again.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of pulmonary nodules is usually made with a radiographic evaluation. A systematic approach to rule out infectious or granulomatous causes (as warranted by geography) or other foci of neoplasia (i.e., primary lesions elsewhere that have resulted in the identified pulmonary nodules) is paramount.

DIFFERENTIAL DIAGNOSIS

- Solitary lung mass: primary neoplasia, metastatic neoplasia, granuloma, cyst, infarct, localized hemorrhage, focal pneumonia, abscess
- Multiple pulmonary masses: primary or metastatic neoplasia, fungal disease (blastomycosis, histoplasmosis), pulmonary osteomas (rarely more than 3-4 mm in diameter and more radiopaque than soft-tissue nodules because of mineral composition). Bacterial abscesses and granulomas uncommonly cause multiple pulmonary masses.
- One or more cutaneous or subcutaneous nodules, one or more nipples, and intrahepatic mineralizations can be mistaken for focal pulmonary lesions, especially if only one radiographic projection is made.

INITIAL DATABASE

- Thoracic radiographs: the source of initial identification of pulmonary nodules in most cases (less commonly at surgery or necropsy)
- CBC, serum biochemistry profile, urinalysis: typically unremarkable in patients with incidentally discovered pulmonary nodules. Hypercalcemia may occur with neoplasia, fungal, and other granulomatous diseases.
- Pleural effusion, if present, should be sampled and evaluated with fluid and cytologic analysis, and if evidence of infection exists, bacterial culture (aerobic and anaerobic).
- Repeated meticulous physical exam (with particular attention paid to the mammary chains, anal sacs, oral cavity, skin, and digits)

ADVANCED OR CONFIRMATORY TESTING

- Thoracic radiographs: three views if the lesion was found incidentally
- Ultrasonographic studies (of the abdomen and of the heart to screen for primary sites of disease; of the lesion with aspiration for diagnosis if possible)
- CT to assess for lesions too small to be identified with plain-film radiography and/or to be used for CT-guided aspirates or biopsies. See p. 1233.
- The minimum database should be supplemented with fungal serologic examination and microbial (fungal and bacterial) culture based on clinical suspicion and history.
- Thoracotomy with histopathologic evaluation of biopsy specimens. The hilar lymph nodes and lung lobes should be carefully evaluated and sampled as necessary at the time of thoracotomy.

TREATMENT

TREATMENT OVERVIEW

- Resolution of clinical signs (for instance, cough or dyspnea) if present
- Control or elimination of primary disease process (exception: clinically unimportant pulmonary nodules, i.e., pulmonary osteomas)
- Single pulmonary masses are more commonly addressed surgically (focal process).
- Multiple pulmonary masses are usually not addressed surgically, because they typically are part of a generalized process (e.g., neoplastic, fungal). Rather, identifying the underlying cause and systemic (medical) treatment are usually most important.

ACUTE GENERAL TREATMENT

- Once a lesion has been identified, surgical excision should be considered.
  - Treatment of choice for primary pulmonary neoplasia (single pulmonary nodule in which the diagnosis was established with ultrasound- or CT-guided aspiration or biopsy).
- Surgical excision may be considered for solitary pulmonary nodules/masses of unknown tissue type. The slow-growing nature of some single pulmonary nodules means that other concerns (concurrent illnesses, patient age, etc.) may supersede the need for thoracotomy.
- In specific cases, metastasectomy (excision of metastases) can be performed. Consultation with an oncologist is recommended beforehand.

CHRONIC TREATMENT

- Chemotherapy may be attempted for primary pulmonary neoplasia deemed unresectable or with evidence of lymphatic metastasis at the time of diagnosis. Options may include doxorubicin, platinum compounds (cisplatin, carbo-platin), gemcitabine, or vinorelbine.
- Chemotherapy is largely unproven in the management of pulmonary tumors in veterinary medicine.

POSSIBLE COMPLICATIONS

- Hypertrophic osteopathy; typically resolves with removal of pulmonary disease
- Digital or ocular metastasis (cats), particularly with angioinvasive neoplasms

RECOMMENDED MONITORING

- Monthly to quarterly radiographs to assess for recurrence, progression, or changes (cavitation is not uncommon but is often misinterpreted as abscess/infection)
- As required per protocol for chemotherapy patients (i.e., CBC), quality-of-life assessments

PROGNOSIS AND OUTCOME

- Guarded and extremely variable (median survivals in parentheses)
- Dogs with primary lung tumors:
  - 50% of dogs without clinical signs and having peripheral, solitary, small (<5 cm), well-differentiated, low-grade pulmonary adenocarcinomas without lymph node metastasis or pleural effusion have median survival >1 year (12-20 months).
  - In contrast, median survival is shorter (8 months) for patients with clinical signs referable to the pulmonary nodule/mass, or with a large solitary (>5 cm or 100 cm^3) neoplasm, one that involves an entire lobe, squamous cell carcinoma histologically, or nodal metastasis (1-2 months)
- Cats with primary lung tumors: median survival 4 months after lobectomy. Cats with poorly differentiated tumors or enlarged tracheobronchial lymph nodes: median 2 months.

PEARLS & CONSIDERATIONS

COMMENTS

- Metastatic neoplasia is much more common than primary pulmonary neoplasia.
- Half of patients with newly diagnosed pulmonary neoplasia are deemed inoperable because regional or systemic extension is identified at presentation.
- Pulmonary osteomas are benign mineralizations often identified incidentally on the radiographs of older dogs. The diagnosis

of osteoma versus metastasis can be made empirically based on size and relative opacity. The limit of detection for soft-tissue lesions in the pulmonary parenchyma is considered to range from 5-10 mm. Because osteomas are of mineral or bone density, they can be identified in the 2-5 mm range.

- In this author's experience, cats with pulmonary metastases tend to show overt signs, have more advanced disease at the time of presentation, and have markedly shorter survival times than dogs.

EDITOR: KENNETH M. RASSNICK

Pulmonary Lymphoid Granulomatosis

BASIC INFORMATION

DEFINITION

Rare lymphoproliferative neoplasm in which infiltrates of atypical lymphoid cells develop around and destroy pulmonary blood vessels

SYNONYMS

PLG, lymphomatoid granulomatosis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Rare in dogs and reported in a single cat. Young to middle-aged adults of either gender are typically affected.

ASSOCIATED CONDITIONS & DISORDERS: Lymphomatoid granulomatosis may be observed in sites other than the lungs, including lymph nodes, liver, heart, spleen, kidneys, pancreas, adrenal gland, or skin.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Nonproductive cough that is unresponsive to treatment with antimicrobials
- Increased respiratory effort
- Lethargy
- Anorexia and weight loss
- Rarely: fever, lameness, peripheral lymphadenopathy, ascites, or vomiting

PHYSICAL EXAM FINDINGS

- Nonproductive cough
- Tachypnea
- Areas of decreased bronchovesicular lung sounds
- Areas of increased bronchovesicular lung sounds
- Peripheral lymphadenomegaly (occasionally)
- Other sites of infiltration may be identified, including the skin

ETIOLOGY AND PATHOPHYSIOLOGY

- In humans, pulmonary lymphoid granulomatosis (PLG) is considered a precursor to low-grade T-cell lymphoma.
- The disease also seems to be T-cell mediated in the few animals studied to date, although T-and B-cell infiltrates have been documented in a single dog.
- Infiltrates of atypical lymphocytes are centered on the vasculature. While pulmonary vasculature is most commonly targeted, other lymphatic tissues or solid organs may be affected as well.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Metastatic pulmonary neoplasia
- Pulmonary lymphoma
- Other primary lung tumors
- Granulomatous fungal pneumonia
- Eosinophilic bronchopneumopathy/pulmonary infiltrates with eosinophils/eosinophilic granulomatosis
- Severe bacterial pneumonia

INITIAL DATABASE

- CBC: leukocytosis, eosinophilia, and basophilia are common.
- Serum biochemistry profile and urinalysis: usually unremarkable
- Heartworm serology: negative
- Thoracic radiographs:
  - Large pulmonary masses or lobar consolidation are typical.
  - An interstitial lung pattern is commonly observed.
  - Tracheobronchial and/or sternal lymph nodes are often enlarged.
  - Pleural effusion is sometimes present.

ADVANCED OR CONFIRMATORY TESTING

- Pulmonary biopsy is the only means of definitive diagnosis. Samples may be obtained via sternal or intercostal thoracotomy, keyhole biopsy, or thoracoscopy.
- Tracheal wash, bronchoalveolar lavage, and fine-needle aspirates may reveal cells suggestive of either inflammation or lymphoma, but cytologic examination cannot confirm a diagnosis of PLG. These tests are, however, useful in ruling out other potential causes of lung disease.

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are to achieve remission via chemotherapy, and provide short-term support for hypoxemia if required.

ACUTE GENERAL TREATMENT

- If required, oxygen supplementation for hypoxemic animals (seep. 1318)
- Chemotherapy protocols (see pp. 675 and 674) similar to those used for treatment of lymphoma, including the use of cytotoxic agents
- Glucocorticosteroids alone will seldom produce remission.

CHRONIC TREATMENT

Chemotherapy should proceed as for lymphoma (see pp. 671 and 675).

POSSIBLE COMPLICATIONS

Extensive and serious adverse reactions, including leukopenia and immune suppression, are possible in response to many chemotherapeutic agents; drug-specific reactions are also possible (e.g., cyclophosphamide-induced sterile hemorrhagic cystitis).

RECOMMENDED MONITORING

- Repeat thoracic radiographs 2-3 weeks after initial chemotherapy and periodically thereafter. The interval between radiographs can be prolonged as the duration of remission endures.
- Periodically assess CBC for dogs receiving chemotherapy for lymphoma; other specific tests may be needed, depending on the chemotherapeutic agent employed (e.g., cardiac ultrasound for dogs receiving doxorubicin).

PROGNOSIS AND OUTCOME

- Guarded
- Many dogs attain durable remission.
- Lymphoma may follow PLG by months to years.

PEARLS & CONSIDERATIONS

COMMENTS

In humans, PLG is regarded as a slowly progressive precursor to lymphoma.

PREVENTION

There is no means to prevent development of PLG.

TECHNICIAN TIPS

Needle aspiration of lung lesions is commonly performed with 23-G needles and a 6- or 12-mL syringe (seep. 1277).

CLIENT EDUCATION

Owners should understand that even if durable remission is achieved, the disease may progress to lymphoma years later.

Pulmonary Hypertension (Arterial)

BASIC INFORMATION

DEFINITIONS

- Pulmonary hypertension (PH) is defined as elevated pulmonary arterial pressure (PAP) secondary to various disease mechanisms causing cor pulmonale (right ventricular hypertrophy secondary to PH) and eventually right sided heart failure. The World Health Organization (WHO) classification of PH is based on similarities in pathophysiologic mechanisms (see box).
- Pulmonary arterial hypertension (PAH) is a progressive vasoproliferative condition characterized by increased PAP. Patients with PAH by definition do not have significant left heart disease, lung disease, or chronic thromboembolic disease. Idiopathic PAH (formerly primary PH or PPH) is diagnosed when no underlying cause for PH is found, and characteristic histologic abnormalities in small pulmonary arteries can be identified. Histologic abnormalities include intimal, medial, and adventitial proliferation, plexogenic changes consisting of proliferating epithelial cells mixed with myofibroblasts, and necrotizing arteritis. Specific hemodynamic criteria include systolic PAP > 30 mm Hg, diastolic PAP > 20 mm Hg, mean PAP > 25 mm Hg, pulmonary capillary wedge pressure < 15 mm Hg.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: dependent on underlying cause
- Cats: data on any cause of PH are scant, but PAH associated with congenital cardiovascular shunt is probably underrecognized.

GENETICS & BREED PREDISPOSITION

Depending on underlying cause:

- Myxomatous mitral valve disease in poodles, dachshunds, terriers, and other small breeds
- Chronic obstructive upper airway disease in brachycephalic breeds
- Pulmonary fibrosis in West Highland white terriers

Classification of Pulmonary Hypertension

From WHO classification in Chin KM, Rubin U: Pulmonary arterial hypertension, J Am Coll Cardiol 51:1527-1538, 2008, modified and adapted for the dog

WHOGroup 1:Pulmonary Arterial Hypertension (PAH)

- Idiopathic (formerly primary PH, PPH)
- Associated with congenital systemic-to-pulmonic shunts
- Persistent pulmonary hypertension of the newborn
- Associated with drugs, toxins, inflammatory conditions

Group 2:Pulmonary Hypertension Associated With Left Heart Disease

- Left ventricular or atrial disease
- Left-sided valvular disease

Group 3:Pulmonary Hypertension Associated With Respiratory Disease and/or Hypoxemia

- Interstitial lung disease (e.g., pulmonary fibrosis)
- Chronic upper airway obstruction
- Chronic exposure to high altitude

Group 4:Pulmonary Hypertension Due to Thromboembolic Disease

- Primary pulmonary arterial lesion (e.g., *Dirofilaria immitis, Angiostrongylus vasorum)*

- Medical conditions predisposing to pulmonary thromboembolism

Group 5:Miscellaneous

RISK FACTORS

- Protein-losing nephropathies and enteropathies, hyperadrenocorticism, immune-mediated hemolytic anemia, pancreatitis, neoplasia, heartworm disease are risk factors for pulmonary thromboembolism (PTE).
- Ingestion of snails for infection with *Angiostrongylus vasorum* (French heartworm) in Europe and Newfoundland, Canada
- Septic shock, pancreatitis, other systemic inflammatory states for adult respiratory distress syndrome (ARDS)

GEOGRAPHY AND SEASONALITY

- *Dirofilaria immitis* in endemic areas
- *A. vasorum* in endemic areas, Europe, and Newfoundland, Canada
- High altitude (hypobaric hypoxia) causes or contributes to pulmonary hypertension. Dogs living at 2300 m and 3500 m altitude (7500 ft and 11,500 ft) have a mean arterial Po2 of around 62 mm Hg and 52 mm Hg, respectively, and a mean systolic pulmonary artery pressure of around 30 mm Hg and 40 mm Hg, respectively, as determined by Doppler evaluation of tricuspid regurgitation.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

From an intensive care and therapeutic point of view, PH may be further subdivided into acute and chronic categories. Acute PH may reflect a sudden worsening of a chronic condition causing PH (e.g., left-sided congestive heart failure), or it may be precipitated by an acute condition (e.g., acute respiratory distress syndrome, massive PTE).

HISTORY, CHIEF COMPLAINT

- Depends on underlying cause
- Signs of PH itself or of the underlying cause may predominate.
- Signs associated with PH include:
    - Exercise intolerance
    - Collapse, syncope (reflex bradycardia caused by high resistance to forward flow from the right ventricle)
    - Dyspnea, coughing
    - Abdominal distension
    - Rear limb weakness in reverse patent ductus arteriosus (PDA)
    - Right ventricular hypertrophy as incidental finding during echocardiography or electrocardiography

PHYSICAL EXAM FINDINGS

- PAH: exam may be unremarkable. Possible findings include:
    - Pale mucous membranes
    - Respiratory distress
        - May be precipitated or exacerbated by exercise
    - Tachycardia
    - Weak pulse
    - Signs of right-sided congestive heart failure (distended jugular veins or jugular venous pulse, abdominal distension) o Split second heart sound (pulmonic valve closing after aortic valve)
    - Murmur of tricuspid regurgitation (systolic, right-sided)
    - Murmur of pulmonic regurgitation (rare; diastolic and loudest over left heart base)
    - Cyanosis
    - Red oral and conjunctival mucous membranes due to polycythemia in reverse PDA
    - Differential cyanosis in reverse PDA
- PH with left-sided heart disease: depends on underlying disease; possible findings include:
    - Same as PAH (except polycythemia signs and differential cyanosis)
    - Loud murmur of mitral regurgitation
    - Arrhythmia associated with dilated cardiomyopathy
    - Increased lung sounds

- Crackles
- PH with respiratory disease/hypoxia:
  - Same as PAH (except differential cyanosis)
  - Stertorous breathing in brachycephalic syndrome
  - Cough
  - Increased lung sounds, wheezes, crackles
- PH due to PTE:
  - Same as PAH (except polycythemia signs and differential cyanosis)
  - Cough
  - Hemoptysis
  - Increased lung sounds

ETIOLOGY AND PATHOPHYSIOLOGY

- In PAH, the underlying vascular injury is thought to be a final common response to various inciting factors coupled with genetic susceptibility. Eliciting factors may be mechanical (overperfusion), drugs (experimentally inducible with appetite suppressants), toxins, infections, and genetically determined susceptibility to such injuries.
  - Thrombosis elicited by diseased vessel walls may complicate PAH.
- PH is a common complication of different cardiac and extracardiac diseases and results from two main mechanisms: increased left atrial pressure and increased pulmonary vascular resistance. Important causes are:
  - Cardiac:
    - Pulmonary venous hypertension due to increased left atrial pressure in left myocardial failure, most common in advanced chronic mitral regurgitation, also in dilated cardiomyopathy; cor triatriatum sinister, mitral stenosis
  - Hypoxic vasoconstriction:
    - Chronic obstructive lower airway disease (bronchitis, emphysema)
    - Chronic obstructive upper airway disease
    - High-altitude hypoxia
  - Occlusion of the pulmonary vascular bed:
    - PTE
    - Parasites *(D. immitis, A. vasorum)*
  - Pulmonary parenchymal disease:
    - Pulmonary fibrosis (see p. 615)
    - ARDS
  - Combination of mechanisms (e.g., heartworm infection; *D. immitis, A. vasorum):* obstruction by intravascular parasites, vasculitis, thrombosis, and hypoxic vasoconstriction.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A practical clinical diagnosis of PH is made when high-velocity valvular regurgitation (tricuspid, pulmonic, or both) is documented by Doppler echocardiography in the absence of pulmonic stenosis.

DIFFERENTIAL DIAGNOSIS

- For right-sided heart failure:
  - Congenital cardiac disease: pulmonic stenosis, tricuspid dysplasia, tetralogy of Fallot, tricuspid stenosis, cor triatriatum dexter
  - Acquired cardiovascular disease: severe tricuspid myxomatous valve disease/endocardiosis, right ventricular dilated cardiomyopathy, peri-cardial effusion
- For right ventricular hypertrophy:
  - Pulmonic stenosis, tetralogy of Fallot

INITIAL DATABASE

- Thoracic radiographs; dorsoventral view is particularly important.
  - Document right ventricular and main pulmonary artery enlargement; somewhat nonspecific, as findings of “reversed D” and “increased sternal contact” on the lateral view are often overinterpreted in normal dogs and cats (expiratory films, rotation of patient, thoracic conformation).
  - Peripheral pulmonary vasculature may be tortuous and enlarged.
  - Peripheral pulmonary arterial markings may abruptly stop with PTE.
  - Left atrium is enlarged and pulmonary veins are congested with underlying left atrial, ventricular, or mitral valve

disease.
    - Signs of underlying bronchial, interstitial, or alveolar pulmonary disease may be evident.
- Echocardiogram, dual role:
    - Rule in or out causes of PH, including acquired left ventricular heart disease (myxomatous mitral valve disease, dilated cardiomyopathy) and congenital cardiovascular shunt.
    - Confirmation of PH qualitatively and quantitatively:
        - Qualitatively: characteristic two-dimensional and M-mode findings in moderate to severe PH are dilation of right ventricle and atrium, thickening of right ventricular wall and papillary muscles, paradoxical septal motion, and decreased left ventricular chamber size.
        - Quantitatively: Doppler examination is the most useful noninvasive clinical tool to confirm and quantitate severity of PH.
            - Systolic: velocity of tricuspid regurgitation (TR) correlates to right ventricular systolic pressure, and therefore, barring pulmonic stenosis, to pulmonary arterial systolic pressure. The modified Bernoulli equation allows Doppler-derived blood flow velocities to be used for estimating intracardiac pressures: $PG = 4 \times (Vmax)^2$, where PG is the peak pressure gradient between right ventricle and right atrium, in mm Hg, and Vmax is the peak velocity of tricuspid regurgitation (TR), in m/sec. It is assumed that right atrial pressure approximates 0 mm Hg during ventricular systole, such that the right atrial/right ventricular systolic PG equals systolic right ventricular pressure. A TR-PG > 30mmHg (Vmax > 2.8 m/s) suggests/indicates systolic PH.
            - Diastolic pulmonary artery pressure is calculated with Doppler quantification of pulmonary valve insufficiency (PI) instead of tricuspid regurgitation; by this method, PH is considered to be present when PI-PG is >20 mm Hg (Vmax > 2.2 m/s).
- ECG: document right ventricular hypertrophy (RVH; deep S waves in leads I, II, III, aVF), right axis deviation, and possible arrhythmias; in acute PH, ECG abnormalities may not be present; in chronic PH, marked PH must be present to cause ECG abnormalities. Less sensitive and specific than echocardiography.
- Serology for *D. immitis* and Baermann fecal examination for *A. vasorum*
- Platelet count, coagulation profile, and parameters associated with hypercoagulability (e.g., antithrombin levels, D-dimer levels) may be abnormal with vasculitis and thrombosis.
- Arterial blood gas analysis: may show hypoxemia in primary respiratory disease or right-to-left cardiovascular shunt.
- CBC, biochemistry panel, urinalysis: may show abnormalities suggestive of parasitic disease (eosinophilia, baso-philia), chronic inflammation (throm-bocytosis, hyperglobulinemia), and systemic disease predisposing to PTE (e.g., proteinuria, hypoproteinemia, hypoalbuminemia, increased liver enzyme activities consistent with steroid hepatopathy, increased amylase and lipase activity, and increased pancreatic lipase activity consistent with pancreatitis).

ADVANCED OR CONFIRMATORY TESTING

- Contrast ultrasound (microbubbles) of the heart and descending aorta to rule out cardiovascular right-to-left shunt. Shunt is also possible due to pulmonary arteriovenous fistula secondary to pulmonary hypertension; in this case, bubbles will take at least three cardiac cycles from their appearance in the right atrium until their appearance in the left atrium.
- Right-sided cardiac catheterization for invasive measurement of pulmonary wedge pressure as an estimate of left atrial pressure, systolic and diastolic pulmonary artery pressure; evaluation of therapeutic intervention
- Pulmonary angiography; tortuous pulmonary arteries indicate PH; perfusion deficits are present in PTE.
- Pulmonary CT to identify/rule out parenchymal disease and CT-angiography for PTE
- Pulmonary ventilation/perfusion scintigraphy to rule out PTE
- Pulmonary histopathologic evaluation to confirm PAH

TREATMENT

TREATMENT OVERVIEW

- PH of any genesis with signs referable to right ventricular forward or backward failure: lower pulmonary artery pressure.
- PH of any genesis with signs referable to hypoxia: improve oxygenation.
- PH with known pathogenesis and treatable cause: focus should be to correct/improve underlying disease.

ACUTE GENERAL TREATMENT

Oxygen therapy (cage or nasal). See p. 615.

CHRONIC TREATMENT

There is no randomized trial documenting efficacy of medical treatment in naturally occurring PH in dogs; thus the following are merely treatment considerations:

- Therapeutic trial with amlodipine (Norvasc) in moderate PH, starting at 0.05 mg/kg PO q 24 h and titrating dose based on response and systemic blood pressure (avoid hypotension)
- Anticoagulant therapy with low-dose aspirin, 0.5 mg/kg PO q 12 h (dog)
- Sildenafil (Viagra) in severe PH, 2-3 mg/kg PO q 8-12 h. Improves clinical condition in the absence of significant effects on PAP as estimated by TR-PG.
- Oral L-arginine, a precursor of nitric oxide, may be a simple and useful oral medical treatment; however, there are no studies documenting a positive effect.
- Dedicated owner may consider intermittent oxygen therapy at home.
- Pimobendan may lower PAP.
- Furosemide, ACE inhibitor, spironolactone in cases of overt right-sided congestive heart failure (seep. 470)
- Specific treatment of underlying mechanism or disease in secondary PH (see Heart Failure, Chronic, p. 470; Pulmonary Thromboembolism, p. 940; Heartworm Disease, Dog, p. 477; Heartworm Disease, Cat, p. 474; Acute Respiratory Distress Syndrome, p. 34)

POSSIBLE COMPLICATIONS

- PH: right ventricular failure
- Treatment: systemic arterial hypotension with syncope, prerenal azotemia

RECOMMENDED MONITORING

- Most important are simple clinical parameters: general attitude, exercise tolerance, respiration, severity of ascites
- Systemic blood pressure
- Vmax of TR and PR

PROGNOSIS AND OUTCOME

Depends on underlying disease and stage of disease:

- Good in parasitic pulmonary vasculature disease with acute PH
- Fair in right-to-left cardiovascular shunts, myxomatous mitral valve disease, PH secondary to chronic parasitic pulmonary vasculature disease
- Poor in advanced PAH, advanced pulmonary fibrosis, ARDS, nonparasitic PTE, presence of right-sided heart failure

PEARLS & CONSIDERATIONS

COMMENTS

- Most causes of secondary PH are readily detectable.
- Pulmonary thromboembolism and right-to-left PDA in particular may be missed if not considered.
- Idiopathic PAH is a clinical diagnosis of exclusion and definitive confirmation is available only histologically.
- Newer human drugs to decrease pulmonary artery pressure are very expensive: iloprost = prostaglandin analog for inhalation, and bosentan = endo-thelin antagonist for oral administration.

TECHNICIAN TIPS

Oxygen can be administered to patients with respiratory distress secondary to PH by nasal oxygen catheters, flow-by techniques, or by placing the animal in an oxygen cage. Changes in Pao2 following a change in inspired oxygen concentration require time to be appreciated by an arterial blood gas measurement.

CLIENT EDUCATION

In dogs with cardiac disease, travel to higher altitude (above 7000 feet) may aggravate PH to a clinically relevant degree, owing to hypobaric hypoxia.

AUTHOR: TONY M. GLAUS

EDITOR: ETIENNE CÔTÉ

Pulmonary Edema, Noncardiogenic

BASIC INFORMATION

DEFINITION

The well-recognized phenomenon of pulmonary interstitial/alveolar fluid accumulation caused by a disorder other than cardiac congestion

SYNONYMS

Acute respiratory distress syndrome (ARDS), neurogenic pulmonary edema

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats of any age or sex may be affected.

RISK FACTORS

- Acute upper airway obstruction (laryngeal paralysis, brachycephalic upper airway syndrome, critical tracheal collapse, foreign body, mass or infiltration, strangulation, others)
- Electrocution
- Protracted seizures or head trauma
- Major trauma or surgery
- Sepsis or nonseptic systemic inflammatory disease (e.g., pancreatitis, hepatitis)
- Any cause of vasculitis
- Acid aspiration or pneumonia
- Smoke inhalation or other inhaled irritants
- Near-drowning experience
- Drug reaction or overdose

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Cough, tachypnea, and respiratory distress are the most common:
  - Severe edema may cause coughing with expectoration of blood-tinged fluid.
- Other complaints could reflect primary diseases, as already mentioned.

PHYSICAL EXAM FINDINGS

- Acute severe respiratory distress and tachypnea
  - Increased effort noted during inspiration and expiration from increased lung stiffness
- Cyanosis may be present if there is severe alveolar involvement.
- Fine crackles, often at end inspiration and early expiration, in the dorsocau-dal lung fields:
  - Coarse crackles throughout inspiration more often indicate airway disease or progression of an interstitial disease into airways.
  - Crackles may be absent in early or mild edema.
- Lung sounds may be exceptionally quiet in very severe edema, particularly in cats.
- Cardiac murmurs and arrhythmias do not always indicate that edema is of cardiogenic origin.
- Other clinical signs associated with the primary underlying disease process may be present.

ETIOLOGY AND PATHOPHYSIOLOGY

- Pulmonary edema results in arterial hypoxemia and respiratory distress:
  - Hypoxemia is caused by ventilation/perfusión mismatches and, to a lesser extent, diffusion barriers to oxygenation of pulmonary capillary blood.

- Noncardiogenic pulmonary edema arises from three mechanisms:
  - Increased vascular permeability is the most common and is seen with a wide variety of pulmonary and systemic disorders as akeady described.
  - Decreased plasma oncotic pressure, most often from hypoalbuminemia. Pleural effusions (transudative) are more common than pulmonary edema in animals with reduced oncotic pressure as a single driving mechanism.
  - Impaired lymphatic drainage is an uncommon etiology that is usually secondary to neoplasia or lymphangitis.
- Regardless of the mechanism, the edema fluid that infiltrates the interstitial and alveolar spaces is rich in protein (same concentration as plasma), in contrast to cardiogenic pulmonary edema that is characterized by protein-poor fluid.
- Cardiogenic pulmonary edema arises most commonly from increased pulmonary venous hydrostatic pressure secondary to left-sided congestive heart failure (seepp. 468 and 470).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Noncardiogenic edema is typically a secondary phenomenon; recognizing its existence is not analogous to diagnosing the patient's underlying condition. Early differentiation from cardiogenic edema is helpful to discern prognosis and delineate the next diagnostic steps.

DIFFERENTIAL DIAGNOSIS

Any cause of tachypnea, cough, or pulmonary parenchymal infiltration, such as:

- Pneumonia
- Neoplasia
- Fungal disease
- Protozoal infection (e.g., toxoplasmosis in cats)
- Thromboembolic disease
- Complicated bronchial disease
- Inflammatory respiratory disease (i.e., pulmonary infiltrates with eosinophils/eosinophilic bronchopneumopathy)
- Pulmonary contusions
- Cardiogenic pulmonary edema

INITIAL DATABASE

- Thoracic radiographs: “fluffy” interstitial opacities that may progress to an alveolar pattern.
  - Opacities are most often in the caudodorsal lung fields with edema caused by increased vascular permeability (similar to cardiogenic edema).
  - Absence of cardiac and pulmonary venous abnormalities can help distinguish cardiogenic from noncardiogenic edema.
- CBC, biochemical profile, urinalysis, and other tests deemed clinically appropriate may be helpful in determining underlying causes (e.g., pancreatitis, sepsis).
- Historic information may help confirm underlying causes, such as electrocution, major trauma, or near-drowning experience.

ADVANCED OR CONFIRMATORY TESTING

- Respiratory washes or lung aspiration do not often yield abnormalities; occasionally, a primary pulmonary disorder is detected.
- Arterial blood gas (ABG) analysis:
  - Hypoxemia
  - Hypocapnia
  - Widened alveolar-arterial (A-a) gradient
- The ratio of protein content of expectorated edema fluid (E) to circulating plasma protein content (P) in noncardiogenic edema is 79%-90%, whereas E:P ratio in cardiogenic edema is typically <50%. Protein may be measured by refractometer or with biochemical methods.

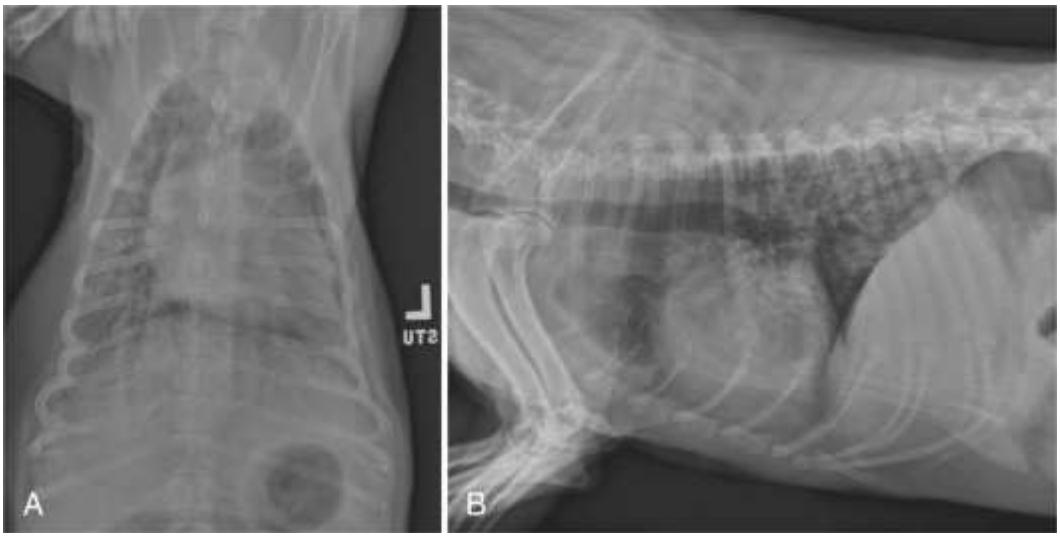
TREATMENT

TREATMENT OVERVIEW

- Improve oxygenation and support respiratory function.
- Minimize stress in severely distressed animals that could experience cardio-pulmonary arrest from simple manipulations.
- Provide other supportive care while primary causes are identified and treated.

ACUTE GENERAL TREATMENT

- Administer oxygen:
  - Face mask, nasal catheter, or oxygen cage (seep. 1318)
- Relieve anxiety and minimize unnecessary oxygen consumption:
  - Light sedation if needed:
    - Dogs: morphine, 0.1-1 mg/kg IV
    - Cats and dogs: acepromazine, 0.03-0.05 mg/kg IV, IM, or SQ
- Diuretics may be overall less beneficial for animals with noncardiogenic (versus cardiogenic) pulmonary edema; the greatest response if noted is usually seen in the initial 24-48 h
  - Furosemide: 2-4 mg/kg IV q 4-12 h
- Bronchodilators may combat bronchospasm, enhance mucociliary function, and diminish diaphragmatic fatigue:
  - Aminophylline, theophylline: dogs, 5-10 mg/kg PO, IV, IM q 8-12 h cats, 5 mg/kg PO, IV, IM q 8-12 h



PULMONARY EDEMA, NONCARDIOGENIC A-B, Dorsoventral and lateral radiographic projection in a Lhasa apso, depicting noncardiogenic pulmonary edema, primarily of caudal lung fields. Note normal cardiac and pulmonary venous structures. Pulmonary edema was thought to be the result of an inhaled irritant (repeat exposure to the substance at a later date produced the same response).

CHRONIC TREATMENT

- Specific therapies that address underlying cause
- Intubation and positive-pressure ventilation (IPPV; see p. 1362) may be necessary in severe cases:
  - IPPV constitutes the treatment of choice for critically dyspneic animals with noncardiogenic pulmonary edema caused by a reversible event (e.g., airway obstruction).

POSSIBLE COMPLICATIONS

- Secondary pneumonia
- Pulmonary thromboembolism
- Fluid therapy may exacerbate fluid exudation into the pulmonary interstitium and should be administered cautiously if at all in animals with pulmonary edema from any cause.
  - Intravenous infusions of vasoactive agents such as dopamine (2.5-10 mcg/kg/min) and/or dobutamine (2.5-20 mcg/kg/min) may help support euvolemic animals with severe systemic hypotension.

RECOMMENDED MONITORING

- Respiratory rate and effort
- Thoracic radiographs
- Blood gas analysis or pulse oximetry
- Monitor hydration status by evaluating volume-related changes

  - Cardiac output, arterial blood pressure
  - Pulmonary capillary wedge pressure
  - Serial packed cell volume (PCV), total protein (TP), electrolyte assays
  - Renal function tests, urine output
  - Body weight
- Underlying disease state

PROGNOSIS AND OUTCOME

- Prognosis guarded to poor
- Depends upon severity of the respiratory dysfunction and underlying disorder
- Early intervention, aggressive treatment, and intensive monitoring can improve outcomes.

PEARLS & CONSIDERATIONS

TECHNICIAN TIPS

- Providing supplemental oxygenation and minimizing unnecessary handling is prudent to avoid acute respiratory compromise during diagnostic evaluation.
- Patients with marked respiratory distress are likely to be more tolerant of thoracic radiographs obtained in ventral recumbency.
- Search online for constant-rate infusion (CRI) calculators to facilitate dose and administration calculations.

PREVENTION

- Avoid leaving unsupervised puppies and kittens in environments where electrical cords could be easily reached.
- Early evaluation in cases of suspected inhalant injury or drug reaction

EDITOR: RANCE K. SELLON

Pulmonary Edema, Cardiogenic

BASIC INFORMATION

DEFINITION

Extravasation of fluid from the pulmonary vasculature into the interstitial and alveolar spaces as a result of elevated pulmonary venous hydrostatic pressure. Hallmark abnormality of left-sided congestive heart failure (CHF).

SYNONYM

Pulmonary congestion

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dependent on underlying cause

GENETICS & BREED PREDISPOSITION

Predisposition reflects breed predilection for underlying heart diseases (e.g., cardiomyopathies, myxomatous mitral valve disease).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Varies with severity of fluid accumulation
- Tachypnea or exertional dyspnea
- Dry cough (uncommon in cats)
- Open-mouth breathing (cats)
- Difficulty breathing in lateral recumbency; trouble sleeping

PHYSICAL EXAM FINDINGS

- Auscultation can vary (absence of auscultable abnormalities or presence of cardiac murmurs, gallop sounds, and arrhythmias).
- Lung sounds: crackles and wheezes possible during both inspiration and expiration.
- Femoral pulse strength might vary based on cardiac output and arrhythmias.
- Severe cardiogenic pulmonary edema may produce pink-tinged secretions from mouth and nares.
- Cyanosis

ETIOLOGY AND PATHOPHYSIOLOGY

- In cardiogenic pulmonary edema, fluid moves from the pulmonary vasculature to the interstitial space as a result of elevated hydrostatic pressure in the pulmonary capillaries.
- This is in contrast to noncardiogenic pulmonary edema, in which fluid extravasates as a result of increased pulmonary vascular permeability.
- Elevated pulmonary capillary pressures secondary to left-sided heart failure:
    - Left ventricular volume overload caused by:
        - Primary valve disease (mitral or aortic insufficiency). Causes include myxomatous valve disease/endocardiosis, endocarditis, valve dysplasia, and mitral valve stenosis.
        - Primary heart muscle disease (dilated cardiomyopathy in dogs, various cardiomyopathies in cats)
        - Congenital left-to-right cardiac shunts (patent ductus arteriosus, aorticopulmonary window, atrial septal defect, ventricular septal defect, arteriovenous fistula)
        - Iatrogenic (overzealous fluid therapy)
        - Severe anemia
    - Left ventricular dysfunction:
        - Arrhythmias
        - Ischemic disease (rare)
        - Myocarditis

- Thyrotoxic cardiac disease
- Sepsis
- Myocardial toxins (i.e., chemotherapeutic agents such as doxorubicin)
- Constrictive pericarditis.
- Obstructive disease of the left atrium (rare): neoplasia, thrombus, cor triatriatum sinister.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Pulmonary edema is suspected when a patient is presented for evaluation of cough, dyspnea, or orthopnea/discomfort/restlessness. Suspicion is heightened if a cardiovascular abnormality such as a heart murmur is present. Still, many patients have such signs from coexisting disorders (without pulmonary edema), and thoracic radiographs are required for confirmation.

DIFFERENTIAL DIAGNOSIS

- Other causes of pulmonary edema (e.g., head trauma, seizures, electrocution) versus other cause for coughing and dyspnea:
  - Primary lower respiratory disease (pneumonia, bronchitis, heartworm disease, neoplasia)
  - Upper airway disease (collapsing trachea, tracheitis)
- Expiratory-phase radiographs
- Obesity

INITIAL DATABASE

- Thoracic radiographs: interstitial and/or alveolar infiltrates are present, primarily in the caudal dorsal region (perihilar region in dogs). With severe disease, the pulmonary opacities can occur throughout the lung fields. A large cardiac silhouette, particularly with left atrial enlargement, is common.
- CBC: usually normal. Abnormalities may suggest a noncardiogenic cause (severe anemia, increased white blood cell count may suggest sepsis).
- Serum biochemistry panel: electrolyte abnormalities/azotemia from concurrent renal failure or previous diuretic usage, increased liver enzymes from passive congestion
- Urinalysis: usually unremarkable except with systemic disorders
- Electrocardiogram (ECG): sinus tachycardia may be present with ectopic premature contractions (depends on severity of cardiac disease and underlying etiology). The presence of atrial enlargement (wide and/or tall P waves) and left ventricular enlargement (tall R waves) are sensitive (although nonspecific) for chronic chamber enlargements.

ADVANCED OR CONFIRMATORY TESTING

- Echocardiography: cannot identify pulmonary edema but can pinpoint underlying cardiac disorder
- Right heart catheterization: pulmonary capillary wedge pressure can be measured using a Swan-Ganz catheter: this is a surrogate for left atrial pressure (pressures > 20 mm Hg are indicative of cardiogenic pulmonary edema). Rarely performed clinically.
- Measurement of plasma BNP and ANP levels: may help distinguish between cardiac and noncardiogenic causes of congestive heart failure.
- Response to treatment: administration of appropriate doses of diuretics should be followed by improvement/resolution of radiographic markings in 24-48 hours.

TREATMENT

TREATMENT OVERVIEW

Three main goals: (1) reduction of excessive pulmonary venous return (preload); (2) reduction of systemic vascular resistance (afterload); and (3) inotropic support in a subset of patients (see pp. 468 and 470)

ACUTE GENERAL TREATMENT

- Avoid/reduce stress.
- Oxygenation
- Intravenous furosemide (2-5 mg/kg in dogs, 2-4 mg/kg in cats) q 1-2 h until labored respirations and respiratory rate decrease to normal, then decrease the dose of furosemide and frequency of administration based on clinical response.

- Furosemide constant rate infusion IV CRI for refractory cases (0.7-1 mg/kg/h, cats and dogs). The authors have used up to 2 mg/kg/h. If starting a CRI, initially give a 2 mg/kg IV bolus, then start the CRI. Judicious monitoring of blood pressure and renal function is necessary.
- ± Nitroprusside (see p. 468)
- ± Dobutamine (see p. 468)

CHRONIC TREATMENT

See Heart Failure, Chronic (p. 470)

POSSIBLE COMPLICATIONS

Pulmonary edema eventually returns despite medical therapy (lesion progression).

RECOMMENDED MONITORING

- Thoracic radiographs to assess response to therapy. A 12- to 24-hour lag period between clinical improvement and radiographic improvement is common, however.
- Serum electrolytes and renal status
- Respiratory status

PROGNOSIS AND OUTCOME

Long-term prognosis is guarded because underlying disease is rarely cured. Exceptions can include correctable congenital defects (patent ductus arteriosus, pulmonic stenosis, others) and taurine-responsive dilated cardiomyopathy.

PEARLS & CONSIDERATIONS

COMMENTS

Owners should monitor resting respiratory rate at home. If it increases by more than 25% for 2 days in a row, a call to the veterinarian is warranted.

CLIENT EDUCATION

- Monitor for recurrence of presenting signs (see History, Chief Complaint above).
- Rapid deterioration is possible; rechecks necessary.

EDITOR: ETIENNE CÔTÉ

Pulmonary Contusions

BASIC INFORMATION

DEFINITION

A pulmonary contusion is a lesion consisting of intrapulmonary hemorrhage and inflammation secondary to blunt trauma.

SYNONYM

Traumatic lung injury

EPIDEMIOLOGY

SPECIES, AGE, SEX

Young male dogs are at increased risk of trauma.

GENETICS & BREED PREDISPOSITION

None; larger dogs are more likely to roam unsupervised.

RISK FACTORS

Free-roaming behavior

GEOGRAPHY AND SEASONALITY

More common in warmer months

ASSOCIATED CONDITIONS & DISORDERS

- Pneumothorax
- Diaphragmatic hernia
- Flail chest
- Hit by car (HBC) injury
- Fracture

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Traumatic event; increased respiratory rate and effort

PHYSICAL EXAM FINDINGS

- External evidence of trauma: cutaneous abrasions or lacerations, fractures
- Increased respiratory rate and effort
- Increased bronchovesicular sounds
- Pale mucous membranes
- Tachycardia

ETIOLOGY AND PATHOPHYSIOLOGY

- Trauma results in intraparenchymal pulmonary hemorrhage. Extracapillary hemorrhage results in the recruitment of inflammatory cells and protein into the alveolar and interstitial spaces.
- Pulmonary hemorrhage results in ventilation/perfusion mismatch and subsequent hypoxemia.
- Sequelae of pulmonary contusion may vary from very mild to rapidly fatal.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Suspected clinically because of association with blunt trauma; clinical confirmation is generally radiographic.

DIFFERENTIAL DIAGNOSIS

- Nontraumatic pulmonary hemorrhage (anticoagulant rodenticide, neoplasia)
- Congestive heart failure (pulmonary edema)
- Pneumonia
- Pain (tachypnea)

INITIAL DATABASE

- Thoracic radiographs: document a patchy to diffuse interstitial alveolar pattern.
  - Radiographic changes may lag behind clinical signs.
  - May be indistinguishable from other patchy interstitial infiltrates, especially pulmonary edema in cats
- CBC, serum biochemistry profile: generally unremarkable

ADVANCED OR CONFIRMATORY TESTING

- Arterial blood gas (ABG) analysis (seep. 1196) or pulse oximetry may be useful to characterize the degree of hypoxemia. These are especially useful for determining whether tachypnea is due to pain (results are normal) or pulmonary lesions (hypoxemia commonly observed).
- Central venous pressure monitoring (seep. 1227), pulmonary wedge pressure measurement: Assess right- and left-sided vascular pressures, respectively (helps rule out cardiogenic causes). Pulmonary wedge pressure specifically assesses the propensity for pulmonary edema but is a somewhat cumbersome procedure and is especially challenging in cats and small dogs.

TREATMENT

TREATMENT OVERVIEW

Treatment goals are to maintain adequate intravascular volume but avoid overhy-dration, which may worsen pulmonary contusions, and to provide supplemental oxygen and rest.

ACUTE GENERAL TREATMENT

- Judicious administration of IV fluids as needed to maintain perfusion
  - Administration of boluses of 5-10 mL/kg of crystalloid fluids (e.g., lactated Ringer's solution) until adequate blood pressure (BP) and pulse quality are obtained
- Administration of supplemental oxygen
- Evaluation for other associated injuries
- Note that glucocorticoids, antibiotics, and diuretics are not indicated for treatment of pulmonary contusions.

POSSIBLE COMPLICATIONS

- Infection (rare)
- Respiratory failure
- Severe pulmonary contusion may require intermittent positive-pressure ventilation (see p. 1362) with positive end-expiratory pressure (PEEP) and/or may progress to acute respiratory distress syndrome (ARDS).

RECOMMENDED MONITORING

- Hourly respiratory rate and effort
- Pulse oximetry

PROGNOSIS AND OUTCOME

Guarded to good prognosis. Most animals surviving a trip to the hospital will also survive pulmonary contusions with appropriate supportive care. Concurrent injuries (e.g., vertebral body fractures) are more likely to compromise the prognosis; other than very severe cases, pulmonary contusions are generally incidental findings that resolve with supportive care.

PEARLS & CONSIDERATIONS

COMMENTS

Avoid excessive volume resuscitation; administer IV fluids judiciously, and adjust the rate frequently based on the animal's response and evolution of the case.

PREVENTION

Prevent roaming.

CLIENT EDUCATION

Pulmonary contusions are “lung bruises;” the injured animal will often get worse over the first 24 hours, and then the lesions regress in the following 48 hours.

SUGGESTED READING

Powell LL, et al: A retrospective analysis of pulmonary contusion secondary to motor vehicle accidents in 143 dogs: 1994-1997. J Vet Emerg Crit Care 9:127–136, 1999.

AUTHOR & EDITOR: ELIZABETH ROZANSKI

Ptyalism

BASIC INFORMATION

DEFINITION

Production of excessive amounts of saliva, commonly manifested as drooling

SYNONYMS

Hypersalivation, polysialia, sialonhea

EPIDEMIOLOGY

SPECIES, AGE, SEX

- No species, age, or sex predilection except as dependent on underlying etiology
- Young animals: portosysternie shunts, seizure disorders
- Older animals: oral neoplasia, such as malignant melanomas (dogs), and squamous cell carcinoma (cats)

GENETICS & BREED PREDISPOSITION

Predisposition dependent on underlying cause

RISK FACTORS

- Trauma of oral/pharyngeal region or nerves
- Exposure to toxins
- Esophageal disorders (esophagitis, esophageal obstruction)
- Oral foreign bodies
- Severe dental disease and/or dental abscesses
- Metabolic or physical disorders causing nausea or abdominal pain
- Primary or secondary neurologic disorders affecting saliva production
- Nausea
- Unvaccinated pets exposed to contagious diseases that may cause oral lesions or metabolic disorders

CONTAGION & ZOONOSIS

- Zoonotic: rabies
- Contagion: viral infections causing oral lesions, such as calicivirus in cats

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

All or some may be present:

- Dysphagia
- Pawing at mouth
- Halitosis
- Oral discomfort with oral or pharyn-geal causes
- Anorexia or weight loss
- Coughing and/or dyspnea (from aspiration pneumonia)
- Gagging or retching with esophageal or gastric causes
- Seizures, facial twitching, behavioral changes possible with intoxications or portosystemic shunts

PHYSICAL EXAM FINDINGS

- Saliva around mouth, salivary staining of fur

- Oral lesions, including masses, foreign bodies, abscesses, stomatitis, gingivitis, or other dental diseases
- Swelling of salivary glands, facial paralysis, atrophy of temporal or facial muscles
- Loss of gag reflex, inability to use tongue, dysphagia
- Mentation changes, seizures, tremors, or anxiety
- Painful abdomen
- Nausea

ETIOLOGY AND PATHOPHYSIOLOGY

Etiology:

- Oral lesions: stomatitis, gingivitis, dental disease, neoplasia, foreign bodies
- Neurologic: peripheral nerve injury affecting swallowing, movement of tongue, pharynx; central nervous system (CNS) lesions, including neoplasia and infectious disorders such as rabies and feline infectious peritonitis (cats)
- Neuromuscular disorders (myasthenia gravis causing megaesophagus; masticatory myositis, muscular dystrophies)
- Metabolic: hepatic disease (portosystemic shunts), renal disease, nausea
- Toxins: caustic or noxious substances, pesticides (organophosphates), drugs (marijuana)
- Immune disease: polymyositis, pemphigus
- Pain, anxiety, excitement, fear

Pathophysiology:

- Oral secretions are produced by sub-mandibular, parotid, and sublingual salivary glands. Innervation to salivary glands is controlled by the autonomic nervous system, with primary control by the parasympathetic nervous system. Many environmental, physical, or metabolic events may stimulate increased saliva production.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A complete medical history and thorough oral examination, possibly under sedation, will often lead the clinician in the right direction for diagnosis. For instance, an outdoor cat with acute onset of drooling may have oral ulcers, evidence of intoxication, or a foreign body.

DIFFERENTIAL DIAGNOSIS

Ptyalism must be differentiated from drooling caused by certain conformations of the lips (but in which the amount of saliva produced by the salivary glands is normal). History (ptyalism is usually recent in onset, whereas conformation-associated drooling is chronic) and physical examination of the lips are generally sufficient for correct identification.

INITIAL DATABASE

- CBC to evaluate for anemia and evidence of infectious/inflammatory disease
- Serum biochemistry profile and urinalysis to evaluate for metabolic disorders
- Neurologic exam (seep. 1311)
- Thoracic, abdominal, and neck/head radiographs

ADVANCED OR CONFIRMATORY TESTING

- Oral examination with sedation or anesthesia
- Serum bile acids if history, exam, and minimum database consistent with liver disorder
- Abdominal ultrasound
- Electroencephalogram/CT scan, and MRI to evaluate CNS lesions
- Endoscopy to evaluate esophageal or gastric lesions
- Toxin screens
- Specific tests, such as acetylcholine (ACh) receptor antibody testing for myasthenia gravis

TREATMENT

TREATMENT OVERVIEW

Ptyalism is a sign of a predisposing disorder; therefore treatment is aimed at resolution of underlying cause

ACUTE GENERAL TREATMENT

Supportive and nonspecific; possible use of anticholinergics and antinausea or antianxiety medications; identification of underlying etiology and prevention of aspiration

CHRONIC TREATMENT

Treatment as appropriate for underlying etiology. Although surgical ligation or transposition of salivary ducts is sometimes performed in people with ptyalism, this surgery is usually not indicated in animals.

BEHAVIOR/EXERCISE

Behavioral modification and anti-anxiety medication for stress-related hypersalivation

POSSIBLE COMPLICATIONS

- Anticholinergics often cause tachycardia, constipation, and behavioral changes; these require frequent dosing. Antiemetics such as chlorpromazine may cause sedation.
- Antisialagogues may reduce salivary output but do not correct the underlying problem.
- Antianxiety medications may cause sedation, anorexia, gastrointestinal upset.

RECOMMENDED MONITORING

Monitor signs, including coughing, breathing difficulty, and fever, which may suggest aspiration of excessive saliva.

PROGNOSIS AND OUTCOME

Fair to guarded prognosis depending on response to treatment of underlying etiology of disorder. Removal of foreign bodies, resolution of dental disease, repair of traumatic injury, and response to decontamination may have very favorable outcomes. Prognosis may be guarded with more serious disease processes such as immune diseases and neoplasia.

PEARLS & CONSIDERATIONS

COMMENTS

Ptyalism is usually a sign of a more serious disorder and deserves attention aimed at identifying the underlying cause. In addition, many owners find that their pets' hypersalivation is unacceptable even if caused by minor problems and may cause them to choose euthanasia for the animals.

Pseudorabies

BASIC INFORMATION

DEFINITION

Disease caused by infection with pseudorabies virus (PRV), an alphaherpesvirus in the family Herpesviridae. An economically important disease of swine, pseudorabies is capable of causing subclinical, neurologic, or respiratory disease in pigs and causing a rare but severe and almost inevitably fatal central nervous system (CNS) disease in dogs and cats.

SYNONYMS

Aujeszky's disease, mad itch, bulbar paralysis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats are sporadically affected with pseudorabies (uncommon). Pigs are the primary reservoir of the virus because they have become well adapted to the virus and are often only subclinically affected.

RISK FACTORS

- Pets living in areas where pseudorabies virus is enzootic in the swine population
- Feeding raw pork from endemic areas to dogs and cats

CONTAGION & ZOONOSIS

- Pseudorabies virus may be found in porcine respiratory secretions, saliva, blood, and in the CNS and tonsillar tissues. Dogs and cats are commonly infected via the oral route after ingesting contaminated porcine tissue. Pseudorabies has also reportedly been transmitted to a dog by either biting or being bitten by an infected pig.
- Pseudorabies is not considered a zoonotic disease.

GEOGRAPHY AND SEASONALITY: Pseudorabies can be found in most countries of the world except Australia.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Acute onset and rapid progression of neurologic signs until death occurs (usually within 48 hours of disease onset). Initial signs may include lethargy, depression, restlessness, or aggression and occasionally vomiting and diarrhea. Hypersalivation is commonly noted. Intense pruritus, usually of the head region, is probably the most clinically striking and consistent sign of pseudorabies. Animals will frequently excoriate the skin of the face and ears secondary to violent scratching.

PHYSICAL EXAM FINDINGS

- Pruritus with swelling, erythema, excoriation, or ulceration of the skin secondary to self-mutilation, especially of the face and head. Intense scratching may include rubbing the head against floors or walls.
- Altered mentation
- Ptyalism
- Cranial nerve deficits indicative of a brainstem lesion(s)
- Dyspnea secondary to severe pulmonary edema
- Seizures
- Anisocoria and a hoarse voice (see p. 1172) are highly consistent signs in cats.

ETIOLOGY AND PATHOPHYSIOLOGY

- Once infection with pseudorabies virus has occurred, the virus travels retrograde along peripheral nerves from the site of inoculation to the CNS.
- Damage to brain parenchyma results from inflammation and interference of normal neuronal function by the virus.
- Microscopic lesions are located almost exclusively in the brainstem. The incubation period for pseudorabies in dogs and cats

is 3-6 days.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is suspected in dogs with a history of exposure to pigs or raw pork products. Dogs present with severe, acute pruritus of the head and neck. Confirmation requires histopathologic evaluation of the brainstem.

DIFFERENTIAL DIAGNOSIS

- Rabies
- Canine distemper
- Neurotoxicoses

INITIAL DATABASE

- A provisional diagnosis of pseudorabies is usually made on clinical suspicion of the disease. Confirmatory testing is required for definitive diagnosis.
- There are no characteristic hematologic or biochemical abnormalities associated with pseudorabies.

ADVANCED OR CONFIRMATORY TESTING

- Cerebrospinal fluid analysis may show increased protein and mononuclear pleocytosis.
- Definitive diagnosis of pseudorabies has classically been made postmortem. Histopathologic abnormalities are generally limited to the brainstem and include perivascular cuffing, multifocal gliosis, neuronal degeneration, and weak eosinophilic inclusions within the nuclei of glial cells and neurons.
- Immunohistochemical techniques can be used for identifying viral antigen in fixed tissue sections (brain, tonsils).
- Alternatively, inoculation of cell cultures with brain homogenate for virus isolation can be performed. Cultures are observed for cytologic changes characteristic of herpesvirus infection, and immunofluorescent techniques can be applied to the cultures to identify pseudorabies virus.

TREATMENT

TREATMENT OVERVIEW

With very few exceptions, the treatment of pseudorabies in dogs and cats is futile, owing to a generally unavoidable fatal outcome. If treatment is initiated, it is aimed at controlling the major clinical signs and providing supportive care until the animal recovers (rare) or dies.

ACUTE GENERAL TREATMENT

- Heavy sedation or anesthesia as required for control of self-mutilation and/or seizures
- IV fluids if needed and patient not showing dyspnea
- Furosemide (1-3 mg/kg IV, IM, or PO q 6-12 h) for pulmonary edema if causing dyspnea

PROGNOSIS AND OUTCOME

Grave prognosis; despite treatment, death usually occurs within 2-3 days of the onset of clinical signs.

PEARLS & CONSIDERATIONS

COMMENTS

Vaccination of dogs and cats against pseudorabies virus (usually in endemic areas) is possible but of questionable efficacy in the prevention of disease.

PREVENTION

Preventing contact with infected pigs or contaminated pork products is paramount to the prevention of pseudorabies in dogs and cats.

Pseudocyesis

BASIC INFORMATION

DEFINITION

A common syndrome observed in nonpregnant diestrous or early anestrous bitches. It is characterized by different degrees of maternal behavior, mammary gland enlargement, and lactation.

SYNONYMS

Nervous anorexia, pseudopregnancy, overt false pregnancy

EPIDEMIOLOGY

SPECIES, AGE, SEX

Postpubertal female dogs of any age; has not been described in cats

GENETICS & BREED PREDISPOSITION

Any breed; incidence is higher in dalmatian, basset hound, and pointer-breed dogs. German shepherds are rarely affected.

RISK FACTORS

Exogenous administration of progestins, diestrous ovariectomy, and hypothyroidism may trigger its occurrence.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Depending on intensity of clinical signs:

- Covert (physiologic although recognizable from the rest of the estrous cycle)
- Overt, where manifestations can become a clinical problem (clinical pseudocyesis)

HISTORY, CHIEF COMPLAINT

- Estrus 6-12 weeks earlier without an ensuing pregnancy
- Chief complaints: mammary problems (engorgement, lactation, licking of the glands) and abnormalities associated with aberrant maternal behavior (nesting, digging, adoption of animals or objects)
- Depression or anxiety, anorexia, and excessive vocalization (whining) are possible.

PHYSICAL EXAM FINDINGS

- Mammary enlargement, ranging from turgid nipples to painful engorgement and galactostasis:
  - Most evident in the caudal pair of glands
- Intramammary dermatitis is occasionally present if excessive licking occurs.
- Mastitis may also be present.

ETIOLOGY AND PATHOPHYSIOLOGY

- The high plasma concentration of prolactin at the end of the luteal phase, when progesterone concentrations decrease abruptly, is associated with the development and maintenance of pseudocyesis.
- Individual and breed sensitivity to these hormonal changes and environmental factors have been hypothesized to influence its occurrence.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in any diestrous, nonpregnant bitch with mammary enlargement (and milk secretion) in which other mammary disease has been ruled out. Diagnostic imaging confirms absence of pregnancy if necessary.

DIFFERENTIAL DIAGNOSIS

- Pregnancy
- Pyometra
- Mastitis
- Mammary tumors
- Any other cause of anorexia, depression, or anxiety should be ruled out.
- Pseudocyesis can coexist with pyometra, mastitis, and mammary tumors.

INITIAL DATABASE

CBC results are unremarkable.

ADVANCED OR CONFIRMATORY TESTING

Ultrasonographic or radiographic confirmation of the absence of pregnancy or pyometra

TREATMENT

TREATMENT OVERVIEW

Treatment mainly consists of the administration of prolactin-decreasing drugs (dopamine agonists or antiserotonergic compounds).

ACUTE GENERAL TREATMENT

- Administer dopamine agonists with food to reduce digestive side effects: Cabergoline, 5 mcg/kg PO q 24 h for 5-7 days, is a safer choice compared to other prolactin-decreasing compounds.
- Avoid steroid hormones (progestins/androgens); they usually postpone the problem.
- Treat mastitis (see p. 688), acute moist dermatitis (see p. 30).

CHRONIC TREATMENT

Clinical chronic, unresponsive, or recurring pseudocyesis cases should be treated surgically (ovariectomy) after the acute phase of the syndrome has been controlled or during anestrus.

NUTRITION/DIET

No benefit from short-term partial food restriction

BEHAVIOR/EXERCISE

- Discourage maternal behavior, using aversion methods.
- Avoid stimulation of the mammary glands (e.g., padding [either hot or cold], touching, or milking).
- If necessary, Elizabethan collars can be used for preventing licking and self-milking.

DRUG INTERACTIONS

- Avoid administering phenothiazine drugs during pseudocyesis; they increase plasma prolactin concentrations.
- Do not administer antiserotonergic drugs (e.g., metergoline) for anxious and restless bitches because this could potentiate pseudocyesis behavior.

POSSIBLE COMPLICATIONS

- Mammary dermatitis and mastitis (seep. 688) are the most frequent complications and may have an influence in perpetuating the problem.
- Repeated episodes of pseudocyesis have been hypothetically associated with the future development of mammary tumors.

RECOMMENDED MONITORING

Follow up cases until complete resolution. If pseudocyesis does not resolve spontaneously, look for predisposing

PROGNOSIS AND OUTCOME

Pseudocyesis typically resolves spontaneously within a few weeks (2 or 3 weeks) from its onset but can occasionally persist until the next estrous cycle.

PEARLS & CONSIDERATIONS

COMMENTS

- Pseudocyesis is a good indicator of ovulatory estrous cycles.
- Predisposed bitches usually suffer the syndrome after each estrous cycle, with the disorder becoming more severe throughout life.

PREVENTION

- Ovariectomy in predisposed bitches
- Pregnancy does not prevent future episodes.

CLIENT EDUCATION

Teach clients to recognize pseudocyesis and to ask for treatment if it becomes clinically relevant.

AUTHOR: CRISTINA GOBELLO

EDITOR: MICHELLE KUTZLER

Pruritus

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

The unpleasant sensation that triggers the desire to scratch, chew, rub, lick, or bite at the skin

SYNONYM

Itch

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Common in dogs and cats
- Sex and age of onset depend on the underlying etiology.
- Contagious acarioses (mite infestations) are more common in young animals.
- Canine atopic dermatitis is first seen in young adults (6 months to 3 years of age).
- Food allergy, although seen most commonly in young adults, may develop at any age.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Animals scratch, chew, rub, lick, or bite at the skin. In addition, cats can be secretive lickers and present only for extensive self-induced alopecia.

PHYSICAL EXAM FINDINGS

- Skin lesions vary according to etiology.
- Self-induced alopecia, excoriation, and erythema are common findings.
- Typically, no primary skin lesions are noted in canine atopic dermatitis.
- Papules and/or pustules are noted in infectious or parasitic conditions.
- In cats: miliary dermatitis, eosinophilic granuloma complex, self-induced symmetric alopecia, or self-induced ulcerative facial dermatitis.

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiologies of pruritus are numerous.
- For most parasitic infestations, a hyper-sensitivity reaction develops and is responsible for most if not all of the pruritus (often disproportionate to the number of parasites found).
- Pyoderma and yeast dermatitis are frequent causes of pruritus in dogs but are uncommon in cats.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Causes of pruritus are numerous, and the history (notably environment) and physical exam (e.g., lesion distribution) help focus the differential diagnosis. Diagnostic procedures aimed at identifying infections or infestations should be selected first, as these disorders are common, and treatment is generally straightforward. A precise diagnosis is necessary to administer a specific treatment.

DIFFERENTIAL DIAGNOSIS

- Parasitic: fleas, contagious acarioses (*Sarcoptes, Notoedres, Cheyletiella, Otodectes* spp.), lice, *Trombicula* (chiggers), and *Pelodera* spp.

- Bacterial: staphylococcal pyoderma
- Fungal: *Malassezia* sp. dermatitis and otitis
- Allergic: flea bite hypersensitivity, atopic dermatitis, food hypersensitivity, contact hypersensitivity, drug reaction
- Miscellaneous: calcinosis cutis, cutaneous lymphoma

INITIAL DATABASE

- Complete history and dermatologic examination (see p. 1248)
  - Skin scrapings
  - Skin cytologic examination
  - Wood's lamp and dermatophyte culture (in cats)

ADVANCED OR CONFIRMATORY TESTING

- Therapeutic trial with broad-spectrum antiparasitic agents (this is an integral part of the case work-up) is always indicated whenever there is a possibility of a parasitic problem, even if it is low, and in spite of negative skin scrapings.
- Clinicians occasionally use therapeutic trials with antibiotics or antifungal agents in dogs to document the contribution of bacteria and yeast in the degree of pruritus seen.
- Elimination diet: a hypoallergenic dietary trial ideally using home-cooked novel protein and carbohydrate sources; should be initiated after infections and infestations have been excluded/controlled.
- Intradermal skin test: preferred test for identifying atopic dermatitis. Serologic testing is also available, but false-positive reactions are more common.
- Skin biopsies are useful in unusual cases (e.g., calcinosis cutis, cutaneous lymphoma) and may be considered if the diagnosis remains elusive despite approaches described above, or if the clinician suspects these unusual disorders from other aspects of the case. A biopsy may corroborate the diagnosis of allergic skin disease but rarely confirms the specific cause.

TREATMENT

TREATMENT OVERVIEW

The goal is to find the cause to find as specific a treatment as possible. When possible, treatment is limited to one medication at a time to facilitate interpretation of response. When doing therapeutic trials, the most effective treatment regimen that is available and safe should be used to eradicate parasites or infections so interpretation of response is clear.

ACUTE GENERAL TREATMENT

An acute intense pruritic episode can be treated with IM or IV short-acting glucocorticoids (dexamethasone sodium phosphate, 0.1-0.2 mg/kg) followed by a few days of prednisone or prednisolone (1 mg/kg PO q 24 h). Short-term use of glucocorticoids seldom causes serious problems.

CHRONIC TREATMENT

- In long-term management of pruritus, such as in cases of canine atopic dermatitis (seep. 106), clinicians rely on immunotherapy (hyposensitization), glucocorticoids, oral cyclosporine, anti-histamines and/or essential fatty acid supplementation.
- Long-term administration of glucocorticoids should be avoided if possible, unless the maintenance dose is low and/or if the treatment is intermittent. For example, a maintenance dose of 0.2-0.3 mg/kg q 48 h of prednisone and/or a total annual dose of 30-50 mg/ kg or less are rarely responsible for significant side effects.
- Induction and maintenance doses of prednisolone are typically 30% lower than prednisone doses, at least when administered concomitantly with trime-prazine (Temaril-P, Vanectyl-P). Along term treatment goal with these combination products is also to try to administer the minimal effective dose q 48 h.
- In food hypersensitivity, clinicians must find a commercial hypoallergenic diet that maintains the animal free of clinical signs.
- In flea bite hypersensitivity, maintain an effective flea elimination treatment.

RECOMMENDED MONITORING

Animals receiving chronic glucocorticoid therapy should be monitored every 6 months for signs of iatrogenic hyperadrenocorticism or other complications (e.g., urinary tract infection, pyoderma).

PROGNOSIS AND OUTCOME

- Varies according to the etiology
- Excellent for most parasitic and infectious skin problems and food hypersensitivity
- Atopic dermatitis is an incurable disease that requires long-term management of pruritus.

PEARLS & CONSIDERATIONS

COMMENTS

- Treatment of pruritic dermatoses does not always imply use of antipruritic drugs specifically. In fact, antiparasitic drugs, antibiotics, and antifungal drugs (for yeast dermatitis), which are not inherently antipruritic, are among the most useful "antipruritic" drugs. They have a key role in pruritus management because they control or eliminate the underlying cause. Superficial pyoderma is a frequent cause of pruritus in dogs.
- Always rule out parasitic and infectious causes of pruritus before administering long-term steroidal or nonsteroidal antipruritic drugs or before initiating an elimination diet (food trial).
- If pruritus is refractory to a usual maintenance dose of glucocorticoid (i.e., >0.5 mg/kg q 48 h of prednisone in dogs), consider the following diagnoses: sarcoptic mange/scabies, *Malassezia* dermatitis, pyoderma, food hypersensitivity, calcinosis cutis, contact allergic dermatitis, epitheliotropic lymphoma.
- More than one disease may be contributing to pruritus; for example, dogs with atopic dermatitis often have secondary bacterial and/or yeast infections.
- In cats, prednisone is generally not as effective as other glucocorticoids at equivalent doses. Instead, use oral prednisolone, methylprednisolone, dexamethasone, or triamcinolone.

CLIENT EDUCATION

- Owners of dogs with canine atopic dermatitis must be well informed of the chronic and multifaceted aspect of the disease.
- In order to evaluate response to treatment or disease progression, a pruritus score (e.g., on a scale of 0 to 10, 0 = normal and 10 = worst level of pruritus observed so far) can be very useful. It is worth explaining it to the animal's owner. Doing so can add a measure of objectivity and may reduce the owner's perception that treatment is ineffective, or conversely, may support the severity of pruritus perceived by the owner.

SUGGESTED READING

Scott DW, Miller WH, Griffin CE, eds: Muller and Kirk's small animal dermatology, ed 6, Philadelphia, 2001, WB Saunders.

AUTHOR & EDITOR: MANON PARADIS

Protozoal Enteritides

BASIC INFORMATION

DEFINITION

Infection of the small or large intestine with protozoal organisms

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Giardiasis, trichomoniasis, and amebiasis occur in dogs, cats, humans, and many other domestic species.
- Balantidiasis is common in pigs but can also occur in dogs and humans.
- *Tritrichomonas foetus* infection principally causes reproductive problems in cattle but may also cause enteric signs in cats.
- *Cystoisospora* enteritis may affect dogs, cats, pigs, fowl, and other domestic animals.
- Young animals are at higher risk of developing overt, and potentially more severe, clinical signs.

RISK FACTORS: Overcrowding, kennel boarding, unsanitary conditions, and immunosuppression increase the risk of protozoal enteritis.

CONTAGION & ZOONOSIS

- *Cystoisospora:* each species of the organism is host specific and cannot be transmitted between other domestic animal species.
- *Giardia lamblia, Balantidium coli*, and *Pentatrichomonas hominis* enteritides pose a known or suspected zoonotic risk.
- *Entamoeba histolytica* can be transmitted from humans to dogs or cats but generally not from dogs or cats to humans. Dogs and cats do not shed the infective cyst form of *E. histolytica*.

GEOGRAPHY AND SEASONALITY: Protozoal enteritides are distributed worldwide, with increased infection rates in areas of poverty, overcrowding, and poor sanitation-characteristics often associated with puppy mills, animal shelters, and pounds.

ASSOCIATED CONDITIONS & DISORDERS

Many protozoal enteritides are detected as secondary infections due to underlying primary gastrointestinal (GI) diseases.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

B. coli (balantidiasis), *Cystoisospora* or related organisms (coccidiosis; protozoan parasites formerly known as *Isospora*), *E. histolytica* (amebiasis), *G. duodenalis* (giardiasis; see p. 447), *P. hominis* or *T. foetus* (trichomoniasis; see), *Cryptosporidium parvum* (see)

HISTORY, CHIEF COMPLAINT

Most infections with protozoa are subclinical. However, severe infections or infections in young or immunosuppressed animals may be serious, with overt, potentially debilitating clinical signs. The most common clinical sign is acute to chronic diarrhea. Some animals may be depressed or occasionally vomit. *G. duodenalis* and *Cystoisospora* spp. may cause small- or large-bowel diarrhea, while other protozoa generally cause only large-bowel diarrhea.

PHYSICAL EXAM FINDINGS

Physical examination findings may be nonspecific and include depression, mild to severe dehydration, and discomfort on abdominal palpation, with gas or fluid-filled intestinal loops. In milder cases, no physical abnormalities may be present.

ETIOLOGY AND PATHOPHYSIOLOGY

- Transmission of protozoal enteritides is fecal-oral.
- Infective cysts are ingested from the environment and commonly from water contaminated with feces.
- Upon exposure to intestinal enzymes, cysts open and release motile trophozoites that mature and attach to the intestinal epithelium.
- *G. duodenalis* and *Cystoisospora* spp. remain on the surface of the epithelium, causing damage to the microvilli.
- *Entamoeba* and *Balantidium* spp. may invade the colonic wall, causing ulceration.
- *P. hominis* is considered rarely pathogenic.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Standard fecal examinations are simple and provide a definitive diagnosis for these disorders; they are indicated in all cases of acute or chronic diarrhea.

DIFFERENTIAL DIAGNOSIS

- Young dogs: parvoviral, distemper viral, and bacterial enteritides; enteritis caused by helminths (*Toxocara, Ancylostoma, Trichuris* spp.)
- Young cats: feline panleukopenia, feline leukemia virus (FeLV)
- *Sarcocystis* oocysts may be observed on fecal examination; however, this coccidian is not pathogenic in dogs or cats. Herbivores are the intermediate host and develop parasitic cysts in muscle and nervous tissues after consuming the infected feces of dogs.
- *Hammondia* and *Besnoitia* oocysts may be seen on fecal examination; these coccidians are also nonpathogenic.
- Older animals with acute to chronic diarrhea may have a primary underlying intestinal disorder such as inflammatory bowel disease or neoplasia (dogs and cats), ulcerative colitis (dogs), or feline immunodeficiency virus-associated enteritis (cats).
- *Cryptosporidium parvum* (see p. 269) may also produce a primary gastroenterocolitis in both dogs and cats.

INITIAL DATABASE

- Direct fecal smear may reveal motile trophozoites.
- Zinc sulfate fecal flotation may reveal protozoal cysts.
- CBC and chemistry panel are nonspecific but may help rule out other diseases.

ADVANCED OR CONFIRMATORY TESTING

- Multiple fecal examinations may be necessary to find trophozoites or cysts, which may be shed intermittently. Three fecal examinations performed over a period of 3-5 days are recommended in challenging cases.
- A therapeutic trial with fenbendazole and metronidazole may be helpful in animals with chronic diarrhea but multiple negative fecal samples.

TREATMENT

TREATMENT OVERVIEW

Treatment consists of antiprotozoal medication in most cases. Supportive care may be indicated in severe cases.

ACUTE GENERAL TREATMENT

- Initial treatment consists of parenteral fluid therapy to correct hypovolemia and electrolyte and acid base disturbances.
- Fenbendazole, 50 mg/kg PO q 24 h for 3-5 days is the current treatment of choice for giardiasis.
- Metronidazole, 10-20 mg/kg PO q 12-24 h for 5-7 days is an effective treatment for enteritis caused by *Pentatrichomonas, Entamoeba*, and *Balantidium* spp.
- *Cystoisospora* enteritis may be treated with amprolium, 110-200 mg/kg PO q 24 h (dogs), or 50-60 mg/kg PO q 24 h (cats); or sulfadimethoxine for 14 days. Combination therapy may be more effective and allow use of lower doses with fewer side effects.
- There are no effective treatments known at this time for eradication of *T. foetus* in cats. Paromomycin, 125-160 mg/kg PO q 12 h for 5 days may be effective, but some cases of renal toxicity have been reported with the use of this drug in cats.

NUTRITION/DIET

High-quality, easily digestible diets. High-fiber diets may help formation of a firm stool.

PROGNOSIS AND OUTCOME

- Prognosis for most protozoal enteritides is good. Recurrent infection is possible, and complete elimination of the organism may be challenging because some protozoa are commensalistic organisms and/or opportunistic pathogens.
- The prognosis for elimination of *T. foetus* from cats is guarded, although treatment may reduce clinical signs.

PEARLS & CONSIDERATIONS

COMMENTS

- Protozoal enteritides are often secondary infections in adult animals. If appropriate antiprotozoal therapy is not effective, further testing is warranted to seek an underlying disease.
- Protozoal enteritis should not be eliminated as a possible cause of diarrhea in a young animal based on a single negative fecal result.

PREVENTION

Prevention of overcrowding and maintaining a clean environment for young animals will help prevent protozoal infections. Prompt removal of feces should be encouraged.

TECHNICIAN TIPS

Technicians should be able to recognize all forms (both cysts and trophozoites) of the organisms producing protozoal enteritides.

CLIENT EDUCATION

Clients should be advised to seek medical attention if their pet has been diagnosed with protozoal enteritis; *G. duodenalis*, *B. coli*, and *P. hominis* enteritides carry a zoonotic risk.

1ST EDITION AUTHOR: KATHRYN TAYLOR

Protothecosis

BASIC INFORMATION

DEFINITION

A multisystemic disease caused by infection with *Prototheca* algal species

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Cats: cutaneous infection
- Dogs: disseminated infections are more common. Female dogs are overrepresented.

GENETICS & BREED PREDISPOSITION

Collies and German shepherds appear to be predisposed to infection.

RISK FACTORS

Successful infection requires some degree of immunodeficiency in the host.

CONTAGION & ZOONOSIS

Prototheca is an opportunistic pathogen found in soil, sewage, and tree slime flux. Clinical disease has been reported in multiple animal species including humans. Zoonotic transmission is not recorded, but immunocompromised persons should observe hygienic precautions around affected animals (and the environmental source).

GEOGRAPHY AND SEASONALITY

In North America, most cases are reported in the southeastern United States.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Colitis-type diarrhea: mucoid, bloody, and foul-smelling; intermittent or protracted. Weight loss possible in chronic cases.
- Many dogs with diarrhea have ocular lesions (owners may note red or cloudy eyes).
- Central nervous system (CNS) signs include depression, stumbling, falling, or head tilt.

PHYSICAL EXAM FINDINGS

- Palpable fluid-filled bowel loops and blood on thermometer can be noted. Rectal palpation may reveal thickened rectal tissues in some dogs.
- Cachexia with muscle atrophy possible
- Ocular manifestations include signs of conjunctivitis, uveitis, vitreous clouding, and acute blindness due to retinal detachment.
- Neurologic examination findings are consistent with disseminated CNS disease; asymmetric signs of ataxia, head tilt, circling, and paresis are reported in fewer cases.
- Mucocutaneous ulceration, ulcerative, and/or nodular cutaneous lesions: less common

ETIOLOGY AND PATHOPHYSIOLOGY

- *Prototheca zopfii* and *Prototheca wick-erhamii* are the two algae species responsible for clinical disease. Immu-nosuppression due to concurrent disease, administration of immunosup pressive agents, or genetic predisposition at time of exposure are considered key to development and persistence of infection.
- *Prototheca* organisms can be found in the kidney (where they may cause renal failure), liver, heart, intestine, brain, and eyes of infected animals.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in a patient with signs of chronic colitis, with or without ocular or neurologic signs, who lives in a geographic area where *Prototheca* spp. are endemic. Clinical confirmation requires demonstration of the organism cytologically (usually via rectal scrape) or histologically (intestinal biopsy).

DIFFERENTIAL DIAGNOSIS

- Bloody diarrhea: parvovirus infection, clostridial infection, salmon poisoning, giardiasis, *Salmonella* enteritis, inflammatory bowel disease/ulcerative colitis, rectal adenocarcinoma, pythiosis, whipworm infection, coagulopathies caused by tickborne diseases or rodenticide poisoning, and gastrointestinal (GI) lymphoma
- In dogs with protothecal colitis, ocular lesions, and/or neurologic signs, systemic infectious diseases (e.g., mycoses) and lymphoma are important differential diagnoses.

INITIAL DATABASE

- CBC is usually unremarkable. Serum chemistry analysis usually shows mild increases in liver enzymes (alkaline phosphatase [ALP] and alanine amino-transferase [ALT]).
- Urinalysis usually is unremarkable, but inflammatory urine sediment may be seen, indicating possible renal involvement. *Prototheca* organisms have been isolated from the urine of dogs with renal failure secondary to renal invasion.
- Fecal analysis consisting of Sheather's flotation and ZnSO4 flotation is indicated in all suspected cases; *Prototheca* is occasionally found this way (many false-negative results).

ADVANCED OR CONFIRMATORY TESTING

- Organisms can be demonstrated in the cytologic examination of a rectal scrape (see p. 1334) stained with Diff-Quik or Wright's stain. Many falsenegative results.
- Intestinal biopsy (surgical or endoscopic) may yield a diagnosis when lesser invasive means are unsuccessful.
- A complete ophthalmic examination (seep. 1313) is indicated in suspected or confirmed cases, since ocular lesions may be missed initially. Organisms can be recovered from vitreous centesis.
- Neurologic examination (seep. 1311) should be performed on dogs showing CNS signs. Spinal radiographs or CT may be needed in dogs showing paresis. Organisms can be recovered from cerebrospinal fluid, which indicates severe clinical disease and dissemination.
- Culture can be performed on rectal scrape or any biopsy samples.
- Fluorescent antibody testing can differentiate *P. zopfii* from *P. wicker-hamii*

TREATMENT

TREATMENT OVERVIEW

- Abort infection.
- Reduce or prevent further dissemination of infection, particularly to CNS.
- Decrease frequency and volume of diarrhea.

ACUTE GENERAL TREATMENT

- Initial treatment consists of parenteral fluid therapy.
- Antifungal treatment (amphotericin B with/without one of the following: itraconazole, ketoconazole, tetracycline, doxycycline) is beneficial to prevent immediate dissemination.
- Amphotericin B (patient must be hydrated): 0.25-0.5 mg/kg diluted in 5% dextrose and given IV q 48 h to total cumulative dose of 8-10 mg/kg or first signs of nephrotoxicity (monitor BUN, creatinine daily).
- Liposomal amphotericin B: as above, but SQ and for a shorter time period. Less nephrotoxic but still requires monitoring.

CHRONIC TREATMENT

Tetracycline, 25 mg/kg PO q 8 h for 30 days; or doxycycline, 5-10 mg/kg PO q 24 h for 30 days; or ketoconazole or itraconazole, 5-10 mg/kg PO q 24 h with food for 30 days. Limited or no success in most cases.

DRUG INTERACTIONS

Ketoconazole, itraconazole: vomiting, inappetence, and elevated liver enzymes possible. If such signs occur, the drug therapy should be stopped and liver enzymes evaluated.

POSSIBLE COMPLICATIONS

- Treatment of concurrent infections and secondary *Escherichia coli* and *Clostridium* infections can reduce frequency and volume of diarrhea.
- Metronidazole, 7.5-15 mg/kg PO q 12 h can be used for *Clostridium* overgrowth.

RECOMMENDED MONITORING

- Monthly monitoring of the success of therapy is recommended.
- Rectal scrapes with cytologic analysis and culture, ophthalmologic examinations, CBC, serum chemistry, and urinalysis are recommended.

PROGNOSIS AND OUTCOME

- Prognosis is poor, especially with CNS signs, multiple organ involvement, and/or renal failure.
- Survival for >1 year has been reported in some animals with only GI and ocular lesions.

PEARLS & CONSIDERATIONS

COMMENTS

Prototheca is a ubiquitous organism and only an opportunistic pathogen in the irnmunocompromised dog. Further immunosuppressive therapy with glucocorticoids or other agents is contraindicated and counterproductive.

PREVENTION

If a potential area of patient exposure can be identified, the patient and possibly humans should be prevented from further contact with this environment.

CLIENT EDUCATION

The disease is not transmissible. However, owners who are irnmunocompromised should be cautious in handling the feces of infected animals.

Protein-Losing Nephropathy

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A common cause of kidney disease and kidney failure in dogs but less common in cats. Protein-losing nephropathy (PLN) is any condition in which glomerular damage leads to biologically significant loss of plasma proteins. Subsequent nephron loss may lead to chronic or acute kidney failure.

SYNONYMS

PLN, proteinuric renal failure

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Familial nephropathy:
  - Dogs > cats
  - Age at onset of illness varies with breed.
  - Sex predilection present for some (see Genetics & Breed Predisposition)
- Glomerulosclerosis:
  - Either sex
  - Incidence increases with age; average 8 years
- Membranous nephropathy:
  - Either sex
  - Most common PLN in the cat
  - Mean age: cats 3-4 years; dogs 7 years
- Minimal change nephropathy:
  - Uncommonly described in dogs and cats
- See Glomerulonephritis, p. 450
- See Amyloidosis, p. 61

GENETICS & BREED PREDISPOSITION

Familial nephropathy: inheritance not always defined; typical age of onset of signs is in parentheses.

- Glomerular disease:
  - Bernese mountain dog (2-5 years), suspected autosomal recessive inheritance
  - Brittany spaniel (4-9 years), autosomal recessive inheritance
  - Rottweiler (<1 year)
  - Soft-coated wheaten terrier (2-11 years)
  - Beagle (2-8 years)
- Amyloidosis:
  - Beagle (5-11 years)
  - English foxhound (5-8 years)
  - Shar-pei (1-6 years)
  - Abyssinian cat (1-5 years), autosomal dominant with incomplete penetrance
  - Oriental shorthair (<5 years)
  - Siamese (<5 years)
- Basement membrane abnormality:
  - Bull terrier (1-10 years), autosomal dominant inheritance
  - Doberman pinscher (<1-6 years)
  - English cocker spaniel (<2 years), autosomal recessive inheritance
  - Samoyed (<1 year), X-linked dominant (males affected)
- Tubular dysfunction:
  - Basenji (1-5 years)
- Membranous nephropathy:
  - Doberman pinscher, possibly (3-4 years)

RISK FACTORS

- Corticosteroid excess (iatrogenic, hyperadrenocorticism)
- Systemic hypertension
- Diabetes mellitus
- Chronic infections (bacterial, rickettsial, protozoal, fungal, viral, parasitic)
- Chronic inflammatory disease, including immune-mediated disease
- Neoplasia

CONTAGION & ZOONOSIS

Some infectious causes of glomerulonephritis (GN) are zoonotic (see p. 450).

GEOGRAPHY AND SEASONALITY

Some infectious causes of GN are geographically and/or seasonally limited (see p. 450).

ASSOCIATED CONDITIONS & DISORDERS

- Nephrotic syndrome
- Chronic kidney disease (chronic renal failure)
- Hypertension
- Hyperlipidemia
- Thromboembolic disease, including pulmonary thromboembolism

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- GN
- Amyloidosis
- Familial nephropathy
- Glomerulosclerosis
- Membranous nephropathy
- Minimal change disease

HISTORY, CHIEF COMPLAINT

Clinical signs are often absent prior to development of azotemia or severe hypoalbuminemia. Shar-pei dogs may present for lameness and/or fever (see online chapter: Shar-Pei Fever). When signs are present, they may be due to kidney failure, nephrotic syndrome, or to an underlying disease process:

- Lethargy
- Anorexia
- Weight loss
- Polyuria and polydipsia (PU/PD)
- Vomiting (if uremic)
- Halitosis (if uremic)
- Pendulous abdomen (ascites; if hypoalbuminemic)
- Edema (if hypoalbuminemic)
- Dyspnea (if severely uremic, after thromboembolic event, or effusion present)
- Blindness (if hypertensive)

PHYSICAL EXAM FINDINGS

Often unremarkable. Shar-pei dogs may have fever, tibiotarsal joint pain, and joint effusion. Other findings may suggest an underlying disease process. In addition to findings mentioned under clinical signs, other abnormalities may include:

- Dehydration
- Poor haircoat
- Pallor
- Oral ulceration
- Lipid corneal deposits

- Retinal hemorrhage/detachment
- Kidneys may be normal-sized, small, or rarely large

ETIOLOGY AND PATHOPHYSIOLOGY

- Familial nephropathy:
  - Diverse group of hereditary renal diseases
  - Defects vary with individual diseases but include familial amyloidosis, failure of tubular protein resorption, and defects in type IV collagen in the glomerular basement membrane.
  - In some cases, nephropathy is associated with other conditions (e.g., food sensitivity [soft-coated wheaten terrier], complement deficiency [Brittany spaniel]).
- Glomerulosclerosis:
  - Results from hyperfiltration in dogs with “typical” chronic kidney disease, often as an end-stage lesion.
  - Reported in dogs with familial nephropathy, systemic hypertension, diabetes mellitus, hyperadrenocorticism, and postradiation therapy. Multiple other causes described in people.
  - Sclerosis ultimately leads to altered intraglomerular hemodynamics and progressive renal failure.
- Membranous nephropathy:
  - Immune complex deposition in the glomerular basement membrane, without evidence of inflammation
  - Primary (most common) and secondary forms can be distinguished by the location of the immune complex deposition.
- Minimal change nephropathy:
  - Loss of anionic charge in glomerulus leads to selective albumin loss.
  - Because electron microscopy is required for diagnosis, may be underreported in veterinary medicine.
- See Glomerulonephritis, p. 450.
- See Amyloidosis, p. 61.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A diagnosis of PLN is suspected based on proteinuria and an elevated protein/creatinine ratio obtained from a sterile urine sample with inactive sediment. Diagnosis is confirmed after ruling out preglomerular or postglomerular causes of proteinuria.

DIFFERENTIAL DIAGNOSIS

Proteinuria:

- Preglomerular:
  - Bence Jones proteinuria
  - Exercise
  - Hemolysis
  - Fever
  - Seizure
- Glomerular (i.e., the disorders that can cause protein-losing nephropathy):
  - GN
  - Amyloidosis
  - Glomerulosclerosis
  - Familial nephropathy
  - Minimal change disease
- Postglomerular:
  - Urinary tract infection
  - Acute renal failure
  - Neoplasia (e.g., transitional cell carcinoma, prostatic carcinoma)
  - Urolithiasis
  - Urinary hemorrhage
  - Fanconi syndrome
  - Trauma
  - Endocrine disease (e.g., hyperadrenocorticism)

INITIAL DATABASE

- Retinal exam: hemorrhages (acute or chronic) or retinal detachments are possible (both a result of severe systemic hypertension).

- Blood pressure (BP): systemic hypertension is possible (systolic BP > 180 mm Hg repeatably in a calm environment).
- CBC: often unremarkable; nonregenerative anemia may occur with advanced kidney disease, leukocytosis may occur if inflammatory disease is present.
- Serum biochemical profile:
  - Hypoalbuminemia with normal globulin level is common.
  - Hypercholesterolemia accompanies hypoalbuminemia.
  - Hypocalcemia (due to hypoalbuminemia)
  - Azotemia (in advanced disease)
  - Hyperphosphatemia (in advanced disease)
  - Metabolic acidosis (with azotemia)
- Urinalysis: proteinuria is a consistent finding. Urine concentration is variable but often minimally concentrated. Hematuria sometimes present.
  - Proteinuria must be interpreted in light of urine concentration and urine sediment examination.
  - Dipstick measure of proteinuria should be confirmed by sulfosalicylic acid (SSA) method or quantitative measures (e.g., urine protein/creatinine ratio).
  - Proteinuria may be mild in subset of shar-pei dogs and Abyssinians with renal medullary amyloidosis.
  - Significant proteinuria may precede loss of urine concentration or azotemia.
- Urine culture: indicated in all cases.
- Thoracic radiographs: unremarkable. Evidence of underlying disease (neoplasia, chronic infectious or inflammatory disease) or pulmonary thromboembolism occasionally identified.
- Abdominal radiographs: often unremarkable. Kidneys may be large (amyloidosis) or small (chronic GN, sclerosis); may identify evidence of underlying disease (neoplasia, chronic infectious or inflammatory disease).
- Abdominal ultrasound: hyperechoic kidneys (though this is a normal finding in some cats), decreased corticomedullary junction, medullary rim sign, cortical cysts.

ADVANCED OR CONFIRMATORY TESTING

- Microalbuminuria test (early renal disease [ERD] screen) can detect small amounts of urine albumin before dipstick protein is positive:
  - Significance of this test in apparently healthy dogs is not known.
  - May identify animals with familial nephropathy before overt renal damage apparent
  - Used in humans with diabetes mellitus and hypertension as early indicator of glomerulosclerosis
- Urine protein/creatinine ratio:
  - Normal ratio < 0.5 in dogs and <0.4 in cats
  - Only useful when urine sediment is inactive
  - Protein loss tends to be higher in amyloidosis than in GN.
- Urine protein excretion, 24 hours: largely replaced by single-sample protein/creatinine ratio
- Biopsy of the renal cortex for light microscopy, electron microscopy (EM), or immunofluorescence:
  - Amyloidosis: Congo red stain for amyloid
  - GN: morphologic description and immunologic classification
  - Glomerulosclerosis: immunofluorescent microscopy is negative; immunoglobulin and C3 trapping may be present. A segmental increase in mesangial matrix and basement membrane is typically seen.
  - Membranous nephropathy: thickened glomerular basement membrane due to immune complex deposition. Location of immune complexes determined by EM.
  - Minimal change disease: lack of light microscopic glomerular changes; foot process effacement seen on EM
- Antithrombin levels to determine risk of thromboembolic disease
- Blood gas analysis: increased alveolar-arterial (A-a) gradient may support ventilation/perfusion mismatch due to pulmonary thromboembolism.
- Search for underlying disease; in addition to causes of GN (see p. 450), causes of glomerulosclerosis should be considered as well (e.g., systemic hypertension, hyperadrenocorticism, diabetes mellitus).
- Possible C3 levels or perinuclear antineutrophilic cytoplasmic autoantibodies in soft-coated wheaten terriers

TREATMENT

TREATMENT OVERVIEW

Whenever possible, the cause for PLN should be addressed directly. Regardless, treatment of PLN includes measure to reduce proteinuria, reduce thromboembolic risk, address uremic signs and complications, and control systemic hypertension.

ACUTE GENERAL TREATMENT

- Underlying causes should be identified and addressed directly whenever possible.
- Immediate care for PLN includes measures to address uremia (see p. 207), hypertension (see p. 1068), thromboembolic risks

(see pp. 450and88), edema formation (see pp. 131,270 , and 61), and acid/base or electrolyte disorders (see p. 450).
- Occasionally, manual drainage of abdominal or thoracic fluid accumulation will be needed to relieve respiratory effort (see pp. 1338 and 1192).

CHRONIC TREATMENT

- Identification and treatment of causative disease provide the best prognosis for affected animals. PLN is often idiopathic, or causation cannot be treated (e.g., familial disease). In these cases, supportive, nonspecific measures are employed (seepp. 762 ,450 , and 11).
- Specific treatment for amyloidosis may be attempted (see p. 61).
- Immunosuppression (glucocorticoids 2 mg/kg PO q 24 h) may be useful for membranous nephropathy, but only if infectious causes have been ruled out.

DRUG INTERACTIONS

ACE inhibitors may cause hypotension when combined with diuretics or other vasodilators. Nonsteroidal antiinflammatory drugs (NSAIDs) may reduce efficacy of angiotensin-converting enzyme (ACE) inhibitors.

POSSIBLE COMPLICATIONS

- Third-space retention of fluids/nephrotic syndrome
- Worsening renal azotemia as a result of ACE inhibitor use
- Hypotension secondary to ACE inhibitor and Ca channel blocker
- Worsening of renal azotemia with dextran use
- Thromboembolic disease as a result of abnormal antithrombin and protein C
- Bleeding tendency from aspirin, warfarin use
- Gastrointestinal (GI) ulceration as a result of azotemia or aspirin therapy

RECOMMENDED MONITORING

Stable animals may be monitored every 3-4 months. Rechecks should be more frequent when changes are made in therapy or when indicated by changes in clinical signs.

- Physical examination
- Urine protein/creatinine ratio
- Serum blood urea nitrogen (BUN), serum creatinine, and serum phosphorus levels
- Serum albumin
- BP
- Urinalysis and culture

PROGNOSIS AND OUTCOME

- The prognosis of PLN is extremely variable, depending on cause and severity of renal compromise.
- If an underlying disease can be identified and treated, the prognosis may be good.
- If it is not possible to identify or correct an underlying disease process, PLN is usually progressive.
- Animals with PLN may be medically managed for variable periods of time, even when uremic signs develop.
- In general, the prognosis for animals with renal amyloidosis is worse than that of GN.
- Familial renal diseases often begin at a young age and are rapidly progressive with a poor prognosis.
- When glomerulosclerosis is associated with end-stage renal disease, the prognosis is poor.
- Animals with membranous nephropathy may have a better prognosis with appropriate treatment. It is often slowly progressive, and the animal can occasionally go into remission.

PEARLS & CONSIDERATIONS

COMMENTS

- Renal cortical biopsy is the only method to distinguish amyloidosis and GN. While treatment is impacted occasionally, it provides useful prognostic information.
- Shar-pei dogs and Abyssinian cats occasionally have a normal cortical biopsy, since the amyloid may be deposited in the renal medulla.

PREVENTION

- Heartworm prophylaxis
- Tick prophylaxis
- Breeder education for dogs and cats with familial disease

CLIENT EDUCATION

Renal biopsy can help definitively identify the disease process. This may be important for animals with familial renal disease.

AUTHOR: ANNE M. DALBY

EDITOR: LEAH A. COHN

Prostatic Neoplasia

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Prostatic neoplasia is uncommon in dogs and rare in cats. The most common tumor types include adenocarcinoma, urothelial carcinoma, and undifferentiated carcinoma. Prostate tumors are locally invasive and highly metastatic.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Prostate tumors occur almost exclusively in dogs. Sporadic cases have been reported in cats. Median age at diagnosis in dogs is 10 years.

GENETICS & BREED PREDISPOSITION

No breed predilection has been reported; medium- to large-breed dogs are more commonly affected.

RISK FACTORS

The effects of reproductive status on the development of prostate tumors are not fully understood. Exposure to endogenous androgens has been associated with development of prostatic adenocarcinoma in dogs. Castration at a young age appears to increase the risk of other types of prostate tumors.

ASSOCIATED CONDITIONS & DISORDERS

Many patients with prostate tumors may develop secondary lower urinary tract infections.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Forms of disease include the various histologic types including adenocarcinoma, urothelial carcinoma, and undifferentiated carcinoma. The natural behavior of and diagnostic approach to each subtype is identical.

HISTORY, CHIEF COMPLAINT

Clinical signs are often chronic, linked to the urinary tract, and most commonly include hematuria, incontinence, and stranguria. Rarely, patients may present with complete urinary obstruction. Animals with large masses may present with tenesmus caused by compression of the colon by the tumor. Lameness may occur in animals with bone metastasis.

PHYSICAL EXAM FINDINGS

External physical examination is often unremarkable. A large, irregular mass that may be firmly adhered to surrounding pelvic structures is typically found on rectal palpation. Animals with bone metastasis may display evidence of pain during orthopedic examination of the spine, pelvis, and/or hind limbs.

ETIOLOGY AND PATHOPHYSIOLOGY

- Castrated dogs are more likely to develop prostatic neoplasia than intact dogs:
  - Intact or recently castrated dogs are more likely develop adenocarcinoma, while castrated dogs likely develop other tumor types.
- Tumor location often precludes early diagnosis; most tumors are consequently locally advanced and have metastasized (70%-80%) at the time of diagnosis:
  - The ultimate metastatic rate for prostate tumors is 85%-100%.
  - The most common sites for metastasis include lungs (50%), lymph node (>30%), and bone (15%-45%). The pelvis and lumbosacral spine are the most common sites of bony metastasis.

- Cyclooxygenase 2 (COX-2) expression may play a role in tumor development and progression, as 75% of prostatic carcinomas have been shown to express COX-2 protein, whereas such expression is not evident in normal prostatic tissue.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

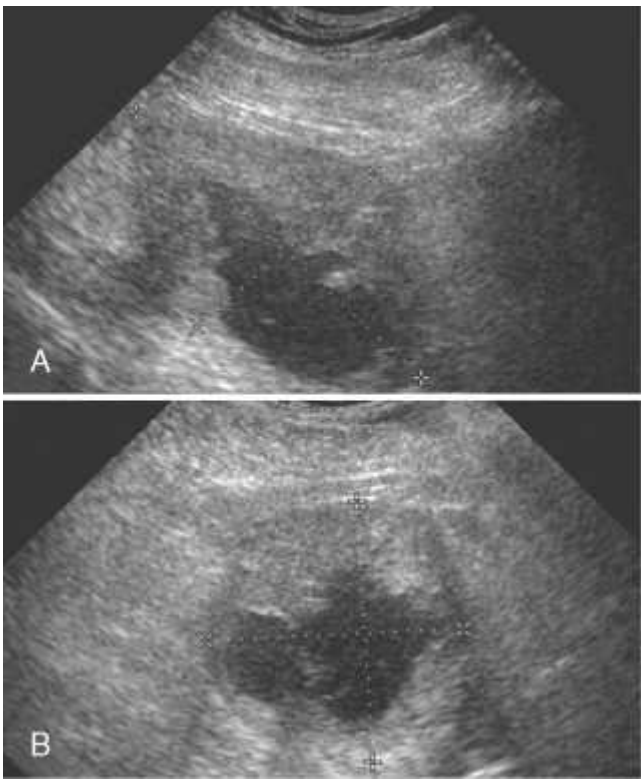
The diagnosis is suspected based on the presence of lower urinary tract signs in a patient with a large, irregular prostate on rectal examination; confirmation requires cytologic or histopathologic evaluation.

DIFFERENTIAL DIAGNOSIS

- Benign prostatic hyperplasia (BPH)
- Prostatic abscess
- Paraprostatic cyst
- Locally invasive transitional cell tumor of the urinary bladder

INITIAL DATABASE

- CBC
- Serum biochemistry profile
- Urinalysis and urine culture if indicated
- Thoracic and abdominal radiographs (including evaluation of bony structures for metastasis)
- Abdominal ultrasound
- Aspirate of regional lymph nodes if indicated to identify the presence of metastatic disease

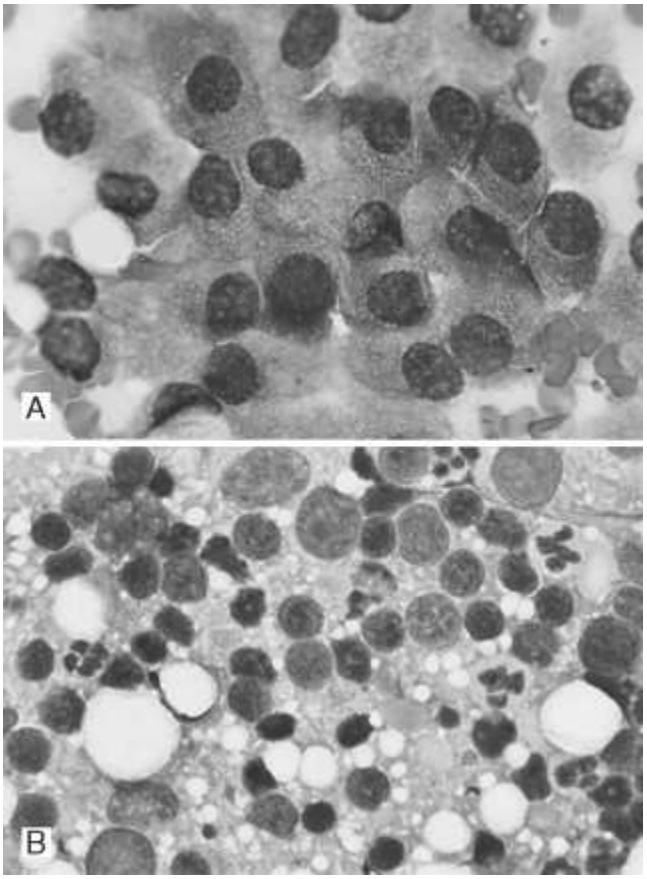


PROSTATIC NEOPLASIA Sagittal **(A)** and transverse **(B)** ultrasonographic images of prostatic adenocarcinoma. Note enlarged size of prostate for a castrated male dog, and increased echogenicity and presence of large, coalescing cysts with hypoechoic luminal contents. Ultrasonographic appearance of a prostatic cyst or abscess may be similar to prostatic carcinoma. Diagnosis should be confirmed by prostatic fluid analysis and/or biopsy.

(From Ettinger SJ, Feldman EC, editors: Textbook of veterinary internal medicine, ed 6, St Louis, 2004, Saunders.)

ADVANCED OR CONFIRMATORY TESTING

- Biopsy for histopathologic evaluation of tumor tissue
- Cytologic evaluation and culture of prostatic aspirate or wash may aid in establishing a diagnosis and rule out concomitant prostatitis.
- Histopathologic evaluation of biopsied tissue for confirmation is essential prior to having patients undergo definitive therapy. Percutaneous aspiration or biopsy of the prostate may be associated with a risk of tumor seeding; however, the need to establish a definitive diagnosis usually supersedes the risk of iatrogenic tumor dissemination with the biopsy instrument.
- CT scan for surgical or radiation treatment planning



PROSTATIC NEOPLASIA Prostatic wash samples made from a normal dog **(A)** and a dog with adenocarcinoma **(B)** (×100).

(From Ettinger SJ, Feldman EC, editors: Textbook of veterinary internal medicine, ed 6, St Louis, 2004, Saunders, pp 1809-1819.)

TREATMENT

TREATMENT OVERVIEW

Long-term disease control is the ultimate goal in any animal but is often not possible owing to extensive local or metastatic disease. In patients with lesions not amenable to definitive therapy, palliation of clinical signs is the primary goal.

ACUTE GENERAL TREATMENT

- Definitive therapy:
  - Curative therapy should only be considered in dogs with no evidence of metastases.
  - Reports describing definitive therapy for dogs with localized prostate tumors are limited. The following treatments could be considered:
    - External beam radiotherapy to prostate ± regional lymph nodes
    - Partial prostatectomy with preservation of the urethra (animals with focal prostatic lesions)
    - Complete prostatectomy with urethral resection/permanent cystostomy tube placement
    - Given the high metastatic rate, chemotherapy (e.g., doxorubicin, mitoxantrone, carboplatin) is indicated in definitively treated animals. The efficacy of chemotherapy has not been established conclusively.
    - COX-2 inhibition with piroxicam, 0.3 mg/kg PO q 24-48 h (caution: gastric ulcerogenic potential) is beneficial in animals with prostatic carcinoma of urothelial origin.

CHRONIC TREATMENT

Palliative therapy:

- Palliative care should be considered in animals with metastatic disease and those with advanced localized disease not amenable to definitive therapy. The efficacy of palliative treatments has not been established conclusively.
- Palliative radiotherapy may provide short-term relief from urinary obstruction or other clinical signs resulting from local disease.
- Permanent cystostomy tube placement/urinary bladder marsupialization may provide relief from urinary obstruction.
- Electrosurgical transurethral resection may result in significant palliation of clinical signs.
- Castration may provide alleviation of signs in intact dogs with concurrent prostatic hyperplasia.
- Systemic treatment with chemotherapy and/or piroxicam

DRUG INTERACTIONS

Patients receiving piroxicam therapy should be given corticosteroids or other nonsteroidal antiinflammatory medications.

POSSIBLE COMPLICATIONS

Potential complications of chemotherapy and radiation treatment are similar to those observed for other tumors. Such complications include gastrointestinal toxicity, bone marrow suppression, and local tissue irritation. Piroxicam therapy may be associated with gastrointestinal ulceration as well as renal failure.

RECOMMENDED MONITORING

Following treatment, recommended monitoring includes routine examination, abdominal ultrasound, and thoracic radiographs. For chemotherapy, routine monitoring should be undertaken based on protocol.

PROGNOSIS AND OUTCOME 

- Due to the severity of clinical disease (advanced local and distant metastasis), most dogs with clinical signs caused by prostate tumors are euthanized within 1 month of diagnosis.
- The prognosis for definitive therapy is largely unknown, with the exception of radiotherapy. Animals treated with a single 30-Gy dose of intraoperative radiation have shown a median survival of 4 months; animals treated with conventional external beam radiotherapy (57 Gy) have shown a median survival of 7 months.
- Dogs receiving COX-2 inhibition therapy have a median survival of 7 months, compared to a median survival of <1 month in those not receiving such therapy.

PEARLS & CONSIDERATIONS 

COMMENTS

- With rare exception, the prognosis for animals with prostatic tumors is poor; advanced disease at the time of diagnosis is the major causative factor for poor prognosis.
- Advances in the treatment of dogs with prostate tumors will more likely come from earlier detection rather than improved treatment.

Prostatic Infections (Prostatitis, Prostatic Abscessation)

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Prostatitis: inflammation of the prostate, almost always as a consequence of infection. There are acute and chronic forms that can differ in clinical presentation.
- Prostatic abscess: severe disorder involving infection of the prostate gland, resulting in the production of pocket(s) of suppurative material and destruction of glandular tissue.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Any age; more likely in dogs >5 years of age
- Male cats have prostate glands, but prostatitis is extremely rare in this species.

GENETICS & BREED PREDISPOSITION

- Doberman pinschers have been reported to have a higher incidence of all prostatic diseases.
- Prostatitis: increased risk reported in the Bouvier des Flandres, Scottish terrier, Bernese Mountain dog, German pointer, and Doberman pinscher.

RISK FACTORS

Sexually intact males are at greatest risk.

CONTAGION & ZOONOSIS

Prostatitis can occasionally be caused by *Brucella canis,* a potential zoonotic pathogen, via a hematogenous route.

ASSOCIATED CONDITIONS & DISORDERS

- Chronic form of prostatitis is almost always associated with benign prostatic hypertrophy/hyperplasia (BPH; see p. 919).
- Squamous metaplasia of the parenchymal ducts and prostatic neoplasia can also predispose to infection and therefore may also increase the likelihood of prostatitis and abscess formation.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute prostatitis: often associated with systemic illness
- Chronic prostatitis: not associated with systemic illness:
    - Prostatic abscess

HISTORY, CHIEF COMPLAINT

- Signs arise from compression or displacement of adjacent structures, prostatic pain, or systemic illness (sepsis).
- Acute prostatitis: tenesmus, dysuria, lethargy, anorexia, weakness, stiff gait, hematuria:
    - >70% of dogs with acute prostatitis have signs of systemic illness.
    - Primarily in younger male (usually intact) dogs
- Chronic prostatitis: clinical signs reported by owner may be minimal:
    - Primarily occurs in older intact male dogs with concurrent BPH
    - Initially, clinical signs include a recurrent urinary tract infection, preputial discharge, and hemospermia/pyospermia.
    - Depending on duration of illness: tenesmus and/or dysuria
    - Infertility is weakly correlated with chronic prostatitis.
    - Signs of systemic illness are unlikely in dogs with chronic prostatitis.
- Prostatic abscess: may be incidental finding or produce signs similar to prostatitis

PHYSICAL EXAM FINDINGS

- Acute prostatitis:
  - Fever
  - Tense, painful abdomen
  - Prostatic pain on rectal exam
  - Abdominal pain
  - Systemic signs of illness such as anorexia and lethargy
- Chronic prostatitis:
  - Urethral/preputial discharge possible (may be hemorrhagic or purulent)
  - Variable rectal examination findings: possibilities include:
    - Prostatomegaly
    - Normal prostatic palpation; minimal prostatic pain on palpation
- Prostatic abscess:
  - Urethral/preputial discharge (may be hemorrhagic or purulent)
  - Asymmetric prostatomegaly on rectal exam
  - Abdominal mass palpated if prostate severely enlarged
  - Prostatic and/or abdominal pain
  - Systemic signs (e.g., fever, depression, systemic shock)

ETIOLOGY AND PATHOPHYSIOLOGY

- Disturbances in normal defense mechanisms (urine flow during micturition, urethral high-pressure zone, bactericidal effects of prostatic fluid, and local IgA production) may predispose to prostatitis.
- Bacterial infection may spread to the prostate from elsewhere in the urinary tract, can be hematogenous, or occur secondary to a cyst that has become infected:
  - The most common organism reported in canine prostatitis is *Escherichia coli,* which gains access to the prostate via an ascending urinary tract infection.
  - Other bacterial causes of prostatitis and abscessation: *Staphylococcus* spp., *Streptococcus* spp., *Proteus* spp., *Pseudomonas* spp., and *B. cants.*
  - Hypersecretory and cystic degenerative changes that occur with BPH create ideal conditions for bacterial overgrowth. In rare cases, prostatitis can result from nonbacterial organisms (e.g., *Blastomyces, Pythium)* that cause systemic disease.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

These disorders may be encountered incidentally (e.g., on routine physical/rectal examination) or when a patient shows overt signs of illness. Rectal palpation of the prostate is essential, and any palpable abnormality or other clue of prostatic disease (e.g., radiographic changes) warrants ultrasound examination +/− diagnostic sampling.

DIFFERENTIAL DIAGNOSIS

- Other prostatic disease: prostatic abscess, prostatic/paraprostatic cyst, benign prostatic hyperplasia, prostatic neoplasia
- Other lower urinary tract disease: neoplasia, urethral calculi, cystitis
- Colonic disease: colitis, neoplasia
- Mass of other tissue origin (e.g., transitional cell carcinoma, fibrosarcoma)
- Other causes of hemospermia/urospermia

INITIAL DATABASE

- CBC: may have an inflammatory leu-kogram (more common in acute prostatitis)
- Serum biochemistry profile: generally unremarkable
- Urinalysis: inflammatory sediment present (regardless of method of collection)
  - Caution if obtaining urine by cystocentesis: do not lacerate a prostatic abscess.
- Urine culture: may be positive for bacterial growth and is essential for accurate antibiotic selection
- Abdominal radiographs:
  - Acute: prostate commonly of normal size, but mild to moderate prostatomegaly may be present.
  - Chronic: often mildly to moderately enlarged; occasionally normal size
  - Prostatic mineralization has been shown to be highly predictive of neoplasia in neutered male dogs but less reliable in intact male dogs.

- Abdominal ultrasound: focal or diffuse heterogenous echogenicity, prostatomegaly, cystic changes

ADVANCED OR CONFIRMATORY TESTING

- Prostatic fluid cytologic analysis (from ejaculate or prostatic massage): increased erythrocytes and leukocytes; bacteria may be seen within neutrophils (see p. 1332).
- Prostatic fluid culture: usually large numbers of a single bacterial species isolated.
- Prostatic fine-needle aspiration is also an effective method of obtaining cells for cytologic examination and culture (should not be performed in dogs with systemic illness):
  - Septic suppurative inflammation
  - Caution with suspected prostatic abscess; risk of spreading infection or causing septic peritonitis.
- *B. canis* testing (see p. 162)

TREATMENT

TREATMENT OVERVIEW

Treatment of prostatic bacterial infections requires prolonged antibiotic therapy with appropriate antibiotics that can penetrate the tissue. Abscessation requires drainage of the abscess.

ACUTE GENERAL TREATMENT

- Initiate antibiotic therapy:
  - Lipid solubility, acid dissociation constant (p*K*a, and degree of protein binding affect penetration into the prostate.
  - Antibiotic penetration into abscess may be inadequate, therefore is combined with surgery or percutaneous drainage.
  - Antibiotics known to readily penetrate the prostatic capsule include:
    - Chloramphenicol, 30-50 mg/kg PO q 8 h (bacteriostatic)
    - Trimethoprim-sulfadiazine, 15 mg/kg PO q 12 h (bactericidal)
    - Fluoroquinolones:
      - Enrofloxacin, 5 mg/kg PO q 12-24 h (bactericidal)
      - Ciprofloxacin has poorer penetration of prostatic tissue.
- Acute prostatitis:
  - Blood-prostate barrier is disrupted.
  - Most antibiotics will penetrate.
  - Initial choice based on likely organism, then adjusted based on culture and sensitivity (C&S) results
- Chronic prostatitis:
  - Antibiotics that can penetrate the intact prostatic capsule (above) must be used, and choice is ideally based on C&S.
  - Reduction of prostatic size allows infection to be cleared more readily (castration or treatment with drugs that reduce prostate size [e.g., finasteride, 5 mg/dog PO q 24 h, assuming 10-40 kg body weight]).
  - Castration may be mandatory if *Brucella* is identified. In some states, *Brucella canis* is a reportable disease. Check local regulatory guidelines for this zoonotic infection.
- Prostatic abscess:
  - Drainage of cavities greater than 1 cm on ultrasound is the standard of care, either by ultrasound guidance or surgery.
  - Current surgical recommendations involve débridement and intracapsular omentalization followed by postdrainage antibiotic therapy.

CHRONIC TREATMENT

- Adjust antibiotic therapy based on culture results.
- Antibiotic therapy should be continued at least 4-6 weeks.
- Finasteride therapy should be continued until the dog is castrated.

BEHAVIOR/EXERCISE

It may be advisable to discontinue breeding of stud dogs during therapy.

DRUG INTERACTIONS

- Chloramphenicol decreases clearance of other drugs that are cleared by cytochrome P450 enzymes (e.g., phenobarbital, phenytoin).
- Trimethoprim-sulfadiazine may prolong coagulation times when used concurrently with warfarin. It displaces highly bound drugs such as thiazide diuretics, among others. Some antacids will increase bioavailability of this antibiotic. It also decreases

the efficacy of cyclosporine when used concurrently.
- Fluoroquinolones may increase theophylline blood levels when used concurrently. Some antacids may prevent absorption of fluoroquinolones. Synergism may occur with other antibiotics (e.g., aminoglycosides, third-generation cephalosporins, and some penicillins).

POSSIBLE COMPLICATIONS

- Antimicrobial side effects
- Trimethoprim-sulfamethoxazole may cause anemia, polyarthritis, and keratoconjunctivitis sicca if given long term.
- Chloramphenicol has been associated with bone marrow toxicity.
- Prostatic abscess formation is a possible sequela of acute prostatitis.
- Prostatic abscess:
  - Morbidity can be high with surgical intervention, but incidence of complications is decreased with prostatic omentalization technique compared to older techniques (e.g., placement of Penrose drains and marsupialization).
  - Possible complications include urinary incontinence; chronic draining tracts; and with uncontrolled abscesses that rupture and/or produce sepsis, peritonitis, septic shock, and death are possible.

RECOMMENDED MONITORING

- Repeat examination including rectal palpation approximately every 2 weeks during therapy.
- Repeat ultrasound of the prostate 2-3 weeks after initial therapy and as needed thereafter to ensure resolution of abscess.
- Prostatic fluid and urine should be collected for culture and cytologic analysis 2 weeks after completion of antibiotics, and again 4 weeks later.
- Infection generally will not recur if finasteride is continued or castration is performed.

PROGNOSIS AND OUTCOME

- Prognosis is fair for prostatitis in general:
  - Acute prostatitis is generally more amenable to cure than chronic prostatitis, but systemic illness makes it a more urgent and potentially life-threatening disease than chronic prostatitis.
- Prognosis is guarded to poor for prostatic abscess:
  - Historically, reported mortality rates of 24%-51% within the first year following therapy for prostatic abscess, but prognosis appears to be better if prostatic omentalization or percutaneous ultrasound guided drainage technique is used.

PEARLS & CONSIDERATIONS

COMMENTS

- Radiographic evidence of prostatic mineralization can occur with bacterial prostatitis or prostatic neoplasia but is more common with the latter.
- Castrated dogs are much less likely to develop prostatitis, compared to the incidence of prostatic neoplasia, which is not reduced by castration.
- Semen cryopreservation may be considered following resolution of the bacterial infection in a valuable breeding animal, so that castration can be performed.
- Owners need to be aware that percutaneous drainage may have to be performed more than one time.

PREVENTION

Castration

CLIENT EDUCATION

- Warn clients of necessity of treating chronic cases with both an antibiotic and finasteride when castration is not an option.
- Warn clients of the guarded prognosis, long-term problems of urinary incontinence, and possible need for subsequent surgery following initial therapy for prostatic abscess.

Prostatic Enlargement (Noninfectious, Non-Neoplastic)

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Enlargement of the prostate gland due to noninfectious, non-neoplastic cause. In dogs, these are benign prostatic hyperplasia (BPH), prostatic cysts and squamous metaplasia. Prostatomegaly is extremely rare in cats.
- Prostatic abscess, prostatitis (see p. 922), and prostatic neoplasia (see p. 924) are discussed separately.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Adult male dogs, almost exclusively sexually intact (exception: prostatic neoplasia, which occurs in castrated or intact dogs)

RISK FACTORS

- Endogenous (e.g., gonadal) or exogenous source of androgens or estrogens
- Increasing age. BPH: 50% prevalence at age 5 years, 95% prevalence by age 9 years.

CONTAGION & ZOONOSIS

Antiandrogen drugs are teratogenic and must not be handled by pregnant women.

ASSOCIATED CONDITIONS & DISORDERS

Prostatic cysts may be at risk for infection. Feminization and bone marrow suppression or other signs of hyperestrogenism in dogs with prostatic squamous metaplasia.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- BPH: most common cause of prostatomegaly in sexually intact, adult dogs
- Prostatic cysts: observed within the prostatic parenchyma, often associated with BPH
    - Large (several centimeters) intraprostatic cysts referred to as retention cysts.
- Paraprostatic cysts: located outside the prostatic parenchyma but are attached to it by a stalk; often extremely large; not necessarily associated with other prostatic pathology.
- Squamous metaplasia of the prostatic epithelium: occurs in response to estrogen

HISTORY, CHIEF COMPLAINT

- Prostatomegaly due to any cause may be an incidental finding, or it may cause tenesmus.
- BPH often causes no clinical signs. When it does, tenesmus and sanguineous urethral discharge not associated with urination are the two most common signs.
    - Unlike the situation in men, BPH rarely causes stranguria or urine retention in dogs.
- Paraprostatic cysts often cause no clinical signs (incidental findings).
    - When present, clinical signs are associated with mechanical interference with abdominal viscera.
- Squamous metaplasia of the prostate may be asymptomatic or cause signs similar to BPH +/− signs of hyperestrogenism.

PHYSICAL EXAM FINDINGS

Careful rectal (see online chapter: Rectal Palpation) and abdominal palpation of the prostate:

- Prostatomegaly in a castrated dog should immediately prompt a search for prostatic neoplasia or the possibility of a remaining crypt orchid testicle(s).
- BPH:

- Symmetric, nonpainful enlargement of the prostate
- ± Sanguineous urethral (preputial) discharge
- Otherwise healthy, sexually intact adult

- Prostatic cysts:
  - Paraprostatic cyst: large mid- or caudal-abdominal mass; otherwise healthy
  - Intraprostatic cyst: as for BPH +/− asymmetry if large
- Squamous metaplasia of the prostate:
  - Symmetric, nonpainful prostate
  - Testicular mass with atrophy of the contralateral testis
  - ± Alopecia, pigmentation, gyneco-mastia, pendulous prepuce and scrotum, or other findings (e.g., bone marrow suppression) caused by hyperestrogenism

ETIOLOGY AND PATHOPHYSIOLOGY

- Prostatomegaly may cause tenesmus due to mechanical interference with defecation.
- BPH and prostatic cysts are androgen dependent:
  - Normal reflux of prostatic fluid into the urinary tract results in sanguineous urethral (preputial) discharge in some dogs with BPH.
- Estrogen causes squamous metaplasia of the prostatic epithelium:
  - The most common source is an estrogen-secreting testicular tumor (e.g., Sertoli cell tumor).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- Prostatomegaly is identified during routine physical examination by careful abdominal and rectal palpation.
- BPH, the most common cause of prostatomegaly in an intact male dog, should be on the differential diagnosis list for tenesmus and for sanguineous urethral (preputial) discharge.
- Ultrasound of the prostate is the single most helpful method for narrowing the list of causes of prostatomegaly; it shows the internal architecture of the prostate, which radiographs do not.

DIFFERENTIAL DIAGNOSIS

- Prostatomegaly from infectious causes (e.g., bacterial prostatitis or abscess; see p. 922)
- Prostatomegaly from neoplastic causes. Prostatic neoplasia (see p. 924) is the most common cause of prostatomegaly in castrated dogs.

INITIAL DATABASE

- Physical examination findings of prostatomegaly and the presence of testicles:
  - Rectal palpation: when symmetric, nonpainful, prostatomegaly is an incidental physical exam finding in an otherwise normal, healthy, older intact male, a tentative diagnosis of BPH is justified. Ultrasound would be confirmatory, but there is usually no urgency. Watchful waiting would also be reasonable
  - The next diagnostic step is to palpate the scrotum for the presence of testicles ± a testicular tumor (see p. 1081).
- Ultrasound:
  - BPH causes symmetric prostatomegaly with a smooth capsule and homogeneous mixed echotexture of the parenchyma ± a few small (<10 mm) cysts. The urethra is normal.
  - Anechoic fluid within intra- and paraprostatic cysts ± concomitant BPH are common. Paraprostatic cysts are often very large (e.g., >15 cm diameter) and may mimic the urinary bladder in ultrasonographic appearance.
  - No lymphadenopathy, which might be present with prostatic infection or neoplasia.
  - Ultrasound testicles if estrogen-secreting tumor is suspected but not palpable.
- Abdominal radiographs indicated if tenesmus is present:
  - BPH, intraprostatic cyst, and squamous metaplasia cause prostatomegaly ± dorsal displacement of colon.
  - Paraprostatic cyst appears as a mid- or caudal-abdominal, soft-tissue mass, sometimes with calcification. Displacement of colon and/or urinary bladder. On survey radiographs alone, may be difficult to differentiate from urinary bladder.
  - No evidence of bone metastasis in pelvis or lumbar vertebra, which might be present with prostatic neoplasia.
- Urinalysis and urine culture indicated if urinary signs are present:
  - Macroscopic or microscopic hematuria may be found.
  - Culture results negative. Positive culture results indicate concomitant urinary tract infection and/or bacterial prostatitis.

ADVANCED OR CONFIRMATORY TESTING

- Not immediately necessary when symmetric, nonpainful prostatomegaly typical of BPH is found in an otherwise normal, healthy, older intact male dog.
- CBC:
  - Indicated if suspected squamous metaplasia (bone marrow suppression from hyperestrogenism)
  - Otherwise should be unremarkable
- Cytologic analysis and culture of prostatic tissue and/or fluid (see p. 1332):
  - Samples are easily obtained by fine needle aspiration using ultrasound guidance.
  - If the lesion does not communicate with the urethra, samples obtained by prostatic wash or third fraction of the ejaculate may produce a false-negative result.
  - Culture results should be negative. Positive culture results indicate concomitant bacterial prostatitis or abscess, and/or urinary tract infection, and/or contamination of the ejaculate with preputial organisms.
  - Hemospermia is often present with BPH, ± the occasional macrophage and nondegenerative neutrophil.
  - Increased numbers of squamous epithelial cells typically are found in prostatic wash and ejaculate samples from dogs with prostatic squamous metaplasia.
- Retrograde cystourethrogram (see p. 1237):
  - Urethra is normal with BPH. o Will clearly differentiate urinary bladder from paraprostatic cyst
- Biopsy, histopathologic evaluation:
  - Rarely necessary or indicated when all the testing described above is consistent with BPH, prostatic cyst, or squamous metaplasia and nothing else.

TREATMENT

TREATMENT OVERVIEW

- Healthy intact dogs with BPH or intraprostatic cysts, showing no clinical signs, do not necessarily require treatment, only watchful waiting. However, dogs with prostatic cysts and BPH may be at greater risk for ascending infection by urethral flora.
- Dogs with squamous metaplasia should be treated promptly by removing the source of estrogen (e.g., via castration if Sertoli cell tumor) before additional sequelae of estrogen toxicity develop.

ACUTE GENERAL TREATMENT

Surgical—castration:

- Castration is the treatment of choice (curative) for dogs with clinical signs due to BPH, prostatic cysts, or estrogen-secreting testicular tumors.
  - Prostatic involution is detectable within days of castration.
  - Prostatic size is expected to decrease by 50% within 3 weeks and 70% within 9 weeks.
  - Clinical signs of BPH typically are completely resolved within 4 weeks after castration.
  - Unilateral castration possible if estrogen-secreting testicular tumor in a valuable stud dog.

Surgical/medical:

- For paraprostatic cysts, complete surgical excision with castration is recommended. When the cyst is not amenable to complete surgical excision, omentalization is recommended. For a valuable stud dog, pharmacologic management, fine-needle drainage, or both may be an alternative, albeit temporary, solution.

CHRONIC TREATMENT

Pharmacologic:

- Less effective alternative to castration
- Treatment is typically given on an asneeded basis when clinical signs recur, until or unless castration is performed.
- Response to pharmacologic therapy is temporary. Semen quality and libido may be altered.
- 5α-Reductase inhibitors suppress conversion of testosterone to dihydrotestosterone, the androgen most active on the prostate:
  - Contraindicated in dogs with hepatic impairment
  - Finasteride (Proscar and Propecia [Merck]), 0.1-0.2 mg/kg PO q 24 h, or 5 mg/dog/d PO; off-label use
  - Clinical improvement of BPH in 1 week. Substantial reduction in prostate size by 8 weeks.
  - Optimal duration of therapy has not been determined, but beneficial effects on BPH appear to persist for 6 months or more after discontinuation.
- Progestins have multiple antiandro-genic mechanisms of action:
  - Contraindicated in dogs with diabetes mellitus

- Medroxyprogesterone, 3 mg/kg SQ once. Clinical signs of BPH relieved for 10-24 months in ≈84% of dogs.
- Delmadinone (Tardak [Pfizer]), 1.5 mg/kg IM or SQ on days 0 and 8. Remission of clinical signs of BPH for 6 months in ≈83% of dogs.
- Osaterone (Ypozane, Virbac), 2.5 mg/kg PO q 24 h for 7 days. Remission of clinical signs of BPH for 6 months in ≈83% of dogs.

NUTRITION/DIET

An herbal remedy from the saw palmetto plant *(Serenoa repens)* was suggested for use in men with BPH. It has no significant effect on the canine prostate.

DRUG INTERACTIONS

- Anticholinergic drugs may precipitate urine retention in BPH.
- Aminoglutethimide, felbamate and rifampin may interfere with progestins.

POSSIBLE COMPLICATIONS

- Adrenal axis suppression, insulin resistance and diabetes mellitus, increased appetite with progestins
- Alopecia and change in coat color may occur at injection site of medroxyprogesterone.
- Decreased fertility (semen quality, libido, and testicular size) with any antiandrogen
- Antiandrogens must not be used in sexually immature animals.

RECOMMENDED MONITORING

If castration is not performed, watchful waiting is recommended. Following castration for testicular tumor, submit for histopathologic analysis to confirm Sertoli cell tumor. Monitor CBC if bone marrow suppression, and treat accordingly.

PROGNOSIS AND OUTCOME

- Excellent for BPH and intraprostatic cysts:
  - Dogs not showing clinical signs may remain so for months to years.
  - Castration is curative of clinical signs of BPH, and cysts decrease in size.
- Pharmacologic therapy will temporarily improve clinical signs, but signs eventually (usually many months later) recur after treatment ends.

PEARLS & CONSIDERATIONS

COMMENTS

- Unlike the situation in men, BPH in dogs rarely causes stranguria or urine retention. When canine prostatic disease causes those signs or urethral involvement, it is more likely due to neoplasia than to BPH.
- Prostatomegaly in a castrated dog should prompt a search for neoplasia, not BPH.
- Dogs with BPH are usually otherwise healthy. If the dog is ill, a diagnosis other than or in addition to BPH should be pursued.

PREVENTION

Castration of juvenile dogs prevents BPH, intraprostatic cysts, and testicular tumors.

TECHNICIAN TIPS

- Care should be taken to avoid the enlarged prostate during urine collection by cystocentesis.
- Adequate restraint and analgesia (usually sedation or anesthesia) are needed to safely perform fine-needle aspiration or percutaneous biopsy of the prostate.

CLIENT EDUCATION

- Treatment may be delayed until clinical signs develop in otherwise healthy, normal, intact dogs with asymptomatic BPH or intraprostatic cysts.
- Castration is the treatment of choice because it is curative for BPH.

- Medical management can be done, but clinical signs will recur sometime (often many months later) after treatment is discontinued.
- The medications used for treating BPH are teratogenic, FDA category X. Women who might be pregnant must not handle the drugs.

Proptosis of the Globe

BASIC INFORMATION

DEFINITION

Forward displacement of the globe (exophthalmos), with posterior entrapment of eyelids

EPIDEMIOLOGY

GENETICS & BREED PREDISPOSITION

Brachycephalic breeds of dogs and cats are at higher risk; however, if traumatic forces are sufficient, proptosis can occur in any breed of either species.

RISK FACTORS

Traumatic forces to the head (mild for brachycephalic; moderate to severe for mesaticephalic and dolichocephalic breeds)

ASSOCIATED CONDITIONS & DISORDERS

Retrobulbar mass or severe orbital abscess or cellulitis (see p. 790) may predispose the eye to proptosis.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Caused by peracute event, usually blunt head trauma (e.g., hit by car, fighting)

PHYSICAL EXAM FINDINGS

Exophthalmos with eyelids entrapped caudal to globe. Any or all of the following may also be present:

- Conjunctival hyperemia or hemorrhage
- Corneal ulceration (see p. 250)
- Abnormal pupil size: constricted or dilated
- Intraocular inflammation and/or hemorrhage (seepp. 1151 and 571)
- Ruptured globe
- Avulsion of extraocular muscle(s), mainly medial and/or ventral oblique recti muscles
- Optic nerve rupture/transection
- Orbital fractures
- Other fractures: facial or appendicular skeleton
- Neurologic deficits from brain trauma
- Hypovolemic shock
- Intrathoracic abnormalities: diaphragmatic hernia, pulmonary contusions, hemothorax, pneumothorax

ETIOLOGY AND PATHOPHYSIOLOGY

- Force(s) applied to the head (i.e., trauma), leading to rostral displacement of the globe and posterior entrapment of eyelids.
- The orbit encircles a lesser proportion of the globe (i.e., is shallower) in brachycephalic individuals, allowing proptosis to occur despite a comparatively milder force of trauma.
- The medial rectus is the first extraocular muscle to avulse during trauma, leading to lateral strabismus. Multiple extraocular muscle avulsions produce a greater degree of proptosis, which indicates a worse prognosis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

History and physical exam provide the diagnosis. Additional evaluation is directed at assessing vision and identification of trauma to the rest of the body.

DIFFERENTIAL DIAGNOSIS

- Exophthalmos secondary to orbital abscess (opening mouth may cause pain), benign or malignant orbital mass (opening mouth is rarely painful), congenital vascular anomalies (opening mouth is rarely painful; forward displacement of globe, but eyelids are in a normal position; rarely peracute; see p. 790).
- Buphthalmos secondary to congenital, primary, or secondary glaucoma (enlarged globe; eyelids in normal position; rarely acute). Unlike proptosis, is not associated with a blunt traumatic event (see p. 778).

INITIAL DATABASE

- Complete physical examination
- Ophthalmic examination (see p. 1313), including:
  - Pupillary light reflexes; a dilated, unresponsive pupil (both direct and consensual) carries a poor prognosis for the eye because optic nerve avulsion or transection is likely.
  - Fluorescein dye application
  - Intraocular pressure (IOP: >30 mm Hg with glaucoma; low [<10-15 mm Hg] with uveitis). IOP measurement should only be performed after the globe has been replaced in the orbit, thus releasing the pressure of the eyelids on the globe.
- Chest radiographs if hit by car, signs of trauma beyond the face, and/or dyspneic
- Skull radiographs if suspect orbital and/or skull fractures (e.g., extensive facial/cranial trauma, bony crepitus, and neurologic compromise such as obtundation).

TREATMENT

THEATMENT OVERVIEW

Although the primary goal is to return the globe to its proper anatomic location, enucleation may be preferable if grave prognostic indicators for vision are present.

ACUTE GENERAL TREATMENT

- Hemodynamic, respiratory, and neurologic stabilization if severe trauma (see pp. 1565,1592 , and1561)
- Keep cornea lubricated. If surgical correction is not immediately possible (e.g., grave anesthetic risk), hourly topical ointment application (alternating between bacitracin-neomycin-polymyxin antibiotic q 2 h and sterile lubricant q 2 h) is recommended.
- Placement of an Elizabethan collar to prevent self-inflicted trauma
- Repositioning of the globe, with patient under general anesthesia:
  - Lateral canthotomy: 1-2 cm incision at the lateral canthus to relieve pressure on the eyelids
  - Eyelids replaced over globe
  - Two to three horizontal mattress sutures exiting meibomian gland openings (4-0 to 6-0 suture material)
  - Segments of Penrose drain or IV tubing stents to distribute tension evenly on upper and lower eyelids
  - Simple interrupted sutures to close lateral canthotomy
  - Removal of medial-most sutures in 1-2 weeks and lateral-most sutures in 2-3 weeks, depending on resolution of exophthalmos
  - Vision, tear production, cornea, and intraocular structures (i.e., lens, retina) assessment within 1-2 weeks following surgery
- Enucleation if globe is ruptured, optic nerve is transected, and/or three or more extraocular muscles are avulsed

CHRONIC TREATMENT

- Topical atropine in medial canthus q 12 h for 3 to 5 days
- Topical triple antibiotic ointment q 6 h for 2 weeks
- Nonsteroidal antiinflammatory drugs (NSAIDs) systemically for 5-7 days. Dogs: carprofen, 2.2 mg/kg PO q 12 h or meloxicam, 0.1 mg/kg PO q 24 h. Cats: tolfenamic acid, 4 mg/kg SQ, IM, or PO q 24 h for 3-5 days.
- Broad-spectrum systemic antibiotics for 5-7 days (e.g., cephalexin, 10-20 mg/kg PO q 8 h)
- Placement of an Elizabethan collar until suture removal
- After repositioning and healing of the globe (days/weeks later), enucleation is sometimes still necessary if:
  - Eye is blind and painful (e.g., chronic uveitis, glaucoma)
  - Glaucoma occurs, especially in cats, owing to risk of posttraumatic ocular sarcoma (see p. 620)

POSSIBLE COMPLICATIONS

- Glaucoma
- Uveitis
- Strabismus (frequently lateral or dorso-lateral due to avulsion of medial rectus or medial and ventral oblique recti muscles, respectively; see p. 790)
- Blindness with mydriasis
- Keratoconjunctivitis sicca (KCS)
- Neurotrophic keratitis (damage to ophthalmic branch of trigeminal nerve supplying cornea, such as in corneal denervation) with chronic corneal ulceration

RECOMMENDED MONITORING

Recheck suture placement 24-48 hours postoperatively, since eyelid swelling could have dramatically improved, thereby causing loosening of sutures.

PROGNOSIS AND OUTCOME

- Varies depending on the extent of trauma (e.g., diffuse hyphema is a poor prognosticator).
- Most proptosed eyes with mild trauma can be salvaged.
- Overall prognosis for vision varies:
  - Poor to grave (dolichocephalic breeds and cats; dilated unresponsive pupil; marked proptosis [globe displaced several centimeters rostral to the l orbit])
  - Guarded to good (brachycephalic l breeds)

PEARLS & CONSIDERATIONS

COMMENTS

- True ocular emergency
- Avoid using topical corticosteroids (corneal ulceration is common).
- A blind comfortable eye can remain and have an excellent cosmetic appearance for the pet.

TECHNICIAN TIP

In the postoperative stage, avoid excessive pressure around the neck to avoid reproptosis (e.g., use harness instead of collar).

PREVENTION

Permanent partial tarsonhaphy (surgery to shorten palpebrai fissure [length of eyelid opening]) in brachycephalic breeds of dogs

CLIENT EDUCATION

- If globe is replaced but remains blind and painful in the postoperative stage, enucleation or evisceration with intraocular prosthesis is warranted.
- Early enucleation of blind and painful eyes in cats to prevent posttraumatic ocular sarcoma

Prolonged Estrus

BASIC INFORMATION

DEFINITION

- In the dog, a combined proestrus and estrus of >6 weeks or a Cytologie estrus that lasts for >21 days
- In the queen, estrus lasting longer than 10 days is considered prolonged.
- *Ovarian remnant syndrome* (ORS) refers to clinical signs indicating presence of functional ovarian tissue in a previously ovariohysterectomized bitch or queen.

SYNONYMS

Persistent estrus (heat), nymphomania

EPIDEMIOLOGY

SPECIES, AGE, SEX: Female dogs and cats >4 months of age.

GENETICS & BREED PREDISPOSITION: Oriental cat breeds (e.g., Siamese) are predisposed to overlapping follicular waves that may present as prolonged or persistent estrus.

RISK FACTORS: Young and very old bitches; previous history of follicular cysts; abnormal karyotype

ASSOCIATED CONDITIONS & DISORDERS: Secondary to chronic estrogen exposure, bone marrow suppression, uterine disease, and mammary disease may occur.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- More than 21 days (dog) or 10 days (cat) of behavioral estrus
- Estrous behaviors in the bitch include receptivity to males, vulvar edema, and serosanguineous vaginal discharge; and in the queen, lordosis and vocalization.
- Recent use of estradiol cypionate as an abortifacient for unintended breedings is sometimes reported although not recommended.
- Use of estradiol supplements to treat urinary incontinence may be reported in the history.

PHYSICAL EXAM FINDINGS

- Bitch or queen may be in good health.
- Chronic exposure to estrogen can result in disease states manifesting as cystic endometrial hyperplasiapyometra complex, bone marrow suppression (anemia, agranulocytosis, thrombocytopenia), mammary and uterine neoplasia, and endocrinologic alopecia.
- Palpable unilateral abdominal mass (ovarian tumor)
- The most common presentation of ORS is recurrent estrus (e.g., vulvar swelling, flagging, standing to be mounted) after ovariohysterectomy.

ETIOLOGY AND PATHOPHYSIOLOGY

Prolonged estrus:

- Etiology depends on source of persistently circulating estradiol (exogenous or endogenous).
- Estrogen-secreting follicular cysts or granulosa cell tumors can result in persistent estrus.
    - Follicular cysts have been reported to occur in 3%-62% of dogs with ovarian cystic disorders. These cysts occur as either single or multiple thin-walled structures that contain a clear, serous fluid.
- In the queen, persistent estrus may result from the overlapping waves of maturing ovarian follicles, resulting in prolonged high concentrations of estradiol.

Recurrent estrus after ovariohysterectomy:

- Failure to remove all ovarian tissue at the time of ovariohysterectomy can result in recurring estrous cycles.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on the presence of estrous behaviors in an ovariohysterectomized animal or prolonged in an intact bitch or queen. Confirmation requires identification of the source of estradiol (exogenous or endogenous) and functional ovarian tissue.

DIFFERENTIAL DIAGNOSIS

- Persistent proestrus
- Split estrus (proestrus without subsequent estrus followed by a normal cycle in about 4 weeks)
- Recurrent estrus (low progesterone or premature luteal failure)
- Pyometra
- Vaginitis
- Coagulopathy
- Ovarian remnant syndrome

INITIAL DATABASE

- CBC (anemia, thrombocytopenia), serum biochemistry profile, urinalysis
- Exfoliative vaginal cytologic examination indicative of estrus: >90% cornification of epithelial cells
- Abdominal ultrasonography to look for endogenous sources of estradiol:
    - Identification of abnormal ovarian structures: anechoic spherical regions in the ovary (follicles) or mixed echogenicity of a tumor
    - Identification of ovarian remnant in an ovariohysterectomized animal

ADVANCED OR CONFIRMATORY TESTING

- Vaginoscopy to rule out foreign body and vaginitis
- Exclusion of abnormal karyotype
- Coagulation panel to rule out coagulopathy
- LH testing (using an in-house kit) is 99% reliable at diagnosing ORS in both cats and dogs.

TREATMENT

TREATMENT OVERVIEW

Treatment of abnormal estrus consists of removing the source of estradiol. For persistent estrus, induction of follicular luteinization, with subsequent monitoring of progesterone concentrations and vaginal cytology for signs of diestrus, or alternatively performing an ovariohysterectomy. For ORS, surgically remove any remaining ovarian tissue.

ACUTE GENERAL TREATMENT

Medical:

- Follicular cysts in dogs and cats may be treated with gonadotropin-releasing hormone (GnRH, 25 mcg IM; use 2.2 mcg/kg if >11 kg) or human chorionic gonadotropin (hCG, 500-1000 IU IM), which results in luteinization of the follicles.
- Monitor serum progesterone, and perform a vaginal cytologic examination weekly following GnRH or hCG administration; monitor for signs of diestrus or anestrus.
- Canine GnRH vaccine can be used in the treatment of ORS where surgical removal of the remnant is not an option.

Surgical:

- When genetic qualities of the dam are not superior, ovariohysterectomy is the treatment of choice following reduction of current hyperestrogenic state.
- Removal of remaining ovarian tissue is the recommended treatment for ORS.

CHRONIC TREATMENT

If acute medical treatment is not effective, surgical treatment is required.

POSSIBLE COMPLICATIONS

- Pyometra sequelae:
  - Progesterone promotes endometrial growth and glandular secretion while decreasing myometrial activity. Cystic endometrial hyperplasia and accumulation of uterine secretions ultimately develop and provide an excellent environment for bacterial growth.
  - Chronic estradiol production by the cystic follicles upregulates progesterone receptors in the uterus. This enhances the effect of the progestins produced following treatment to luteinize the cystic follicles.
- Complication rate for surgical removal of an ovarian remnant in dogs is unknown.

RECOMMENDED MONITORING

Monitor signs of estrus that should subside within 5-7 days of treatment.

PROGNOSIS AND OUTCOME

- Recurrence is possible, but prognosis is good if signs of diestrus follow treatment.
- If estrus persists, increased suspicion of neoplasia or abnormal karyotype yields a poorer prognosis for subsequent fertility, and an ovariohysterectomy is indicated.
- Surgical removal of ovarian remnants results in a good prognosis if signs of cycling cease.

PEARLS & CONSIDERATIONS

COMMENTS

- Although ovarian cancer is rare in the bitch or queen, failure of medical treatment to end signs of behavioral estrus or decrease circulating estradiol concentrations greatly increases the possibility of this diagnosis.
- Timing of exploratory surgery to remove ovarian remnants is important: surgery should be performed when the animal is under an estrogenic influence so ovarian tissue is enlarged and easier to identify.

PREVENTION

In animals of nonbreeding stock, complete ovariohysterectomy will prevent reproductive abnormalities and their sequelae.

CLIENT EDUCATION

- Train owners to recognize signs of estrus, or discuss outward signs of behavioral estrus for the bitch and queen.
- Clinicians and owners should discuss multiple benefits of spaying nonbreeding stock while young.
- Recurrence is more likely in animals with previous follicular cysts.

AUTHOR: TIMOTHY HAZZARD

EDITOR: MICHELLE KUTZLER

Prolonged Anestrus

BASIC INFORMATION

DEFINITION

Duration of interestrous interval >40 weeks. Overall, a rare disorder.

SYNONYMS

Primary or secondary anestrus; prolonged interestrous interval

EPIDEMIOLOGY

SPECIES, AGE, SEX

Female dogs and cats

- Bitches > 12 months old (more common in older bitches)
- Queens > 6 months old

GENETICS & BREED PREDISPOSITION: Longhaired queens have a tendency to experience delayed puberty.

RISK FACTORS: Previous ovariectomy, exogenous hormonal treatment (including glucocorticoids), hyperthyroidism, ovarian disease (cysts or neoplasia), or abnormal karyotype

GEOGRAPHY AND SEASONALITY

- Bitches are nonseasonally monoestrous (exception: basenji dog that only comes into estrus in the fall). The normal interestrous interval in dogs is 26-36 weeks.
- The queen is a seasonally polyestrous long-day breeder (see p. 909). The normal interestrous interval in queens is 12-22 days.

ASSOCIATED CONDITIONS & DISORDERS

Ambiguous or infantile external genitalia may be associated with an intersex condition or abnormal karyotype.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Primary anestrus: delayed puberty
- Secondary anestrus: increased interestrous interval

HISTORY, CHIEF COMPLAINT

Failure to show external signs of proestrus or estrus (failure to cycle)

PHYSICAL EXAM FINDINGS

Abnormal physical findings may include poor or excessive general body condition, overall immature appearance, and ambiguous or infantile external genitalia. The physical examination may be unremarkable.

ETIOLOGY AND PATHOPHYSIOLOGY

- Variable, depending on the cause
- Disruption in the normal cyclical hormonal milieu

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on the absence of estrous behaviors in an intact animal, followed by excluding anatomic abnormalities and endocrine-related illnesses. Confirmation requires histopathologic identification of oophoritis or diagnostic imaging (CT scan) demonstrating pituitary abnormalities.

DIFFERENTIAL DIAGNOSIS

Dogs:

- Silent heat
- Abnormalities in sexual differentiation
- Hyperadrenocorticism
- Hypothyroidism
- Pituitary insufficiency
- Lymphocytic oophoritis
- Luteal ovarian cyst
- Ovarian aplasia
- Ovariohysterectomy

Cats:

- Seasonal or lighting changes
- Pseudopregnancy
- Diabetes mellitus
- Silent heat (social stress in cattery)
- Ovariohysterectomy

INITIAL DATABASE

- CBC and serum biochemistry profile for systemic health status
- Assessment of endocrine-related illnesses via thyroid hormone analysis and dexamethasone suppression tests
- Exclusion of silent heats, using exfoliative vaginal cytologic examination and serum progesterone determination
- Exclusion of abnormal reproductive tract, using abdominal ultrasonography
- Exclusion of abnormal karyotype

ADVANCED OR CONFIRMATORY TESTING

- Confirmation of oophoritis with ovarian histologic examination
- CT scan of pituitary to identify cystic dilation or absence of the gland

TREATMENT

TREATMENT OVERVIEW

Treatment mainly consists of correcting insufficiencies or excesses in endocrine hormones (e.g., hyperadrenocorticism), as well as observation and monitoring for reproductive cyclicity.

ACUTE GENERAL TREATMENT

- Observe bitch or queen closely while housing her near an intact male dog or tom.
- Monitor serum progesterone concentrations monthly to assess cyclicity (serum progesterone >2 ng/mL for 2 months after each estrus in the normal bitch).
- Cohouse anestrous bitch with cycling bitches to stimulate a “dormitory” effect.
- Increase lighting in cattery to 14 hours of light per day.

CHRONIC TREATMENT

Estrus induction: no approved methods of estrus induction in the dog or cat, but many protocols have been described. Possible methods:

- Dogs: after confirming a progesterone concentration <1 ng/mL, administer 1 Ovuplant (deslorelin implant) under the subvestibular mucosa. Proestrus will be initiated in <10 days.
- Cats: after one subcutaneous injection of human chorionic gonadotropin (hCG, 1000 IU), naloxone (0.04 mg/kg) in 20% calcium gluconate solution is administered intramuscularly once a day beginning the day of the hCG injection. A compounded solution can be made by adding naloxone powder to 20% calcium gluconate solution to achieve a final concentration of 0.4 mg/mL naloxone for a dose of 0.1 mL/kg. Proestrus will be initiated in <8 days.

POSSIBLE COMPLICATIONS

Continued release of deslorelin from the Ovuplant implant may result in pituitary downregulation and premature luteal failure. To prevent premature luteal failure, remove the implant once serum progesterone concentration is >2 ng/mL.

RECOMMENDED MONITORING

- Initially, progesterone concentrations should be measured to determine time for implant removal.
- Monitor the bitch and queen for signs of behavioral or physical estrus.

PROGNOSIS AND OUTCOME

- With correction of endocrine abnormalities, future reproductive success is not compromised.
- If chromosomal abnormality, ovarian aplasia, or autoimmune disease exists, the prognosis for successful return to cyclicity is poor.

PEARLS & CONSIDERATIONS

COMMENTS

Evaluation of the entire clinical picture is important:

- Review estrus identification techniques with owner.
- Identify all medications and supplements the animal is receiving.
- Assess the animal's overall metabolic health status.
- Evaluate thyroid and adrenal gland function in bitches.

PREVENTION

In cats, ensure 14 hours of light exposure daily to induce seasonal cycles.

CLIENT EDUCATION

- Provide training for the client so he or she can recognize estrus in the animal, or discuss outward signs of estrus for the bitch and queen.
- Discuss age as a factor for the absence of cyclicity (prepubertal, photoperiod, and older animals).

Primary Ciliary Dyskinesia

BASIC INFORMATION

DEFINITION

A rare congenital disorder in which defective ciliary motility leads to impaired mucociliary transport and recurrent respiratory infection

SYNONYMS

Immotile cilia syndrome, Kartagener's syndrome, PCD

EPIDEMIOLOGY

SPECIES, AGE, SEX: Young dogs of either sex

GENETICS & BREED PREDISPOSITION: Numerous breeds of dogs are affected with primary ciliary dyskinesia (PCD); a monogenic autosomal recessive pattern of inheritance has been demonstrated in Newfoundland dogs and is likely to be present in other breeds as well.

ASSOCIATED CONDITIONS & DISORDERS

- Rhinitis, sinusitis, and pneumonia occur as a result of PCD.
- Bronchiectasis results from repeated airway infections.
- Defective ciliary function in other organs may lead to male infertility, hydrocephalus, or otitis media.
- Situs inversus (mirror-image reversal of the position of organs in the body), bronchiectasis, and PCD define Kartagener's syndrome, seen in a subset of animals.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Young dogs present with signs of recurrent upper and/or lower respiratory tract infection. Nasal discharge, sneeze, and cough are common features, while dyspnea occurs less frequently. Infections often improve dramatically with antibiotic treatment but recur after cessation of antibiotics.

PHYSICAL EXAM FINDINGS

- Bilateral mucopurulent nasal discharge
- Sneezing
- Coughing
- Dyspnea with crackles when pneumonia is present
- Fever possible when pneumonia is present

ETIOLOGY AND PATHOPHYSIOLOGY

- The mucociliary escalator is a major contributor to physical defense of the airways.
- Pathogens and particulates are normally trapped in a layer of mucus overlying the ciliated epithelium.
- Synchronized movement of the cilia propels entrapped pathogens and particles orad for removal from the airways.
- In animals with PCD, structural and/or functional defects in the cilia themselves lead to uncoordinated, asynchronous ciliary motion and ineffective clearance of pathogens and particles trapped in the mucus layer.
- Failure of the mucociliary escalator results in recurrent bacterial infection of the airways.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Secondary (acquired) ciliary dyskinesia

- Primary respiratory infections/inflammatory airway disease
- Inhalation of toxic substances (e.g., smoke)

- Noninfectious respiratory inflammatory disease (e.g. lymphoplasmacytic rhinitis, eosinophilic bronchopneumopathy)
- Congenital immunodeficiency syndromes
- Chronic bacterial or fungal respiratory infections, either treated inappropriately or from infection with atypical pathogens

INITIAL DATABASE

- CBC:
  - Neutrophilic leukocytosis possible if pneumonia is present
- Serum biochemistry: nonspecific
- Thoracic radiographs:
  - Alveolar, bronchiolar, and/or interstitial lung patterns may be observed.
  - Bronchiectasis
  - Situs inversus is detected in some dogs (apex of the heart points to the right; lung anatomy is reversed on the median plane) and is strongly suggestive of PCD.

ADVANCED OR CONFIRMATORY TESTING

- Semen evaluation: abnormal motility of spermatozoa
- Tracheal wash or bronchoalveolar lavage: neutrophilic inflammation, often with intracellular bacteria; samples should be cultured.
- Nuclear scintigraphy: technetium-99 macroaggregated albumin is deposited at the carina, and movement is followed with a gamma camera for 30 minutes. Isotope fails to move orad in dogs with congenital or acquired ciliary dysfunction.
- Electron microscopy: ultrastructural defects can be detected on glutaraldehyde-fixed biopsies of nasal or tracheal mucosa, but detection is technically demanding. Thus, samples should be sent to a pathologist with experience in interpreting these biopsies. Alternatively, ciliated epithelium may be cultured in vitro and resultant tissues examined by electron microscopy.
- Ciliary beat frequency and synchronization: technically demanding process requiring special equipment; allows functional observation of cilia from freshly obtained biopsies; impractical in most instances.

TREATMENT

TREATMENT OVERVIEW

Affected animals typically require repeated courses of antimicrobials throughout life to control infection, as there is no treatment for the primary disease.

ACUTE GENERAL TREATMENT

- Appropriate antimicrobial therapy, based ideally on culture and sensitivity (C&S) results from tracheal or bronchial lavage samples
- For dogs with pneumonia:
  - Consider oxygen supplementation if respiratory distress is present in the face of hypoxemia (Pao2 < 80 mm Hg or SpO2 < 94%). See p. 1318.
  - Maintain hydration with parenteral fluids as needed.
  - Encourage expectoration of mucus from airways via saline nebulization and coupage (see p. 1310).

CHRONIC TREATMENT

- Repeated courses of antimicrobial drugs are required for recurrent infections.
- Avoid treatment with cough suppressants.
- Avoid exposure to respiratory irritants, such as cigarette smoke.

POSSIBLE COMPLICATIONS

- Bronchiectasis
- Pneumonia
- Sepsis
- Cor pulmonale
- Reactive systemic amyloidosis

RECOMMENDED MONITORING

- Evaluate thoracic radiographs at least every 6-9 months in animals with prior episodes of pneumonia.
- Exacerbations of clinical signs due to lower respiratory disease should prompt tracheal or bronchial lavage for cytologic examination and culture.
- Culture and sensitivity testing of respiratory washes becomes increasingly important the more often an affected animal has been treated with antimicrobials.

PROGNOSIS AND OUTCOME

Dependent on severity of ciliary dysfunction. Illness can range from occasional episodes of upper respiratory infection to severe and frequent bronchopneumonia. Lifespan is usually negatively impacted by the condition.

PEARLS & CONSIDERATIONS

COMMENTS

Even when episodes of pneumonia are rapidly addressed, affected dogs are often euthanized because of the inconvenience and expense of treating recurrent respiratory disease and chronic nasal discharge despite appropriate antimicrobial therapy; these treatments may be a nuisance for owners of affected dogs.

PREVENTION

Affected dogs should not be bred.

TECHNICIAN TIPS

Label thoracic radiographs, especially the ventrodorsal or dorsoventral projections, with right or left markers to help confirm the radiographic diagnosis of situs inversus.

CLIENT EDUCATION

Clients should understand that this is an inherited condition that cannot be cured.

AUTHOR: LEAH A. COHN

EDITOR: RANCE K. SELLON

Priapism

BASIC INFORMATION

DEFINITION

Persistent penile erection (uncommon disorder)

SYNONYM

Persistent erection

EPIDEMIOLOGY

SPECIES, AGE, SEX: Male dog or cat

GENETICS & BREED PREDISPOSITION: None reported

RISK FACTORS: Reproductive status: intact males are more likely than neutered males to develop priapism secondary to trauma.

ASSOCIATED CONDITIONS & DISORDERS

- Neurologic disorder (e.g. spinal cord injury, distemper encephalomyelitis)
- Circulatory disturbance (e.g. hemoglobinopathy)
- Penile neoplasia
- Achalasia

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Traumatic: during mating or castration
- Nontraumatic: priapism results from disturbances in the normal mechanisms of penile flaccidity (not sexual stimuli).
    - Neurologic: spinal cord injuries (trauma), inflammation (genitourinary, spinal cord [distemper]), mechanical compression (constipation) or pharmacologic (acepromazine-induced priapism [dogs, cats]), leading to the stimulation of the erection center or the pelvic nerve
    - Circulatory: occlusive penile thromboembolism that decreases venous outflow; occlusive pelvic mass (tumor, abscess) impairing glans penis venous drainage; secondary to systemic disease (e.g. hemoglobinopathy)

HISTORY, CHIEF COMPLAINT: Persistent erection or inability to withdraw erect penis into prepuce

PHYSICAL EXAM FINDINGS

- Persistent, usually painful, erection lasting >1 hour
- Bulbus glandis may be within or outside the prepuce.
- Penile mucosa may be dry, inflamed, excoriated and is often purple (blood stasis). Eventually, the penis will become necrotic. The male frequently licks the penis and self-mutilation may occur.
- An enlarged (or ruptured) bladder is possible if urethral obstruction is present.

PRIAPISM Priapism in a 7-year-old male boxer; ventral aspect of inguinal region, cranial is to the left. This penis had been persistently erect for 7 days. Penile mucosal erosion and congestion were evident as well as periscrotal edema.

(Used with permission from Martins-Bessa A, Santos T, Machado J, et al: Priapism secondary to perineal abscess in a dog: a case report. Reprod Domest Anim 45:558-563, 2010. Published online Dec 2008, DOI: 10.1111/j/1438-0531.2008.01257.x.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Alteration of penile blood, causing vascular stasis in the corpus cavernosum and spongiosum
- Sluggish, damaged erythrocytes occlude venous outflow.
- Erythrocyte stagnation triggers carbon dioxide release, trabecular edema.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is made entirely on physical examination. Diagnostic tests aim to identify the cause; test selection is based on other features of the history and general physical exam.

DIFFERENTIAL DIAGNOSIS

- Normal erection
- Paraphimosis (see p. 835) without priapism
- Penile paralysis

INITIAL DATABASE

- Examination and palpation will confirm whether the penis is firm (persistently erect) or flaccid (as in the case of paraphimosis without priapism).
- Observation of urination or urethral catheterization to confirm that the urethra is not obstructed
- Neurologic examination to determine if any other neurologic deficits are present
- CBC if suspicious of hemoglobinopathy

ADVANCED OR CONFIRMATORY TESTING

- Serum chemistry panel and urinalysis if patency of the urethra and integrity of the bladder is questioned
- A penile cavernogram can be used for identifying thromboemboli or masses and the extent of venous outflow impairment
    - Dynamic cavernosography consists of infusing heparinized saline at increasing rates (3-25 mL/min) until the intracavernous pressure plateaus at full erection pressure, followed by infusing 60% Hypaque meglumine contrast medium to opacity abnormally draining veins.
    - Butterfly needles (21-G) can be inserted into the corpora cavernosa and connected to a pressure transducer.
- Angiography can also be used for identifying abnormal circulatory patterns.

TREATMENT

TREATMENT OVERVIEW

The goal of priapism therapy is to achieve detumescence and restore normal circulation in the penile erectile tissues. Treatment aims to preserve the penis from severe exposure and constrictive injury, and prevent urethral obstruction. A prompt diagnosis of the underlying cause is essential for optimal treatment, though the underlying cause may not be identifiable in many cases.

ACUTE GENERAL TREATMENT

- Conservative treatment: cool hypertonic compresses several times daily; topical lubrication; systemic corticosteroids at antiinflammatory doses (e.g., prednisone, 1 mg/kg PO q 12 h × 5 days), antibiotics, and diuretics. Generally unsuccessful.
- Manual reduction of the penis into the prepuce (with or without incisional preputioplasty) is unrewarding or impossible.
- Medical treatment with intravenous benztropine mesylate (0.015 mg/kg), an anticholinergic and antihistaminergic drug, has been used successfully in horses but must be administered within 6 hours after the onset of priapism.
- Increasing venous outflow via drainage and flushing of the erectile tissues to remove the clotted blood with heparinized saline (0.9% NaCl) solution in combination with infusion of phenylephrine, norepinephrine, or epinephrine (successful in humans and horses; must be applied soon after onset)
- Surgery: tunica albuginea incision (includes incision of the bulbus glandis and pars long glandis) is usually successful without permanent damage; must be performed within 12 hours of onset.

CHRONIC TREATMENT

If the penis is irreparably damaged or urethral patency cannot be maintained, penile amputation with a prescrotal urethrostomy (and castration if still intact) are necessary.

RECOMMENDED MONITORING

- Urination should be closely monitored and a catheter placed if stranguria develops.
- If severe penile necrosis develops, the penis should be amputated.

PROGNOSIS AND OUTCOME

If priapism is treated aggressively, the prognosis is guarded, but aggressive acute treatment may prevent the necessity for penile amputation.

PEARLS & CONSIDERATIONS

COMMENTS

Priapism is an emergency condition requiring aggressive acute treatment to induce detumescence.

PREVENTION

Care should be taken during surgical castration to avoid the stimulating pelvic nerves, which could result in priapism.

CLIENT EDUCATION

Breeders should confirm that detumescence occurs after each breeding and contact their veterinarian if an erection persists for more than 1 hour.

SUGGESTED READING

Johnston SD, Root Kustritz MV, Olson PNS: Disorders of the canine penis and prepuce. In Canine and feline theriogenology, Philadelphia, 2001, WB Saunders Company, pp 356–367.

AUTHOR AND EDITOR: MICHELLE KUTZLER

Preputial Discharge

BASIC INFORMATION

DEFINITION

Common disorder consisting of the presence of normal or abnormal secretions emerging from the penile sheath (prepuce). Discharge can be physiologic or pathologic and either primary or secondary to other reproductive or systemic diseases.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Canine; prepubertal or adult
- Normal males, males with preputial abnormalities or with preputial tumors, male pseudohermaphrodites

GENETICS & BREED PREDISPOSITION: Prevalence is higher in inbred lines or certain breeds (i.e., brachycephalic).

RISK FACTORS

- Acquired or congenital penile anatomic abnormalities
- Acquired or iatrogenic hormonal imbalances
- Poor hygiene/kennel management
- Transmissible venereal tumor (sticker sarcoma)
- Canine herpesvirus type 1 or *Brucella canis* infection
- Prostatic disease
- Anticoagulant rodenticide exposure
- Foreign body (e.g., grass awn)

CONTAGION & ZOONOSIS

Preputial discharge may be contagious if caused by canine herpesvirus type 1 (seep. 525), *B. canis* (seep. 162), or transmissible venereal tumor (see p. 162p. 1114).

ASSOCIATED CONDITIONS & DISORDERS

Balanitis (inflammation of the penis), balanoposthitis (inflammation of penis and prepuce), urinary tract infection, prostatic disease

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Preputial discharge of any type (observed by owner)
- Preputial licking
- Preputial discomfort/pain if touched
- Preputial enlargement or lesions observed
- Additional signs depend on underlying disease (e.g., lethargy, pollakiuria, dysuria)

PHYSICAL EXAM FINDINGS

Depending upon cause:

- Preputial anatomic abnormalities
- Preputial or penile lesions
- Pain resulting from inflammation exacerbated during manipulation
- Preputial opening atrophy
- Preputial mucosal vesicles (canine herpesvirus type 1)
- Prominent preputial lymphoid follicles (nonspecific)
- Masses (e.g., cauliflower-like friable lesions in transmissible venereal tumor [TVT])

- Systemic signs (e.g., lethargy, sluggishness, possibly other sites of bleeding) with anticoagulant rodenticide toxicosis

ETIOLOGY AND PATHOPHYSIOLOGY

- Normal preputial discharge: small amount of yellow-white smegma
- Abnormal preputial discharge:
  - Mucoid: hormonal imbalance in prepubertal dogs
  - Purulent: infection, foreign body
  - Hemorrhagic: coagulopathy, trauma, neoplasia, prostatic disease, testicular disease
    - In juvenile dogs, most common causes include:
      - Congenital abnormality
      - Coagulopathy
      - Hormonal imbalance preceding puberty (diagnosis of exclusion for mucoid discharge in juvenile animal)
    - In mature dogs, potential causes include:
      - Chronic congenital abnormality
      - Infectious disease of the external genitalia (canine herpesvirus type 1 or *B. canis*) or urinary tract or iatrogenic origin (improper antibiotic treatment)
      - Systemic or reproductive tract diseases including prostatic disease, trauma, or tumor

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Age allows for discrimination between juvenile or adult forms of preputial discharge. Juvenile forms are generally benign, most often involving hormonal imbalance rather than infection or congenital abnormalities. Adult forms generally are more serious, more often are chronic, and require a diagnostic workup that is more extensive (typically including microbiologic and serologic testing).

DIFFERENTIAL DIAGNOSIS

- Primary: preputial or penile problem:
  - Anatomic abnormality (phimosis or paraphimosis, penile frenulum, adhesion, hypospadias)
  - Trauma (fighting, biting, mating, os penis fracture)
  - Foreign body (e.g., grass awn)
  - Infection (canine herpesvirus type 1, *B. canis,* or abnormal microbiological flora)
  - Neoplasia
- Secondary: other general or reproductive diseases:
  - Prostatic disease
  - Hormonal imbalance (particularly around puberty or associated with Sertoli-cell tumor or hormonal treatments)
  - Urinary tract infection
  - Urethral neoplasm
  - Bladder disease
  - Coagulopathy

INITIAL DATABASE

- Complete preputial examination, including retraction of the prepuce to caudal to the bulbus glandis; may require sedation or anesthesia if painful
- Coagulation profile and platelet count if hemorrhagic preputial discharge
- Preputial swab for culture and cytologic examination:
  - Normal flora: mixed, including *Escherichia coli, Pseudomonas* spp., *Streptococcus* spp., *Pasteurella* spp., *Staphylococcus* spp., *Klebsiella* spp., *Mycoplasma* spp., *Ureaplasma* spp.
  - Antibiotics are not indicated and should not be administered to treat a normal mixed population of preputial bacteria.
  - A heavy growth of a single type of bacteria associated with clinical signs suggests infection.

ADVANCED OR CONFIRMATORY TESTING

- Physical examination of the penis at rest and during erection
- Complete systemic and urogenital exam, including urinalysis, prostatic ultrasonography, semen and prostate fluid analysis, and possibly urethrography if stranguria/pollakiuria
- *Ureaplasma* spp. and *Mycoplasma* spp. culture
  - Both isolated from the prepuce of 60%-85% of normal dogs

- *Mycoplasma* spp. more prevalent (92%-95%) when balanoposthitis is present
- *Ureaplasma* spp. infection associated with infertility

- CBC and serum biochemistry profile if systemic signs of illness are manifested
- Endoscopic examination of prepuce: if foreign body or mass is suspected but not seen otherwise
- Biopsy or cytologic examination of preputial masses

TREATMENT

TREATMENT OVERVIEW

Treatment depends on the cause and may vary from local cleansing and disinfection to surgical removal of any masses or systemic antibiotics.

ACUTE GENERAL TREATMENT

- Varies depending on the origin and the causal agents
- In all cases, excessive discharge should be cleansed by flushing with warm (98°F/38°C) saline.
- Selected examples:
  - Anatomic defects: surgical correction of the abnormality
  - Hormonal imbalance: benign neglect; antibiotic treatment is contraindicated
  - Preputial foreign body: removal

CHRONIC TREATMENT

Chronic cases refractory to basic treatment should be referred to a theriogenologist, particularly if the future reproductive potential is a concern.

BEHAVIOR/EXERCISE

Owners should prevent the dog from licking the prepuce and/or penis.

POSSIBLE COMPLICATIONS

- Primary recurrent and/or chronic infections: urinary tract infections, prostatic disease, and possibly orchitis
- Canine herpesvirus type 1 and *B. canis:* associated with infertility and transmissible to other dogs
- If transmissible venereal tumor is diagnosed, check for the presence of oral and/or respiratory mucosal lesions (licking) and prevent transmission to other dogs.

RECOMMENDED MONITORING

In adult animals, long-term systemic antibiotic treatment is indicated to reduce the risk of complications (e.g., prostatitis, urinary tract infection).

PROGNOSIS AND OUTCOME

Generally good in young animals. Fair to guarded in older animals, depending upon the origin.

PEARLS & CONSIDERATIONS

COMMENTS

- A small amount of yellow-white smegma is normal at the preputial opening of male dogs of any age or neuter status.
- More of an annoyance than a real disease in juvenile animals, except if it is of anatomic origin (defect) or systemic (e.g., coagulopathy).
- Preputial discharges generally resolve spontaneously without treatment in juvenile (prepubertal) dogs.
- Secondary infection is rare except when systemic antibiotics are administered, leading to selection of resistant bacteria.
- Preputial discharges are often of secondary origin in older animals, and identifying the primary cause of the discharge should always be the initial objective after a systematic physical exam of the external genitalia.

PREVENTION

- Often related to prepubertal hormonal imbalance, prevention is impossible.
- As potentially related to canine herpesvirus type 1, *B. canis,* or transmissible venereal tumor, avoiding contact with affected or potentially affected animals is advised.

TECHNICIAN TIPS

- Preputial discharge can be considered normal and of no clinical significance in most dogs except if abundant or associated with clinical signs. Pain can then be a component of the disease and should be considered at the time of examination as well as during the period of treatment.
- Normal preputial discharge in dogs used for reproduction may need to be cleaned away before semen collection, using physiologic saline to avoid possible contamination of the ejaculate.

CLIENT EDUCATION

- The benign nature of normal preputial discharge should be explained to clients. Antimicrobial therapy should never be used without bacterial culture demonstration of pathogens.
- Clients should be informed to call their veterinarian if the discharge is unusual, abundant, or associated with clinical signs including licking or pain.

AUTHORS: JOHN VERSTEGEN, KARINE ONCLIN

EDITOR: MICHELLE A. KUTZLER

Pregnancy

BASIC INFORMATION

DEFINITION

- The period of gestational development within the uterus, beginning at conception and continuing through parturition
- Bitch: gestation length is 65 days from the luteinizing hormone (LH) surge (54-60 days from the first day of diestras and 57-72 days from breeding)
- Queen: gestational length is 64 days from LH surge. Cats are induced ovulators, and the LH surge corresponds to 24 hours following the first breeding date.

SYNONYM

Gestation

EPIDEMIOLOGY

SPECIES, AGE, SEX

Canine and feline: postpubertal intact female (usually >6 months old)

GENETICS & BREED PREDISPOSITION

Fertility and fecundity are heritable traits. Mixed breeds and outcross matings generally result in higher pregnancy rates and larger litter sizes. Litter size is also dependent on maternal size; smaller breeds have fewer offspring/litter.

RISK FACTORS

Intact females exposed to intact males

GEOGRAPHY AND SEASONALITY

- Canine: most domestic breeds cycle twice yearly irrespective of season, with the potential to become pregnant during each estrous cycle. Wolf hybrids cycle annually during the spring (long-day breeders), and basenjis cycle annually during autumn (short-day breeders).
- Feline: domesticated cats are polyestrous, long-day breeders (queening during spring and summer) with seasonal anestrus during the winter months. It is possible for a queen to have multiple litters each year.

ASSOCIATED CONDITIONS & DISORDERS

- Insulin resistance (pregnancy-associated diabetes)
- Pregnancy anemia
- Pyometra
- Hydrops (amnion or allantois)
- Overt false pregnancy/pseudocyesis
- Abortion or early embryonic loss

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Intentional breeding
- Unintentional breeding
- Unexplained weight gain
- Unexplained mammary development and lactation
- Nesting behavior

PHYSICAL EXAM FINDINGS

- Embryonic vesicles or fetuses palpable abdominally:
  - Embryonic vesicles are palpable approximately 25-35 days post LH surge.
  - Fetuses are palpable after approximately 45 days post LH surge.
- Mammary development and lactation usually emerge in the last 2 weeks of pregnancy.

ETIOLOGY AND PATHOPHYSIOLOGY

- Ovulation occurs 48 hours post-LH surge in dogs and 48 hours post breeding in cats.
  - Bitches are most fertile 2-4 days post ovulation (4-6 days post LH surge); however, pregnancy can result from breedings preceding ovulation by as much as 7 days if the sperm survive within the uterine tubes until the ova mature.
- Fertilization occurs in the uterine tube (ampulla-isthmus junction), and the embryos enter the uterus approximately 10-11 days post-LH surge in the bitch (5-6 days post-LH surge in the queen).
- Embryos migrate within the uterus and may implant in the horn ipsilateral or contralateral to ovulation.
- Implantation occurs 15-17 days post-LH surge in the bitch (14-15 days post-LH surge in the queen).
- Pregnancy is progesterone-dependent throughout gestation. Corpora luteal production of progesterone is required for pregnancy maintenance. Prolactin is luteotropic and maintains the corpus luteum during the second half of pregnancy in both dogs and cats.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Transabdominal ultrasound (>20 days post-LH surge) is the most informative method to confirm pregnancy, but it also requires the greatest experience. All methods of diagnosis may result in misdiagnosis if performed too early in gestation and warrant repeat evaluation 1-2 weeks later if a definitive diagnosis cannot be made.

DIFFERENTIAL DIAGNOSIS

- Pyometra
- Mucometra
- Overt false pregnancy/pseudocyesis

INITIAL DATABASE

- Abdominal ultrasound (see figure): Embryonic vesicles can be detected as early as 20 days post-LH surge (16 days post-LH surge in cats). The embryo can be detected after 25 days post-LH surge.
  - False positives (diagnosis of pregnancy in a nonpregnant animal) may result from misinterpretation of early pyometra or mucometra.
  - False negatives (diagnosis of no pregnancy in a pregnant animal) may occur in early pregnancy if the ultrasonographer is inexperienced or if the embryonic vesicle is too small to visualize or obscured by viscera.
  - Fetal viability can be readily assessed by evaluating fetal heart rates after 25 days post-LH surge.
  - Gestational age can be estimated by fetal measurements and presence of fetal structures.
  - Litter size can only be approximated. Accurate counts are especially difficult in late gestation or with large litters.
- Serum relaxin: relaxin is a hormone produced by the placenta and is a confirmatory test of pregnancy after 30 days post-LH surge. A commercially available test is labeled for dogs and has been validated for use in cats.
  - False positives may result when relaxin levels remain elevated after fetal death (up to 2 days) or in cases of large ovarian cysts (queens).
  - False negatives can occur in early pregnancy or in singleton litters that do not generate sufficiently elevated relaxin for detection.
  - Litter size and fetal viability do not correlate well with relaxin concentrations.
- Abdominal radiographs: pregnancy can be diagnosed by visualization of ossified fetal skeletons >45 days post-LH surge.
  - False negatives may occur with small litters if a full colon obscures fetuses.
  - False negatives may occur prior to 45 days post-LH surge.
  - Fetal loss of viability can be evaluated by fetal posture (appearance of disarticulation), bone juxtaposition (especially skull), and intrafetal presence of gas.
  - Litter size is most reliably estimated by radiographs.

PREGNANCY Transabdominal ultrasonogram from a pregnant bitch that illustrates a gestational sac containing a fetus. The body diameter measurement made between the cursors indicates that this fetus is 34 days past the LH surge (31 days before whelping).

(Courtesy Dr. Michelle A. Kutzler.)

ADVANCED OR CONFIRMATORY TESTING

- Serum progesterone levels can be monitored to ascertain if endogenous levels are high enough to maintain pregnancy (>2 ng/mL).
  - May be assessed on bitches diagnosed nonpregnant to rule out luteal insufficiency as the cause (see p. 7)
  - May be run on bitches with high-risk pregnancy to monitor progesterone supplementation therapy
- Uterine monitoring (www.WhelpWise.com) may be required for high-risk pregnancies.

TREATMENT

TREATMENT OVERVIEW

- Intentional, normal pregnancies require no treatment.
- Unintentional, unwanted pregnancies may be terminated (see p. 912).
- High-risk, threatened pregnancies require advanced and continuous monitoring. Many of the therapeutic options are inferred from human medicine, may have no proven efficacy, and may be detrimental to the welfare of the dam or the fetuses.

ACUTE GENERAL TREATMENT

- To halt premature uterine contractions: terbutaline, 0.01-0.03 mg/kg PO or SQ q 8 h. Dosage should be titrated to effect based on uterine monitoring.
  - If terbutaline treatment is required throughout the remainder of pregnancy, it should be discontinued 24 hours prior to due date.
  - Efficacy of oral treatment is disputed in human literature.
  - Safety and efficacy in dogs has not been properly researched.
  - Tachycardia is a common and potentially life-threatening side effect of terbutaline. The effect on fetuses is uncertain.

CHRONIC TREATMENT

- For maintenance of pregnancy when endogenous progesterone levels prematurely fall below 2 ng/mL:
  - Progesterone in oil: 2 mg/kg IM q 72 h. Discontinue 3 days prior to due date.
  - Altrenogest (Regumate): 0.088 mg/kg PO q 24 h. Discontinue 24 hours prior to due date.
- Serum progesterone levels can be used for monitoring endogenous progesterone if altrenogest is used but not if progesterone in oil is used. Altrenogest is a synthetic progestogen that is not reliably measured with standard progesterone assays.

NUTRITION/DIET

- No supplemental nutrition is required during pregnancy if the bitch or queen is receiving high-quality feed. Supplementing calcium during pregnancy may be detrimental to whelping or result in postpartum complications (see pp. 1552 and 332).
- Caloric intake should be increased 1.5-to 3-fold following whelping/queening to sustain the dam's energy requirements during lactation.

BEHAVIOR/EXERCISE

No alteration to normal physical activity is required during pregnancy. Active and athletic dogs may continue normal activity throughout gestation. Obese dogs may be encouraged to increase exercise during pregnancy to improve muscle tone and reduce fat stores (decreasing feed is not recommended for weight loss during pregnancy).

DRUG INTERACTIONS

- Certain drugs may be detrimental to the developing fetuses and should be avoided unless the health of the dam outweighs the risk to the fetus. Consult package inserts for all drugs prior to use.
  - Antifungals (e.g., ketoconazole, griseofulvin)—teratogenic
  - Antibiotics (penicillins and cephalosporins are the antibiotics of choice):
    - Fluoroquinolones (e.g., enrofloxacin)—inhibit cartilage formation
    - Tetracyclines—inhibit dental enamel production
    - Chloramphenicol—suppresses bone marrow
    - Aminoglycosides—may be neurotoxic (gentamicin appears to be safe but should be used with caution and owner consent).
  - Chemotherapeutics—teratogenic or abortifacient
  - Cimetidine—may decrease androgen production, resulting in increased risk of cryptorchidism
  - Glucocorticoids—may cause anasarca or induce abortion
  - Hormone supplementation (e.g., altrenogest, diethylstilbestrol, estradiol benzoate, testosterone)—may affect sexual development
  - NSAIDs (e.g., ketoprofen, aspirin, carprofen)—teratogenesis
  - Opioids (e.g., buprenorphine)—are the analgesics of choice during pregnancy and lactation. However, chronic use has been associated with adverse fetal effects; overdosage may result in the dam's inattention to neonates and accidental smothering.

POSSIBLE COMPLICATIONS

- Dystocia (see p. 329)
- Abortion (see p. 7)
- Early embryonic loss (fetal resorption)

RECOMMENDED MONITORING

- In high risk, threatened pregnancies, serum progesterone levels should be monitored every other day or as needed to confirm that levels are above 2 ng/mL.
- Uterine monitoring (www.WhelpWise.com) may be required for high-risk pregnancies in bitches with a history of premature labor or uterine inertia.

PROGNOSIS AND OUTCOME

Parturition usually occurs without complications.

PEARLS & CONSIDERATIONS

COMMENTS

- Superfecundation: a bitch bred to multiple males can have pups within the same litter that are from different sires. Paternity can be determined for registration by DNA testing.
- Elevated serum progesterone levels do not automatically indicate pregnancy. Progesterone concentrations remain elevated throughout diestrus whether or not pregnancy is established. Progesterone concentrations remain elevated for ≥65 days post-LH surge in the nonpregnant bitch and for 40 days post-LH surge in the nonpregnant queen.

PREVENTION

Preventing unwanted pregnancies: castration of nonbreeding animals and proper supervision of intact animals.

TECHNICIAN TIPS

Pregnant dogs and cats brought to the veterinary clinic for pregnancy diagnosis are generally healthy. Because other patients visiting the veterinary clinic may have contagious diseases detrimental to pregnancy (e.g., herpesvirus, parvovirus, *Leptospira* spp.), it is recommended that bitches or queens presenting for pregnancy diagnosis be escorted out of the public waiting room as soon as possible to await examination in a clean and disinfected exam room.

CLIENT EDUCATION

- Over 4 million unwanted dogs and cats are euthanized annually in humane societies; up to 30% of these are purebred.
- Breeding is recommended to improve the breed standard and is not encouraged “to witness the miracle of birth.”
- “Designer breeds” (e.g., cockapoo, labradoodle) are first-generation crosses of purebred dogs. They do not breed true to their own phenotype and should not be purchased as breeding animals.

Pregnancy Termination

BASIC INFORMATION

DEFINITION

Elective nonsurgical abortion of a litter prior to 55 days of gestation, where gestation is based upon days from the LH surge (term = 65 ± 1 days).

SYNONYMS

Elective abortion, mismating/misalliance options

EPIDEMIOLOGY

SPECIES, AGE, SEX: Postpubertal intact bitches and queens

RISK FACTORS: Intact cycling females

ASSOCIATED CONDITIONS & DISORDERS: Depending upon the method of pregnancy termination used and the timing, pyometra, pseudocyesis, or delivery of premature viable offspring may occur.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Stages when pregnancy termination may be performed:

- Prior to pregnancy diagnosis (<20 days past the onset of the LH surge)
- Prior to fetal ossification (20-44 days past the onset of the LH surge)
- After fetal ossification (>44 days past the onset of the LH surge)

HISTORY, CHIEF COMPLAINT

Female bred to an unintended male and/or at an unintended time

PHYSICAL EXAM FINDINGS

- Typically healthy female
- Abdominal palpation of focal, discrete uterine enlargements during the fourth week of gestation. Accuracy will depend on the expertise of the examiner and the stage of pregnancy.

ETIOLOGY AND PATHOPHYSIOLOGY

- Luteal support (via progesterone production) is required for the entire length of a successful canine or feline pregnancy.
- Pregnancy in the bitch and queen can be terminated by administration of drugs that prematurely lyse the corpora lutea (CL) on the ovary.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Pregnancy diagnosis (see p. 909)

DIFFERENTIAL DIAGNOSIS

For pregnancy:

- Pseudopregnancy
- Pyometra
- Mucometra/hydrometra

INITIAL DATABASE

The diagnosis of pregnancy can be made with abdominal ultrasound, serum progesterone assay, abdominal radiographs, or serum relaxin assay. The advantages, drawbacks, and expected results of each are described in Pregnancy, p. 909.

TREATMENT

TREATMENT OVERVIEW

- Reduce serum progesterone concentrations to <2 ng/mL via lysis of the corpus luteum (CL).
- Perform a complete evacuation of the uterus.
- The owner and clinician should discuss the advantages and drawbacks of medical versus surgical (ovariohysterectomy) pregnancy termination to develop an appropriate treatment plan.

ACUTE GENERAL TREATMENT

Depending on the protocol, premature lysis of the CL (luteolysis) can be induced before or after a pregnancy diagnosis has been made.

- Prostaglandin F2a(PGF2α): q 8-12 h SQ to effect; usually 3-9 days of therapy is needed. PGF2α therapy can be initiated as soon as day 5 of diestrus, as determined by vaginal cytologic examination, and as late as day 45.
  - Canine: dinoprost, 0.1-0.25 mg/kg; or cloprostenol, 1-2.5 mcg/kg
  - Feline: dinoprost, 0.25-0.5 mg/kg
- Combination of PGF2α with a prolactin inhibitor
  - PGF2α: SQ q 8 h (see dose previously listed). PGF2α may be needed for an additional 1-2 days following the last treatment with a prolactin inhibitor for complete uterine evacuation.
  - Prolactin inhibitor: bromocriptine, 10 mcg/kg (0.01 mg/kg); or cabergoline, 5 mcg/kg (0.005 mg/kg) PO q 8 h. Usually 3-4 days of therapy needed. Protocols using prolactin inhibitors are initiated during the middle third of pregnancy (from 20-44 days from the onset of the LH surge), when the clinician is able to verify the diagnosis of pregnancy by palpation or ultrasonography.
- Prolactin inhibitor in queens: cabergoline, 25-50 mcg/cat PO q 24 h for 3-5 days
- Dexamethasone: 0.1-0.2 mg/kg PO q 8-12 hr at decreasing dose for 5-10 days or 5 mg IM q 12 h for 10 days (large dog). Fetal death occurs 5-13 days post treatment and fetal expulsion starts at 7-15 days. Treatment efficacy is highest when treated up to 10 days after day 35 of gestation. Treatment failure has been reported in bitches treated between 30-35 days of gestation. Concurrent treatment with PGF2α does not improve efficacy.
- Aglepristone in bitches and queens: 10 mg/kg SQ, two doses 24 hours apart. Aglepristone is a progesterone receptor antagonist and has few side effects. Not manufactured in the United States. May be administered during mid-pregnancy and has been successful at terminating pregnancies between 23-42 days post breeding. Side effects include localized swelling at the injection site.

CHRONIC TREATMENT

If pregnancy termination does not occur following an initial treatment, and pregnancy termination is still desired, the protocol should be repeated or a different treatment regimen should be used.

BEHAVIOR/EXERCISE

Depending upon the pregnancy-termination method utilized, pseudocyesis (inappropriate lactation) may develop. If this occurs, dams should not be allowed to lick the mammary glands, as this may stimulate further lactation.

POSSIBLE COMPLICATIONS

- Side effects secondary to pregnancy termination include anorexia, vaginal discharge, discomfort, depression, and shortened interestrus interval at first estrus post treatment.
- Side effects of PGF2α (occur 30-40 minutes after injection; decrease with subsequent injections) include salivation, panting, vomiting, defecation/diarrhea, and vocalization in queens.

RECOMMENDED MONITORING

Ultrasonography and serum progesterone concentrations to verify completion of abortion and uterine evacuation.

PROGNOSIS AND OUTCOME

Good prognosis for future fertility

PEARLS & CONSIDERATIONS

COMMENTS

- Since >50% of bitches will not be pregnant after a misalliance situation, waiting until the pregnancy is positively diagnosed to begin a protocol to terminate a pregnancy is recommended.
- Administration of estrogen during estrus has been reported to be a safe and effective method for pregnancy termination. Estrogen treatment should not be repeated even if the bitch or queen gets bred again during the same estrus.
  - Estradiolcypionate:canine, 0.044 mg/kg IM once; feline, 0.25 mg/cat IM once
  - Possible side effects of estrogen treatment include pyometra and severe, irreversible bone marrow suppression (canine). Due to the potential severe side effects of estrogen therapy, client education and specific written permission should be obtained prior to its use.
- The combination protocols using PGF2α and prolactin inhibitors achieve success more quickly and with fewer side effects than using either individually.
- If pregnancy termination protocols are initiated after 50 days of gestation, birth of viable puppies or kittens may occur.

PREVENTION

- Effective physical control of cycling bitch or queen during estrus.
- Ovariectomy or ovariohysterectomy will eliminate the problem of mismating permanently.

CLIENT EDUCATION

- In the bitch or queen not intended for breeding, ovariectomy or ovariohysterectomy should be performed as early in gestation as possible.
- Shortening the luteal phase will shorten the interestrus interval. Clients should be advised to expect the next cycle to occur sooner than normally expected.

AUTHOR: BEVERLY PURSWELL

EDITOR: MICHELLE A. KUTZLER

Potpourri Toxicosis

BASIC INFORMATION

DEFINITION

Liquid potpourri: combination of essential oils and cationic detergents. Acute toxicosis occurs (mostly in cats) from accidental dermal and oral exposure and is characterized by hypersalivation, vomiting, protrusion of the tongue, dysphagia, corrosive burns on the skin and oral cavity, hyperthermia, muscle weakness, and ataxia.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- All pets of all ages and both sexes are susceptible.
- Cats are more sensitive to essential oils, and grooming behavior can increase toxicosis from dermal exposures.

RISK FACTORS: Preexisting liver disease can increase risk and severity of toxic effects.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Dermal and/or oral contact with liquid potpourri
- Clinical signs begin within minutes to up to 8 hours post exposure.
- Lethargy, drooling, vomiting, vocalizing, anorexia, and tongue protrusion

PHYSICAL EXAM FINDINGS

- Liquid potpourri may be felt (oily texture on haircoat) or smelled on the coat and/or breath.
- Hypersalivation, dysphagia, vomiting (± hematemesis), diarrhea, corrosive burns of the oral, pharyngeal, and/or esophageal mucosa (ulceration could take several hours to appear).
- Hyperthermia
- Dyspnea, wheezing, abnormal respiratory sounds (caused by aspiration pneumonia or pulmonary edema), hypotension
- Muscular weakness, ataxia
- Hair loss (focal), skin erythema, dermatitis, edema, pain, and ulceration (dermal exposure)
- Ocular exposure: mild irritation to severe corneal injury (ulcer)

ETIOLOGY AND PATHOPHYSIOLOGY

- Liquid potpourri is a mixture of essential oils and cationic detergents.
- Essential oils are volatile oils or a mixture of terpenes (complex hydrocarbons) obtained from plants through a distillation process.
- Cationic detergents include quaternary ammonium compounds (benzalkonium and benzethonium chlorides), pyridinium compounds (cetylpyridinium, cetrimonium), and quinolinium compounds (dequalinium chloride).
- Cationic detergents (depending on concentration) can be irritating or corrosive to mucous membranes. They can cause local as well as systemic effects. Usually <1% concentration causes irritation to mucous membranes and >7.5% can cause corrosive injury.
- The exact mechanism responsible for the systemic effects of cationic detergents is not known. Current belief is that these compounds have a ganglionic blocking effect and a curare-like action, with paralysis of the neuromuscular junction of striated muscle.
- Essential oils can cause mucous membrane irritation and have central nervous system (CNS) depressant effects. Metabolism of terpenes occurs in the liver. The terpenes and their metabolites are mainly conjugated through glucuronidation before excretion through the kidneys. Cats are deficient in their glucuronidation ability and therefore more sensitive to essential oil toxicosis.
- Toxicosis is acute, with signs occurring within minutes to a few hours after exposure.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis rests on history and physical exam: observed or suspected exposure may be described, but evidence of exposure (smell, oily skin) is highly specific. Compatible clinical signs are supportive (hypersalivation, oral ulcers, anorexia, lethargy, protrusion of tongue) when seen within minutes to hours after the exposure. Specific confirmation is possible but not clinically practical.

DIFFERENTIAL DIAGNOSIS

- Corrosives (acids, alkali) toxicoses
- Household products (detergents, bleaches, pine oils) toxicoses
- Acetylcholinesterase (AChE) inhibitor pesticides (organophosphates, carbamates) toxicoses
- Upper respiratory tract infection
- Uremic ulcers (renal failure)
- Food indiscretion, garbage toxicosis
- Foreign body

INITIAL DATABASE

- CBC: inflammatory leukogram
- Serum chemistry profile ± blood gas analysis: essential oils causing hepatic damage may produce increased serum levels of liver enzymes (uncommon) and acid-base or electrolyte abnormalities.

ADVANCED OR CONFIRMATORY TESTING

- Gas chromatography and mass spectrometry (GC/MS) on urine can identify both essential oils and metabolites (this can confirm exposure if history of exposure not available).
- Necropsy: no characteristic lesions
- If indicated by clinical findings, endoscopic examination of esophagus and stomach may be considered within 12-24 hours to rule out perforation of gastrointestinal (GI) tract.

TREATMENT

TREATMENT OVERVIEW

Immediate treatment is topical (oral exposure: rinse mouth and dilute by giving milk or water; topical exposure: bathing using mild dishwashing liquid solution; ocular exposure: ocular rinse with tepid water or saline for several minutes). Subsequent treatment is supportive in response to specific lesions if any.

ACUTE GENERAL TREATMENT

- Oral: dilution with oral administration of milk or water (dogs: ½ cup [125 mL] per 15 kg; cats: 1-2 tbsp [15-30 mL] per cat; most effective if performed early)
- Dermal exposure: immediate bathing of the pet, using a mild liquid dishwashing detergent solution; monitoring for erythema, swelling, pain, or pruritus. Adjunctive treatment may include administering analgesics, anti-inflammatories, and antibiotics, because lesions may be painful and portals of entry for bacterial infection.
- Ocular: ocular flushing for 20-30 minutes with tepid tap water or physiologic saline; fluorescein stain of the cornea to assess for corneal ulceration (see p. 250).
- Induction of vomiting, gastric lavage, and activated charcoal administration are contraindicated (liquid potpourri is a caustic agent).
- Protecting GI mucosa:
  - Sucralfate slurries (dog: 0.5-1 g PO q 8-12 h; cat: 0.25-0.5 g PO q 8-12 h)
  - Gastric acid reduction:
    - H2 antagonist: famotidine (dogs/cats): 0.5 mg/kg PO, SQ, IM, IV q 12-24 h; *or*
    - Proton pump inhibitor: omeprazole, 0.5-1 mg/kg PO q 24 h
- Pain control: buprenorphine (dogs/cats), 0.005-0.03 mg/kg IV, IM, SQ q 6-12 h; *or*
- Tramadol: dogs 1-4 mg/kg PO q 8-12 h; cats: 12.5 mg/cat or 4 mg/kg PO q 12 h
- Fentanyl patch: see formulary (Section VI) for various sizes.
- Broad-spectrum antibiotics (for caustic burns)
- Antiinflammatory medications:
  - Corticosteroids (dexamethasone, 0.1-0.2 mg/kg IV or IM q 24 h for 3-5 days; *or* prednisolone, 0.25-1 mg/kg PO q 24 h). Use is controversial; may use for several days if esophageal damage has occurred; appear to help reduce risk of esophageal stricture but concurrently increase risk of GI ulcers and opportunistic infection (e.g., pneumonia);

concurrent use of broad-spectrum antibiotics unproven to reduce risk.

- IV fluids: most commonly indicated in cases involving anorexia, dehydration, electrolyte imbalances, or hyperthermia

CHRONIC TREATMENT

If aspiration pneumonia develops (due to dysphagia), oxygen supplementation and a broad-spectrum antibiotic may be necessary (see p. 885).

NUTRITION/DIET

Nutritional support: with severe oral lesions, food prepared as a liquid slurry or soft, mashed foods are appropriate. In 2/6 cases, placement of an esophagostomy tube was necessary for nutritional support (see p. 1267). With severe oral lesions and/or concurrent anorexigenic disorders (e.g., hepatic lipidosis) such treatment should be considered.

DRUG INTERACTIONS

Nonsteroidal antiinflammatory drugs (NSAIDs) can worsen GI ulcers by reducing protective prostaglandins. Corticosteroids use can also worsen GI ulcers (weigh benefits and risks before using).

POSSIBLE COMPLICATIONS

- Esophageal stricture/perforation, infection
- Aspiration pneumonia

RECOMMENDED MONITORING

- Body temperature (elevation may indicate inflammation, pneumonia or other secondary infection)
- White blood cell count
- Endoscopic examination of esophagus and stomach if clinical concern of severe mucosal erosion, perforation, or subsequent stricture

PROGNOSIS AND OUTCOME

With supportive care, signs resolve in a few hours to several days, depending on the degree of exposure and severity of damage.

PEARLS & CONSIDERATIONS

COMMENTS

- Essential oils in liquid potpourri are rapidly absorbed both orally and dermally.
- Hepatic damage from essential oils in potpourri is possible but very uncommon.
- Dry potpourri contains small amounts of essential oils and is essentially a foreign-body risk if ingested.
- Liquid potpourri can cause burns even if the liquid is not hot (chemical burns).

TECHNICIAN TIP

Patients with lesions that are not so severe as to require feeding tube placement may benefit greatly from gentle coaxing (see p. 1377), slurry-like food preparation, and a variety of diets to encourage them to eat despite the oral lesions.

PREVENTION

Owners should keep simmer pots out of the reach of pets.

Postpartum Management of the Bitch

BASIC INFORMATION

DEFINITION

Care of the female dog and offspring following parturition

SYNONYMS

Postparturient care, postwhelping management

EPIDEMIOLOGY

SPECIES, AGE, SEX: Canine postpubertal female

GENETICS & BREED PREDISPOSITION: Toy breeds are at a greater risk of developing postparturient hypocalcemia.

RISK FACTORS

- Maiden bitches: some do not have good mothering ability; some are susceptible to subinvolution of placental sites (SIPS; see p. 1060).
- Older bitches are more predisposed to postpartum disorders (e.g., metritis, mastitis; see p. 688).
- Excessively large litters (more than 6 pups for small breeds [<9 kg], more than 9 pups for medium breeds [9-20 kg], more than 10 pups for large breeds [20-40 kg], and more than 12 pups for giant breeds [>40 kg])

CONTAGION & ZOONOSIS: Canine herpesvirus (see p. 525), *Brucella canis* (see p. 162), and *Leptospira* spp. organisms may be shed in high concentrations in lochia following late-term abortions.

ASSOCIATED CONDITIONS & DISORDERS

SIPS, metritis, mastitis, caesarean section

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Healthy dam and pups versus unhealthy dam and/or pups

HISTORY, CHIEF COMPLAINT

- Recent whelping
- No complaints unless a postpartum disorder exists

PHYSICAL EXAM FINDINGS

- Healthy dam and pups
- If postpartum problems exist: exam findings in the dam may reveal depression, inappetence, poor mothering, inadequate lactation (evident by anxious or distressed puppies), prolonged or abnormal vaginal discharge, and engorged or inflamed mammary glands.
    - Rectal temperatures may normally be elevated for 24-48 hours postpartum but should not be >103°F (>39.4°C).
    - Lochia (vaginal discharge; normal endometrial drainage) can be evident for 4-6 weeks postpartum and may last as long as 12 weeks.
    - Typically green-black to brick red and has no significant odor
    - Abnormal if creamy color or if associated with a foul odor
- Mammary glands should be evaluated daily for heat, pain, or changes in consistency.
    - Milk should be white or slightly yellow.
    - Discoloration or purulent discharge is abnormal and suggests mastitis.

ETIOLOGY AND PATHOPHYSIOLOGY

Variable, depending on associated conditions

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Most problems can be clarified and some fully diagnosed from thorough history (environmental, medical) and physical exam of the dam and offspring.

DIFFERENTIAL DIAGNOSIS

- Normal postpartum female
- Prolonged or abnormal-appearing vaginal discharge: SIPS, metritis, retained placenta
- Swollen mammary glands: mastitis, galactostasis

INITIAL DATABASE

None necessary unless abnormalities present in history or physical

ADVANCED OR CONFIRMATORY TESTING

- CBC, serum chemistry panel, fibrinogen: healthy postpartum dams may be slightly anemic with an elevated fibrinogen.
- Vaginal cytologic examination: healthy dams typically have erythrocytes and hemosiderophages present in vaginal discharge for 4-6 weeks postpartum.
- Vaginal culture: healthy postpartum dams have positive vaginal bacterial cultures, similar to all healthy bitches.
- Milk cytologic examination, pH, and culture
- Abdominal ultrasonography

TREATMENT

TREATMENT OVERVIEW

To wean as many pups as possible

ACUTE GENERAL TREATMENT

- Oxytocin injections are often requested postpartum by breeders.
    - These are no longer considered necessary postpartum; suckling puppies have the same effect.
    - May give 2-10 units (up to a maximum of 20 units) IM to aid in uterine involution if retained placentas are suspected or pups are born dead and obstructive dystocia is ruled out

CHRONIC TREATMENT

Treatment of an associated disorder depends upon the specific condition; dam may need to be separated from pups (weaning).

NUTRITION/DIET

Cooked pumpkin is a useful food additive to help correct diarrhea following placental ingestion.

BEHAVIOR/EXERCISE

Dog Appeasing Pheromone diffuser may help to calm nervous or agitated bitches.

POSSIBLE COMPLICATIONS

Many therapeutics are excreted into the milk, which can then be ingested at high (even toxic) levels by the nursing offspring. Verification of the potential for milk excretion and the effects of the drug on the neonatal pups is essential prior to prescribing a drug to a lactating bitch.

RECOMMENDED MONITORING

- Physical exam, then diagnostic testing based on findings.
- Exam allows for early detection of periparturient disorders should they arise.

PROGNOSIS AND OUTCOME

- Good prognosis for bitches without associated disorders
- Specific prognosis depends on accompanying disorder

PEARLS & CONSIDERATIONS

COMMENTS

- A clean, warm environment affording the bitch privacy should be provided postpartum.
- Attention to hygiene reduces the risk of infection both to the dam and pups.

PREVENTION

Ambient temperature in the puppy area should be maintained at 75°F-85°F (24-29°C), with space away from the puppies available for the bitch.

TECHNICIAN TIPS

Behavior:

- Owners should not leave first-time mothers and nervous bitches alone with puppies until they are sure the mother will not cannibalize the pups.
- Typically it takes 2-3 days, especially after a caesarean section, before a bitch can be left alone.
- It may be necessary initially to hold the bitch down to allow the puppies to suckle.
- If the bitch continues to refuse to accept the puppies, she needs to be evaluated for causes such as mastitis (causing mammary pain).

CLIENT EDUCATION

Nutrition:

- It is important during lactation to provide enough energy to the bitch so she will produce enough milk for the puppies and maintain her own body weight:
  - Small breeds have a higher energy requirement per pound of body weight than larger breeds.
  - First week, 1½ times maintenance; second week, two times maintenance; and third week to weaning, three times maintenance.
  - Good quality, high-energy, easily digested food is recommended.
- The bitch may express reluctance to leave the whelping box and her puppies, so food and water may need to be provided in the whelping/nursing box.
- The bitch should be encouraged to get fresh air and exercise while the whelping box is being cleaned.

Portosystemic Shunt

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Macroscopic vascular communication allowing blood flow between the portal and systemic circulation without first passing through the liver
- The shunt can be congenital or acquired

SYNONYM

Portocaval shunt, portosystemic vascular anomaly, PSS

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats
- Congenital shunts typically produce clinical signs by 6 months of age; with rare exceptions, most animals are diagnosed by 2 years of age.
- Acquired shunts can occur at any age but typically are noted in middle-aged to older dogs.
- Congenital PSS: 2:1 male to female ratio in the cat; in the bichon frise, the relative risk is 12 times greater in females than males.

GENETICS & BREED PREDISPOSITION

- Congenital PSS:
  - Inherited in the Maltese terrier and Irish wolfhound and thought to be inherited in the Yorkshire terrier (relative risk: 20 times greater than general dog population)
  - Dogs: golden and Labrador retrievers, Old English sheepdog, Irish wolfhound, Samoyed, bichon frise, Australian shepherd, and Australian cattle dog (intrahepatic); Yorkshire terrier, poodle, Maltese, shih tzu, dachshund (extrahepatic)
  - Cat: Persian and Himalayan
  - Prevalence: in cats, 2.5 per 10,000; in dogs, variable reports ranging from 2.5 to 60 per 10,000
- Acquired PSS: greater prevalence in breeds with breed-associated chronic hepatopathies (cocker spaniels, Doberman pinschers)

RISK FACTORS

Acquired: chronic hepatic diseases causing portal hypertension

ASSOCIATED CONDITIONS & DISORDERS

Hepatic microvascular dysplasia and cryptorchidism

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Congenital versus acquired:
  - Congenital shunts are typically single, are present from birth, and are usually treated surgically. They are intrahepatic or extrahepatic.
  - Acquired shunts are multiple, occur in the context of chronic liver disease (they are portosystemic anastomoses resulting from chronic portal hypertension), and are not treated surgically because new shunts would arise to replace them. They are always extrahepatic.
- Congenital intrahepatic versus congenital extrahepatic:
  - Intrahepatic: more common in larger breed dogs and more difficult to correct surgically
  - Extrahepatic: more common in smaller breed dogs and more easily corrected surgically

- Cats: either (extrahepatic > intrahepatic)

HISTORY, CHIEF COMPLAINT

- Congenital or acquired:
  - Waxing/waning course of clinical signs is typical.
  - Animals often have only one or a few signs.
- Congenital:
  - Central nervous system (CNS) signs are all secondary to hepatic encephalopathy: lethargy, ataxia, weakness, abnormal behavior, abnormal vocalization, hypersalivation/ptyalism (especially cats), head pressing, bumping into objects due to central blindness, incessant pacing or circling, stupor, seizures, or coma.
  - Gastrointestinal (GI): intermittent anorexia, vomiting, diarrhea or constipation, polyphagia, pica
  - Urinary tract: hematuria, pollakiuria, or dysuria from ammonium urate urolithiasis
  - Miscellaneous: stunted growth, polyuria and polydipsia (PU/PD), intense pruritus
  - High-protein meal, GI bleeding, constipation, azotemia, hypokalemia, metabolic alkalosis, tranquilization, and methionine-containing supplements or medications can exacerbate clinical signs.
  - Intolerance to or slow recovery from anesthetic agents or tranquilizers
  - Incidental findings of microhepatica, ammonium biurate crystalluria, shunt visualization on abdominal ultrasound
- Acquired: signs of chronic hepatopathy/liver failure usually predominate.

PHYSICAL EXAM FINDINGS

- Signs: see History, Chief Complaint above.
- Plump kidneys
- Small body stature
- Small liver (inability to palpate liver margins)
- Poor haircoat, excoriations if intensely pruritic
- Copper-colored irises without green or yellow pigment in some cats with congenital shunts
- Ascites:
  - Since congenital PSSs represent a path of lesser resistance than the normal hepatic vasculature, ascites does not typically occur. Congenital shunts presenting with ascites usually have severe hypoalbuminemia, or a disorder other than congenital PSS (e.g., hepatic arteriovenous malformation) is present.
  - Acquired PSSs, since they occur due to portal hypertension, often exist concurrently with ascites.
- Icterus:
  - Does not typically occur with congenital PSS; if icterus is present, consider another diagnosis (primary hepatobiliary disorder, hemolysis).
  - Commonly observed with chronic liver diseases causing acquired PSS
- Physical exam can be unremarkable.

ETIOLOGY AND PATHOPHYSIOLOGY

- Congenital intrahepatic shunts are most often embryonic vessels that failed to regress postnatally. In dogs, persistent ductus venosus is the most common form. Congenital extrahepatic shunts are usually anomalous vessels that are not present in a normal dog or cat.
- Acquired shunts arise from rudimentary nonfunctional collateral vessels when portal hypertension occurs due to end-stage parenchymal disorders, such as cirrhosis, or severe vascular disorders (noncirrhotic portal hypertension).
- Hepatic encephalopathy and resultant CNS signs (see p. 501) occur with either type of PSS from toxins and nutrients absorbed from the intestines that are allowed to bypass metabolism by the liver and circulate in much higher concentrations than normal. Many of these substances (ammonia, methyl mercaptans, short-chain fatty acids, benzodiazepine-like substances) are directly toxic to the CNS or alter its normal metabolism.
- Reduced hepatic blood flow and lower concentrations of hepatotrophic factors, such as glucagon, insulin, and nutrients, result in microhepatica.
- High levels of urinary excretion from elevated blood levels of ammonia and uric acid can result in development of urate urolithiasis (renal, ureteral, bladder) in up to 50% of cases.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Congenital PSSs are identified for the purpose of treatment: surgical ligation or occlusion, or transvenous coil occlusion. Acquired PSSs may be identified incidentally in animals with chronic hepatopathies, but their presence does not typically affect the diagnostic and treatment approach used for managing animals with chronic liver disease.

DIFFERENTIAL DIAGNOSIS

- CNS signs: infectious diseases, toxins, other metabolic encephalopathy (hypoglycemia), idiopathic epilepsy, and congenital malformations (e.g., hydrocephalus)
- GI signs: parasitism, foreign body, dietary indiscretion, dietary allergy, inflammatory/infiltrative intestinal diseases
- Urinary tract signs: urinary tract infections, other calculi

INITIAL DATABASE

Tests for acquired shunts are those for underlying chronic hepatopathy. For congenital PSS:

- CBC: microcytic normochromic red blood cells (RBCs), mild nonregenerative anemia, and target cells are possible. In vitro changes in blood stored in EDTA may mask microcytosis, especially if there is a delay in processing.
- Serum biochemistry panel: mild elevations in hepatic enzyme activities, low blood urea nitrogen (BUN) concentration, hypoglycemia, hypoalbuminemia, hypocholesterolemia may be seen.
- Coagulation profile: mild activated partial thromboplastin time elevation and low fibrinogen concentration can be present. Will normalize after shunt ligation.
- Urinalysis: isosthenuria or hyposthenuria, ammonium biurate crystalluria, hematuria, or pyuria possible
- Abdominal radiographs: microhepatica, mild to moderate renomegaly; urate calculi often undetectable unless complexed with magnesium and phosphate
- Initial testing can be normal in affected animals.

ADVANCED OR CONFIRMATORY TESTING

Tests for acquired shunts are those for underlying chronic hepatopathy. For congenital PSS:

- Serum bile acids (preprandial and postprandial): Preprandial sample (drawn after a 12-hour fast) may be normal in 20% of cases. Postprandial sample (drawn 2 hours after a meal) is typically markedly elevated, often over 100 µM/L. False-positive and false-negative results are uncommon; if clinical suspicion persists despite normal postprandial bile acid values, additional testing is warranted.
- Urinary bile acids: though urinary bile acids are highly specific in detecting hepatobiliary disease, they are less sensitive than serum bile acids for detecting portosystemic shunting. Therefore they should not be used as a screening test
- Fasting serum ammonia levels: may be more sensitive and specific than serum bile acids testing, but inappropriate sample handling when samples are not assessed on site may dramatically increase false-positive results.
- Plasma protein C levels may increase suspicion for clinically significant liver disease and may aid in differentiating between PSS and hepatic microvascular dysplasia (HMD). In one study, a protein C activity of <70% was much more likely to indicate PSS and >70% more indicative of HMD, although some overlap between groups existed.
- Abdominal ultrasound: skilled clinicians may be able to image a shunting vessel. Intrahepatic shunts are easier to identify than extrahepatic shunts. A portal vein/aortic ratio of <0.75 is strongly suggestive of PSS.
- Other common findings are a small liver and a subjective decreased visualization of hepatic vascular structures.
- Transcolonic portal scintigraphy (see p. 1259): identifies excessive shunting of portal blood bypassing the liver; confirms the presence of a shunt but cannot identify its location or differentiate between congenital or acquired shunts. False-negative results can rarely occur, and the test is only available at referral institutions.
- Transsplenic portal scintigraphy: requires less radionuclide than transcolonic administration and may result in a more detailed image, allowing for more accurate identification of shunt location and number.
- Radiographic mesenteric portography:
  - Performed either intraoperatively or with percutaneous splenic catheterization guided with ultrasound
  - Intrahepatic most likely if the most caudal loop of the shunt or the point where the shunt diverges from the portal vein is cranial to vertebra T13
- Helical CT angiography:
  - Noninvasive and very accurate for both the presence of a shunt and in identifying its anatomic location
  - CT or portography is the test of choice to confirm the presence of a shunt and identify its location.
- Liver biopsy: indicated in all suspected and confirmed PSS cases; typically reveals hepatic arteriolar hyperplasia, small portal triads, increased smooth muscle thickness of hepatic venules, and an increase in small vascular structures in the periportal area in dogs with congenital PSS. If a PSS is absent, these histologic findings are diagnostic for micro vascular dysplasia. Many pathologists believe the histologic findings in dogs with hepatic microvascular dysplasia are indistinguishable from those of dogs with PSS. Histologic changes are not prognostic for outcome after shunt ligation.

TREATMENT

TREATMENT OVERVIEW

- Aimed at reversal of hepatic encephalopathy
- Congenital: complete or partial attenuation of congenital shunts, which halts or limits the bypass of blood around the liver and reverses some or all of the signs of hepatic encephalopathy and other clinical signs
- Acquired: management of the underlying liver disease. Acquired PSSs are not treated surgically (other shunts would form to replace them).

ACUTE GENERAL TREATMENT

- See Hepatic Encephalopathy,p. 501.
- Congenital: supportive care prior to general anesthesia for portography or shunt attenuation/ligation

CHRONIC TREATMENT

Treatment for congenital PSS:

- Primary therapy for congenital PSS is complete or partial shunt attenuation.
    - Preoperative patient preparation is essential and typically involves:
        - Prophylactic medical treatment and nutritional modification for prevention of hepatic encephalopathy for several days or more prior to general anesthesia if the animal's neurologic status is stable
        - More aggressive or intensive management in cases of severe hepatic encephalopathy (seizures, coma)
        - Identification and treatment of associated abnormalities that could create complications if not addressed (e.g., hypoglycemia, hypoalbuminemia, gastric ulceration)
- With complete shunt ligation or obliteration (e.g., complete occlusion or with ameroid constrictor/cellophane band placement), most animals are able to live normal lives without dietary therapy and medications. Complete ligation may not be possible, owing to the development of intraoperative portal hypertension, requiring partial ligation only.
- Without surgery or with only partial attenuation, animals may need to be managed chronically with restricted protein diets, lactulose, and/or antibiotic therapy.

NUTRITION/DIET

Restricted protein diets or those formulated for use in hepatic disease should be considered to reduce the overall production of ammonia. Avoid methioninecontaining supplements.

DRUG INTERACTIONS

- Be careful with drugs requiring hepatic metabolism.
- Congenital portosystemic shunts increase glomerular filtration rate, which may raise the rate of excretion of some medications.

POSSIBLE COMPLICATIONS

- Intraoperative and postoperative complications include portal hypertension, hypoglycemia, hemorrhage, and intractable seizures.
- Sedative and anesthetic agents should be used with caution.

RECOMMENDED MONITORING

Monitoring for congenital PSS:

- Post ligation: monitor for reversal of clinical signs while discontinuing medications and changing to a normal protein diet after 6-8 weeks. If clinical signs recur, then repeat transcolonic scintigraphy to ensure complete shunt attenuation. If scintigraphy indicates continued shunting, repeat portography and consider surgery.
- Partial ligation: complete closure facilitated by scar tissue formation may occur after 2-3 months. If clinical signs recur after termination of medications and low-protein diet, consider repeat transcolonic scintigraphy after 3 months. If shunting is still present, a second surgery can be considered to attempt complete ligation.
- Repeat bile acids measurement 6-8 weeks postoperatively; bile acids concentrations may decrease dramatically but often continue to be abnormally elevated even with complete attenuation, owing to the presence of concomitant hepatic microvascular dysplasia.
- Obtain a serum biochemical profile 6-8 weeks postoperatively. With complete ligation, serum liver enzyme activities, albumin, and glucose levels will typically normalize.

PROGNOSIS AND OUTCOME 

- Excellent long-term prognosis with complete ligation
- Fair to poor prognosis for cure with partial ligation. Many partially ligated shunts will completely close over time, but up to 50% of animals with partial ligation will have recurrence of clinical signs.
- Poor prognosis with medical therapy alone. In some animals, clinical signs can be controlled for a few years, but most develop refractory neurologic signs.
- Animals that present later in life with clinical signs (often due to urinary tract calculi) have a good prognosis with surgery.

PEARLS & CONSIDERATIONS 

COMMENTS

- Always obtain postprandial bile acid concentrations to increase the sensitivity of the test.
- Consider a congenital portosystemic shunt as a differential diagnosis in any young cat or dog with clinical signs of neurologic disease or with unexplained poor or stunted growth, delayed or difficult anesthetic recovery, waxing and waning appetite or GI signs, or in any animal presenting with urate urolithiasis.
- In unexplained polyuria and polydipsia (PU/PD) in young animals, consider bile acids measurement to assess for a portosystemic shunt.
- Intrahepatic shunts are much more difficult to ligate, either partially or completely, and have a much higher perioperative mortality rate than extrahepatic shunts. Percutaneous transvenous coil embolization has been performed successfully in dogs with this type of shunt and has a much lower mortality rate.

EDITOR: KEITH P. RICHTER

Polyuria/Polydipsia

BASIC INFORMATION

DEFINITION

- Polydipsia (PD): excessive consumption of water (>60-80 mL/kg/d)
- Polyuria (PU): production of excessive volumes of urine (>30-40 mL/kg/d)

EPIDEMIOLOGY

SPECIES, AGE, SEX

Cats and dogs, any age, either sex

ASSOCIATED CONDITIONS & DISORDERS

Diet (e.g., formulation [dry kibble versus moist/canned], salt content) will affect water consumption in both normal and ill dogs and cats.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- PU with secondary PD
- PD with secondary PU

HISTORY, CHIEF COMPLAINT

- Common chief complaints:
  - Increased frequency and amount of drinking
    - "Water-starved" behavior (pets actively seeking to drink water from abnormal or typically inaccessible locations) is possible in extreme cases or if owner is restricting water intake.
  - Urination in inappropriate indoor locations
  - Prolonged duration of individual urinations
  - Need to change litter with increased frequency (cats)
- Clinicians should initially ask owners what the water consumption is like as compared with 6-12 months earlier. The clinician can also ask whether there has been any change in water consumption, not whether water consumption has increased (to avoid leading the owner's answer).
- It is usually not possible to determine whether PU is primary, with secondary PD, or vice versa from the history alone.
- History should aim to differentiate PU from pollakiuria, stranguria, inappropriate elimination/urinary incontinence, and urinary marking/spraying.
- Basic environmental questions include duration of time indoors between walks (most normal dogs need to urinate at least every 8-12 hours), introduction of new pets or family members (suggesting behavioral changes/marking), new environment (behavior/marking or exposure to toxins), and change in litter type, location, or hygiene (cats).
- Some owners may not be aware of water consumption or urination because the pet mainly lives outdoors. Clinicians should view PD in dogs in a hospital setting with initial skepticism because occasionally, dogs drink voluminous amounts of water because of anxiety or excitement. More commonly, dogs with a history of PD drink less in the hospital as a result of excitement or anxiety.
- Medication history: glucocorticoids, phenobarbital, diuretics, thyroid supplementation can cause PU/PD
- Intoxication history should cover recent and distant potential exposures (ethylene glycol, grapes, raisins, lilies [cats]) and nephrotoxic medications (see p. 1411).

PHYSICAL EXAM FINDINGS

- Dehydration: consistent with any cause of PU/PD other than psychogenic PD
- Thin body condition
  - Some dogs with diabetes insipidus drink excessively and choose water over food, leading to weight loss.
  - With a poor haircoat: consistent with chronic kidney disease, chronic liver disease, diabetes mellitus, hyperthyroidism,

chronic gastrointestinal (GI) disease
- Dyspnea, tachypnea: may occur concurrently with metabolic acidosis, severe hypovolemia/shock (many possible causes)
- Panting (excessive): may be noted in dogs whose PU/PD is due to:
  - Hyperadrenocorticism
  - Hyperthyroidism
  - Also common in anxious or obese animals (i.e., nonspecific finding)
- Bilaterally symmetric truncal alopecia: endocrine disease (e.g., hyperadrenocorticism)
- Rectal examination: assess for primary disorders (e.g., adenocarcinoma of the anal sac causing PU/PD via hypercalcemia) and for causes of urinary incontinence other than PU (urethral or trigone thickening, suggesting inflammation or infiltration; prostatitis).
- Vaginal exam (seep. 1360):
  - Always attempt to identify a neoplastic process (mass) that might cause PU/PD via hypercalcemia of malignancy.
  - Purulent exudative discharge suggests pyometra.
- Abdominal palpation:
  - Kidneys: small (e.g., chronic kidney disease) or large (e.g., polycystic kidney disease, renal lymphoma, other renal neoplasia, pyelonephritis)
  - Hepatomegaly (e.g., primary hepatopathies, hyperadrenocorticism, diabetes mellitus, iatrogenic [glucocorticoids, barbiturates], lymphoma causing malignancy-associated hypercalcemia)
  - Splenomegaly (e.g., lymphoma causing malignancy-associated hypercalcemia)
  - Duodenal/jejunal thickening may be palpable with diffuse intestinal infiltrative diseases.
  - Uterine enlargement may be palpable (abdominal palpation must be performed gently because the uterus is potentially friable) with pyometra.
- Cardiac auscultation: tachycardia, heart murmur, third heart sound/gallop, and/or arrhythmia possible with hyperthyroidism

ETIOLOGY AND PATHOPHYSIOLOGY

- Normal daily water consumption:
  - Dogs: up to 60-80 mL/kg/d (higher in dogs <4 kg; up to 132 mL/d in dogs that weigh 1 kg)
  - Cats: up to 250 mL/d
- Mechanisms of PU/PD:
  - Chronic kidney disease: overload of glomerular filtrate to remaining functional nephrons presents excessive amounts of urea and sodium to distal tubules, eliciting an osmotic diuresis (primary PU, secondary PD).
  - Pyelonephritis: inflammation of the renal pelvis can destroy the counter-current concentrating mechanism in the renal medulla (primary PU, secondary PD).
  - Hyperadrenocorticism: suspected secondary antidiuretic hormone (ADH) deficiency (i.e., reversible central diabetes insipidus; primary PD, secondary PU)
  - Liver disease: compromised renal medullary concentration gradient due to impaired urea synthesis (primary PU, secondary PD); possibly impaired cortisol metabolism (primary PD, secondary PU)
  - Hypokalemia: interferes with renal tubular action of ADH (i.e., reversible nephrogenic diabetes insipidus; primary PU, secondary PD)
  - Hypoadrenocorticism: chronic hyponatremia depletes the renal medullary concentration gradient (primary PU, secondary PD).
  - Diabetes mellitus: glucosuria creates an osmotic diuresis (primary PU, secondary PD).
  - Diabetes insipidus (DI): lack of adequate ADH formation or release at the hypothalamic level (central DI) or ineffective ADH action on the renal collecting tubules (nephrogenic DI). Both central and nephrogenic DI cause a primary PU with secondary PD.
  - Intoxication: osmotic diuresis initially, followed by renal failure (ethylene glycol; both mechanisms cause primary PU, secondary PD). Mechanisms for lily, raisin, grape toxicosis: unknown.
  - Psychogenic PD: neurobehavioral changes with secondary renal medullary washout (primary PD, secondary PU)
  - Hyperthyroidism: increased medullary blood flow causing secondary decreased renal medullary concentration gradient; also hypokalemia (both primary PU, secondary PD).
  - Renal medullary washout: usually a secondary effect of other disorders listed here. Decreased renal medullary concentration gradient causes osmotic diuresis (primary PU, secondary PD).
  - Pyometra: *Escherichia coli* endotoxin interferes with ADH action on renal tubules (reversible nephrogenic diabetes insipidus; primary PU, secondary PD).
  - Hypercalcemia: calcium in excess interferes with the action of ADH at renal tubular level (reversible nephrogenic diabetes insipidus; primary PU, secondary PD).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

When present, polyuria and/or polydipsia are generally noticed and reported by owners in the medical history. Physical exam and

basic laboratory tests identify the cause in a large proportion of cases.

DIFFERENTIAL DIAGNOSIS

- PD:
  - Normal water intake (e.g., overinterpretation of seasonal variation)
- PU:
  - Inappropriate elimination/urinary incontinence: poor control of voiding, but overall daily volume of urine is normal (post-spay incontinence, for example).
  - Pollakiuria: frequent voiding of small volumes of urine, but overall daily volume is normal (bladder stones, bladder mass, for example).
  - Spraying/marking: small amounts of urine are eliminated, usually onto vertical surfaces.

INITIAL DATABASE

- CBC:
  - Anemia of chronic disease occurs with a few causes of PU/PD.
  - Stress leukogram possible with many disorders that cause PU/PD (though not common with central or nephrogenic diabetes insipidus).
  - Neutrophilia with evidence of inflammation (band forms, toxic change in neutrophils): rule out pyometra; may not be present with pyelonephritis (counterintuitive).
  - Normal lymphocyte and eosinophil counts in a clinically severely ill dog (i.e., absence of stress leukogram): rule out hypoadrenocorticism.
- Serum chemistry profile:
  - Hyperglycemia: rule out diabetes mellitus (clinical signs, glucosuria, fructosamine).
  - Increased blood urea nitrogen (BUN), creatinine, and phosphorus with isosthenuria (urine specific gravity [USG] 1.008-1.012): most consistent with kidney disease; less commonly, may also occur in animals with normal kidneys that have hypoadrenocorticism or diabetes insipidus.
  - Hypoalbuminemia, low BUN, hypocholesterolemia, hypoglycemia, hyperbilirubinemia (all, or any combination): consider liver failure (remember, many causes of PU lead to decreases in BUN; diabetes insipidus or hyperadrenocorticism are examples).
  - Hypercalcemia: rule out malignancy, primary hyperparathyroidism (both usually have concurrent low-normal to hypophosphatemia), vitamin D toxicosis, chronic kidney disease (cats; phosphorus usually normal or elevated), and other conditions (seep. 553). Idiopathic hypercalcemia (cats) is not usually associated with PU/PD.
  - Hyperkalemia with hyponatremia suggests hypoadrenocorticism.
- Urinalysis:
  - Owners should collect a fresh sample prior to the appointment.
  - True PU is almost always associated with dilute urine (USG < 1.012), “relatively” dilute urine (USG > 1.012 but <1.022), or glucosuria.
  - Concentrated urine (USG > 1.025) without glucosuria is inconsistent with PU/PD; other causes to explain clinical signs, such as lower urinary tract disorders, should be sought.
  - Diabetes mellitus causes PU but relatively concentrated urine (USG 1.025-1.045), at least in part due to glucosuria.
  - Isosthenuria (USG = 1.008-1.012) can be caused by kidney disease (tubules fail to concentrate urine) or by normal free water excretion (e.g., after a normal animal has drunk a large volume of water).
  - Calcium oxalate dihydrate crystals suggest postacute ethylene glycol ingestion.
  - Ammonium biurate crystals suggest liver failure (shunt, cirrhosis, etc).
- Urine culture and sensitivity (C&S): routinely performed in all animals with PU/PD. Urinary tract infection may complicate virtually any cause of PU/PD, may not produce additional overt clinical signs, often escapes diagnosis on urinalysis alone due to dilute urine, and is treatable and curable.
- Serum thyroid hormone levels: rule out hyperthyroidism (cats >6 years old).

ADVANCED OR CONFIRMATORY TESTING

- Abdominal ultrasound: evaluate kidneys (chronic kidney disease, pyelonephritis, neoplasia); urinary bladder (signs of cystitis, urolithiasis, or mass [e.g., neoplasm] producing pollakiuria or stranguria rather than PU); GI tract (evidence of infiltration); liver (chronic hepatopathies, portosystemic shunt, nonspecific enlargement, and hyperechogenicity [diabetes mellitus, hyperadrenocorticism, others]); adrenal glands (mass; subtle changes related to pituitary-dependent hyperadrenocorticism, although 50% of dogs with pituitary-dependent hyperadrenocorticism have structurally normal adrenal glands on ultrasound exam); and uterus (pyometra)
- Radiographs (thoracic, abdominal)
- Others as dictated by specific etiologies suspected

TREATMENT

TREATMENT OVERVIEW

Successful treatment requires identification of cause. PU and PD are not diseases but clinical manifestations of primary underlying disorders. Therefore, nonspecific treatment such as withholding water is unlikely to succeed and may be dangerous.

GENERAL TREATMENT

Withholding water can be dangerous or life threatening in all cases of PU/PD for which the underlying disease produces primary PU with secondary PD (see Etiology and Pathophysiology above).

POSSIBLE COMPLICATIONS

- Dehydration
- Progression of the primary problem if not identified and addressed

RECOMMENDED MONITORING

Physical examination, including body weight; diagnostic testing as indicated by underlying disease process, results obtained to date, and evolution of case.

PROGNOSIS AND OUTCOME

Highly variable from excellent to poor, depending on underlying cause and response to treatment.

PEARLS & CONSIDERATIONS

COMMENTS

- Any time an owner is concerned about their pet exhibiting “inappropriate urination” (any problem with urine), they should be instructed to collect about a teaspoon (5 mL) of urine to bring in at the time of examination. This allows easy separation of a pet with lower urinary tract disease (bladder stones) from one with diabetes mellitus (glycosuria) from one with nondiabetic PU/PD. Urine specific gravity <1.012 (sometimes <1.020; see below) always indicates PU.
- Isosthenuria (USG = 1.008-1.012) implies that the USG is the same as the specific gravity of plasma. Since dehydrated animals may have hyperosmolar plasma, USG up to 1.020 may still be consistent with isosthenuria in some

AUTHOR: EDWARD C. FELDMAN

EDITOR: ETIENNE CÔTÉ

Polyradiculoneuritis

BASIC INFORMATION

DEFINITION

An idiopathic inflammatory disorder primarily involving both axons and myelin of ventral nerve roots; probably the most common polyneuropathy in dogs. An analogous polyneuropathy has been described in cats (much less common).

SYNONYMS

Acute idiopathic polyradiculoneuritis (PRN), Coonhound paralysis (CHP)

EPIDEMIOLOGY

SPECIES, AGE, SEX

Affects dogs of any breed and either sex; usually adult age

GENETICS & BREED PREDISPOSITION

Hunting dogs, specifically coonhounds of certain lineages may be predisposed

RISK FACTORS

Raccoon bites or scratches in a genetically susceptible animal

ASSOCIATED CONDITIONS & DISORDERS

- Aspiration pneumonia
- Urinary tract infections
- Muscle atrophy/contracture
- Pressure induced skin ulcerations
- Hypoventilation/respiratory paresis or paralysis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Two subcategories appear identical in terms of onset, clinical signs, disease course, diagnostics, and pathology and are likely representative of the same disease syndrome:

- Coonhound paralysis (CHP)
  - History of being bitten or scratched by a raccoon 7-10 days before onset of signs
- Acute idiopathic polyradiculoneuritis (PRN)
  - Identical disorder but no possible exposure to raccoons

HISTORY, CHIEF COMPLAINT

- Acute-onset lower motor neuron (LMN) paresis/plegia, usually beginning in pelvic limbs and eventually progressing to thoracic limbs. Some dogs may initially develop a stilted gait.
- Progression to nonambulatory tetraparesis/tetraplegia typically within 10 days of onset (as little as 72 hours)
- Clinical signs occasionally begin in the thoracic limbs and progress to pelvic limbs or present as acute-onset tetraparesis/tetraplegia.
- Duration of paralysis varies from several weeks to 2-5 months.

PHYSICAL EXAM FINDINGS

- Nonambulatory LMN paraparesis/plegia or tetraparesis/plegia

- Recumbent, yet alert with normal mentation
- Afebrile
- Generalized hyporeflexia or areflexia; absent spinal reflexes (with exception of perineal reflex)
- Hypotonia/atonia
- Neurogenic muscle atrophy commonly develops within 7-10 days and can be severe.
- Sensory function is normal to heightened; some dogs are hyperesthetic.
- Hypoventilation and/or development of a life-threatening respiratory paralysis can occur, especially in acute-onset, rapidly progressive cases.
- Loss of voice (dysphonia, aphonia) is common.
- Cranial nerves are usually normal; occasionally slight facial weakness. Proprioceptive placing is normal in those animals with enough remaining motor ability.
- Patients retain the ability to urinate and defecate and will readily eat and drink if the head is supported.

ETIOLOGY AND PATHOPHYSIOLOGY

Presumptive Etiology:

- The antigenic stimulus in dogs is currently unknown, although raccoon saliva is thought to be one source.
- There may also be a genetic predisposition for this disease in breeds of coonhounds.

Pathophysiology:

- After exposure to the specific antigen, whether from raccoon saliva, vaccine, or some other source, alteration of the patient's immune system occurs. An autoimmune reaction against axons and myelin of the ventral nerve roots is theorized. In humans with polyradiculoneuritis (Landry-Guillain-Barré syndrome), molecular mimicry and concurrent infection with *Campylobacter jejuni* gastroenteritis are thought to be involved in the pathogenesis. The bacterium's capsular antigens mimic the components found on the patient's peripheral nerves. After the immune system is exposed to *Campylobacter jejuni,* the antibodies formed during the immune attack destroy not only the bacterium but also the peripheral nerve.
- Numerous exogenous antigens have components that mimic molecules found in canine axons; molecular mimicry may be involved in the pathogenesis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Polyradiculoneuritis is a diagnosis of exclusion. A working clinical diagnosis is based on the typical clinical presentation of an acute-onset LMN paraparesis/plegia that rapidly progresses to tetraparesis/plegia. Although not confirmatory, ancillary testing is helpful in ruling out other differential diagnoses.

DIFFERENTIAL DIAGNOSIS

Botulism, tick paralysis (United States and Australia), myasthenia gravis, protozoan polyneuritis/polymyositis, paraneoplastic neuropathy

INITIAL DATABASE

- Three-view thoracic radiographs: unremarkable unless secondary aspiration pneumonia or metastasis; useful in ruling out paraneoplastic neuropathies and megaesophagus
- CBC, serum biochemistry profile, urinalysis: unremarkable unless secondary urinary tract infection present
- Antiacetylcholine receptor antibody test: should be negative; useful in ruling out myasthenia gravis
- Lumbar cerebrospinal fluid (CSF) tap (see p. 1228): can support diagnosis if an increase in protein with a normal cell count (albuminocytologic dissociation) is seen
- Serum muscle enzyme levels: should be normal or only mildly elevated due to recumbency (versus marked elevations in polymyositis)
- Electrodiagnostics (see online chapter: Electromyography and Nerve Conduction Velocity): majority of (if not all) affected dogs will exhibit abnormal electromyographic activity (fibrillation potentials and positive sharp waves consistent with denervation) with normal or slightly reduced motor nerve conduction velocities (NCV).

ADVANCED OR CONFIRMATORY TESTING

- Nerve biopsies: demyelination, leukocytic infiltration, axonal degeneration, and segmental demyelination are consistent with polyradiculoneuritis but nonspecific because the inflammatory process occurs primarily at the ventral nerve roots.

- Arterial blood gas analysis: to help determine if mechanical ventilation is warranted

TREATMENT

TREATMENT OVERVIEW

Therapy is nonspecific, supportive, and often very protracted (major determinant of prognosis). Cornerstones are persistent supportive care and rehabilitation to prevent secondary complications. Most patients will show signs of improvement within 3 weeks and completely recover by 3-5 months. Rarely, severe, rapidly progressive cases require mechanical ventilation.

ACUTE GENERAL TREATMENT

Monitor pulmonary function and ventilatory status with arterial blood gas analysis inrecumbent patients. If hypoventilation is evident, provide mechanical ventilatory support (seep. 1362).

CHRONIC TREATMENT

- Supportive care, physical rehabilitation, and proper nutrition are essential for recovery:
  - Animals should be turned at least 6-8 times daily to prevent complications secondary to prolonged recumbency (hypostatic lung congestion, decubital ulcers etc.).
  - Passive range-of-motion exercises and massage of limbs should be performed at least four to five times daily to keep joints flexible and muscle supple (see p. 1329).
  - Hydrotherapy provides exercise and helps preclude muscle atrophy.
  - Proper bedding is essential to prevent pressure-induced skin ulcerations; water beds are useful.
  - Assisted feedings help prevent aspiration pneumonia.
  - Ensure the patient's environment is clean and dry.
  - Monitor for bladder overdistension, and intervene as necessary.
- Glucocorticoid treatment has been suggested, but there is no evidence of efficacy.
- The role of plasmapheresis and intravenous immunoglobulin administration, an established treatment in humans with signs of PRN, has not been proven in dogs.

POSSIBLE COMPLICATIONS

- Aspiration pneumonia, pressure-induced skin ulcerations, urinary tract infections, and muscle contracture and severe atrophy occur secondary to prolonged recumbency.
- Respiratory paresis/paralysis can occur in severe cases.

RECOMMENDED MONITORING

If patient is not hospitalized, weekly recheck examinations to assess recovery progress

PROGNOSIS AND OUTCOME

- Prognosis for full recovery is usually favorable. Owing to the transient nature of the inflammatory phase, damaged axons remyelinate and to some degree regrow over a period of 3-6 weeks. If pulmonary function is unaffected, with adequate supportive care, most animals will show signs of improvement within 3 weeks and full recovery within 3-5 months.
- Large/heavy dogs, dogs living in dense urban environments, and dogs whose owners or families are unable to provide supportive care may have a worse prognosis because of the difficulties these factors impose on home care.
- If mechanical ventilation is needed or if severe disease complications such as aspiration pneumonia and significant muscle contracture are present; recovery may be significantly prolonged or incomplete.
- Animals with significant axonal degeneration may not show clinical improvement.

PEARLS & CONSIDERATIONS

COMMENTS

- Once an animal has been affected with polyradiculoneuritis, recurrence of clinical signs is possible if the patient is subsequently reexposed to the inciting antigen.
- Chronic forms of this disease do exist and are characterized by waxing and waning clinical signs. Tetraplegia is generally not

seen with such forms of disease.

PREVENTION

Reexposure to raccoons should be avoided in dogs having recovered from CHP, as it may trigger a disease relapse.

TECHNICIAN TIPS

Treatment success for this disease greatly relies upon intensive daily nursing care and physical rehabilitation. Patience and persistence over extended periods of time do tend to be rewarded with recovery of the patient. Sometimes it can take months for these patients to recover.

CLIENT EDUCATION

- Clients need to be aware of, and persistent with, at-home nursing care and physical rehabilitation. They must also be aware of secondary complications. Frequent rechecks are necessary.
- Veterinary physical rehabilitation centers are available to aid with physical therapy.

EDITOR: CURTIS W. DEWEY

Polyphagia

BASIC INFORMATION

DEFINITION

Increased appetite or frequency of eating. Caloric consumption exceeding expected metabolic requirement.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dependent on underlying cause. In any age group, behavioral polyphagia (gluttony) is possible.
- Cats:
  - Young: parasites, pregnancy, lactation
  - Adult and geriatric: diabetes mellitus (DM), acromegaly, hyperthyroidism, intestinal infiltration (e.g., inflammatory bowel disease [IBD], gastrointestinal [GI] lymphoma)
- Dogs:
  - Young: parasites, pregnancy, lactation, exocrine pancreatic insufficiency (EPI)
  - Adult: DM, sudden acquired retinal degeneration syndrome (SARDS), hyperadrenocorticism (HAC), IBD, GI lymphoma
  - Geriatric: DM, SARDS, HAC (Cushing's disease), IBD, GI lymphoma, hyperthyroidism (rarely)

GENETICS & BREED PREDISPOSITION

Dogs: EPI in German shepherd; HAC in poodle, dachshund, terriers

RISK FACTORS

Risk factors exist for certain diseases that commonly cause polyphagia:

- DM: obesity (cats), concurrent HAC, concurrent acromegaly
- EPI: severe pancreatitis (rarely)

ASSOCIATED CONDITIONS & DISORDERS

Certain polyphagia-inducing diseases are in turn associated with other disorders:

- Acromegaly: DM, myocardial hypertrophy
- Hyperthyroidism: myocardial hypertrophy, cardiac arrhythmias, systemic hypertension, retinal detachment, renal failure, cerebral vascular accident, vomiting, diarrhea, weight loss, thyroid carcinoma (rare)
- DM: hyperlipidemia, pancreatitis, cataracts (dog), urinary tract infection (UTI)
- HAC: hyperlipidemia, DM, pyoderma, calcinosis cutis, UTI, pulmonary thromboembolism, cranial cruciate ligament rupture

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Iatrogenic/drug-induced (anticonvulsants, benzodiazepines, glucocorticoids, insulin excess, cyproheptadine)
- Primary polyphagia: behavioral, psychogenic, ventromedial hypothalamic lesion
- Secondary polyphagia: increased metabolic rate/physiologic (growth, pregnancy, lactation), hyperthyroidism, acromegaly. Decreased nutrient availability: DM, EPI, parasitism, infiltrative bowel diseases. Hypoglycemia: insulinoma. Miscellaneous: SARDS, HAC

HISTORY, CHIEF COMPLAINT

- Increased food consumption with:
  - Weight loss: hyperthyroidism, EPI, DM, infiltrative bowel disease, parasitism
  - Weight gain: psychogenic, drug-induced, physiologic, acromegaly, HAC, SARDS, insulinoma
- Polyuria and polydipsia: DM, HAC, acromegaly, hyperthyroidism, SARDS

- Panting: HAC, SARDS
- Hair loss: HAC
- Vomiting, diarrhea: hyperthyroidism, EPI, infiltrative bowel disease
- Weakness, seizures: insulinoma, HAC (rare)

PHYSICAL EXAM FINDINGS

- Disorientation: insulinoma, HAC (rarely), SARDS, hypothalamic lesions
- Alopecia, comedones: HAC
- Cataracts: DM
- Dilated pupils: SARDS (initially normal fundic examination)
- Thin to emaciated: EPI, hyperthyroidism, DM, infiltrative bowel disease
- Tachycardia, murmur, arrhythmias: hyperthyroidism.
- Panting: HAC, SARDS, obesity
- Obesity: behavioral, DM (especially cats), SARDS, HAC, insulinoma
- Hepatomegaly: HAC, DM

ETIOLOGY AND PATHOPHYSIOLOGY

- Varies with disease
- Primary: damage to satiety center (trauma, infectious, inflammatory, neoplastic)
- Behavioral: may be related to boredom or interindividual variation
- Secondary:
  - Accelerated metabolism
  - Diminished nutrient availability

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

The first diagnostic step consists of establishing whether polyphagia exists as a clinical sign of a medical disorder or whether the animal is simply gluttonous. This should be extracted from the history by: (1) asking the client whether any changes have occurred in food consumption independent of dietary change and mirroring the course of other clinical signs if present; and (2) avoiding leading questions (“Does your pet consume a lot of food?”), which can lead to overdiagnosis of polyphagia as a medical sign, in favor of open-ended questions (“Have you noticed a change in food consumption? How so, and since when?”).

DIFFERENTIAL DIAGNOSIS

- Weight loss: poor nutrient quality, owner underfeeding
- Weight gain: physiologic (cold environment, growth, pregnancy)

INITIAL DATABASE

- CBC: anemia (parasites), leukocytosis (HAC, SARDS), eosinophilia (parasites)
- Serum biochemistry panel: liver enzymes (HAC, DM, SARDS), glucose (DM, insulinoma)
- Urinalysis: low specific gravity (HAC, SARDS, hyperthyroidism), glucose, (DM), ketones (DM), bacteriuria (HAC, DM)
- T4: hyperthyroidism

ADVANCED OR CONFIRMATORY TESTING

- Low-dose dexamethasone suppression or ACTH stimulation: HAC
- Ultrasound: pancreatic nodules, adrenal size, thickened bowel, pregnancy
- CT/MRI of brain: hypothalamic lesions, pituitary macrotumors
- High-dose dexamethasone suppression: discriminates between adrenal-dependent HAC and pituitary-dependent HAC; generally replaced by abdominal ultrasound
- Endogenous ACTH level: discriminates between adrenal-dependent HAC and pituitary-dependent HAC
- Free T4: may clarify thyroid status that is unclear with total T4
- Technetium-99 thyroid scan: to confirm hyperthyroidism, determine bilateral versus unilateral disease

TREATMENT 

TREATMENT OVERVIEW

Depends on underlying causes

DRUG INTERACTIONS

With HAC: concurrent phenobarbital and o,p'-DDD (mitotane [Lysodren]) lessens effectiveness of o,p'-DDD. Trilostane concurrently with ketoconazole can result in hypoadrenocorticism.

POSSIBLE COMPLICATIONS

- Iatrogenic hypoadrenocorticism (o,p'-DDD, or trilostane treatment)
- Renal insufficiency, hypothyroidism (hyperthyroidism treatment)
- Ketoacidosis (uncontrolled diabetes)
- Thromboembolism (untreated HAC)
- Urinary tract infection (secondary to DM or HAC)

RECOMMENDED MONITORING

- EPI: weight gain
- DM: clinical signs improving, glucose curves, fructosamine
- HAC: clinical signs improving; ACTH stimulation
- Hyperthyroidism: weight gain; lower or normal serum T4 levels

PROGNOSIS AND OUTCOME

Varies depending on underlying cause

PEARLS & CONSIDERATIONS

COMMENTS

- Start by distinguishing polyphagia with weight gain from polyphagia with weight loss. A shorter list of problems causes polyphagia with weight gain.
- Thorough history and physical examination will help eliminate many differential diagnoses.

AUTHOR: DENNIS SPANN

EDITOR: ETIENNE CÔTÉ

Polymyositis, Autoimmune

BASIC INFORMATION

DEFINITION

An autoimmune inflammatory disease of unknown pathogenesis that primarily affects appendicular musculature

EPIDEMIOLOGY

SPECIES, AGE, SEX: Although any breed or age of dog can be affected, the majority of reported cases are middle-aged, large breeds. There is no apparent sex predilection.

GENETICS & BREED PREDISPOSITION: Newfoundlands and boxers appear to be overrepresented. Newfoundlands tend to develop the disease at a younger age than other breeds. A substantial number of boxers with polymyositis may develop the disorder as a preneoplastic condition.

ASSOCIATED CONDITIONS & DISORDERS: Uncommonly, dogs with autoimmune polymyositis may have concurrent masticatory myositis. This combination is referred to as *overlap syndrome*. Another uncommon associated condition in dogs with autoimmune polymyositis is thymoma.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Clinical signs may be acute or chronic. The animal's medical history or clinical complaints include generalized weakness (often worsened by exercise), stiff gait, generalized muscle atrophy, dysphonia, myalgia, dysphagia, regurgitation (megaesophagus may be present), fever, and muscle swelling.

PHYSICAL EXAM FINDINGS: Physical examination findings typically concur with the animal's medical history and clinical complaints.

ETIOLOGY AND PATHOPHYSIOLOGY

This is an idiopathic autoimmune disorder.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in a dog with signs of regional or diffuse muscle weakness and pain. Elevation of muscle enzymes on routine serum biochemistry panels is common. A definitive clinical diagnosis is achieved with muscle biopsy results in combination with normal (negative) serologic titers for potential infectious causes.

DIFFERENTIAL DIAGNOSIS

- Infectious polymyositis (e.g., toxoplasmosis, neosporosis)
- Overlap syndrome
- Preneoplastic myositis
- Myasthenia gravis

INITIAL DATABASE

- CBC, serum chemistry profile, urinalysis: elevated aspartate aminotransferase (AST) possible
- Serum creatine kinase: usually elevated, often markedly so
- Serologic titers for infectious diseases (e.g., toxoplasmosis, neosporosis)

ADVANCED OR CONFIRMATORY TESTING

- Electrodiagnostics: electromyogram (EMG) is usually abnormal

- Muscle biopsy (see p. 1305). A nonsuppurative inflammatory infiltrate is typically evident. Immunohistochemical staining of muscle tissue can verify immunoglobulin localization to the sarcolemma.

TREATMENT

TREATMENT OVERVIEW

The goal of therapy is to achieve clinical remission of myopathic signs.

ACUTE GENERAL TREATMENT

Immunosuppressive doses of prednisone (e.g., 1-2 mg/kg PO q 24 h) are generally used as initial therapy.

CHRONIC TREATMENT

- Once clinical remission of signs is achieved, the dosage of prednisone is slowly tapered over several months and is discontinued if possible.
- If prednisone cannot be effectively tapered or discontinued, alternative immunosuppressive drugs can be instituted (e.g., azathioprine, 2 mg/kg PO q 24 h for 5 days, then q 48 h; or mycophenolate mofetil, 5-10 mg/kg PO q 12 h).

POSSIBLE COMPLICATIONS

- Either inadequate or excessive immunosuppression
- Drug side effects or complications, including polyuria and polydipsia (PU/PD), polyphagia, weight gain, iatrogenic hyperadrenocorticism (glucocorticoids), bone marrow effects (azathioprine), and others

PROGNOSIS AND OUTCOME

The prognosis is favorable in approximately 80% of cases. Relapses may occur with tapering or discontinuation of immunosuppressive drugs.

PEARLS & CONSIDERATIONS

COMMENTS

When tapering prednisone in cases of autoimmune polymyositis, dose reductions should not be made more frequently than every 4 weeks.

AUTHOR & EDITOR: CURTIS W. DEWEY

Polycythemia Vera

BASIC INFORMATION

DEFINITION

An inappropriate, absolute increase in red blood cell (RBC) mass as measured by RBC count, hematocrit (Hct), and hemoglobin (Hb) concentration

SYNONYMS

- Polycythemia rubra vera
- Primary erythrocytosis. Strictly speaking, this is the more accurate term for this disorder *(polycythemia* implies increases in all circulating blood cell lines), but *polycythemia vera* is used more commonly.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Usually middle-aged to older dogs or cats

ASSOCIATED CONDITIONS & DISORDERS: Hyperviscosity syndrome (see p. 570)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Mainly caused by or associated with hyperviscosity

- Neurologic changes (e.g., behavior, motor, or sensory), mental dullness
- Seizures
- Lethargy, exercise, intolerance
- Hemorrhage (e.g., epistaxis, hyphema)

PHYSICAL EXAM FINDINGS: None, one, or many may be present:

- Hyperemic or cyanotic mucous membranes
- Erythema of the skin
- Polyuria and polydipsia (PU/PD)
- Splenomegaly

ETIOLOGY AND PATHOPHYSIOLOGY

- Absolute primary erythrocytosis
- Autonomous production of RBCs (erythropoietin independent)
- Myeloproliferative clonal disease
- Arises from a multipotent hematopoietic progenitor cell in the bone marrow, resulting in the accumulation of morphologically and functionally normal RBCs
- Polycythemia may lead to the hyperviscosity syndrome and resultant clinical signs.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The goals are to determine whether a true increase in red cell mass is present, and then rule out erythrocytosis secondary to increased erythropoietin. Since polycythemia vera is an autonomous increase in red cells, repeatable elevations in Hct, RBC count, and Hb are expected. Polycythemia vera is a diagnosis of exclusion: a complete diagnostic workup is indicated to rule out all other possibilities in the differential diagnosis.

DIFFERENTIAL DIAGNOSIS

- Relative polycythemia (pseudoerythrocytosis):

- Elevated Hct, with normal or decreased RBC mass
- Decrease in plasma volume associated with severe dehydration and increased serum total protein (TP) concentration
- Rarely causes clinical signs of hyperviscosity

- Absolute secondary polycythemia; erythropoietin dependent; appropriate or inappropriate response:
  - Appropriate (secondary to decreased tissue oxygenation):
    - High altitude
    - Chronic pulmonary disease
    - Right-to-left cardiovascular shunts (ventricular septal defect, reversed patent ductus arteriosus [PDA], tetralogy of Fallot, atrial septal defect)
    - Hemoglobinopathies (abnormal hemoglobins, methemoglobin reductase deficiency)
  - Inappropriate (normal tissue oxygenation):
    - Renal neoplasia (e.g., lymphoma, nephroblastoma, carcinomas, fibrosarcomas)
    - Other renal disease (e.g., polycystic kidney disease, rarely amyloidosis or glomerulonephritis)
    - Other neoplasms (e.g., cecal leiomyosarcoma, hepatic tumors)

INITIAL DATABASE

- CBC: persistently increased Hct, RBC count, and Hb concentrations with normal total protein concentration. The RBC morphology is normal.
- Serum biochemistry profile, urinalysis: generally unremarkable
- Arterial blood gas (ABG) analysis: to rule out hypoxemia as a cause of secondary polycythemia
- Abdominal ultrasound:
  - To identify renal masses or other potential erythropoietin-producing tumors
  - Nonspecific findings (hyperechoic kidneys, splenomegaly noted in 25% of cats and 10% of dogs with polycythemia vera).
- Thoracic radiographs:
  - Bronchial or interstitial changes are nonspecific. If thought to cause hypoxemia (and polycythemia secondarily), ABG measurement is indicated for confirmation.
- Echocardiography:
  - To identify myocardial hypertrophy (secondary to hyperviscosity [left ventricle; mild] or right ventricular outflow obstruction/pulmonary hypertension [right ventricle; marked]), right-to-left shunts, or other abnormalities that could cause secondary polycythemia.

ADVANCED OR CONFIRMATORY TESTING

- Measurement of plasma erythropoietin concentration:
  - Generally normal to low in polycythemia vera
  - Test has low diagnostic specificity; substantial overlap with the normal range; other types of polycythemia (e.g., relative polycythemia) are associated with similar results.
  - Measurement is indicated to help rule out secondary polycythemia (high plasma erythropoietin concentration).
- Bone marrow aspiration and cytologic examination or bone marrow core biopsy:
  - Not useful: cannot distinguish primary from secondary polycythemia

TREATMENT

TREATMENT OVERVIEW

Decrease blood viscosity and RBC mass to reduce or resolve clinical signs (palliation).

ACUTE GENERAL TREATMENT

Initial treatment is phlebotomy:

- 20 mL/kg of blood collected from external jugular or other central vein
- Avoid hypotension due to volume depletion by replacement with equivalent volume of IV 0.9% NaCl.
- Target Hct is <55% in dogs, <50% in cats.
- Replacement of coagulation factors and albumin if multiple phlebotomies in short period of time (rare). Clinicians can use autologous plasma (centrifuge phlebotomized blood, discard RBCs, and administer patient's own plasma) or use allogenic fresh frozen plasma.

CHRONIC TREATMENT

- Periodic phlebotomies if needed
- Alternatively, hydroxyurea (Hydrea), 30 mg/kg PO q 24 h for 7-10 days, then decrease the dose to 15 mg/kg daily, and titrate dose to maintain normal Hct; reduces RBC production. Monitor CBC for myelosuppression.
- Other chemotherapy agents such as chlorambucil have been used less often.
- Radioactive phosphorus (^{32}P) for myelosuppression: rarely used in animals. Only available in specialized centers.

POSSIBLE COMPLICATIONS

Hydroxyurea can cause myelosuppression. With chronic use, adverse effects including nail sloughing, macrocytosis (increased mean corpuscular volume [MCV]), methemoglobinemia (cats), and induction of secondary neoplasia, including leukemia, have been reported.

RECOMMENDED MONITORING

- CBC counts weekly at first until Hct stabilizes, then every 4-6 weeks
- Physical examination and diagnostic testing as needed; opportunistic infections, myelosuppression, and other complications of varying degrees of concern can occur during treatment with chemotherapeutic agents.

PROGNOSIS AND OUTCOME

Polycythemia vera can be successfully managed for years.

PEARLS & CONSIDERATIONS

COMMENTS

- The diagnosis is usually made by excluding other causes of polycythemia.
- Most pets tolerate treatment well.

CLIENT EDUCATION

Infections can occur secondary to myelosuppression. Routine follow-up evaluations are necessary during treatment, even when clinical signs are well controlled.

AUTHOR: PASCALE GRIESSMAYR

EDITOR: SUSAN M. COTTER

Polycystic Kidney Disease

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Inherited renal disease characterized by the presence of at least one cyst in one kidney. The condition is common in certain cat breeds (especially Persians) and in bull terrier dogs.

SYNONYMS

PKD, autosomal dominant polycystic kidney disease (ADPKD)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Cats of either gender affected. While diagnosis can be made in kittens, clinical signs become apparent from 3-10 years of age (average 7 years).
- Has been reported uncommonly in dogs with clinical signs in middle and late adulthood.

GENETICS & BREED PREDISPOSITION

- Persians, Himalayans, long-haired cats, and exotic short-haired cats are commonly affected; increasingly documented in short-haired cats.
- Inherited as an autosomal dominant trait that is not strictly associated with long haircoat or brachycephalic facial conformation. A mutation in PKD1 gene is responsible for most cases of feline PKD.
- About 40% of all Persians and Persian-related cats are affected.
- Bull terrier dogs also affected; very rare reports in other dog breeds.

ASSOCIATED CONDITIONS & DISORDERS

- Chronic kidney disease (CKD)
- Polycystic liver disease
- In bull terriers, may be inherited with hereditary nephritis; affected bull terriers have a higher incidence of cardiac disease.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Animals with overt manifestations of illness present for signs of chronic kidney disease (CKD): polyuria, polydipsia, anorexia, lethargy, nausea, vomiting, weight loss, poor body condition, and the like.
- Young animals presented for screening appear healthy.

PHYSICAL EXAM FINDINGS

- Early disease: normal
- Moderate disease: enlarged kidneys, but contour may be smooth
- Advanced disease: enlarged, irregular kidneys usually bilaterally, although may not be symmetric. Other findings of overt CKD (see p. 207)

ETIOLOGY AND PATHOPHYSIOLOGY

- Cysts (usually multiple) present at birth slowly enlarge compressing adjacent renal tissue. When sufficient renal parenchymal damage is present, CKD results. Rate of progression variable.
- Abnormal proteins, polycystin 1 and polycystin 2, are the result of mutations in the polycystic kidney gene. Cysts are abnormal dilations of renal tubules. Any section of the renal tubule may be affected by cyst formation.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Either genetic testing or ultrasound evaluation can be used to diagnose PKD in cats.

DIFFERENTIAL DIAGNOSIS

For enlarged kidneys: perinephric pseudocysts, renal lymphoma or other neoplasia, ureteral obstruction with hydronephrosis, feline infectious peritonitis, hematoma, perinephric abscess, and compensatory hypertrophy (unilateral)

INITIAL DATABASE

- Healthy-appearing young cats presenting for screening: renal ultrasound or genetic testing
- Clinically ill cats with enlarged kidneys: CBC, serum biochemistry profile, and urinalysis to assess renal function and identify uremia-associated complications (see p. 207)
- Abdominal ultrasound
- Blood pressure: especially important in azotemic animals

ADVANCED OR CONFIRMATORY TESTING

- Abdominal ultrasound can establish diagnosis (75% sensitivity for diagnosis in cats <16 weeks; 90% sensitivity in cats by 36 weeks). Cysts are anechoic, spherical structures with smooth, sharply marginated walls and far field enhancement. Cysts are easier to identify in cortex than medulla.
- Genetic testing is available for cats >8 weeks old (Veterinary Genetics Laboratory, University of California—Davis: www.vgl.ucdavis.edu). Buccal swab samples can be collected by owner.

TREATMENT

TREATMENT OVERVIEW

Affected animals should not be used for breeding. Animals with clinical signs related to PKD should be managed as are other animals with CKD.

ACUTE GENERAL TREATMENT

No treatment specific for polycystic kidney disease (PKD); treat for CKD and associated complications.

CHRONIC TREATMENT

Same as for CKD (see pp. 205 and 207)

POSSIBLE COMPLICATIONS

Cysts can become infected. Alkaline and lipid-soluble antibiotics including fluoroquinolones, clindamycin, chloramphenicol, and trimethoprim-sulfonamide penetrate cysts well.

RECOMMENDED MONITORING

- Cats with no clinical signs: blood urea nitrogen (BUN), creatinine, urine specific gravity every 6-12 months to help predict progression to renal failure
- Cats with azotemia: monitor as for CKD of any cause.

PROGNOSIS AND OUTCOME

- Not all cats with PKD will develop azotemia.
- Onset of clinical signs usually occurs after 7 years of age.
- PKD tends to progress more slowly than many other types of CKD. Once azotemia develops, long-term prognosis is poor.

PEARLS & CONSIDERATIONS

COMMENTS

Although hypertension is very common in people with ADPKD, hypertension is uncommon in overtly healthy cats with PKD.

PREVENTION

Eliminate affected animals from breeding population.

CLIENT EDUCATION

- Because PKD is an autosomal dominant trait, 50% of offspring from an affected animal will have PKD. Screening and subsequent removal of positive animals suggested in commonly affected breeds.
- Kittens can be screened by ultrasound at >16 weeks, but if negative, screening should be repeated at >10 months of age or genetic testing completed.
- Genetic screening can be completed at >8 weeks with samples that can be collected by owner.
- If an individual cat with PKD is important to a breeding program, breed only to PKD-negative cats and screen offspring. Half of the offspring will be affected and should be neutered; the unaffected individuals can be bred.

AUTHOR: CATHY LANGSTON

EDITOR: LEAH A. COHN

Polyarthritis

BASIC INFORMATION

DEFINITION

Inflammation of two or more joints

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dependent on underlying cause.
- With immune-mediated polyarthritis (IMPA), the age of onset is variable.
- Infectious polyarthritis in dogs: male > female
- Cats: feline chronic progressive polyarthritis (male > female)

GENETICS & BREED PREDISPOSITION

- Certain histocompatibility alíeles are associated with rheumatoid arthritis in dogs.
- Breed-associated polyarthritis is seen in the Akita, weimaraner and boxer. Meningitis may also be present.
- Familial amyloidosis is a cause of polyarthritis in the shar-pei (see online chapter: Shar-Pei Fever).
- Adverse reaction to sulfonamide drugs, causing polyarthritis: Doberman pinscher

RISK FACTORS

- Dogs: recent vaccination, treatment with sulfonamides or other antibiotics, exposure to ticks, bacterial endocarditis, pyometra, diskospondylitis, urinary tract infection, neoplasia, inflammatory bowel disease, and bacterial enteritis
- Cats: calicivirus vaccination (especially kittens)

ASSOCIATED CONDITIONS & DISORDERS: IMPA is sometimes associated with systemic lupus erythematosus (SLE; see p. 1070) or drug eruption/hypersensitivity (seep. 323), secondary infections, and gastrointestinal (GI) disease or neoplasia.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Noninfectious, nonerosive IMPA
  - Idiopathic
  - Reactive disorder; an immune response to antigens outside the joint (see Risk Factors) can trigger polyarthritis.
  - Associated with SLE
  - Breed-associated
- Infectious, erosive and nonerosive arthritis
- Noninfectious erosive arthritis
  - Feline progressive polyarthritis: periosteal new bone formation and bony erosions; acute (more common, young cats) or chronic (less common, slower onset, adult/older cats)
  - Rheumatoid arthritis (see ',','');return false;">p. 989)

HISTORY, CHIEF COMPLAINT

- Difficulty walking
- Stiffness, lameness
- Weakness, inability to rise
- Inappetence
- Lethargy, weight loss, vomiting, diarrhea
- Animals that have idiopathic IMPA typically experience a sudden onset of signs with multiple symmetric joint involvement.

PHYSICAL EXAM FINDINGS

- Joint pain, swelling:
  - Characteristic physical finding in polyarthritis.
  - May be difficult to localize source of stiffness; sometimes articular pain may be absent on initial examination.
  - Firm, complete flexion of carpi should be performed whenever polyarthritis is possible; may reveal signs of pain that otherwise would escape notice.
  - Distal, symmetric joint involvement (commonly carpi and tarsi) in IMPA
  - Usually one but occasionally two or more proximal joints involved with septic bacterial polyarthritis
- Fever; in some cases of IMPA, pain and joint swelling may be absent and fever may be the only sign.
- Lymphadenopathy
- Neck pain if meningitis present

ETIOLOGY AND PATHOPHYSIOLOGY

- Noninfectious, nonerosive IMPA is the most common form.
  - Possible mechanisms include immune complex formation in response to a microbial infection, with subsequent deposition in joints; immune responses to microbial antigens in the joint; genetic predisposition in certain individuals; and molecular mimicry, in which antibodies to certain antigens (from bacteria, viruses, tumors, drugs, or diets) cross-react with joint antigens.
  - Once joint inflammation has occurred, autoantigens such as altered collagen are produced that stimulate an immune response, helping perpetuate the inflammation.
  - The majority of cases are idiopathic, indicating that the typical case of polyarthritis is “uncomplicated” by underlying disease.
- Infectious:
  - Recognized etiologies:
    - Bacterial: borreliosis, ehrlichiosis (especially *Ehrlichia ewingii), Streptococcus, Staphylococcus, Erysipelothrix, Corynebacterium, Escherichia coli,* and L-forms
    - Other: calicivirus, heartworm, *Mycoplasma, Leishmania, Babesia, Hepatozoon,* and systemic fungal infections
  - May occur following direct penetration of a joint (surgery, trauma, bite wound, arthrocentesis) or from hematogenous spread. Bite wounds are common in cats, whereas hematogenous spread from an unidentified source of infection is common in dogs. Preexisting damage to a joint may aid in the establishment of infection. Single joint involvement is more common, but infection may spread to a second joint; multiple joint involvement is more common with systemic bacterial infections (e.g., bacterial endocarditis [which may also cause IMPA], omphalophlebitis [umbilical vein inflammation/infection], deep pyoderma, pyelonephritis, diskospondylitis, pyometra, periodontal disease, and prostatitis).
- Vaccines (calicivirus, canine distemper, others): may trigger a nonerosive IMPA
- Drugs (especially sulfonamide antibiotics but also lincomycin, cephalosporins, penicillins, and others): may act as antigens or combine with haptens to form antigens and trigger a systemic vasculitis, which may manifest as polyarthritis, fever, thrombocytopenia, and other such conditions
- Autoantibodies to nuclear material (e.g., SLE; see ',','p1070');return false;">p. 1070):
  - Antibodies to nuclear material, immune complex formation, and subsequent deposition in tissues cause multisystemic disease that commonly manifests with nonerosive polyarthritis, dermatitis, and/or glomerulonephritis (GN).
- Erosive IMP As include rheumatoid arthritis (rare in the cat) and periosteal proliferative polyarthritis (common in the cat).
  - Rheumatoid arthritis (see',','');return false;">p. 989) is usually associated with autoantibodies to immunoglobulin G (rheumatoid factor).
  - Periosteal proliferative polyarthritis is characterized by periosteal new bone formation and bony erosions. It affects young adult cats, often castrated males, and is usually acute in onset. Chronic progressive polyarthritis is a milder form, is insidious in onset, and affects older cats.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Polyarthritis can be suspected and occasionally diagnosed with history and physical examination alone. Fever, lethargy, lameness, and the presence of painful or swollen joints, especially distal joints, should arouse the clinician's suspicion. Confirmation rests on arthrocentesis with fluid analysis of multiple joints. Radiography may be done to evaluate for erosive changes. Further testing —including tick titers, cultures, screening for cancer—is required to determine an underlying cause and guide management. Successful management of polyarthritis requires that any underlying cause be identified and treated.

DIFFERENTIAL DIAGNOSIS

Many conditions should be ruled out for a patient that is unable to rise and ambulate normally:

- Neurologic disease (e.g., spinal cord or brain disorders, neuromuscular diseases)

- Muscular disease (e.g., polymyositis)
- Orthopedic disease (e.g., bilateral cranial cruciate ligament rupture, degenerative joint disease)
- Cardiac disease (e.g., pericardial effusion)
- Metabolic disease (e.g., hypoglycemia, hypocalcemia)
- Hematologic disease (e.g., acute blood loss)

INITIAL DATABASE

- Orthopedic and neurologic examinations to help rule out other disorders
- CBC, serum biochemistry profile, urinalysis:
  - Anemia and leukocytosis are common in idiopathic polyarthritis but are nonspecific.
  - Serum chemistry profile to assess dysfunction in other organs
  - Proteinuria may be indicative of GN (immune-mediated) or amyloidosis
- Radiographs to distinguish erosive from nonerosive polyarthritis:
  - Erosive polyarthritis is characterized by subchondral bone destruction, which is seen as an irregular joint surface or "punched-out" erosion of bone at the joint space. In advanced cases of joint deformity, loss of mineralization of the epiphysis and calcification of soft tissues of the joint may be seen.
  - Nonerosive polyarthritis presents no bony radiographic abnormalities; signs of joint effusion and soft-tissue swelling may be apparent.

ADVANCED OR CONFIRMATORY TESTING

- Arthrocentesis (see ',",'cesec49');return false;">p. 1199); two or more joints should be sampled.
  - The tarsi and carpi are especially useful because of frequency of involvement and ease of access to the synovial space.
  - Gross appearance: normal synovial fluid is viscous (tenacious), scant in volume, and clear, whereas synovial fluid of animals with polyarthritis is generally thin/watery and may be copious (several milliliters) and potentially turbid (more so with infectious/septic polyarthritis).
- Synovial fluid analysis; neutrophils are the predominant cell in inflammatory polyarthritis (distinguishing them from the more common degenerative arthropathies), and total cell counts are always >3000/µL and often 40,000/µL or higher. Cytologic examination is seldom helpful in distinguishing septic from nonseptic arthritis (only occasionally are intracellular, phagocytized organisms seen), although the presence of degenerate or toxic neutrophils is suggestive of septic arthritis.
- Culture: synovial fluid cultures are usually negative. When clinicians suspect septic arthritis, they should consider a culture of synovial membrane, blood, and/or urine. Special media are needed to culture L-form bacteria and *Mycoplasma.*
- Titers: Lyme disease *(Borrelia burgdorferi), Ehrlichia* (especially *canis, ewingii),* and *Anaplasma phagocytophila* (formerly *Ehrlichia equi).*
- Echocardiogram if suspicious of bacterial endocarditis (e.g., heart murmur, especially if new in onset, and/or diastolic; see ',",'para693');return false;">p. 346)
- Serum antinuclear antibody and rheumatoid factor if the clinician suspects SLE or rheumatoid arthritis, respectively; the tests are of limited accuracy
- Cerebrospinal fluid tap if the clinician suspects meningitis
- Thoracic radiographs and abdominal ultrasound examination to evaluate for remote infection, GI disease, or neoplasia if suspected

TREATMENT

TREATMENT OVERVIEW

Treatment depends on the etiology. Sometimes despite treating the underlying cause, however, a course of prednisone is required to resolve the polyarthritis. For cases of IMPA, immunosuppressive doses of prednisone/prednisolone are the treatment of choice and following resolution of clinical signs, usually within 2 weeks, corticosteroids should be slowly tapered over 4-6 months. Insufficient dosages and/or administration for insufficient periods of time are important causes of treatment failure.

ACUTE GENERAL TREATMENT

- Doxycycline, 10 mg/kg PO q 24 h for 28 days for tickborne infections, *Mycoplasma,* and L-form bacteria
- Prednisone/prednisolone, 1.1 mg/kg PO q 12 h initially for nonerosive and erosive noninfectious IMPA
- Broad-spectrum antibiotics (e.g., amoxicillin-clavulanate, 22 mg/kg PO q 12 h) or cephalosporins (e.g., cephalexin, 22 mg/kg PO q 8 h) pending cultures in suspected or confirmed cases of septic arthritis
- Surgical joint lavage and drainage sometimes are required for septic arthritis.

CHRONIC TREATMENT

- For IMPA: prednisone/prednisolone, 1.1 mg/kg PO q 12 h (20 mg/m^2 PO q 12 h for dogs >25 kg; seep. 675) until resolution of signs (usually 2-4 weeks), then slowly reduce the dose and administer q 48 h. Average of 3-6 months and rarely lifelong treatment is required.
- If glucocorticoid side effects are marked or high doses are necessary, to suppress signs, consider other immunosuppressive drugs such as azathioprine, cyclophosphamide, gold salts, methotrexate, or leflunomide to keep clinical signs suppressed while using lower doses of glucocorticoids.
- Septic arthritis: antibiotics required until 2 weeks after infection has resolved; often a minimum of 6 weeks.

NUTRITION/DIET

Caloric control is necessary to avoid weight gain in patients on corticosteroids. Treatment of obesity when present is an important adjunctive therapy for chronic polyarthritis cases.

DRUG INTERACTIONS

Many drugs can potentially interact negatively with the drug in question; clinicians should consult a formulary for possible interactions.

POSSIBLE COMPLICATIONS

- Secondary infections from immuno-suppressive drugs
- Prednisone has many potential adverse effects including polyuria and polydipsia (PU/PD), polyphagia, panting, weight gain, muscle wasting, and elevated liver enzymes.
- Azathioprine: myelosuppression, hepatotoxicity, acute pancreatitis; avoid in cats
- Cyclophosphamide: myelosuppression, hemorrhagic cystitis

RECOMMENDED MONITORING

- Primarily resolution of clinical signs; if uncertainty exists, repeat arthrocentesis to see if cell counts have returned to normal.
- Monthly CBCs are required for animals receiving cyclophosphamide or azathioprine.
- Monitor liver enzymes in animals receiving glucocorticoids.

PROGNOSIS AND OUTCOME

- Nonerosive IMPA: good to guarded. About 30% of cases relapse and may be difficult to control or may require lifelong treatment.
- Juvenile hereditary arthritis of Akitas: very poor. Does not respond to immunosuppressive therapy.
- Calicivirus infection of cats: excellent. Generally resolves in 3 days with supportive care.
- Noninfectious erosive arthritis: guarded. Arthrodesis may improve quality of life.
- Infectious arthritis: provided the condition is nonerosive and the infection can be treated, the prognosis is good.

PEARLS & CONSIDERATIONS

COMMENTS

- Polyarthritis should be suspected in any animal that is reluctant to walk or in any case of fever of unknown origin. Even in the absence of joint pain or swelling, arthrocentesis of multiple joints is indicated in such animals to confirm or refute a diagnosis of IMPA.
- Cats with polyarthritis may be described only as lethargic by owners; polyarthritis might be missed unless cats are observed walking in the exam room.
- Empirical treatment with doxycycline may be considered while completing a workup.
- The majority of cases of polyarthritis are idiopathic, immune mediated, and nonerosive.

TECHNICIAN TIPS

- Dogs receiving immunosuppressive doses of prednisone/prednisolone should be monitored closely for adverse effects (see above). The goal is to start at a high dose, resolve clinical signs, then taper gradually to lowest possible dose so as to minimize unacceptable side effects including polyuria and muscle wasting.
- Pain associated with polyarthritis should not be mistaken for reluctance or other behavioral traits; these patients may be too painful to walk, may be more prone to aggression if handled, or both.

PREVENTION

Tick prevention if relevant (dogs in endemic regions)

CLIENT EDUCATION

- Close monitoring is required while patients are receiving immunosuppressive therapy.
- Relapses are possible.
- Genetic counseling for hereditary forms

AUTHOR: ORLA MAHONY

EDITOR: SUSAN M. COTTER

Pollakiuria, Stranguria

BASIC INFORMATION

DEFINITION

- Pollakiuria: increased frequency of attempts to urinate
- Stranguria: straining to urinate
- Both are clinical signs of lower urinary tract inflammation, infection, and/or obstruction.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Owners may confuse these clinical signs with inappropriate elimination, polyuria, or tenesmus.
- Other clinical signs can include dysuria and malodorous urine.
- Often pollakiuria/stranguria is the only presenting clinical sign.

PHYSICAL EXAM FINDINGS

- Important to determine if urethral obstruction is the cause:
  - Obstruction: bladder enlarged/firm, nonexpressible, often painful
  - Nonobstruction: bladder small/soft, expressible; bladder wall may be thickened, often painful as well.
- Bladder should be palpated before and after the patient voids:
  - Uroliths, masses, and bladder wall thickness/irregularities may be assessed more easily in the flaccid bladder.
- Rectal exam may reveal urethral, prostatic, or bladder trigone abnormalities.

ETIOLOGY AND PATHOPHYSIOLOGY

- Any disease that causes lower urinary tract infection (LUTI), inflammation, or obstruction can cause pollakiuria or stranguria.
- Localizes the lesion to the lower urinary tract (bladder, urethra)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Beyond a complete history and physical exam, a sterile urine sample for urinalysis (and bacterial culture and sensitivity [C&S] in the canine patient) should be the first diagnostic test in the pollakiuric or stranguric patient. Diagnostic imaging should be considered in a patient with a negative culture in the face of pollakiuria/stranguria.

DIFFERENTIAL DIAGNOSIS

Feline:

- Most common cause is idiopathic feline lower urinary tract signs (FLUTS; see p. 387):
  - Also called *feline idiopathic cystitis* (FIC), *feline lower urinary tract disorder* (FLUTD), and *feline urologic syndrome* (FUS)
  - Primary bacterial infection in cats is rare; infection is present in <2% of cats <10 years of age with lower urinary tract signs

Canine:

- Most common cause is bacterial cystitis
- Nonbacterial causes of cystitis:
  - Polypoid: chronic irritation
  - Emphysematous: bacterial fermentation of glucose in devitalized bladder wall
  - Drug induced: usually associated with cyclophosphamide

    - Idiopathic
    - Fungal, algal: uncommon
- Other bladder diseases:
    - Cystic calculi (uroliths)
    - Neoplasia
- Prostatic:
    - Neoplasia (transitional cell carcinoma [TCC], adenocarcinoma)
    - Trauma
- Urethral disease:
    - Urethrorectal fistula
    - Urethral prolapse
    - Urethritis
    - Urethrolithiasis
    - Neoplasia (TCC, squamous cell carcinoma)
    - Trauma

INITIAL DATABASE

- CBC and serum biochemistry panel
    - Metabolic or systemic disease (diabetes mellitus, pyelonephritis, many others)
- Urinalysis
    - Cystocentesis preferred
    - Comparison with free-catch sample may assist in anatomic localization of lesion
- Urine C&S
    - Cystocentesis preferred
- Abdominal radiographs
    - Mass effect
    - Prostatomegaly
    - Radiopaque calculi
- Abdominal ultrasound
    - Bladder wall thickness
    - Presence of bladder mass (inflammatory, neoplastic, or blood clot)
    - Architecture of prostate
    - Proximal urethra

ADVANCED OR CONFIRMATORY TESTING

- Advanced imaging
    - Double contrast cystogram
    - Voiding urethrogram
    - Excretory urethrogram
- Cystoscopy
- Voiding urohydropulsion
    - Appropriate if small calculi are present
    - Noninvasive method to collect calculi for chemical analysis
- Cystotomy
    - Biopsy of mass
    - Removal of calculi
    - Culture of bladder wall

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are to relieve discomfort associated with LUTI and treat underlying cause.

ACUTE GENERAL TREATMENT

Of greatest immediate concern is urethral obstruction (see p. 1131). No matter the cause, establish urine flow to prevent life-threatening hyperkalemia if complete obstruction is present (urinary bladder moderately to markedly enlarged): see and

- Assess azotemia and potassium level.

- Gently try to pass a urinary catheter using retrograde hydropulsion if obstruction is met.
- If catheterization is unsuccessful:
  - Cystocentesis:
    - Relieving pressure may allow urethral catheter to pass.
    - Insert needle relatively caudally (near trigone) and direct it caudodorsally to minimize risk of contacting devitalized bladder wall.
  - Urethrotomy
  - Cystostomy tube
- Provide fluid and electrolyte support while diagnostic tests are pursued.
  - Consider IV fluid without potassium as first choice until serum potassium level is known (e.g., choose 0.9% NaCl).
- If a bacterial infection is suspected, a C&S is vital for directed antibiotic therapy.

CHRONIC TREATMENT

Dependent on accurate diagnosis of underlying cause

PEARLS & CONSIDERATIONS

- Pollakiuria and stranguria localize the problem to the lower urinary tract.
- Further diagnostic evaluation is necessary to determine the exact cause of these signs.
- While bacterial infection is the most common cause in dogs, this is rare in cats.
- FLUTS (FLUTD/FUS/FIC) is the most common cause of pollakiuria and stranguria in cats.
- With any episode of pollakiuria or stranguria, urinary obstruction must be ruled out as soon as possible.

TECHNICIAN TIPS

- Any client who calls with concerns of pollakiuria/stranguria should be advised of risk of urinary obstruction and urged to bring the pet in for examination without delay. Owners often misidentify stranguria as constipation (both involve “straining”), so a telephone question regarding constipation likewise warrants an immediate evaluation to rule out urethral obstruction.
- Concurrent analysis of cystocentesis and free-catch urine samples can help localize the lesion.

AUTHOR: CLAIRE WEIGAND

EDITOR: ETIENNE CÔTÉ

Poisoning, General Management

BASIC INFORMATION

DEFINITION

A poison is a substance that causes death or injury when introduced into or absorbed by a living organism.

SYNONYM

Intoxication, toxicosis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Young animals are more likely to accidentally ingest poisonous materials.
- A cat's unique metabolism may cause it to be predisposed to certain toxicoses (e.g., acetaminophen).

RISK FACTORS

- Lack of supervision
- Access to poisonous materials
- Individual behavior (some animals routinely ingest materials while others seldom do).
- Poisoning of companion animals is rarely malicious.

CONTAGION & ZOONOSIS: Several animals may be affected simultaneously from the same source.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Key components of the history may include witnessed exposure, evidence of exposure (e.g., chewed medication container), and characteristic behavior or clinical signs. It is common for some owners to believe their animal has been poisoned when it becomes ill for any reason. A thorough history will help establish the likelihood of poisoning.
- Additional important information may include the exact nature of the poison (if known), maximum possible dose ingested, time elapsed since ingestion, and time elapsed since clinical signs were first observed.

PHYSICAL EXAM FINDINGS: Highly dependent on the poison involved; common categories of signs include:

- Central nervous system (CNS) alterations and seizures (lead, metaldehyde, organophosphates, carbamates, tremorgenic mycotoxins, alcohol, blue-green algae, marijuana, chocolate, ivermectin)
- Muscle weakness, paresis, and paralysis (coral snakes, black widow spiders, phenoxy herbicides [including 2,4-D], macadamia nuts)
- Acute blindness (horse dewormer medication, salt)
- Oral mucosal lesions (corrosive acids, alkalis, cationic detergents, liquid potpourri, formaldehyde)
- Acute renal failure (ethylene glycol, lily plants [cats])
- Acute hepatic damage or failure (mushrooms, blue-green algae, iron, sago, or cycad palm plants/trees)
- Severe anemia (onions, garlic, naphthalene mothballs, anticoagulant rodenticides, acetaminophen [cats])
- Cardiac arrhythmias (foxglove, lily of the valley, oleander, azalea/rhododendron, and yew plants; bufo toads)
- Gastrointestinal (GI) signs (many, including several already listed; arsenic, castor beans, nitrogen-phosphate-potassium (NPK) fertilizers, zinc oxide, oxalate-containing plants)

ETIOLOGY AND PATHOPHYSIOLOGY

The possibility of poisoning should be considered when a young and otherwise healthy animal exhibits an acute onset of neurologic signs, organ failure, or other systemic signs and after all other common diseases have been ruled out.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

When an inciting cause is unknown, owners may express concern that their pet has been poisoned. The clinician should remember that unless clinical signs are consistent with poisoning and there is a reasonable chance of exposure to the poison, the illness is likely caused by something other than malicious poisoning.

DIFFERENTIAL DIAGNOSIS

Other systemic or metabolic diseases

INITIAL DATABASE

- Packed cell volume/serum total protein
- Azo stick (blood urea nitrogen)
- Blood glucose
- Urine specific gravity and dipstick
- Samples of urine, blood, and gastric contents should be saved for possible toxicologic analysis.

ADVANCED OR CONFIRMATORY TESTING

Serum levels or tissue analysis for specific toxin

TREATMENT

TREATMENT OVERVIEW

Treatment of poisoning should focus on maintaining cardiovascular, respiratory, and neurologic stability and preventing further absorption of toxin. ASPCA Animal Poison Control (888-426-4435; www.aspca.org/pet-care/poison-control/) may be a useful resource to determine the best method of treatment. Goals of treatment are to:

- Achieve cardiovascular stability.
- Prevent further absorption of the toxin.
- Administer antidote if available.

ACUTE GENERAL TREATMENT

- Triage principle: life-threatening complications must be addressed first if present. “Start with the animal, not the toxin.”
  - Airway support or intubation if respiratory arrest
  - IV catheter placement if animal is showing systemic signs
  - Electrocardiogram (ECG), blood pressure (BP), and pulse oximetry monitoring as dictated by physical examination findings
  - IV fluid and oxygen support as indicated by cardiovascular and respiratory status
- Decontamination of the patient:
  - Skin: dermal exposure (i.e., topical pyrethrin exposure) warrants bathing with warm water and a mild dishwashing detergent. Care should be taken to prevent hypothermia.
  - Emesis: (see p. 1364) consider if ingestion has occurred within 2 hours of visit. Contraindicated in animals that ingested potentially caustic substances (acids, alkalis, petroleum distillates) or are unable to protect the airway because of depression, seizures, or other neurologic dysfunction.
  - Gastric lavage (see p. 1281): used when emesis is contraindicated because of the animal's inability to protect its airway; requires induction of general anesthesia in conscious animals and intubation of the airway. This procedure involves passage of the distal end of a large-bore tube into the stomach and administration of 5-10 mL/kg of tepid water. The water is then withdrawn through the tube with gravity flow. Lavage is repeated until gastric contents are clear.
  - Activated charcoal: the most commonly used general treatment for intoxications; dose is 1-4 g/kg PO (suspension: 5-10 mL/kg PO). It is ineffective in removing heavy metals. Some animals will eat the activated charcoal willingly, but most require orogastric administration. Clinicians must be careful to prevent aspiration pneumonia. Elimination of toxins that undergo enterohepatic circulation may be hastened by additional doses of activated charcoal every 4-6 hours for up to 24 hours. Owners must be made aware the animal will have black stool for several days.
  - Cathartics: accelerate fecal elimination of toxin. Sorbitol is most commonly used in combination with activated

charcoal. Other available cathartics include sodium sulfate, magnesium sulfate, or citrate. Contraindications include GI obstruction, recent bowel surgery, volume depletion, electrolyte imbalance, and ingestion of a corrosive substance.
- Fluid diuresis: may be used for accelerating elimination of toxins that are renally extracted.

PROGNOSIS AND OUTCOME

Prognosis depends on the toxin, total dose of exposure, and severity of clinical signs.

PEARLS & CONSIDERATIONS

COMMENTS

- Most of the specific intoxications seen in small animal practice are discussed individually and in detail elsewhere in this book.
- Many poisons cause signs similar to those caused by other common diseases. The diagnosis of toxicity should not be reached without strong historical or physical evidence of exposure.

PREVENTION

Owners should prevent their pets from accessing toxins.

CLIENT EDUCATION

Discussions on common poisoning should be made available to clients.

AUTHOR: SCOTT P. SHAW

EDITOR: ELIZABETH ROZANSKI

Pododermatitis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

An inflammatory skin disease affecting the paw. Disorders of the footpads are discussed on .

SYNONYMS

Interdigital dermatitis, interdigital pyoderma, pedal dermatitis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Pododermatitis is more common in dogs than cats. Foot lesions in cats more commonly involve the footpads, claws, and periungual areas, whereas dogs often present with interdigital lesions.
- Dogs and cats of any age or sex can be affected.

GENETICS & BREED PREDISPOSITION

- Short-haired dog breeds (e.g., English bulldog, Great Dane, basset hound, mastiff, bull terrier, boxer, dachshund, dalmatian, German short-haired pointer, weimaraner) are more commonly affected.
- Long-haired breeds that are more often affected include German shepherds, golden retrievers, Irish setters, and Pekingese dogs.

RISK FACTORS: In cats, immunosuppression caused by feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), or diabetes mellitus can predispose to infectious pododermatitis.

CONTAGION & ZOONOSIS: Dermatophytosis is contagious and zoonotic. Sporotrichosis (especially feline: zoonotic hazard) and blastomycosis (common-point source of infection or accidental inoculation) also may affect humans.

GEOGRAPHY AND SEASONALITY: Atopic dermatitis and allergic or irritant contact dermatitis can be seasonal.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Owners can observe lesions on a single foot or multiple feet. Licking or chewing of the affected areas and lameness may also be apparent. In addition, pododermatitis may be part of a more generalized skin condition.

PHYSICAL EXAM FINDINGS: Lesions can be present on the dorsal and/or the ventral aspects of the feet. One or several interdigital spaces can be affected. Possible lesions include:

- Erythema
- Nodules
- Swelling of the feet
- Interdigital serosanguineous or seropurulent exudates
- Interdigital bullae or draining tracts
- Ulcers and erosions
- Scales and crusts
- Alopecia
- Paronychia (inflammation/infection of the claw folds)
- Eosinophilic plaques (cat)
- Salivary staining
- Occasional pitting edema of associated metatarsus or metacarpus
- Regional lymphadenopathy may be present

PODODERMATITIS Interdigital deep pyoderma on ventral aspect of a foot in a 5-year-old female weimaraner. Skin near the footpad of the second digit is mildly swollen, erythematous, and eroded.

(Courtesy Dr. Nadia Pagé.)

ETIOLOGY AND PATHOPHYSIOLOGY

Pododermatitis can arise following various pathologic mechanisms, including:

- Contact with irritant substances or physical trauma that can induce skin injury and inflammation
- Infectious agents that can induce an immune response from the host, resulting in tissue inflammatory cell infiltrates
- Hormonal imbalances (hypothyroidism, hyperadrenocorticism) that can predispose to infectious pododermatitis
- Allergic disease, where self-trauma can result in skin lesions, alopecia, and salivary staining
- Immune-mediated disorders: the development of antibodies or activated lymphocytes against normal body constituents or inciting antigens (drugs, bacteria, viruses) can cause tissue damage.
- Neoplastic cell infiltrates can disturb the normal structure of the skin.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Pododermatitis is apparent on physical examination; etiology is determined based on number of feet affected, appearance of lesions, possible environmental causes, and results of tests selected based on lesion distribution and extradermatologic physical exam findings.

DIFFERENTIAL DIAGNOSIS

- If lesions are restricted to one foot:
  - Foreign bodies, trauma
  - Neoplasia
  - Localized bacterial or fungal infection
  - Osteomyelitis
- If multiple feet are involved:
  - Environmental/traumatic: contact chemical dermatitis, clipper burn
  - Infectious: bacterial, fungal (dermatophytosis, *Malassezia* dermatitis, sporotrichosis, mycetoma, blastomycosis, cryptococcosis), parasitic (demodicosis, hookworm, and *Pelodera* dermatitis, trombiculiasis), rick-ettsial (canine Rocky Mountain spotted fever), viral (papillomatosis)
  - Allergic: food hypersensitivity, atopic dermatitis, contact allergic dermatitis
  - Immune-mediated: pemphigus (foliaceous, erythematosus, vulgaris), bullous pemphigoid, systemic lupus erythematosus (SLE), and immunomodulatory-responsive lymphocytic plasmacytic pododermatitis (dog) and plasma cell pododermatitis (cat)
  - Metabolic/endocrine: superficial necrolytic dermatitis (hepatocutaneous syndrome); hypothyroidism and hyperadrenocorticism can predispose an animal to bacterial or dermatophyte-induced pododermatitis and to

adult-onset demodicosis.
- Miscellaneous: behavioral (self-induced lesions), zinc-responsive dermatosis, foreign-body reaction (occasionally affects multiple feet), sterile pyogranulomas, nodular dermatofibrosis (German shepherds)

INITIAL DATABASE

Selection of diagnostic tests is based on evidence provided by the history and physical examination:

- Skin scrapings: *Demodex* spp.
- Wood's lamp examination: dermatophytosis (fluorescent strains of *Microsporum cants*)
- Cytologic examination: fungal organisms, bacteria and inflammatory cells (bacterial pododermatitis), acantholytic keratinocytes (pemphigus), neoplastic cells
- Elimination diet: food allergy
- Intradermal skin testing (serologic allergy testing could also be considered): atopic dermatitis
- Fecal flotation: hookworm ova
- Radiographs: osteomyelitis, radiopaque foreign bodies
- CBC, biochemistry panel, urinalysis: results depend on the underlying cause; often normal or nonspecific unless systemic disease.

ADVANCED OR CONFIRMATORY TESTING

- Culture: bacterial, fungal
- Skin biopsy: foreign bodies, demodicosis or other parasites, bacterial or fungal infections, neoplasia, immune-mediated diseases, superficial necrolytic dermatitis, zinc-responsive dermatosis
- Antinuclear antibody (ANA): positive in virtually all animals with SLE
- Endocrine tests and serologic titers if relevant

TREATMENT

TREATMENT OVERVIEW

The goal of treatment is to achieve permanent cure or control of the disease. Sometimes palliative treatment is the only option (nonresectable tumors).

ACUTE GENERAL TREATMENT

Specifics depend on the underlying cause:

- Minimizing foot trauma (e.g., owner education; use of booties)
- Draining lesions can benefit from soaks in a magnesium sulfate solution (Epsom salt, 30 mg/L of warm water), q 12-24 h until drainage stops (5-7 days).
- Surgery: neoplastic lesions, surgical exploration (foreign bodies), or débridement
- Laser surgery can be useful in removing cystic lesions and sinuses (dogs).
- Bacterial pododermatitis can necessitate several weeks (8-12 weeks) of appropriate systemic antibiotics. The causative organism is often *Staphylococcus pseudintermedius.* If cytologic examination suggests infection with this bacterium, an acceptable initial choice is cephalexin, 22-30 mg/kg PO q 12 h; or amoxicillin/clavulanate, 12.5-22 mg/kg PO q 12 h.
- If other bacteria are involved or the empirical choice of antibiotic does not resolve the infection, the clinician should correct the antibiotic selection based on culture and sensitivity (C&S) results.
- Manage parasitic or fungal infections with appropriate antiparasitic or anti-fungal medications.
- Atopic dermatitis often requires management with combination therapy: antiinflammatory agents, allergen-specific immunotherapy, and antimicrobial drugs to control secondary bacterial or yeast infections.
- Immunosuppressive treatments are usually required for treating immune-mediated diseases.

PROGNOSIS AND OUTCOME

Variable, depending on the cause of pododermatitis

PEARLS & CONSIDERATIONS

COMMENTS

- Interdigital pyoderma can often be a frustrating disease to treat. Even after the resolution of the infection, the remaining fibrosis and scarring may predispose the animal to relapse.
- In severe refractory cases, clinicians may have to consider drastic measures such as surgery (fusion podoplasty).
- Cases of canine pododermatitis with substantial footpad involvement are more commonly seen with autoimmune diseases, drug reactions, zinc-responsive dermatosis, superficial necrolytic dermatitis, and distemper.

TECHNICIAN TIP

Patients with pododermatitis may have painful feet. Their reluctance to walk should not be misinterpreted as stubbornness, and they may need support to walk comfortably.

EDITOR: MANON PARADIS

Pneumothorax

BASIC INFORMATION

DEFINITION

Accumulation of air within the pleural space

SYNONYM

Collapsed lung

EPIDEMIOLOGY

SPECIES, AGE, SEX: Young, large-breed male dogs are predisposed to trauma and subsequent pneumothorax.

GENETICS & BREED PREDISPOSITION: Northern breeds (Siberian husky or Alaskan malamute) are predisposed to spontaneous pneumothorax.

RISK FACTORS

- Trauma (hit by car, bite wounds, falls from elevated heights)
- Surgical intervention (cranial abdominal, intervertebral disk, and other surgeries)
- Pleural effusion (centesis may lead to iatrogenic pneumothorax)

GEOGRAPHY AND SEASONALITY: Trauma is more common in warmer months.

ASSOCIATED CONDITIONS & DISORDERS

- Pulmonary contusions
- Diaphragmatic hernia
- Flail chest
- Fracture
- Asthma
- Pleural effusion

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Traumatic: due to damage to the pulmonary parenchyma or chest wall
- Spontaneous: due to abnormal pulmonary parenchyma without trauma
- Iatrogenic: due to damage to the lung parenchyma following thoracocentesis for removal of pleural effusion, following aspiration of a pulmonary mass, or during surgery

HISTORY, CHIEF COMPLAINT

- Trauma
- Acute-onset coughing or tachypnea
- Worsening tachypnea following an intervention

PHYSICAL EXAM FINDINGS

- Dyspnea/increased respiratory effort is the hallmark finding:
  - Expiratory or both expiratory and inspiratory but not inspiratory alone (which would more commonly suggest upper airway disease, not pneumothorax)
  - May be absent in mild cases
- Other evidence of trauma, either blunt (e.g., hit by car) or penetrating (e.g., bite, gunshot, stabbing)
- Dull or muffled lung sounds (auscultation, percussion)

ETIOLOGY AND PATHOPHYSIOLOGY

- Air may enter the pleural space either from damage to the pulmonary parenchyma (e.g., rupture of a pulmonary bleb), which permits the leakage of air from the respiratory system into the pleural space, or via damage to the chest wall, which permits air to rush into the pleural space.
- When the lung parenchyma is normal, small injuries (e.g., needlestick during centesis) heal rapidly.
    - Intrapleural volumes of air of up to 45 mL/kg cause no clinical signs and take about 2 weeks to resorb spontaneously in healthy dogs.
    - Iatrogenic pneumothorax occurring during thoracocentesis is almost invariably associated with chronic effusions (especially chylothorax), diseased lung tissue, an uncooperative patient, or an inexperienced operator.
- A "tension" pneumothorax is a severe pneumothorax from any cause that results in cardiovascular collapse due to inadequate cardiac filling.
- Rarely, foreign bodies (grass awns, wooden toothpicks, porcupine quills, etc.) may migrate intrathoracically and cause pneumothorax.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on a history of thoracic trauma (field or surgical), dyspnea, or both. The confirmatory test of choice is thoracic radiography.

DIFFERENTIAL DIAGNOSIS

Dyspnea in an animal that has undergone trauma:

- Pleural effusion
- Pulmonary contusions
- Primary lung or airway disease
- Pain
- Hypovolemia

INITIAL DATABASE

- Thoracic radiographs are the test of choice; left-lateral recumbency is the most sensitive view for detecting small volumes of air in the pleural space.
- Routine laboratory testing (CBC, serum chemistry profile, urinalysis): generally unremarkable

ADVANCED OR CONFIRMATORY TESTING

- CT scan may be useful in spontaneous pneumothorax.
- Arterial blood gas (ABG) measurement or pulse oximetry: may help elucidate whether dyspnea in a trauma animal with pneumothorax may be in part due to the pneumothorax itself (e.g., Pao2 < 90 mm Hg on room air and/or O2 desaturation <96%) or to pain, hypovolemia, or other conditions associated with trauma. Pulmonary contusions may also cause hypoxemia and desaturation, however.
- Analysis of pleural effusion, if present

TREATMENT

TREATMENT OVERVIEW

The course and severity of the patient's clinical signs and suspected inciting cause help determine whether to pursue conservative management or thoracotomy. Treatment goals for conservative management include removal of air from the pleural space and measures that encourage formation of a seal to prevent further leakage; surgical treatment aims to eliminate the source of the leak.

ACUTE GENERAL TREATMENT

- Supplemental oxygen will result in more rapid resolution of a closed (not ongoing) pneumothorax, because the trapped air is higher in nitrogen, and if inhaled oxygen is administered, the trapped air will move more quickly down its concentration gradient.

- Traumatic pneumothorax:
  - No clinical signs, identified incidentally on radiographs: no treatment; monitoring is important.
  - Clinical signs: thoracocentesis warranted (see p. 1338). If large volumes (>200 mL/kg), no end point, or recurrent pneumothorax, then place thoracostomy tubes (see). Apply the "three-strike rule," meaning if three or more thoracocenteses are required within 24 hours following a trauma, a thoracostomy tube should be placed.
- Spontaneous pneumothorax (no trauma):
  - If the clinician suspects a bulla or bleb (no masses on radiographs), a thoracotomy is warranted.
  - If the clinician suspects a necrotic neoplasm, a thoracic CT scan followed by thoracotomy is warranted.
  - If the clinician suspects an underlying feline asthma or chronic bronchitis, conservative therapy may be adequate.
- Iatrogenic:
  - If there are no clinical signs (radiographic diagnosis only), monitoring of the patient is adequate.
  - If the patient is showing clinical signs, repeating the thoracocentesis and monitoring the animal closely are recommended. The animal may require a thoracostomy tube or exploratory thoracotomy if not responsive. Underlying disease may require specific treatment.

CHRONIC TREATMENT

Correction of the underlying cause if applicable

POSSIBLE COMPLICATIONS

Ongoing pleural effusion or pneumothorax

RECOMMENDED MONITORING

- Respiratory rate and effort
- Pulse oximetry

PROGNOSIS AND OUTCOME

- Fair to good; often with trauma, the associated injuries are more likely to predict outcome.
- Dyspnea and duration of intensive care are negative prognostic factors in dogs and cats with pneumothorax.

PEARLS & CONSIDERATIONS

COMMENTS

- Traumatic pneumothorax rarely requires surgical correction; most cases rapidly resolve (within 72 hours).
- Spontaneous pneumothorax commonly requires surgical treatment because most cases will not resolve without surgery.

TECHNICIAN TIP

Technicians involved in caring for patients with pneumothorax should be familiar with management of chest tubes.

PREVENTION

- Owners should prevent free roaming of pets.
- Clinicians should use caution when performing a thoracocentesis.

AUTHOR & EDITOR: ELIZABETH ROZANSKI

Pneumonia, Bacterial

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Inflammation of the lower respiratory tract or interstitium from bacterial infection

EPIDEMIOLOGY

SPECIES, AGE, SEX: Puppies acquired from community situations (shelters, pet stores) are more likely to have pneumonia from *Bordetella bronchiseptica* than other pathogens. No other species, age, or gender predilections noted except in cases of bacterial pneumonia secondary to congenital defects (e.g., primary ciliary dyskinesia).

GENETICS & BREED PREDISPOSITION: No breed or genetic predispositions other than for those associated with underlying primary diseases or associated conditions

RISK FACTORS: Any disease that compromises respiratory defenses or increases the potential for aspiration:

- Laryngeal disease:
  - Laryngeal paralysis post tieback surgery
  - Laryngeal neoplasia
- Esophageal disease
  - Esophagitis
  - Megaesophagus
  - Esophageal diverticula
- Altered consciousness
- Chronic vomiting
- Bronchial masses or foreign bodies
- Bronchiectasis
- Viral respiratory infection (e.g., distemper)
- Congenital immune deficiencies
- Ciliary dyskinesia
- Risk factors for *B. bronchiseptica* pneumonia include dense housing (dogs and cats) and the presence of a dog with clinical signs of upper respiratory tract disease (cats).

ASSOCIATED CONDITIONS & DISORDERS

- Sepsis
- Systemic inflammatory response syndrome
- Multiple organ dysfunction syndrome
- Respiratory foreign body
- Bronchial obstruction (foreign body, mass)
- Hemothorax (uncommon)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Bronchopneumonia involves inflammation of both airways and alveolar/interstitial compartments.

HISTORY, CHIEF COMPLAINT: Chief complaint may be related to pneumonia or to the predisposing disease:

- Pneumonia:
  - Cough
  - Nasal discharge
  - Sneezing
  - Exercise intolerance
  - Anorexia, lethargy
  - Hemoptysis (uncommon)
  - Acute death (uncommon but reported)
- Predisposing disease:

    - Regurgitation
    - Recurrent/persistent infections (usually respiratory, but occasionally other)
- Some animals may exhibit no clinical signs.
- Mild, vague signs (e.g., delayed postoperative recovery, failure to thrive) may be the earliest manifestations of the onset of bacterial pneumonia as a complication of another disorder (e.g., sepsis, systemic inflammatory response syndrome, multiple organ dysfunction syndrome).
- The lack of signs referable to the respiratory system does not exclude the diagnosis.

PHYSICAL EXAM FINDINGS: Physical examination may be unremarkable or reflect only signs relating to the underlying predisposing disorder in the presence of mild or moderate bacterial pneumonia. Lack of signs referable to the respiratory system cannot exclude the diagnosis. Findings are variable:

- Cough
    - Hemoptysis possible
- Nasal discharge
- Crackles or wheezes, sometimes focally; focal absence of breath sounds also possible
- Fever
- Tachypnea
- Increased respiratory effort or overt respiratory distress

ETIOLOGY AND PATHOPHYSIOLOGY

- Bacterial pneumonia is most often a complication of another disease that disrupts mechanical or immunologic pulmonary clearance and defense mechanisms:
    - Impaired mucociliary clearance
    - Impaired reflex closure of the glottis
    - Absent or impaired cough reflex
    - Abnormal immune function:
        - Innate
        - Acquired
- *B. bronchiseptica* is capable of causing disease as a primary pathogen in dogs or cats without other apparent underlying risk factors or concurrent disease.
- Bacteria most often enter lungs via airways but can enter hematogenously. With impaired clearance and defense mechanisms, bacteria can proliferate and initiate local inflammatory responses:
    - Common isolates in dogs and cats include gram-negative aerobes such as *Escherichia coli, Klebsiella, Bordetella, Pasteurella,* and *Staphylococcus* spp.
        - Acutely fatal pneumonia associated with hemothorax and bleeding into airways, caused by *Streptococcus equi* subsp. *zooepidemicus,* has been described in dogs from dense housing situations.
    - Regionally endemic diseases, such as plague and tularemia, can be causes of primary pneumonia.
- Local inflammatory responses cause pulmonary lesions, impair lung function, and can contribute to respiratory and systemic disease manifestations.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

Definitive diagnosis of bacterial pneumonia hinges on demonstration of bacteria either by culture and sensitivity testing (most sensitive) or by cytologic examination of respiratory wash samples. A second key for many patients is pursuit of underlying or concurrent disease that increases risk for bacterial pneumonia.

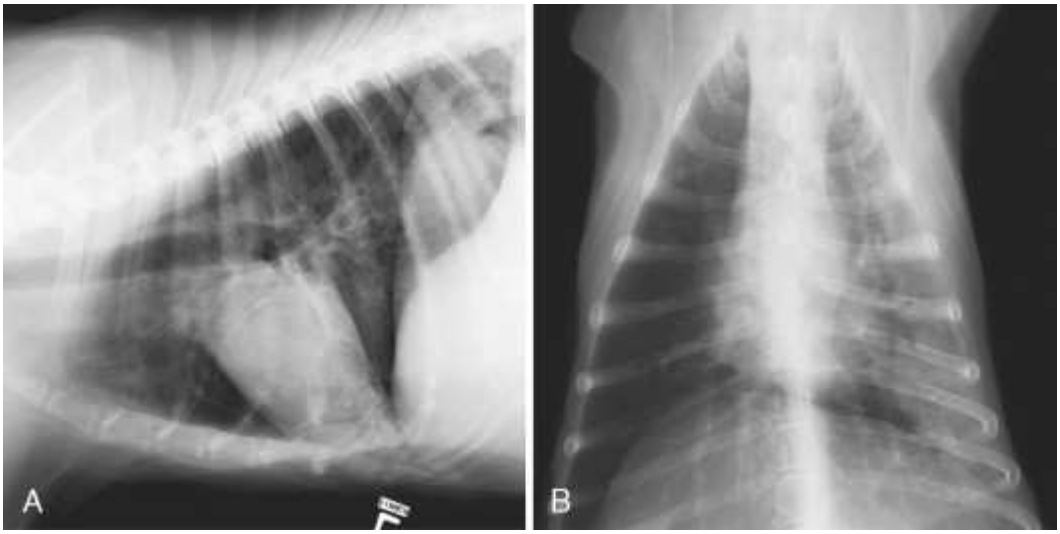
DIFFERENTIAL DIAGNOSIS

Many diseases share clinical and diagnostic similarities, including:

- Noninfectious inflammatory respiratory diseases
- Pulmonary neoplasia
- Respiratory parasites
- Pulmonary edema
- Fungal pneumonia, particularly blastomycosis and coccidioidomycosis in dogs

INITIAL DATABASE

- CBC: inflammatory leukogram (with or without left shift) expected although not seen in all cases
    - Neutropenia is also possible, especially with severe sepsis. Conversely, bacterial pneumonia can develop secondary to primary neutropenic disorders (e.g., myelosuppression from chemotherapy).
- Serum biochemical profile/urinalysis: often normal
- Thoracic radiographs:
    - Two or more views (at least one lateral and either a ventrodorsal [VD] or dorsoventral [DV]) are recommended in all cases.
        - Obtaining both right and left lateral recumbent views can be useful, since pneumonia infiltrates may only be apparent in nondependent lung.
    - Alveolar pattern in dependent regions of lung lobes expected in most cases.
        - Right middle lung lobe is commonly affected and may require careful examination on the lateral projection because it overlies the heart.
    - Interstitial patterns, with or without alveolar patterns, are also possible.
    - In some cases, lobar consolidation will be the prominent radiographic abnormality.
    - Other abnormalities that reflect underlying primary disease (as examples):
        - Megaesophagus
        - Bronchiectasis
        - Neoplasia



PNEUMONIA, BACTERIAL A, Left lateral thoracic radiograph in a 14-year-old mixed-breed dog with pneumonia. Alveolar infiltrates are visible over the cardiac silhouette (especially the apex) but are not striking. Microcardia is also present, suggesting hypovolemia. **B,** Dorsoventral thoracic radiograph of same dog. Left-sided alveolar infiltrates are more clearly apparent than in **A,** where they were obscured by being on the dependent side and overlying the cardiac silhouette.

ADVANCED OR CONFIRMATORY TESTING

- Confirmatory tests help rule out predisposing diseases/risk factors:
    - Respiratory washes (see p. 1350) and bronchoalveolar lavage (see p. 1220):
        - Primarily septic, suppurative inflammation:
            - Bacteria are not always evident in cytologic exams, so clinicians should submit wash specimens for culture and sensitivity testing irrespective of cytologic findings.
    - Fine-needle aspiration for cytologic analysis: may help exclude fungal pneumonia or neoplasms:
        - Limited sensitivity: absence of neoplastic cells or fungal organisms does not definitely exclude their presence
        - Theoretical risk of needle-tract seeding if aspiration of a solitary pulmonary tumor
    - Bronchoscopy (see p. 1220):
        - Endobronchial masses or foreign bodies may be evident in some cases.
        - Mucopurulent exudate in airways of affected regions may be seen.
        - Dilated/sacculated airways (bronchiectasis)
    - CT scan: superior delineation of the extent of pneumonia but often not needed when good-quality thoracic radiographs are consistent with the diagnosis.
    - Barium esophagram: if clinician suspects megaesophagus or esophageal motility dysfunction, and this condition is not clearly apparent on survey thoracic radiographs.
- Arterial blood gas (ABG) analysis:
    - Hypoxemia and hypocapnia are the most common abnormalities; when present, generally indicate severe pneumonia or presence of a complicating factor (e.g., acute respiratory distress syndrome [ARDS]) and therefore a more guarded prognosis.

- Other tests specific for underlying diseases (e.g., serum acetylcholine receptor antibody titers for myasthenia gravis-induced megaesophagus).

TREATMENT

TREATMENT OVERVIEW

Administration of antimicrobials is the cornerstone of treatment, but clinicians also need to treat/resolve predisposing factors to the extent possible.

ACUTE GENERAL TREATMENT

- Broad-spectrum antibiotics:
  - Clinically unstable animals should be treated with broad-spectrum IV antibiotics:
    - Ampicillin (22 mg/kg IV q 8 h) or cefazolin (22 mg/kg IV q 8 h) and either enrofloxacin (3-5 mg/kg IV q 24 h [dogs]) or an aminoglycoside such as amikacin (20 mg/kg SQ or IV q 24 h); aminoglycosides, however, should not be used in animals that are dehydrated or that have renal compromise.
    - The clinical condition of the animal, if severe, may warrant therapy before obtaining respiratory samples for culture.
  - Clinically stable animals may be treated with oral antibiotics, ideally selected based on culture and sensitivity (C&S) testing. Empirical choices while awaiting results include:
    - Ampicillin or amoxicillin/clavulanate 22 mg/kg q 8 h; *or*
    - Trimethoprim-sulfa 15 mg/kg q 12 h
  - Because of concerns about the pathogenic potential of *Mycoplasma* species in pneumonia, doxycycline (3-5 mg/kg PO q 12 h) may be considered, particularly for animals that show no response to therapy with other antibiotic choices.
- Saline nebulization several times daily
- Oxygen (nasal cannula, oxygen cage, face mask) for hypoxemic animals or those in respiratory distress (see p. 1318)
- IV fluids as needed
- Bronchodilators as needed
  - Theophylline: dosage varies with formulation.
  - Terbutaline: 1.25-5 mg/dog PO q 8 h; 0.625 mg/cat PO q 12 h, or 0.1-0.2 mg/kg PO q 12 h (cat)

CHRONIC TREATMENT

- Thoracic coupage and position changes in recumbent animals
- Identification and management of underlying causes when identified
- Antibiotic therapy continued at least 1 week beyond radiographic resolution of infection
- Lung lobectomy is occasionally needed to resolve infection when extensive single-lobe involvement has failed medical therapy or is associated with recurrent infection.
  - Prognosis associated with lobectomy is considered best if done for foreign-body pneumonia.

POSSIBLE COMPLICATIONS

- Lung lobe abscess
- Bronchiectasis
- Recurrence if underlying cause not identified and treated

RECOMMENDED MONITORING

- Clinical signs (respiratory rate, effort, etc.):
  - Carefully reevaluate animals that are not clinically better within 48-72 hours of starting empirical therapy or deteriorate substantially at any time; consider pursuing more diagnostic tests and/or changing therapy.
- Thoracic radiographs:
  - Radiographic changes can lag as much as 48 hours behind clinical changes.
  - Repeating thoracic radiographs approximately 1 week after cessation of antibiotics may demonstrate focal primary diseases (e.g., neoplasia) not evident on initial radiographs.
- ABG analysis
- CBC

PROGNOSIS AND OUTCOME

Varies with severity of disease and nature of predisposing factors:

- Prognosis for uncomplicated pneumonia is generally good.
- Prognosis for animals with risk factors depends on ability to treat/resolve the risk factor.
    - Recurrent infections are common in animals with unresolved primary diseases.

PEARLS & CONSIDERATIONS

COMMENTS

Bacterial pneumonia should be viewed as a complication of another underlying disease; *B. bronchiseptica* infections are an exception. Therefore, patients should be rigorously evaluated for risk factors if such factors are not immediately apparent.

TECHNICIAN TIPS

- Puppies with bacterial pneumonia, particularly those that came from pet stores or shelters, should ideally be isolated from other animals in the hospital, including cats, because *B. bronchiseptica* is common in those animals.
- For respiratory washes, make sure the wash solution does not contain bacteriostatic agents.

CLIENT EDUCATION

- Following recommended diagnostic and monitoring suggestions is important for most effective long-term resolution.
- Home treatment may include:
    - Respiratory humidification by inhalation of “cold steam” is best accomplished by having a pet in a closed, unventilated bathroom (but not in the bath/shower) for 10-15 minutes once to three times a day while a warm shower runs.
    - This is often followed by coupage, which is a series of brusque pats to both sides of the chest, performed for 10-30 seconds after each humidification session, with the intention of loosening pulmonary secretions and pus to facilitate expectoration.
    - Pet owners should only perform these treatments on the recommendation of a veterinarian; they can make a condition worse if used inappropriately.

AUTHOR & EDITOR: RANCE K. SELLON

Pneumonia, Aspiration

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Infection associated with inhalation of oropharyngeal secretions. In veterinary medicine, the term is often used in reference to aspiration pneumonitis, which is chemical injury caused by inhalation of gastric contents (most commonly) or other materials (e.g., barium, mineral oil).

SYNONYMS

Aspiration pneumonitis, Mendelson syndrome

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats of either sex and any age

RISK FACTORS

- Diseases of:
  - Pharynx or larynx (e.g., laryngeal paralysis)
  - Esophagus (e.g., megaesophagus)
  - Stomach or intestine (e.g., pyloric obstruction)
- Forced enteral administration of drugs or foods
- Impaired protective reflexes (e.g., coma, anesthesia, seizure)

ASSOCIATED CONDITIONS & DISORDERS

- Acute respiratory distress syndrome
- Bacterial pneumonia
- Hypoxemia
- Lung lobe abscessation
- Pneumothorax
- Shock
- Airway obstruction

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute or chronic
- Fulminant or insidious

HISTORY, CHIEF COMPLAINT: Clinical signs may be absent or severe; when present, they may include:

- Anorexia
- Collapse
- Cough
- Lethargy
- Respiratory distress
- Others that reflect predisposing cause (e.g., regurgitation, anesthetic episode)

PHYSICAL EXAM FINDINGS: Findings may be absent or severe; when present, they may include:

- Tachypnea
- Inspiratory and expiratory distress
- Auscultatory abnormalities (may be localized if present):
  - Crackles

    - Wheezes
    - Increased or decreased bronchovesicular sounds
- Cyanosis
- Fever (fewer than half of affected animals are febrile)
- Shock
- Others that reflect predisposing cause (e.g., exercise intolerance with myasthenia gravis)

ETIOLOGY AND PATHOPHYSIOLOGY

- Inhalation of particulates or fluid into the larynx and lower respiratory tract triggers injury.
    - Gastric contents are typically sterile, but acid and particulate matter can cause potentially severe damage:
        - Acid causes direct, caustic epithelial damage that is followed by inflammation.
        - Particulate material may obstruct airways.
    - Infection may follow aspiration of colonized oropharyngeal secretions or is a secondary (opportunistic) complication of respiratory damage.
- Severity of injury depends on volume, toxicity, pH, and particulate and pathogen content of aspirated material. Sequelae may include:
    - Airway obstruction
    - Bronchoconstriction
    - Pulmonary hemorrhage
    - Epithelial necrosis
    - Pulmonary inflammation

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Differentiation of aspiration pneumonia from bacterial pneumonia or pulmonary edema is often dependant on circumstantial evidence such as witnessed episodes of aspiration, history of vomiting or regurgitation, or involvement of the typical lung lobes.

DIFFERENTIAL DIAGNOSIS

- Infectious pneumonia
- Cardiogenic or noncardiogenic pulmonary edema
- Neoplastic infiltrates

INITIAL DATABASE

- Neurologic examination reflects underlying neurologic disease if present.
- CBC: neutrophilic leukocytosis common but not essential (absence does not exclude aspiration pneumonia)
- Serum biochemical profile and urinalysis: no specific changes
- Thoracic radiographs: abnormalities may lag aspiration by up to 24 hours:
    - Both right and left lateral views should be acquired.
    - Alveolar or interstitial pattern or consolidation in affected lung lobes:
        - Common in the lobes that were dependent at the time of aspiration
        - If the patient was conscious during aspiration, abnormalities usually occur in the right middle, right cranial, or caudal portion of the left cranial lung lobe.

ADVANCED OR CONFIRMATORY TESTING

- Pulse oximetry and/or arterial blood gas (ABG) analyses to assess oxygenation
- Tracheal lavage (submit samples for aerobic culture and sensitivity [C&S]):
    - Neutrophilic inflammation
    - Bacteria possible
    - Hemorrhage
    - Particulates/debris
    - Lipid-laden macrophage
- Bronchoscopy indicated only if clinician suspects large-airway obstruction
- Search for predisposing cause of aspiration (e.g., acetylcholine receptor antibody titer for myasthenia gravis-related megaesophagus)

TREATMENT

TREATMENT OVERVIEW

Severity of aspiration pneumonia varies, and therefore intensity of therapeutic intervention varies as well. Adequate oxygenation must be assured and further aspiration prevented when possible. Most animals are treated with antimicrobial drugs because of concerns related to secondary bacterial infection.

ACUTE GENERAL TREATMENT

- If aspiration is witnessed, immediately suction material from pharynx/airways and ensure airway patency.
- If respiratory distress or evidence of hypoxemia exists, administer supplemental oxygen using the lowest effective oxygen concentration (typically, Fio2 around 40%). See p. 1318.
    - If Pao2 < 50 mm Hg or if Pco2 > 50 mm Hg, intubate for positive-pressure ventilation.
- Bronchodilators may relieve bronchospasm (cats especially): aminophylline (dose varies with preparation of the medication) or terbutaline (0.01 mg/kg SQ).
- IV crystalloid fluids may be warranted:
    - Maintenance rate of 60 mL/kg per day after correction of dehydration; more if there are ongoing losses
    - Rarely, shock occurs, requiring aggressive fluid therapy.
        - Caution: excessive parenteral fluids may precipitate edema in the damaged lung.
- Antimicrobials are often suggested for these animals, since secondary infection is common.
    - Choice ideally based on C&S (tracheal or bronchial lavage)
    - Initial choice often parenteral broad-spectrum antibiotics (e.g., combination of ampicillin, 22 mg/kg IV q 8 h; and enrofloxacin, 5 mg/kg 12 h [dogs] or 5 mg/kg q 24 h [cats])
- Physiotherapy: coupage, movement (see p. 1310)
- Saline nebulization
- If aspiration is suspected but respiratory distress is absent, only careful observation may be warranted.

CHRONIC TREATMENT

- Prevent further aspiration or reduce severity of injury from aspiration (see Prevention below)
- Discontinue oxygen when Pao2 remains above 65 mm Hg and the animal can breathe comfortably without it.
- Continue antibiotics 1 week past radiographic resolution (typically 3-4 weeks).

NUTRITION/DIET

Animals with severe ongoing vomiting/regurgitation should not be fed by mouth.

BEHAVIOR/EXERCISE

- Recumbent animals with severe pneumonia should not be allowed to lie with the most functional lobes on the down side.
- Movement may facilitate beneficial cough and airway clearance.

POSSIBLE COMPLICATIONS

- Administration of high concentrations of oxygen for prolonged periods can contribute to respiratory epithelial injury.
- Parenteral fluids may worsen noncardiogenic pulmonary edema.

RECOMMENDED MONITORING

- Oxygenation (ABG or pulse oximetry): depending on severity of disease, q 4-24 h until normalized
- Thoracic radiographs: until abnormalities are resolved with frequency determined by severity of signs and baseline abnormalities; ideally repeated 1-2 weeks after discontinuation of antibiotics
- CBC: rechecked at least weekly until leukocytosis resolved

PROGNOSIS AND OUTCOME

Depends on volume and character of aspirated material. Prognosis cannot be predicted by severity of radiographic change.

PEARLS & CONSIDERATIONS

COMMENTS

Because aspiration pneumonia rarely occurs in the absence of an underlying cause, animals should be evaluated for risk factors.

TECHNICIAN TIPS

- Sudden respiratory signs in hospitalized animals should be brought to the attending veterinarian's attention immediately.
- For animals with regurgitation, maintaining an upright position with the head and chest elevated above the stomach for at least 30 minutes after oral feeding may minimize the risk of aspiration.

PREVENTION

- Address underlying diseases that predispose the animal to aspiration.
- Fast animals at least 6 hours before general anesthesia, and use properly inflated, cuffed endotracheal tubes during anesthesia.
- For animals at high risk, consider administration of antacids (H2 antagonists, proton pump inhibitors) to increase gastric pH, and administration of prokinetic agents (e.g., metoclopramide) to enhance gastric emptying and increase lower-esophageal sphincter tone. Unfortunately, these measures have not been shown to improve outcomes in humans at high risk for aspiration.
- Use caution in forced administration of drugs or foodstuffs.
- Feeding tubes should not cross the lower-esophageal sphincter.

CLIENT EDUCATION

When a predisposing cause is not reversible (e.g., idiopathic megaesophagus), repeated aspiration events are common.

AUTHOR: LEAH A. COHN

EDITOR: RANCE K. SELLON

Pneumocystosis

BASIC INFORMATION

DEFINITION

Infectious opportunistic disease of the lungs; associated with immune incompetence

SYNONYM

Pneumocystis carinii pneumonia

EPIDEMIOLOGY

SPECIES, AGE, SEX: Young animals, primarily dogs of either sex

GENETICS & BREED PREDISPOSITION: Miniature dachshunds, Shetland sheepdogs, and Cavalier King Charles spaniels

RISK FACTORS

- Congenital or acquired immune-suppressive diseases
- Syndrome of common variable immunodeficiency in the miniature dachshund

CONTAGION & ZOONOSIS: Transmission to an HIV-infected person is possible.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Some or all of the following may prompt an owner to seek veterinary consultation:

- Tachypnea/respiratory distress
- Exercise intolerance
- Weight loss

PHYSICAL EXAM FINDINGS

- Tachypnea
- Respiratory distress
- Poor body condition
- Marked increase in respiratory sounds on thoracic auscultation
- Cyanosis with severe infections

ETIOLOGY AND PATHOPHYSIOLOGY

- Pneumocystosis is caused by *P. carinii*, a saprophyte of the mammalian respiratory tract whose life cycle is completed within the alveolar spaces.

Only a single species name has been assigned to the genus *Pneumocystis*, but antigenic differences suggest that several strains may exist.

- Based on nucleic acid analysis, the organism is classified as an atypical fungal organism.
- *P. carinii* can be present in low numbers in the pulmonary alveoli of healthy animals and is only associated with pneumonia and respiratory distress when there is immune compromise.
- With immune compromise, *P. carinii* proliferates within the alveoli, resulting in alveolar capillary blockage and ventilation/perfusion mismatch. Thickening of alveolar septa occurs, but there is rarely extension of the infection into the pulmonary interstitium.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other infectious pneumonias:
  - Bacterial
  - Viral
  - Protozoal
  - Mycotic
- Pulmonary fibrosis
- Congestive heart failure

INITIAL DATABASE

- CBC:
  - Erythrocytosis
  - Thrombocytosis
  - Mild neutrophilic leukocytosis
  - Eosinophilia and monocytosis in some cases
- Serum biochemistry profile:
  - Normal serum protein levels or a low to low-normal globulin level
- Urinalysis: usually normal
- Serum protein electrophoresis: hypogammaglobulinemia
- Thoracic radiographs:
  - Mixed alveolar and interstitial pattern
  - Bronchial pattern
  - Cor pulmonale (right-sided cardiomegaly)

ADVANCED OR CONFIRMATORY TESTING

- Other laboratory tests:
  - Arterial blood gas (ABG) analysis:
    - Hypoxemia
    - Normocapnia to hypocapnia
    - Increased alveolar-arterial (A-a) oxygen gradient
- Serologic tests: available for humans but of uncertain value for dogs
- Other diagnostic procedures:
  - Definitive antemortem diagnosis of *P. carinii* is established by direct visualization of either the trophozoite or cyst in respiratory washes collected by transtracheal aspiration or bronchoalveolar lavage, lung needle aspirates, or lung biopsies obtained by thoracotomy or thoracoscopy.
  - Histochemical stains and diagnostic immunohistochemistry tests may facilitate observation of organisms.
  - PCR test on respiratory samples can also document presence of the organisms.

TREATMENT

TREATMENT OVERVIEW

Eradicate infection.

ACUTE GENERAL TREATMENT

- Oxygen administration (see p. 1318)
- Mucolytics:
  - Acetylcysteine (10% or 20% solution) 50 mL/hr for 30-60 minutes q 12 h by nebulization
  - Bromhexine, 1 mg/kg PO q 12 h
  - Administration of bronchodilators beforehand is recommended.
- Bronchodilators: aminophylline, 10 mg/kg PO q 8 h; or terbutaline, 0.625-2.5 mg PO total dose q 8 h
- Saline nebulization to liquefy hyperviscous mucus and thus promote the removal of secretions from the respiratory tree

CHRONIC TREATMENT

- Drug of choice: trimethoprim-sulfonamide, 15 mg/kg PO q 8 h for 3 weeks
- Pentamidine isethionate: 4 mg/kg IM q 24 h for 2 weeks
- Atovaquone: 15 mg/kg PO q 24 h for 3 weeks

- Clindamycin and primaquine: 3-13 mg/kg PO q 8 h for 3 weeks
- Carbutamide: 50 mg/kg IM q 12 h for 3 weeks
- Drug combinations: dapsone (1 mg/kg PO q 8 h) and pyrimethamine (1 mg/kg PO q 24 h)

POSSIBLE COMPLICATIONS

Respiratory failure, respiratory arrest

RECOMMENDED MONITORING

- Thoracic radiographs
- ABG analysis

PROGNOSIS AND OUTCOME

Dependent on severity of infection

PEARLS & CONSIDERATIONS

COMMENTS

Infection with *P. carinii* is associated with immunologic defects.

PREVENTION

Because of the probable genetic basis to immune compromise in most animals, owners should not breed affected animals.

TECHNICIAN TIPS

- When preparing for respiratory washes, be sure to use solutions that do not contain bacteriostatic additives. If available, prewarm solutions for respiratory lavage in a 37°C incubator (or suitable alternative).
- Needle aspiration of the lung is commonly performed with 23-G needles and a 6- or 12-mL syringe in the dorsal lung fields, defined by rib spaces 6-8.
- Educate the owners to the importance of ensuring good nutrition and warmth, short leash-controlled walks, and avoiding close contact with animal's face.

CLIENT EDUCATION

- Affected animals have an underlying immunologic defect.
- May be a zoonosis in persons who are immunocompromised.

Pleural Effusion

BASIC INFORMATION

DEFINITION

Accumulation of fluid within the pleural space

SYNONYMS

Pleural fluid, thoracic effusion, hydrothorax (pure transudate or modified transudate), hemothorax (hemorrhage; see p. 493), chylothorax (chyle; see), pyothorax (exudate; see p. 956)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats
- Pyothorax may be more common in younger cats.
- Pleural effusion secondary to congenital cardiac disease is more common in young animals, and pleural effusion secondary to acquired heart disease (including thyrotoxicosis) is more common in middle-aged to older animals.

GENETICS & BREED PREDISPOSITION

- Pyothorax secondary to aspiration of grass awns is most common in hunting/sporting dogs.
- As a component of congestive heart failure, pleural effusion may occur more commonly in specific breeds predisposed to certain cardiovascular diseases.

RISK FACTORS

- Hydrothorax: heart disease (cats > dogs), hypoalbuminemia, neoplasia, lung lobe torsion
- Hemothorax: trauma, intrathoracic neoplasia, anticoagulant toxicity
- Chylothorax: heart disease (cats > dogs), neoplasia, trauma, intestinal lymphangiectasia
- Pyothorax: penetrating injury, inhalation of foreign body, pneumonia, mediastinitis, esophageal perforation (septic); feline infectious peritonitis (FIP) (nonseptic). Higher incidence of FIP in multicat households.

CONTAGION & ZOONOSIS: Based on certain specific causes (e.g., FIP)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Hydrothorax
- Hemothorax
- Chylothorax
- Pyothorax

HISTORY, CHIEF COMPLAINT

- Severity of clinical signs varies with underlying cause, volume of effusion, and rate of fluid accumulation
  - If rate of accumulation is slow, large volumes may be present before clinical signs are apparent (especially cats).
- Restrictive breathing pattern, tachypnea, orthopnea/general discomfort, dyspnea (e.g., abdominal component of respirations) noted by owners
- Lethargy, exercise intolerance
- Cough
- Signs related to underlying disease:
  - Chronic cough
  - Weight loss
  - Inappetence

- Abdominal effusion
- Diarrhea
- Other signs of trauma
- Exercise intolerance

PHYSICAL EXAM FINDINGS: In general for pleural effusion:

- Dyspnea, including wide chest excursions, possibly abducted elbows when standing, extension of the neck, reluctance to lie in lateral recumbency, anxious facial expression, and abdominal lift (cats). These animals typically have a prolonged inspiratory phase and very short expiratory phase.
- Muffled heart and lung sounds ventrally
- Normal to increased bronchovesicular lung sounds (breath sounds) dorsally
- Ventral hyporesonance with thoracic percussion; a fluid line may be detected.
- Other signs associated with specific underlying cause

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology and fluid classification reflect basic pathophysiologic mechanisms of effusion formation:
  - Reduced plasma colloid oncotic pressure (hydrothorax: pure transudate)
    - Hypoalbuminemia: protein loss (renal: glomerulonephritis [GN], amyloidosis; gastrointestinal [GI]: inflammatory bowel disease, lymphangiectasia, neoplasia, others; vasculitis: infectious or noninfectious) or synthetic failure (chronic hepatopathy, portal vascular anomalies)
  - Increased capillary hydrostatic pressure (hydrothorax: usually modified transudate)
    - Congestive heart failure, Budd-Chiari-like syndromes
    - Thoracic or mediastinal neoplasia
- Reduced lymphatic drainage/lymphatic obstruction (hydrothorax, chylothorax, or pyothorax: modified transudate to exudate):
  - Thoracic or pulmonary neoplasia
  - Chylothorax
- Increased vascular permeability (pyothorax: exudate):
  - Pyothorax
  - FIP
- Disruption of vascular integrity or hemostatic abnormalities (hemothorax):
  - Rupture of neoplastic mass
  - Coagulopathy
  - Trauma
- Respiratory dysfunction can reflect hypoventilation and ventilation/perfusion mismatch

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Physical examination can provide a suggestion of pleural effusion. Presence of the effusion can be confirmed via imaging (thoracic radiographs, thoracic ultrasound) or thoracocentesis. Thoracocentesis and fluid analysis can provide more precise information on the nature of the fluid and perhaps the etiology.

DIFFERENTIAL DIAGNOSIS

- Other pleural space disease:
  - Masses
  - Pneumothorax
  - Constrictive/fibrosing pleuritis (can occur concurrently with pleural effusion—often chylothorax or pyothorax—and typically causes very rounded lung lobe contours that may be difficult to distinguish radiographically from those caused by pleural effusion).
- Pulmonary parenchymal or airway disease
- Thoracic wall disease
- Diaphragmatic hernia
- Neuromuscular disease

INITIAL DATABASE

- In animals with pleural effusion causing severe dyspnea, some clinicians prefer to perform thoracocentesis first and then take thoracic radiographs.

    - Advantages of centesis first: therapeutic value (removal of effusion), diagnostic value (fluid analysis, improved radiographic visualization of parenchymal structures)
    - Advantage of radiographs first: safety (confirms pleural effusion; can identify displacement of cardiac silhouette, to be avoided during centesis)
- Thoracic radiographs; radiographic signs of pleural effusion vary with fluid volume and can include:
    - Interlobar fissures:
        - Approximately 100 mL of fluid is present in a medium-sized dog if fissure lines are evident.
        - Small volumes may be better appreciated on ventrodorsal views.
    - Impaired heart visualization, especially on dorsoventral view
    - Retraction ("scalloping") of lungs from thoracic wall with interposed fluid opacity
    - On lateral radiographs, increased opacity dorsal to the sternum and ventral scalloping of lung margins. The lateral view is prone to misinterpretation, and standard two-view thoracic radiography is recommended in all cases.
    - Blunting of lung margins at costophrenic angles (ventrodorsal view)
    - Obscured diaphragm
    - Widened mediastinum
    - Fractured ribs, diaphragmatic hernia, and other orthopedic injuries may be present if traumatic etiology.
    - Pyothorax and chylothorax may cause constrictive pleuritis, preventing full expansion of lungs after thoracocentesis. The lung lobes appear rounded in contour.
    - Evaluation of radiographs post thoracocentesis for underlying pulmonary disease as visualization of intrathoracic structures improves
- Clinicopathologic abnormalities depend on etiology; possibilities include:
    - CBC:
        - Inflammatory leukogram
        - Thrombocytopenia
        - Anemia
    - Biochemical panel:
        - Hypoalbuminemia
        - Hypoglobulinemia or hyperglobulinemia
        - Hypoglycemia
        - Hypocholesterolemia
        - Azotemia
        - Electrolyte abnormalities
        - Increased liver enzyme activities
        - Hypercalcemia possible with mediastinal lymphoma
    - Urinalysis:
        - Proteinuria
- Thoracocentesis (see p. 1338):
    - Fluid in EDTA (lavender top) and plain (red top) tubes for analysis; prepare fresh smears.
    - If pyothorax is suspected, a culture and sensitivity (C&S) is indicated (aerobic and anaerobic in all cases):
        - Most common canine isolates are *Peptostreptococcus, Bacteroides* spp., *Escherichia coli, Klebsiella pneumoniae, Enterobacter, Fuso-bacterium, Pasteurella* spp., *Actinomyces* spp., and *Nocardia* spp.
        - Most common in cats are *Bacteroides* spp., *Pasteurella* spp., *Peptostreptococcus, Fusobacterium* spp., and *Actinomyces* spp.
    - Measurement of effusion triglyceride and cholesterol concentration if chylothorax suspected
    - An effusion albumin/globulin ratio of >0.8 makes FIP unlikely (exception: if protein clot forms in vitro; false negative).
- Thoracic ultrasonography:
    - Often performed before thoracocentesis to improve the acoustic window, unless the animal is uncomfortable/dyspneic during restraint for the examination
    - Can identify mediastinal masses, consolidated lung lobes, pulmonary masses, and abdominal organs in the thoracic cavity with hernias
    - Can help identify localized fluid for sampling

ADVANCED OR CONFIRMATORY TESTING

Based on nature of effusion and diagnostic test results to date.

- Hydrothorax: pure transudate (effusion [total protein] <2.5 g/dL)
    - Urine protein/creatinine ratio
    - Liver function tests
    - Possibly intestinal biopsies (surgical or endoscopic) if protein-losing enteropathy suspected
- Hydrothorax: modified transudate (effusion [total protein] 2.5-5 g/dL; no cytologic evidence of infection or hemorrhage)
    - Thoracic ultrasound exam
    - Echocardiography, especially if there are signs of cardiac disease
    - CT for masses or pulmonary disease
    - Fine-needle aspirates and cytologic examination of lung or mass if lesion is identified

- Thoracoscopy or thoracotomy for pleural or lung biopsy
- Chylothorax:
  - Lymphangiography is occasionally performed to identify the site of disruption of the thoracic duct if an underlying cause (e.g., congestive heart failure, intestinal lymphangiectasia) has not been identified.
  - Echocardiography (especially cats) if there are signs of cardiac disease
  - CT scanning to check for masses
  - Thoracotomy/thoracoscopy
- Hemothorax:
  - Coagulation profile (PT, PTT, platelet count)
    - If abnormal, toxin screens may sometimes be performed.
    - If normal, imaging (ultrasound and/or CT scan) is indicated, and thoracoscopy/thoracotomy may be warranted if a mass lesion is identified or suspected.
- Pyothorax:
  - Careful examination of skin and haircoat (especially in long-haired pets, possibly including extensive shaving of hair over the thorax to improve visualization) for evidence of penetrating injury/foreign body.
  - Postcentesis/postdrainage thoracic radiographs or CT scan to identify masses, foreign bodies
  - Exploratory thoracotomy is indicated if an intrapleural foreign body is suspected. Thoracotomy may improve outcome in dogs with pyothorax, because pyothorax is often secondary to a migrating foreign body.

TREATMENT

TREATMENT OVERVIEW

Thoracocentesis is commonly needed acutely to improve respiratory function. Ultimately, identification and correction of the underlying disease provides the best chance for resolution of effusion.

ACUTE GENERAL TREATMENT

- Oxygen supplementation if dyspnea is present
- Minimize stress
- Thoracocentesis (seep. 1338)
- For pyothorax: bilateral (assuming bilateral involvement) thoracostomy tubes (see p. 1230) or thoracotomy and thoracic lavage/drainage:
  - Lavage through large-diameter chest tubes with sterile, warm (body temperature) isotonic fluids (10-20 mL/kg) 2-4 times a day for 5-7 days.
  - Drain thoracostomy tubes regularly.
  - Minimize risk of iatrogenic pneumothorax with thoracostomy tubes with clamps on tubes, three-way stopcocks, bandaging, and Elizabethan collars.
  - Analgesia as necessary; cats are often uncomfortable with thoracostomy tubes.
  - Removal of tubes when fluid production <2 mL/kg/d, and cytologic analysis (gram stain ideally) of fluid suggests it is sterile.
- For hemothorax:
  - Blood transfusion if severe anemia
  - Both plasma transfusion (see p. 1347) and vitamin K, 2.5-5 mg/kg SQ in multiple sites q 12 h, if anticoagulant rodenticide toxicity (see p. 83) is identified or suspected as the cause of hemothorax
- Support of circulation and respiratory function if effusion results from trauma

CHRONIC TREATMENT

- For some, correction of the underlying disorder may resolve effusion without thoracocentesis.
- With hypoalbuminemia, cardiac disease, vasculitis, or immune-mediated disease, therapy must be directed at the underlying cause.
- For pyothorax, antimicrobials are necessary but are generally ineffective without proper drainage.
  - Empirical choices based on Gram stain findings and common organisms (see previous paragraphs and Pyothorax, p. 956)
  - If filamentous organisms *(Actinomyces* or *Nocardia*) are identified, ampicillin (22 mg/kg IV q 8 h) and trimethoprim-sulfonamide (30 mg/kg PO q 12 h) are suitable choices.
  - Modify antimicrobial choices based upon results of C&S.
  - If using trimethoprim-sulfonamide, a physical exam and monitoring of tear production, hematologic parameters (including CBC), and liver function are indicated.
  - Administer antibiotics for 1 to 2 months.
  - Consider thoracotomy if there is a poor response to medical therapy over a few days or if pyothorax recurs after antibiotics are discontinued.

        - Some studies suggest better and more rapid resolution with early surgical intervention.
        - Submit any excised tissue for histopathologic examination.
- For hemothorax, consider thoracotomy if there is no evidence of coagulopathy, thrombocytopenia, or trauma and if there is poor/no response to medical treatment.
- Chemotherapy may be indicated when pleural effusion is neoplastic in origin. Confirmation of type of neoplasm (cytologic or histopathologic) is necessary.
- The use of vascular access ports attached to intrathoracic Jackson-Pratt drains has been described for chronic effusions refractory to therapy of the underlying disease.
- Pleuroperitoneal shunts can be used for chronic effusions (see p. 1542) but can have many associated complications.
- Thoracic omentalization has been described in combination with chemotherapy for the long-term treatment of neoplastic pleural effusion in a cat.

POSSIBLE COMPLICATIONS

- Iatrogenic pneumothorax and hemothorax from thoracocentesis or thoracostomy tube
- Constrictive/fibrosing pleuritis from pyothorax or chylothorax
- Disseminated intravascular coagulation (DIC) or systemic inflammatory response syndrome from pyothorax
- Recurrence of pyothorax if migrating foreign body remains or if inappropriate antibiotics are used
- Complications of thoracocentesis (and corresponding precautions) include:
    - Lung laceration (less likely if needle is introduced and withdrawn in linear fashion, without side-to-side or rotatory motions once the needle tip is in the pleural space) and subsequent pneumothorax
    - Reexpansion pulmonary edema; less likely if large-volume effusions are withdrawn periodically over several hours rather than all at once, and more likely with chronic effusions
    - Pleural shock: a sudden bradycardia of vagal origin caused by needle contact with the pleura (no prevention; responds to immediate administration of atropine 0.04 mg/kg IV)
    - Bronchopleural fistula: when constrictive/fibrosing pleuritis prevents further lung expansion during thoracocentesis and ongoing fluid withdrawal creates excessive negative pressure in the pleural space, a rupture of the bronchial wall into the pleural cavity may occur (possibly less likely to occur if large-volume effusions are withdrawn periodically over several hours rather than all at once, especially if lung lobes are very round on radiographs, suggesting constrictive/fibrosing pleuritis).

RECOMMENDED MONITORING

- Thoracic radiographs
- Daily cytologic examination and Gram stain of chest tube fluid withdrawn from pyothorax cases to assess antimicrobial response

PROGNOSIS AND OUTCOME

- Varies with cause and severity of underlying disease
- Pleural effusion may worsen the short-term prognosis of the underlying disease by potentially causing acute respiratory compromise.

PEARLS & CONSIDERATIONS

COMMENTS

- If pleural effusion is suspected, clinicians can consider thoracocentesis, which can be both diagnostic and therapeutic, before thoracic radiographs.
    - Drainage of only some fluid can improve respiratory function.
    - First obtain dorsoventral view, which is often sufficient to confirm effusion.
    - Alternatively, a very brief ultrasound evaluation may provide an initial confirmation of pleural effusion, justifying centesis. Radiographs may then be taken more safely after centesis.
    - Thoracic percussion also helps identify pleural effusion and supports preradiograph thoracocentesis.
- Ultrasonography can rapidly demonstrate pleural effusion in sternal recumbency or standing, with minimal restraint and stress.
- Cats with pleural effusion can be easily stressed by radiographs, so consider thoracocentesis early.
- Hemothorax usually develops from trauma, coagulopathies, or neoplasia.
- Grass awns can be located in multiple sites (including the pericardial sac) in dogs with pyothorax.
- Retrosternal fat and interindividual variation may give the false impression of pleural effusion on lateral radiographic projections of animals without pleural effusion. For this reason, and to determine whether the effusion is unilateral or bilateral,

standard two-view thoracic radiography is always indicated when pleural effusion is suspected or known to be present.

PREVENTION

Avoid trauma and exposure to anticoagulant rodenticides.

TECHNICIAN TIPS

- Animals with larger-volume pleural effusions can be very fragile and susceptible to stress with handling. Therefore minimal handling is important.
- Supplemental oxygen can be very helpful in a dyspneic patient with a pleural effusion.
- Avoid dorsal recumbency (ventrodorsal view) for radiographs in animals with pleural effusions.
- The basics for an emergency thoracocentesis include clippers, skin preparation materials, a butterfly needle or needle with an extension set, three-way stopcock, and syringes.
- The complications of thoracocentesis include pneumothorax and hemothorax. If your patient suddenly develops a high respiratory rate or effort after pleural drainage, alert the attending physician as soon as possible.

Platelet Dysfunction

BASIC INFORMATION

DEFINITION

A hemostatic defect caused by impaired platelet activation response. Platelet dysfunction is broadly classified as acquired or hereditary.

SYNONYMS

Thrombocytopathia, thrombopathia

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Acquired: depends on the underlying disease or treatment
- Hereditary: dogs and cats of both sexes; severe defects typically manifest by 1 year of age

GENETICS & BREED PREDISPOSITION

- All hereditary traits are autosomal, with recessive or unknown expression pattern.
- Affected dog breeds: basset hound, boxer, cocker spaniel, collie, German shepherd, Great Pyrenees, Landseer Newfoundland, otterhound, spitz
- Affected cat breeds: Persian cat, domestic shorthaired cat

RISK FACTORS: Acquired platelet dysfunction is associated with systemic disease (anemia, uremia, liver failure, hyperproteinemia), drug therapy (nonsteroidal antiinflammatory drugs [NSAIDs], heparin, plasma expanders, sulfonamides), and disseminated intravascular coagulation.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Acquired:
  - Mild to moderate bleeding tendency accompanying a primary disease or drug therapy
  - Hematuria, epistaxis, melena, persistent posttraumatic bleeding
- Hereditary: recurrent mucosal bleeds and ecchymoses, prolonged bleeding from loss of deciduous teeth or minor wounds, blood loss anemia after surgery or trauma

PHYSICAL EXAM FINDINGS

- Petechiae and ecchymoses
- Abnormal bleeding from traumatic/surgical wounds and catheter and venipuncture sites
- Mucosal hemorrhage (epistaxis, gingival hemorrhage, melena, hematuria)

ETIOLOGY AND PATHOPHYSIOLOGY

- Acquired: often multifactorial due to intrinsic changes in platelet metabolism or extrinsic alterations in blood viscosity:
  - Platelet effects of NSAIDs such as aspirin are irreversible (i.e., effects last as long as the platelet lifespan-several days), whereas others (e.g., colloids/plasma expanders) inhibit platelet function only during the time of administration.
- Hereditary defects: pathophysiologic classification:
  - Membrane glycoprotein (GP) disorders. Most common is thrombasthenic thrombasthenia (fibrinogen receptor [GP IIb/IIIa] defects)
  - Secretory granule (storage pool) defects
  - Signal transduction defects
  - Platelet procoagulant deficiency

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Thrombocytopenia and von Willebrand disease are the most common acquired and hereditary primary hemostatic defects, respectively. Along with ruling out these disorders, disorders of the coagulation cascade (coagulation profile), and vascular integrity as causes for clinical signs mentioned above, clinicians should consider platelet dysfunction.

DIFFERENTIAL DIAGNOSIS

- Thrombocytopenia
- Hereditary or acquired coagulation factor deficiencies
- von Willebrand disease
- Vasculopathy or erosive/infiltrative vessel defect
- Defect of fibrinolysis

INITIAL DATABASE

- Physical exam (including funduscopic and rectal exam) to differentiate systemic versus localized or focal site of hemorrhage
- Platelet count: usually normal
- Coagulation screening tests (e.g., activated partial thromboplastin time [APTT], prothrombin time [PT], activated clotting time [ACT]): usually normal
- CBC, serum biochemistry profile, urinalysis to define acquired disorders. Avoid cystocentesis
- Thorough history of drug or dietary supplement administration

ADVANCED OR CONFIRMATORY TESTING

- Buccal mucosal bleeding time: usually increased (normal: 2-4 minutes)
- Platelet morphology review
- Point-of-care hemostasis analyzer: the Platelet Function Analyzer (PFA100 [Dade Behring]) is a tabletop instrument that measures platelet adhesion and aggregation in whole-blood samples. The test endpoint (closure time) is sensitive to platelet adhesion and aggregation defects in dogs, but anemia, thrombocytopenia, and low plasma von Willebrand factor levels also cause prolonged closure time.
- Platelet testing for classification of hereditary defects (may require referral):
    - Clot retraction
    - Platelet aggregation and secretion studies
    - Flow cytometry
    - Electron microscopy
- Mutation detection test (basset hound, Landseer Newfoundland, spitz, otterhound, Great Pyrenees)

TREATMENT

TREATMENT OVERVIEW

- Control active bleeding with medical or transfusion therapy.
- Avoid invasive procedures pending correction of acquired disease (or transfusion):
    - For an acquired dysfunction:
        - Identify and correct underlying disease condition
        - Discontinue or substitute drug therapy
        - Platelet transfusion (although rarely needed)
    - For a hereditary dysfunction:
        - Transfuse sufficient platelets to support hemostasis

ACUTE GENERAL TREATMENT

- Control superficial sites of hemorrhage (gingival or cutaneous wounds).
    - Direct pressure, wound glue, suture, bandage
- Replace red blood cells (RBCs) for severe blood loss anemia (see p. 1347). Adjust initial doses based on hematocrit (Hct) and ongoing loss.
    - Fresh whole blood (e.g., 12-20 mL/kg IV)

- Packed RBCs (e.g., 6-12 mL/kg IV)
- Bovine hemoglobin polymer (Oxyglobin): cats, up to 10 mL/kg; dogs, up to 30 mL/kg). Measure hemoglobin, not hematocrit, to monitor effect.

- Initiate platelet replacement to control systemic bleeding: platelet-rich plasma has a short shelf life (days) and is less widely available and more expensive compared to other blood components. The half-life of transfused platelets is shorter than the half-life of RBCs, but it is still longer than most clotting factors and von Willebrand factor. A single platelet-rich plasma (PRP) transfusion may supply sufficient platelets to form a hemostatic plug, so in vivo half-life is not necessarily a limitation of the product.
  - Fresh whole blood (12-20 mL/kg IV)
  - Platelet-rich plasma (6-12 mL/kg IV; >5 × 10^9 plat/kg IV)

CHRONIC TREATMENT

- For hereditary dysfunction:
  - Avoid invasive procedures unless essential.
  - Do not administer drugs with antiplatelet effects.
  - Administer a perioperative transfusion to supply platelets.
- For prophylactic treatment:
  - Give platelet-rich plasma to animals with clinically severe hereditary platelet function disorders (i.e., showing or having shown overt clinical signs of bleeding) before any surgical procedure.
  - Consider additional transfusion(s) at 2- to 8-hour intervals; these may be needed for major surgery or if excessive hemorrhage is noted.
  - Administer desmopressin acetate (DDAVP; 1 mg/kg SQ); this may be sufficient to prevent abnormal bleeding due to acquired platelet dysfunction if invasive procedures must be performed. The need for additional transfusions is based on falling hematocrit and/or abnormal bleeding from the surgical site.

BEHAVIOR/EXERCISE

Dogs and cats with hereditary thrombopathias should be managed to prevent injuries (e.g., no access to sharp toys, bones, no unobserved outside activity).

DRUG INTERACTIONS

Judicious use or avoidance of drugs with antiplatelet or anticoagulant effects (e.g., NSAIDs, sulfonamides, heparin, warfarin, clopidogrel, plasma expanders, cytotoxic drugs, estrogens)

RECOMMENDED MONITORING

- Physical exam to monitor external blood loss and petechiae/ecchymoses
- Serial hematocrit and plasma protein determinations to help identify internal or chronic hemorrhage

PROGNOSIS AND OUTCOME

- Acquired dysfunction: good prognosis if underlying disease or drug therapy is reversed
- Hereditary dysfunction:
  - Depends on severity of defect
  - Repeated transfusions are required to maintain patients having severe defects.
  - Transfusion typically required for any major surgical or traumatic injury

PEARLS & CONSIDERATIONS

COMMENTS

- Acquired platelet dysfunction is common but rarely causes severe spontaneous hemorrhage. Animals that are bleeding severely should be evaluated for other potential underlying causes (anticoagulant rodenticide intoxication, severe thrombocytopenia, etc.).
- Hereditary platelet dysfunction is relatively uncommon but is likely underdiagnosed because of the need for referral to document and classify specific traits. Platelet dysfunction belongs on the differential diagnosis of abnormal bleeding in any young dog or cat after common disorders (thrombocytopenia, von Willebrand disease, coagulopathies) have been ruled out.
- Platelets stick to glass, including the inside of anticoagulant-filled blood collection bottles. Therefore, whole blood given to

replace platelets should be collected in plastic blood bags.
- The differential diagnoses for animals with persistent bleeding and a normal platelet count, normal PT, and normal APTT should include platelet function defects, von Willebrand disease, fibrinolytic defects, and diseased or damaged blood vessels.
- The website addresses for some of the veterinary blood banks operating in North America are http://www.hemopet.com/; http://www.midwestabs.com/; http://www.evbb.com/products.html; http://www.ssabb.com/; and http://www.rrc.mb.ca/abb/.

TECHNICIAN TIPS

- Dogs and cats with platelet dysfunction are at risk for abnormal hemorrhage at venipuncture and catheter sites. As a general rule, peripheral veins-not the jugular vein-should be used for venous access.

CLIENT EDUCATION

- Owners should avoid giving dietary supplements containing fish oils or plant alkaloids to any pet with acquired or hereditary platelet dysfunction.
- Platelet function testing and/or mutation detection tests may be indicated (before breeding or surgery) for breeds or lines with high prevalence of hereditary thrombopathias.

Plant Toxicoses

AV, Atrioventricular; *CNS,* central nervous system; *CV,* cardiovascular; *GI,* gastrointestinal tract; *V/D,* vomiting/diarrhea.

Some Common Garden and Household Toxic Plants

Botanical Name and Classification	Common Name(s)	Toxic Principle (if Known), Common Clinical Findings, and Species Sensitivity
Plants That Cause Central Nervous System (CNS) Stimulation		
Brunfelsia spp. (see p. 164)	Yesterday-today-and-tomorrow plant	Hopeanine, brunfelsamidine; vomiting/diarrhea (V/D), hyperesthesia, tremor, seizures in dogs
Ipomoea spp.	Morning glory	Lysergic acid; seeds; agitation, tachycardia, ataxia, hallucination; V/D, mostly dogs
Nicotiana spp. (see p. 766)	Tobacco	Nicotine; V/D, lacrimation, anxiety, shaking, agitation, tachycardia, followed by respiratory and cardiovascular (CV) collapse; mostly dogs
Plants That Cause CNS Depression		
Cannabis sativa (seep. 694)	Marijuana, pot, Mary Jane	Delta-9-THC; prolonged sedation, mydriasis, urinary incontinence, bradycardia, hypothermia, hypotension, hyperexcitability; mostly dogs
Macadamia integrifolia (see p. 681)	Macadamia nuts	Unknown toxin(s); depression, hyperthermia, mild tremor, weakness (especially in the hind limbs of dogs), muscular rigidity, ataxia
Plants That Cause Mixed CNS Effects		
Ricinus communis (see p. 180)	Castor bean	Ricin; vomiting, hemorrhagic enteritis, tremor, seizure/coma, death
Hepatotoxic Plants		
Amanita phalloides mushroom (see p. 734)	Death cap	Amatoxins: V/D, depression/lethargy, severe hepatic necrosis and failure, death; mostly in dogs
Cycas spp., *Zamia* spp. (see p. 814)	Sago palm, cycad palm	Cycasin; hemorrhagic gastroenteritis, hepatic encephalopathy, seizures, death
Cardiotoxic Plants		
Convallaria majalis (see p. 175)	Lily of the valley	Cardenolides; typically V/D; cardiac arrhythmias possible
Digitalis purpurea (see p. 175)	Foxglove	Cardiac glycosides; V/D, lethargy, cardiac arrhythmias, hyperkalemia
Kalanchoe spp. (see p. 175)	Kalanchoes	Bufadienolide; V/D, lethargy, cardiac arrhythmias in dogs possible but uncommon
Persea americana	Avocado	Persin; unsubstantiated cardiovascular toxicity reported in South Africa; not reported in the United States; vomiting in some dogs (gastroenteritis +/− pancreatitis, or due to intestinal obstruction from the large stone)
Nerium oleander (see p. 780)	Oleander	Cardiac glycosides (nerioside, oleandrin); V/D, digitoxin-like effect with bradycardia, tachycardia (any type of arrhythmia); hyperkalemia

Botanical Name and Classification	Common Name(s)	Toxic Principle (if Known), Common Clinical Findings, and Species Sensitivity
Phorandendron spp. (seep. 175)	Mistletoe	Toxalbumin, pharatoxin; V/D most common; very rarely bradycardia
Rhododendron spp. (see p. 175)	Rhododendron, azalea	Grayanotoxin; V/D; possible but uncommon conduction disturbances, with hypotension, bradycardia, AV block
Taxus spp.	Yew, Japanese yew	Taxine; V/D more common in dogs; tremor, hypotension, bradycardia, seizures
Plants That Affect the Respiratory System		
Hydrangea macrophylla	Hydrangea	Cyanogenic glycosides; V/D with or without blood; cyanide poisoning unlikely
Prunus spp.	Apple, cherry, bitter almond, plum, apricot, peach, nectarine	Cyanogenic glycosides (seeds); generally only cause V/D; cyanide poisoning unlikely; seeds must be masticated or ingested in large quantities for significant cyanide effect (hyperpnea, agitation, anxiety)
Nephrotoxic Plants		
Hemerocallis spp. (seep. 656)	Day lily	Unknown toxin(s); vomiting, lethargy, acute renal failure in cats at minimal exposures; only mild GI upset in dogs
Lilium spp. (see)	Easter lily, tiger lily, Asiatic lily, rubrum lily, Japanese show lily	Unknown water-soluble toxin(s); all parts toxic; vomiting, lethargy, acute renal failure in cats at minimal exposures; only mild GI upset in dogs
Oxalis spp.	Shamrock	Soluble (absorbable) calcium oxalates; hypersalivation, vomiting, possible renal failure (rare)
Rheum spp.	Rhubarb	Soluble (absorbable) calcium oxalates; hypersalivation, vomiting, possible renal failure (rare)
Vitis spp. (see p. 458)	Grapes and raisins	Unknown toxin(s); V/D, lethargy, acute renal failure, death in dogs
Plants Causing Hemolysis		
Allium spp.	Onion, garlic, chives	*N*-propyl disulfide; V/D, weakness, hemolytic anemia; cats more sensitive than dogs
Plants Affecting the Skin		
Toxicodendron spp.	Poison ivy, poison oak	Urushiol; hyperemia, pruritus possible; small-breed dogs with short-haired coats are more likely to be affected.
Plants Causing Severe Gastrointestinal (GI) Upset with Potential Systemic Effects		
Amaryllis spp.	Amaryllis, Aztec lily, orchid lily, and others	Lycorine; V/D, lethargy; tremors and cardiovascular signs (hypotension) also possible
Colchicum autumnale	Autumn crocus	Colchicine; vomiting, hemorrhagic enteritis, bone marrow suppression, tremor, seizure, death possible
Cycas spp., *Zamia* spp. (see p. 814)	Sago palm, cycad palm	Cycasin; hemorrhagic enteritis, liver necrosis, death
Hemerocallis spp. (seep. 656)	Day lily	Unknown toxin(s); vomiting; acute renal failure in cats, not dogs
Lilium spp. (see p. 656)	Easter lily, tiger lily, Asiatic lilies	Unknown toxin(s); vomiting, acute renal failure in cats, not dogs

Botanical Name and Classification	Common Name(s)	Toxic Principle (if Known), Common Clinical Findings, and Species Sensitivity
Narcissus spp.	Daffodil, jonquil, hyacinth	Lycorine; V/D, lethargy; moderate to severe V/D with ingestion of the bulb; tremors and CV signs (hypotension) possible with large ingestions
Ricinus communis	Castor bean	Ricin; vomiting, hemorrhagic enteritis, tremor, seizure, and coma, death
Vitis spp.	Grapes, raisins	Unidentified toxin(s); V/D, anorexia, lethargy, acute renal failure in 24-72 hours in dogs
Plants Causing Mild to Moderate GI Upset Without Systemic Effects		
Alocasia antiquorum	Elephant ear	Insoluble calcium oxalate crystals; oral irritation, hypersalivation, local inflammation, swelling of mucous membranes of pharynx and tongue; rarely causes dyspnea; may also cause histamine release
Cyclamen spp.	Cyclamen	Terpenoid saponins; hypersalivation, V/D. Cardiac arrhythmia, seizures with large ingestions (especially tuber portion of plant)
Dieffenbachia	Dumb cane	Insoluble calcium oxalate crystals; hypersalivation, V/D, oral pain.
Dracaena spp.	Corn plant, *Dracaena* plants	Saponins; salivation, V/D +/− hematochezia, anorexia
Epipremnum spp.	Golden pothos	Insoluble calcium oxalate crystals; V/D, hypersalivation, oral pain
Euphorbia spp.	Poinsettia	Latex sap; mild V/D (not deadly, as has been historically reported)
Hedera helix	English ivy	Saponins; mostly V/D, rarely agitation, ataxia, weakness
Philodendron spp.	Philodendron	Insoluble calcium oxalate crystals; hypersalivation, V/D, oral pain
Phytolacca americana	Pokeweed	Saponins, oxalates; V/D common, generally not life threatening; ingestion of berries may cause red-colored urine.
Schefflera spp.	Schefflera	Insoluble calcium oxalate crystals; V/D, hypersalivation, renal damage not expected
Schlumbergera bridgesii or *truncata*	Christmas cactus, Easter cactus	Unknown; mild V/D
Spathiphyllum spp.	Peace lily	Insoluble calcium oxalate crystals; hypersalivation, V/D, oral pain
Zantedeschia aethiopica	Calla lily	Insoluble calcium oxalate crystals; hypersalivation, V/D, oral pain

Plague

BASIC INFORMATION

DEFINITION

A zoonotic infection caused by *Yersinia pestis,* a non-spore-forming, nonmotile, gram-negative bacterium

SYNONYMS

Bubonic plague, yersiniosis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Cats are most susceptible; no age, sex, or breed predilection. Dogs are thought to be resistant to infection.

RISK FACTORS: Cats that hunt and are exposed to wild rodents and fleas are at highest risk for infection.

CONTAGION & ZOONOSIS

- *Y. pestis* is highly contagious and zoonotic; the bacterium is considered a bioterrorism risk.
- Humans are most commonly infected by flea bites. Cats and other domestic species may temporarily harbor infected fleas.
- Although rare, humans may be infected through direct contact with infected cats, rabbits, or rodents.
- Fomites appear to play a minimal role (the organism is sensitive to desiccation, temperatures above 105°F (40°C), and routine disinfectants). It can remain for weeks to months in organic material (e.g., carcasses), with freezing temperatures prolonging survival.
- Hygienic precautions involving gloving, gowning, mask usage, and avoiding contact between discharge/abscess fluid and open cuts or mucosal membranes, and the like, are essential when plague is possible.
- Direct transmission of zoonoses to veterinary personnel and cat owners has occurred via aerosol (from cats with plague-associated pneumonia). Therefore, in addition to flea elimination, precautions involving protection from respiratory secretions of cats should be implemented when plague is considered possible.
- A greater degree of human morbidity and mortality also appears to exist with delayed diagnosis, emphasizing the veterinarian's role in public health.

GEOGRAPHY AND SEASONALITY: Foci of plague occur most commonly in semi-arid, cooler climates usually adjacent to a desert. Plague is endemic in the western part of the United States, including New Mexico, Arizona, California, and Colorado. Plague is seasonal, with most cases occurring during the summer months.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Three geographic variants of plague exist (*Y. pestis* orientalis, antiqua, and mediaevalis) but are of equal virulence. Of greater clinical relevance, three clinical forms of plague can develop in humans and cats: bubonic, septicemic, and pneumonic.

HISTORY, CHIEF COMPLAINT: Cats may have a history of hunting, ingesting wild rodents, or being exposed to rodent fleas. Clinical signs reported by dog and cat owners usually are acute and nonspecific, including lethargy, fever, and depression. Some owners may notice swollen lymph nodes or draining cutaneous wounds.

PHYSICAL EXAM FINDINGS: Cats with plague will typically present with a fever (≥105°F [≥40.6°C]) and depression.

- Bubonic form: cats have enlarged and often abscessed, draining, or painful lymph nodes, (buboes; most commonly the retropharyngeal, cervical and submandibular lymph nodes).
- Septicemic form: cats demonstrate signs of septic shock with evidence of multiorgan involvement. The spleen is most commonly affected in people and the lungs in cats.
- Pneumonic form: cats may cough, sneeze, and have nasal discharge or dyspnea. The pneumonic form commonly occurs as a dissemination of the bubonic or septicemic forms.
- Dogs usually lack evidence of clinical disease.

ETIOLOGY AND PATHOPHYSIOLOGY

- Wild rodents (prairie dogs, squirrels, chipmunks, wood rats, mice) are reservoir hosts.
- Rodent fleas carry the infectious bacteria and transmit the infection to humans and animals through a bite. Domestic species may be infected through ingestion of a reservoir rodent.
- *Y. pestis* replicates within the host mononuclear cells, which carry the organism to the lymph nodes, resulting in the formation of characteristic buboes (abscessed lymph nodes). Alternatively, the infection may develop rapidly into a septicemia with hematogenous spread to multiple organs.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Presumptive diagnosis is made based on physical examination, relevant history, or suspicion of exposure in endemic areas. The local public health department should be contacted if there is suspicion of disease. Samples can be submitted for cytologic examination, Gram stain and culture, but care must be used to avoid zoonotic exposure. Paired titers are diagnostic, but treatment must be initiated before the disease is confirmed.

DIFFERENTIAL DIAGNOSIS

- Tularemia
- Bite wound abscess
- Other causes of systemic bacterial infection
- Feline panleukopenia virus
- Lymphoma (buboes)

INITIAL DATABASE

- CBC: possible marked leukocytosis
- Gram stain of draining material/fluid: gram-negative coccobacilli
- Chest radiographs: diffuse interstitial pattern or development of abscesses
- Aspiration and cytologic examination of enlarged lymph nodes

ADVANCED OR CONFIRMATORY TESTING

- The local public health department can confirm the diagnosis of plague with antigen detection using immunofluorescent antibodies on tissue samples or aspirates.
- Do not attempt an in-house culture of any material from an animal suspected of having *Y. pestis*.
- Serologic confirmation can be made by submitting two samples drawn 10-14 days apart. A 4-fold (or greater) increase in titer is necessary to confirm the diagnosis.
- A PCR test for tissue, blood, or fleas has been established to identify the organism.

TREATMENT

TREATMENT OVERVIEW

Intensive therapy should be started as soon as possible owing to the rapid course of the disease. Gentamicin is the antibiotic of choice but should not be given until the patient is rehydrated and stabilized with intravenous fluid therapy. Care must be used to avoid exposure and development of zoonotic disease. Antibiotic therapy should be continued for 3-4 weeks. Patients should remain hospitalized and isolated because of the contagious and zoonotic risks.

ACUTE GENERAL TREATMENT

- Fluid resuscitation of infected animals that have concurrent dehydration, shock, or other hypovolemic states
- Administration of supplemental oxygen and other critical care measures; these may be necessary depending on the animal's respiratory effort.
- Institution of treatment with the antibiotic of choice (gentamicin, 6 mg/kg IM or IV q 24 h) and brisk rehydration and fluid diuresis as well as monitoring of renal function. Streptomycin has also been used.
- Alternative antibiotics: trimethoprim-sulfonamide, doxycycline, or fluoroquinolones. These may be less effective. Chloramphenicol has been used in animals with the CNS form.
- Surgical incision and flushing of abscessed lymph nodes for drainage (caution because of public health risk)

CHRONIC TREATMENT

Treatment with antibiotics for a minimum of 21 days and continuation beyond resolution of clinical signs

DRUG INTERACTIONS

Gentamicin should not be used in combination with other nephrotoxic, ototoxic, or neurotoxic drugs. Gentamicin must be used carefully when in combination with cephalosporins or nonsteroidal antiinflammatory drugs (NSAIDs) because of renal effects.

POSSIBLE COMPLICATIONS

When zoonosis occurs, veterinary professionals are most commonly affected.

PROGNOSIS AND OUTCOME

- Mortality of cats approaches 50% the pneumonic form is the most lethal. Septicemic form is usually fatal within 1-2 days.
- Cats with spontaneous draining wounds may have better outcomes.
- Cats with previous exposure to plague (via vaccine or natural exposure) may have a shortened disease course.

PEARLS & CONSIDERATIONS

COMMENTS

- Veterinarians who suspect a clinical case of plague should immediately contact the public health department and observe precautions described above.
- People who have been exposed to an infected animal should seek medical advice.

PREVENTION

- Prevent unsupervised outdoor activities.
- Apply a flea preventive to cats and dogs during high-risk months.
- No vaccine is available against plague in animals.

CLIENT EDUCATION

- Inform clients of the increased risk of infectious diseases in outdoor cats.
- Emphasize proper flea and rodent control.
- Dogs may bring plague-infected fleas into households; sleeping with dogs may increase the human risk of acquiring the disease.

AUTHOR: KHRISTEN CARLSON

EDITOR: DOUGLASS K. MACINTIRE

1ST EDITION AUTHOR: KATHRYN TAYLOR

Pituitary Dwarfism

BASIC INFORMATION

DEFINITION

Rare clinical syndrome of congenital deficiency in growth hormone (GH)

SYNONYM

Congenital hyposomatotropism

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats
- Signs usually apparent at 2-3 months of age
- No gender predilection

GENETICS & BREED PREDISPOSITION: Inherited as an autosomal recessive trait in the German shepherd and the Karelian bear dog but also occurs in other dog breeds and in cats

ASSOCIATED CONDITIONS & DISORDERS: Can occur as part of combined pituitary hormone deficiency with concurrent congenital hypothyroidism (cretinism), hypoadrenocorticism (Addison's disease), and hypogonadism

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Poor growth, stunted stature, alopecia

PHYSICAL EXAM FINDINGS

- Stunted stature
- Bilaterally symmetric alopecia affecting the trunk, neck, and caudomedial thighs, with sparing of the head and extremities
- Soft, wooly haircoat
- Possible hyperpigmentation and scaling of exposed skin
- Delayed dental eruption
- Possible open fontanelles

ETIOLOGY AND PATHOPHYSIOLOGY

- Clinical signs result from a deficiency in pituitary production of GH and a resulting deficiency in insulin-like growth factor 1 (IGF-1), which is produced by the liver under the influence of GH.
- Pituitary dwarfism can occur as a result of pressure atrophy of the anterior pituitary gland secondary to congenital cystic enlargement of the craniopharyngeal duct (Rathke's pouch), or due to pituitary hypoplasia secondary to a defect in organogenesis of the pituitary gland.
- Animals with a combined pituitary hormone deficiency may also lack thyroid-stimulating hormone, prolactin, luteinizing hormone, folliclestimulating hormone, and adrenocorticotropic hormone.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of pituitary dwarfism is based on finding decreased GH or IGF-1 concentrations in conjunction with appropriate clinical signs.

DIFFERENTIAL DIAGNOSIS

See Stunted Growth, p. 1056.

INITIAL DATABASE

- A CBC, serum biochemical profile, and urinalysis should be performed to help rule out other causes of stunted growth.
  - Results are usually normal.
  - Hypercholesterolemia is possible if concurrent hypothyroidism is present.

ADVANCED OR CONFIRMATORY TESTING

- Availability of GH testing is limited.
  - Basal serum GH concentrations may overlap between affected and normal animals and therefore should not be used alone as a confirmatory test.
  - GH stimulation (measurement of GH before and 15, 30, 45, 60, and 120 minutes following administration of clonidine [10 mcg/kg IV], xylazine [100 mcg/kg IV], or GH-releasing hormone [1 mcg/kg IV] is more useful than basal GH concentrations. Potential adverse effects of clonidine and xylazine include sedation, bradycardia, hypotension, and collapse. Confirm the protocol with the laboratory prior to performing the test. Pituitary dwarfs will have no increase in GH.
- Basal serum IGF-1 concentrations are decreased in dogs with pituitary dwarfism and may be useful when GH measurement is not available. Serum IGF-1 levels vary based on breed size; interpretation of results requires consultation with the laboratory performing the assay.
- Screening of animals for combined pituitary hormone deficiency is recommended (see pp. 588 and 573).
- Dermatohistopathologic examination of a skin biopsy shows changes similar to those in other endocrinopathies. A decrease in the quantity and size of dermal elastin fibers suggests pituitary dwarfism.

TREATMENT

TREATMENT OVERVIEW

The goal of therapy for pituitary dwarfism is to normalize serum concentrations of IGF-1 while monitoring closely for adverse effects caused by the treatment. Therapy of concurrent hypoadrenocorticism or hypothyroidism may be required.

CHRONIC TREATMENT

- Exogenous canine GH is not available.
- Human GH is not effective because dogs form antibodies against it.
- Porcine GH has been used in dogs but can be difficult to obtain.
  - An initial dose of 0.1 IU/kg subcutaneously three times a week for 4-6 weeks is recommended, with subsequent adjustment of the dose and interval based on clinical response and plasma IGF-1 concentrations.
- With GH therapy, a beneficial response is generally seen within 6-8 weeks.
- Progestins may stimulate mammary GH secretion and can be considered as an alternative treatment in dogs.
  - Medroxyprogesterone acetate (2.5-5 mg/kg SQ q 3 weeks, then q 6 weeks) has been shown to improve clinical signs in affected dogs.
  - Proligestone, a synthetic progestin, has been used successfully in 3 dogs at an initial dose of 10 mg/kg SQ q 3 weeks.
  - The efficacy of progestin therapy in affected cats is unknown.

POSSIBLE COMPLICATIONS

- GH supplementation may cause hypersensitivity reactions, carbohydrate intolerance, and overt diabetes mellitus.
- Progestin therapy may cause pyoderma, cystic endometrial hyperplasia in intact females, acromegaly, and diabetes mellitus.

RECOMMENDED MONITORING

- Periodically measure serum glucose and urine glucose levels to monitor for development of serum hyperglycemia and glucosuria associated with diabetes mellitus.
- GH-induced diabetes mellitus can be permanent if GH supplementation is not promptly discontinued.

PROGNOSIS AND OUTCOME

Even with treatment, the long-term prognosis for dogs and cats with pituitary dwarfism is guarded and dependent on maintenance of normal IGF-1 concentrations and avoidance of complications of GH or progestin therapy.

PEARLS & CONSIDERATIONS

COMMENTS

A DNA test (4 mL EDTA blood; cost: $130 U.S./100 Euro) is available through the University of Utrecht to identify unaffected carriers of the mutated gene that leads to pituitary dwarfism in the German shepherd breed; this will allow for the removal of identified carrier dogs from breeding programs.

Pinnal Diseases

Additional Images Available on Website

BASIC INFORMATION

DEFINITION

Diseases affecting the skin, cartilage, or other tissues of the pinna (externally visible part of the ear). Disorders may affect only the pinna or be part of a more widespread dermatologic disease.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Depends on underlying cause

GENETICS & BREED PREDISPOSITION: Breed predispositions exist for some pinnal diseases:

- Acquired pattern alopecia (see p. 846): dachshund, Boston terrier, Italian greyhound
- Ear margin seborrhea: dachshund
- Sebaceous adenitis (see p. 1007): standard poodle, Akita, Samoyed
- Canine familial dermatomyositis (see online chapter: Dermatomyositis): Shetland sheepdog, collie
- Primary seborrhea (see p. 255): cocker spaniel
- Actinic keratoses, squamous cell carcinoma (see p. 1045), hemangioma: light-colored cats
- Color dilution alopecia (seep. 233): Doberman pinscher, many others
- Canine leproid granuloma syndrome: boxers and other short-coated dogs
- Pigmented viral plaques: pug, miniature schnauzer
- Psoriasiform-lichenoid dermatosis: English springer spaniel
- Hereditary lupoid dermatosis: German shorthair pointer (seep. 271)

CONTAGION & ZOONOSIS: Contagious and zoonotic etiologies affecting the pinna include dermatophytes, *Sarcoptes, Notoedres,* and *Otodectes. Demodex gatoi* and lice are also contagious but not zoonotic.

GEOGRAPHY AND SEASONALITY: A distinct geographic distribution exists for leishmaniasis, notoedric mange, *Demodex gatoi* infestation, and canine leproid granuloma syndrome.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Some conditions are pruritic or painful; others only alter pinnal appearance.
- Clients may note folding of a previously erect pinna.
- Lesions may be limited to the ear or more widespread.
- Some conditions have a predilection for the more densely haired (convex) aspect of the pinna; others are more commonly found on the concave surface.

PHYSICAL EXAM FINDINGS

- Various presentations are seen: crusts, scales, ulcers, alopecia, nodules, plaques, edema, lichenification, pigmentary changes, erythema, hemorrhage, tissue loss, diffuse thickening or deformation of the normal shape of the pinna.
- A full physical and dermatologic examination should be performed in all affected animals.
- Otoscopic examination is indicated, as some pinnal disorders are extensions of a primary process affecting the ear canal.
- Pruritic animals should be assessed for a pinnal-pedal reflex by rubbing or scratching the edge of one pinna and observing for a scratching motion in the ipsilateral hind leg.

ETIOLOGY AND PATHOPHYSIOLOGY

- As the pinna consists of skin and cartilage, a disease process affecting these tissues can result in pinnal lesions.
- Certain diseases are more likely to affect the pinna than other cutaneous sites:
  - Ear margin seborrhea, proliferative and necrotizing feline otitis externa, and aural hematomas are limited to this location.
  - Vasculitis and other ischemic conditions affect the pinna because of its limited collateral blood supply.
  - The feline pinna is prone to both UV-induced damage and frostbite.

- Lesions of canine leproid granuloma syndrome and fly bites have a predilection for this site.
- Conversely, the pinna is a rare location to find pyoderma, otherwise the most common cause of cutaneous crusting in dogs.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Localization of lesions to the pinnae should prompt complete dermatologic and physical examinations; unless the diagnosis is apparent from physical exam alone, cytologic analysis of pinnal lesions via skin scrapings should follow. Further testing is selected based on the list of differential diagnoses (see below).

DIFFERENTIAL DIAGNOSIS

- Parasitic causes:
  - Sarcoptic mange (dogs): positive pinnal pedal reflex, but it may be difficult to find mites on skin scrapings.
  - Notoedric mange (cats): usually easy to find mites on skin scrapings
  - Demodicosis (dogs): may cause erythema in inner pinna, which may be the only affected site
  - Pediculosis (louse infestation)
  - Other: trombiculiasis, fly bites (often *Stomoxys calcitrans,* affecting ear tips or folds), *Otodectes* (primarily affects the ear canal), *Demodex gatoi* (cats)
- Infectious causes:
  - Dermatophytosis (feline > canine)
  - Canine leproid granuloma syndrome: nodules on convex pinna caused by an unidentified species of mycobacteria with a distinct geographic distribution
  - Leishmaniasis (dogs > cats): pinnal scaling and alopecia; infected animals are systemically ill.
  - Pigmented viral plaques: deeply pigmented, scaly plaques
- Hypersensitivity disorders:
  - Atopic dermatitis and food allergy: commonly cause pinnal erythema and pruritus
  - Contact hypersensitivity: most often due to topically applied ear medications (e.g., neomycin, propylene glycol)
  - Mosquito bite hypersensitivity (cats): seasonal; convex pinna is a common site
- Immune-mediated disorders:
  - Pemphigus foliaceus: may resemble pyoderma, which is rare on the pinna. Very common site of lesions in cats.
  - Vasculitis and ischemic dermatopathy: fairly common cause of pinnal lesions in dogs, this diverse group of diseases may be idiopathic, hereditary (e.g., Jack Russell terriers), or iatrogenic (e.g., rabies vaccine-induced). Ulcerative and crusted lesion, often on the distal concave pinna.
  - Less common, also affecting other sites: pemphigus erythematosus, discoid lupus erythematosus, bullous pemphigoid, cold agglutinin disease, alopecia areata
  - Less common, limited to the pinna: proliferative thrombovascular necrosis auricular chondrosis (swollen, misshapen, painful pinnae)
- Hereditary causes:
  - Acquired pattern alopecia: affects dogs (most commonly dachshunds) before 1 year and progresses to complete pinnal alopecia due to diminution of still-active hair follicles
  - Canine familial dermatomyositis: lesions usually present by 6 months of age; immune-mediated cause suspected.
  - Color dilution alopecia: progressive hair loss in blue or fawn dogs
  - Other: primary seborrhea, psoriasiform-lichenoid dermatosis of English springer spaniels, hereditary lupoid dermatosis of German shorthaired pointers, congenital hypotrichosis, black hair follicular dysplasia
- Neoplastic diseases:
  - Squamous cell carcinoma: most common in light-colored cats; often preceded by premalignant actinic keratoses (small areas of crusting and hyperkeratosis). Pinnal lesions on light-colored cats warrant investigation.
  - Histiocytoma and sebaceous gland tumor: the pinna is a common location in dogs.
  - Basal cell tumor: the pinna is a common location in cats.
- Miscellaneous conditions:
  - Aural hematoma (see p. 120): usually straightforward diagnosis. Subcutaneous accumulation of hemorrhagic fluid forming a flocculent pocket within the pinna. Assess for causes of head shaking (e.g., otitis externa).
  - Ear margin seborrhea: pendulouseared dogs, particularly dachshunds. Keratinous deposits on concave and convex pinnal margins; fissures may form in chronic cases. Similar changes can be seen in hypothyroid dogs.
  - Sebaceous adenitis: scaling and follicular casts predominantly in the haired pinna
  - Acquired folding of ear pinnae: associated with iatrogenic hyperadrenocorticism in cats due to topical or systemic steroid use.
  - Proliferative and necrotizing otitis externa of cats: highly characteristic presentation of adherent, dark, keratinous debris on the concave aspect of the pinna, usually in young cats
  - Canine sterile eosinophilic pinnal furunculosis
  - Melanoderma and alopecia of Yorkshire terriers (probably a variant of pattern alopecia)

PINNAL DISEASES Pinnal crusting in a cat with pemphigus foliaceus.

INITIAL DATABASE

Varies depending on differential diagnoses but may include:

- None; diagnosis may be presumptive (e.g., aural hematoma, acquired pattern alopecia)
- Skin scrapings (see p. 1248)
- Pinnal-pedal reflex: 82% sensitivity and 94% specificity for canine sarcoptic mange (seep. 1006)
- Cutaneous cytology
- Wood's light examination, fungal culture
- Trichography (demodicosis, color dilution alopecia, pediculosis)
- Fine-needle aspirates from nodular lesions
    - Acid-fast stain of aspirates if mycobacteria suspected
- Skin biopsies
    - Prior to the procedure, advise clients that pinnal biopsies might result in permanent cosmetic changes.
    - Skin biopsies from the pinna can be difficult and may require general anesthesia, so sample other areas of the skin if they are similarly affected.
    - The pinna may be clipped to identify the major blood vessels (to be avoided). Do not clip hair from the biopsy site, however.
    - For a good cosmetic outcome, sample lesions on the edge of the pinna with a thin shave biopsy of the pinnal margin.
    - Larger wedges can be removed, leaving skin distal to the cartilage for closure.
    - With extensive pinnal necrosis, affected tissue may be excised to create a more proximal margin.
    - Use a biopsy punch to sample skin from nonmarginal lesions. Take care not to cut through underlying cartilage; otherwise a permanent hole will result. Allow skin to heal by second intention.
    - Always include crusts in the biopsy.
- CBC, serum chemistry profile, thyroid hormone levels, urinalysis, antinuclear antibody titers, and so forth as appropriate.
- Response to empirical therapy (e.g., *Sarcoptes)*

TREATMENT

TREATMENT OVERVIEW

Varies depending on cause. For aural hematomas, various surgical and medical techniques are described (see p. 120).

PROGNOSIS AND OUTCOME

Varies depending on cause

PEARLS & CONSIDERATIONS

COMMENTS

- Due to the difficulty of collecting diagnostic skin biopsies from the pinna, seek out and sample other affected areas of skin to sample.
- While both diseases are most common in dachshunds, ear margin seborrhea is characterized by scaling and skin lesions, whereas pattern alopecia is not.
- Consider empirical treatment for *Sarcoptes* in dogs with pinnal pruritus, even with negative skin scrapings and no pinnal-pedal reflex.

TECHNICIAN TIPS

The ear margins in dogs bleed easily with trauma, biopsies, and certain diseases. Head shaking greatly exacerbates hemorrhage. A gentle and effective technique to protect the pinnae from this self-trauma uses a surgical stockinette “tube” placed over the head and secured to the forehead by surgical tape. The stockinette may be used in a single layer or doubled over with loose holes cut out for the ears in the bottom layer. The stockinette is placed over the head such that the ears rest in an anatomically normal position; the stockinette must not be tight. The aim is to keep the ears from “flapping” when the head is shaken.

AUTHOR: KINGA GORTEL

EDITOR: MANON PARADIS

Pilonidal Cyst

BASIC INFORMATION

DEFINITION

Tubular skin lesion that extends ventrally from dorsal midline, usually as a blind sac but may connect to dura mater; congenital defect

SYNONYMS

Pilonidal sinus, dermoid cyst, dermoid sinus

EPIDEMIOLOGY

SPECIES, AGE, SEX: Young dogs, either sex

GENETICS & BREED PREDISPOSITION: Primarily Rhodesian ridgeback; believed to be hereditary (simple recessive gene)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Single or multiple dermal draining tracts
- Subcutaneous cystic mass(es) along dorsal midline

HISTORY, CHIEF COMPLAINT

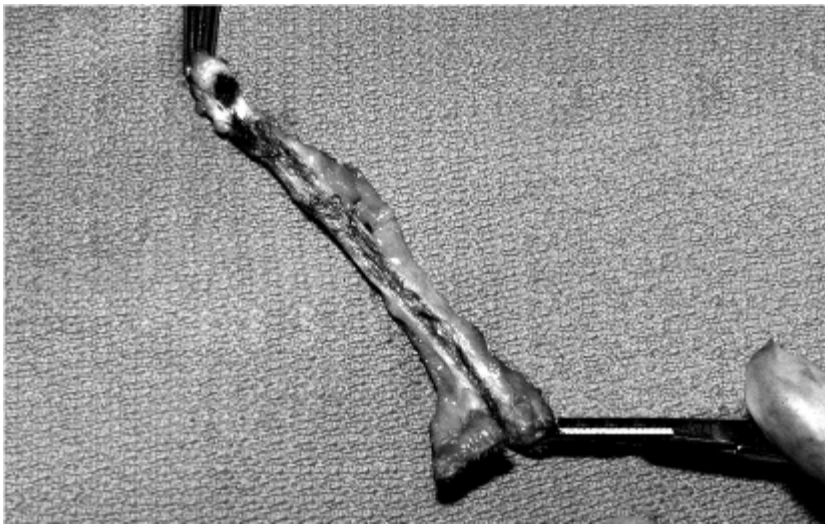
- Opening in the skin on dorsal midline, with hair protruding from opening
- Mass in hair on dorsal midline (mass is a concretion of accumulated hair, sebum, and debris overlying the lesion)

PHYSICAL EXAM FINDINGS

- Single or multiple openings in the skin along dorsal midline:
    - Occurs precisely on the dorsal midline
    - Hair protruding from opening
    - Cord of tissue palpably extending down through subcutaneous tissue toward the spine:
        - May be confined to subcutaneous tissue
        - Can extend to the spine:
            - Cervical sinus often attached to dorsal spinous process of C2
    - Lumen filled with inspissated sebum, exfoliated keratin, hair:
        - May be infected
- Subcutaneous cystic mass and swelling on dorsal midline
- If cyst is infected and connects with the spine:
    - Clinical signs associated with myelitis, meningomyelitis, or encephalitis may be seen:
        - Pain, weakness
        - Neurologic deficits in limbs
        - Seizures

PILONIDAL CYST Dorsal lumbosacral region of a Rhodesian ridgeback dog; cranial is to the left. Appearance of a porelike opening and/or subcutaneous nodule on the dorsal midline skin is the main physical characteristic of a pilonidal cyst.

(Courtesy Dr. Richard Walshaw.)



PILONIDAL CYST Excised pilonidal cyst from same dog. This longitudinal section of the cyst shows its length as well as the haired nature of the cystic tissue. Exterior (skin surface) is at bottom right; other extremity of the cyst *(upper left of image)* was its deepest point, near the spinal cord.

(Courtesy Dr. Richard Walshaw.)

ETIOLOGY AND PATHOPHYSIOLOGY

Congenital neural tube defect:

- Incomplete separation of the skin and neural tube during embryonic development
- Sinus can extend to and connect with dura mater.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is established entirely with signalment (breed) and physical examination findings.

DIFFERENTIAL DIAGNOSIS

- Epidermal inclusion cyst
- Follicular retention cyst
- Sebaceous cyst
- Foreign body
- Abscess
- Hair follicle tumor
- Myiasis

INITIAL DATABASE

Presurgical CBC and serum chemistry profile

ADVANCED OR CONFIRMATORY TESTING

Rarely necessary; physical findings are usually sufficient:

- Fistulography and myelography:
  - If there is concern about connection to the spine and neurologic signs are present
- Histopathologic examination of excised tissue to confirm diagnosis
- Cytologic examination and microbiologic culture and sensitivity (C&S) testing:
  - If infected
  - If connects to spine

TREATMENT

TREATMENT OVERVIEW

Complete excision of sinus tract, and cyst if present, is required.

ACUTE AND CHRONIC TREATMENT

Complete surgical resection: strict aseptic technique is essential if sinus extends to dura mater.

POSSIBLE COMPLICATIONS

- Recurrence due to incomplete excision:
  - Potential problem if extends to and involves dura mater
  - Development of a chronic draining tract
- Postoperative meningitis:
  - If dura mater involved and surgical wound infection occurs

RECOMMENDED MONITORING

- Monitor the incision site for evidence of recurrent draining tract.
- Look for appearance of new lesions:
  - Examine animals for subcutaneous cystic structures.

PROGNOSIS AND OUTCOME

- Excellent with complete excision and no involvement of spinal structures
- Guarded if:
  - Neurologic signs are present prior to surgery
  - Surgical wound infection develops and dura mater is involved

PEARLS & CONSIDERATIONS

COMMENTS

Avoid clipping, shaving, or cutting a mat of hair located on the dorsal midline without first cleaning and carefully examining the area.

Trauma to a pilonidal cyst may lead to subsequent infection and potentially myelitis.

CLIENT EDUCATION

- Common problem in the Rhodesian ridgeback breed
  - Clients should be aware of this problem if considering purchasing a Rhodesian ridgeback
  - Believed to be a heritable defect
- Does occur rarely in other purebred dogs; infundibular keratinizing acanthomas or benign sebaceous adenomas (which can occur anywhere on the body) are much more common, especially in aged dogs. Seepp. 275 , .

Phosphate Enema Toxicosis

BASIC INFORMATION

DEFINITION

Toxicosis due to administration of sodium phosphate enemas in cats and small-breed dogs, resulting in severe hyperphosphatemia, hypernatremia, and hypocalcemia

SYNONYM

Fleet enema toxicosis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Younger animals; cats and small-breed dogs. Small body size produces a disproportionate ratio of enema fluid to body weight.

RISK FACTORS: Constipation, obstipation, colonic disease, and renal disease may increase the risk for problems from administration of sodium phosphate enemas by decreasing sodium and phosphate excretion (renal disease) or enhancing sodium and phosphate absorption (others).

ASSOCIATED CONDITIONS & DISORDERS: Hyperphosphatemia, hypernatremia, hypocalcemia (potentially severe/critical)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Within 30 minutes to 4 hours of administration of enema, signs that may be apparent include:

- Depression
- Ataxia
- Vomiting
- Diarrhea with or without blood

PHYSICAL EXAM FINDINGS

Common:

- Tachycardia
- Pallor
- Prolonged capillary refill time
- Weakness

Possible:

- Hyperthermia or hypothermia
- Tachypnea
- Tetany
- Seizure

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

Phosphate enemas are available over-the-counter (without a prescription) at pharmacies and in the drug aisles of supermarkets and convenience stores.

Mechanism of Toxicosis:

- Hypernatremia and hyperphosphatemia can occur after administration of sodium phosphate enemas via massive absorption of sodium and phosphate from the colon. Prolonged retention, overdose, colonic disease (dilation or ulceration), or

preexisting electrolyte disturbances as seen with chronic kidney disease increase the risk of toxicosis.
- Hypocalcemia occurs if calcium-phosphorus solubility product is exceeded; phosphorus binds and precipitates calcium, leading to hypocalcemia.
- Hyperosmolality:
  - Hypernatremia
  - Hyperglycemia is only a minor contributor to increased osmolality and is believed to be due to stress release of catecholamines and hypertonicity that alter cellular glucose uptake and metabolism; it can also result from pancreatic insulin release.
- Metabolic acidosis with increased anion gap

DIAGNOSIS

DIAGNOSTIC OVERVIEW

History of administration of an enema to a patient weighing <10 kg, with hyperphosphatemia, hypernatremia, and/or hypocalcemia on a serum biochemical profile taken within 12 hours of enema administration, provide a clinical diagnosis.

DIFFERENTIAL DIAGNOSIS

- Hypernatremia (see p. 559)
- Hypocalcemia (see p. 576)

INITIAL DATABASE

- CBC: generally unremarkable
- Serum chemistry panel; common abnormalities include:
  - Hyperphosphatemia
  - Hypernatremia
  - Hypocalcemia
  - Hyperkalemia or hypokalemia
  - Metabolic acidosis (decreased serum [$HCO3^-$]) with increased anion gap:
    - Anion gap: ([Na^+] + [K^+]) - ([Cl^-] + [$Hco3^-$]); normal = 12-24 mEq/L.
  - Hyperosmolality:
    - Measured directly and also calculated according to formula: 2[Na^+] + blood urea nitrogen (BUN) (mg/dL)/2.8 + glucose (mg/dL)/18; result is in milliosmoles per kilogram.
    - Normally, and in phosphate enema toxicosis, the difference between calculated and measured values (“osmol gap”) should be <10 mOsm/kg.
- Urinalysis: generally unremarkable

TREATMENT

DIAGNOSTIC OVERVIEW

No antidote; treatment aims to correct hypernatremia and hypocalcemia and provide supportive care. Sepsis may occur in animals with compromised colonic mucosa, requiring treatment.

ACUTE GENERAL TREATMENT

- IV fluids to address hypernatremia (see p. 559):
  - Initial choice (assuming <24 h since enema administration): either 5% dextrose in water or 0.45% saline with 2.5% dextrose (with potassium supplementation if hypokalemia is present). Concurrent furosemide (2 mg/kg IV) can increase natriuresis.
  - Initial rate: one to two times the maintenance rate (30-60 mL/lb/day [65-130 mL/kg/day]) plus a dehydration deficit and ongoing losses compensation if applicable; proceed with caution if the patient has heart disease.
  - Adjustment/change in fluid type and rate based on response and results of ongoing monitoring.
- Plain-water enema
  - May help to reduce hypernatremia; the colon has a large surface area and can absorb free water rapidly.
  - Administer 10 mL/kg of plain water as a retention enema (see p. 1258); repeat q 2-4 hours.
- Calcium gluconate if hypocalcemia-associated tetany is present:
  - IV route if tetany is severe and/or if hyperthermia is present concurrently

    - 10% calcium gluconate = 100 mg/mL calcium gluconate. This corresponds to 9.3 mg elemental calcium per milliliter.
    - Give 50-200 mg/kg calcium gluconate (= 0.5-2 mL/kg; typical cat dose = 3 mL) slowly IV over a period of 15-30 minutes with electrocardiogram (ECG) monitoring, administered to effect. Clinical normality usually will not occur immediately; mild to moderate improvement in signs is sought during the infusion, which warrants stopping administration.
    - If heart rate decreases significantly, or if an onset of ST-segment elevation/depression or QT-interval shortening is seen, the infusion must be stopped promptly.
- Calcium gluconate in stable, hypocalcemic patient:
    - 150-250 mg/kg calcium gluconate (1.5-2.5 mL/kg), diluted with two to four times more sterile water and given SQ q 6-8 h
- Phosphate-binding agents (e.g., Amphojel, 64 mg Al(OH)3/ml; or ALternaGEL, 120 mg Al(OH)3/mL):
    - 10-30 mg/kg (or higher) PO q 6-12 h, based on serum phosphorus levels; may cause inappetence
- Antibiotics (e.g., ampicillin, 22 mg/kg IV q 6-8 h; and enrofloxacin, 5 mg/kg diluted 1 : 1 in sterile water and given slowly IV q 12 h [q 24 h in cats]) in cases with history of colonic disease and suspicion or evidence of sepsis due to translocation of enteric bacteria

DRUG INTERACTIONS

- Sodium bicarbonate is not recommended (unless acidosis is severe) because of its hypertonic nature; it may exacerbate hypokalemia and hypocalcemia and may cause metabolic alkalosis.
- Insulin for hyperglycemia is not indicated because spontaneous resolution is expected.

POSSIBLE COMPLICATIONS

Hyperthermia due to ongoing hypocalcemia-induced muscle fasciculations; cerebral edema if hypernatremia is long-standing and then is corrected overly rapidly

PROGNOSIS AND OUTCOME

- Patients treated promptly (when earliest signs are noted or sooner) and thoroughly have a good prognosis: complete recovery is expected.
- Patients for whom treatment is delayed or that develop central nervous system (CNS) dysfunction or complications such as severe hyperthermia due to hypocalcemic tetany have a guarded and potentially poor prognosis, depending on the timing and extent of subsequent treatment.

PEARLS & CONSIDERATIONS

COMMENTS

- Hypernatremia that lasts more than 12-24 hours may need to be treated as a chronic condition (see p. 559). In such cases, the serum sodium level may require slow reduction over 48 hours at a rate of not more than 0.5 mEq/L per hour.
- Avoid administration of phosphate-containing enemas to small patients (<10 kg) or patients with severe obstipation or suspected/known compromise of the colonic wall; marginal or compromised renal function; or preexisting hypernatremia, hyperphosphatemia, or hypocalcemia.
- For injectable calcium, calcium chloride is generally not recommended owing to its potentially severe corrosive effects if it leaks perivascularly/subcutaneously.
- Doses for injectable calcium can be listed in milligrams of elemental calcium (Ca^{2+}) or in milligrams of compound (e.g., calcium gluconate, calcium chloride). It is important to be clear which dose is used to avoid overdosing or underdosing. For example, a 10% calcium chloride (CaCl2) solution has 100 mg/mL calcium chloride, which is 27.2 mg Ca^{2+}/mL CaCl2.

TECHNICIAN TIP

A phosphate enema (Fleet or other brands) is formulated as a clear liquid usually supplied in a transparent, soft plastic bottle and is never appropriate in cats or small dogs. Many safe alternatives (such as DSS enemas or other products made specifically for small animals) are available instead.

Phobias

BASIC INFORMATION

DEFINITION

Behaviors characterized by persistent and extreme anxiety and avoidance, and occurring only in response to specific triggers. The fear response is out of proportion given the objective threat, is beyond voluntary control, and may be preceded by anticipatory anxiety.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats, any age. As with most behavioral conditions, phobias most commonly develop during social maturity (about 12-36 months in dogs, 24-48 months in cats).

GENETICS & BREED PREDISPOSITION: Predispositions suspected, but modes of inheritance, population and breed variability mostly unproven. Candidate gene regions have been identified that are associated with noise-reactive phenotypes in Australian shepherds, border collies, and German shepherds.

RISK FACTORS: Mild signs may exacerbate quickly after exposure to a trigger of large magnitude.

CONTAGION & ZOONOSIS: A young dog that seems well adjusted and joins a home with a phobic dog may learn (and/or may react to) some of the behaviors associated with the phobia (e.g., reactive barking), especially if these behaviors engender attention.

GEOGRAPHY AND SEASONALITY: Holidays that are celebrated with fireworks, gunfire, or cannon blasts; seasonal thunderstorms

ASSOCIATED CONDITIONS & DISORDERS: Comorbidity of thunderstorm phobia and separation anxiety (see p. 1012) is high.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Thunderstorm phobia
- Noise phobia (single or combination noise types such as booming, metallic, electronic, other noises)
- Neophobia (fear of new objects or circumstances)
- Panic
- Other phobias (e.g., reflective surfaces or floors, nighttime, other animals)

HISTORY, CHIEF COMPLAINT

- Exposure to or anticipation of exposure to discrete triggering events eliciting observable signs of sympathetic arousal (e.g., trembling, shaking, pacing, hypervigilance and scanning of the environment, restlessness, vocalization, mydriasis, piloerection, ptyalism, elimination, anal sac expression, immobility, repeated startle responses and behaviors associated with avoidance)
- The onset may be acute, with or without an identifiable trigger, or may worsen over time. If escape attempts are interrupted, growling, snarling, lunging, or biting may be elicited.
- The aroused state may persist for minutes/hours.
- Clients' chief complaints may only be destructive behavior, excessive vocalization, or house soiling, without awareness of their meaning as markers of anxiety. Since many owners crate their dogs to "resolve" such behaviors, it is important to query owners regarding the reason they do so; otherwise, signs may be missed until the dog escapes the crate, frequently injuring himself/herself in the process.
- Cats may show signs that the owners may misinterpret as "normal," such as frequent and extended hiding out of context with the situations that trigger the behaviors (so-called scaredy cats).

PHYSICAL EXAM FINDINGS

- Generally unremarkable exam findings; damage to teeth, nails, or feet in extreme cases
- Self-inflicted injuries as dogs attempt to break out of crates in which they are confined as "treatment" for anxiety-associated behaviors

ETIOLOGY AND PATHOPHYSIOLOGY

Dogs, like humans, may have susceptibility genes for development of problematic anxieties. Dysfunction or dysregulation of caudate nuclei in the brain has been implicated in some phobic states. Inadequate in utero nutrition has also been associated with heightened reactivity. Cats may remain aroused for 24-48 hours after an event of profound hypothalamic stimulation. The worse the panic, the more insensitive the animal is to routine physical or social stimuli.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A diagnosis of phobia is made using the history: when extreme fear or anxiety (anticipatory fear) is provoked by specific triggers, and the severity of the fearful response is out of context with the risk the trigger represents.

DIFFERENTIAL DIAGNOSIS

- Generalized anxiety disorder
- Separation anxiety
- Learned fear following a traumatic event
- Attention-seeking behavior

INITIAL DATABASE

- CBC, serum chemistry profile, urinalysis: generally unremarkable; to assess systemic illness triggering or contributing to phobic states; also prior to initiating medication (if indicated)
- Perform additional tests based on history and physical exam findings (e.g., feline leukemia virus [FeLV] and feline immunodeficiency virus [FIV] serum assays and serum T4 in most adult cats).

ADVANCED OR CONFIRMATORY TESTING

If signs of neurologic dysfunction are present or develop, a primary behavioral abnormality is virtually never the sole diagnosis; extracranial and intracranial medical disorders should be investigated as appropriate.

TREATMENT

TREATMENT OVERVIEW

The goal is to produce a decreased or ablated response to the inciting trigger as evidenced by a reduction in or elimination of overt signs of sympathetic arousal.

ACUTE GENERAL TREATMENT

- The owner should help the pet avoid all exposure to the panic-inciting stimulus if it has been identified.
- The owner should reward any spontaneous decrease in reactivity to phobic triggers.
- Anxiolytics, specifically the benzodiazepines (BZD) for their quick onset of action and specific panicolytic effects, should be prescribed in combination with other psychotropic medications such as tricyclic antidepressants (TCAs) or selective serotonin reuptake inhibitors (SSRIs).
    - TCA medications:
        - Amitriptyline: dogs, 1-2 mg/kg PO q 12 h for a minimum of 30 days; cats, 0.5-1 mg/kg PO q 12-24 h for a minimum of 30 days. First drug of choice in mild cases without medical contraindications to their use; inexpensive.
        - Clomipramine (Clomicalm): dogs, 2-3 mg/kg PO q 12 h for a minimum of 8 weeks; cats, 0.5 mg/kg PO q 24 h for a minimum of 8 weeks. Most successful when the behaviors have a ritualistic component or elimination component.
    - SSRI medications:
        - Fluoxetine (Prozac, Reconcile): dogs, 1 mg/kg PO q 24 h for 8 weeks minimum; cats, 0.5 mg/kg PO q 24 h for 8 weeks minimum
        - Paroxetine (Paxil); dogs, 1 mg/kg PO q 24 h for 8 weeks minimum; cats, 0.25-0.5 mg/kg PO q 24 h for 8 weeks minimum
        - Sertraline (Zoloft): dogs, 1 mg/kg PO q 24 h for 8 weeks minimum; cats, 0.5 mg/kg PO q 24 h for 8 weeks minimum. Can be successful for situations in which other medications have been less helpful.

- BZD medications:
  - Diazepam or oxazepam: 0.2-0.4 mg/kg PO q 12-24 h for a minimum 30 days
  - Alprazolam: 0.01-0.025 mg/kg PO q 8-24 h or q 4-6 h for panic (dose should be increased to at least 2 mg/dose for a medium-sized dog until effect or sedation before deciding the medication is not effective)
  - Clonazepam (dogs): 0.01-0.05 mg/kg PO q 12-24 h or q 4-6 h for panic as needed.
  - Response to benzodiazepines is very individualized, so constant communication between practitioner and owner to achieve adequate titration of the patient's dose is necessary.

CHRONIC TREATMENT

- Owners should teach dogs to relax while making eye contact with them so that this new behavior can be used when the dog encounters a situation about which it is anxious or unsure. Owners can teach their dogs this behavior over time with positive reinforcement. Owners should learn to monitor facial cues, body postures, pupil size and shape, and respiratory behavior associated with relaxation versus anxiety.
- Avoidance of exposure to the panic-inciting stimulus
- Desensitization to the triggers can be accomplished if two criteria can be met: triggers can be identified and can be reproduced faithfully and in a systematic and incremental fashion.
- Owners should continue offering positive reinforcement to their animals for all relaxed and calm behaviors, particularly in the face of phobic triggers.

DRUG INTERACTIONS

- BZDs, TCAs, and SSRIs can all be combined at lower than normal dosages if needed, but there is potential for sedation, and patient response must be evaluated on a case-by-case basis.
- TCAs and SSRIs should not be given with monoamine oxidase inhibitors (MAOIs), which are found in many flea and tick collars and dips and in some medications to treat cognitive dysfunction.
- Use of SSRIs with tramadol, which has a weak serotonin reuptake inhibiting effect, may increase the risk of serotonin syndrome and should be avoided if possible. If their use together is necessary, starting both at reduced doses, titrating each to effect, and keeping watch for signs of serotonin syndrome reduces but does not eliminate the risk, and the client should be informed.
- TCAs can worsen existing cardiac arrhythmias and should be used with caution in patients with existing hepatic or thyroid disease.
- Paroxetine should be avoided in renal disease. Anecdotal reports of constipation are more common in cats, so owners of feline patients should be cautioned to monitor stool consistency.

POSSIBLE COMPLICATIONS

- Generalization to triggers which are similar to the original stimulus (e.g., a thunderphobic dog begins to respond to firework displays, then reacts to all loud noises in general)
- Phobias are almost always co-morbid conditions, for which all patients should be screened (most common: separation anxiety, panic disorder, and generalized anxiety disorder).
- BZDs have the potential for drug diversion and abuse by clients.

RECOMMENDED MONITORING

- Animals that take BZDs require a physical exam every 6 months in most U.S. states. The potential for human abuse of the drugs warrants vigilance around refills.
- Yearly CBC, serum chemistry profile, urinalysis, and thyroid screen (q 6 months in geriatric pets) if taking psychotropic medications. Cardiac monitoring may be recommended if syncope or other suspected cardiac signs are involved in panic.

PROGNOSIS AND OUTCOME

Prognosis is variable and depends on:

- Timeliness of diagnosis (early diagnosis: prognosis more favorable)
- Maintenance of frequent and thorough communication between clinician and client so treatment can be adjusted according to the animal's response and needs: prognosis more favorable
- Client factors:
  - Diligence of treatment (comprehensive, persistent treatment plan, and follow-up: prognosis more favorable)
  - Client compliance (good compliance: prognosis more favorable)
- If the best outcome is to be obtained, early intervention is essential.
- If the problem has been ongoing for some time before treatment was sought, treatment may well be lifelong, especially if there

are other comorbid anxiety-related conditions.

PEARLS & CONSIDERATIONS

COMMENTS

- Because client observations and reports are critical in data collection, it is important to spend time understanding the clients' use of language. Asking clients to describe what they see their pet do, as opposed to their interpretation of the behavior, is key in obtaining behavioral data.
- The single best tool for evaluating behavior is observation of the behavior itself. Video cameras and webcams make this possible. All practices should have a video camera clinicians can use in the practice and also lend to clients.

PREVENTION

- When selecting breeding stock, clients should assess temperament as well as conformation and medical phenotypes, because genetic predisposition is suspected to be a strong contributor to mood disorder development.
- At the first sign of any fearful behavior, clients should watch for any worsening of the behavior and pay attention to possible triggers that might indicate the development of a phobia.
- Veterinarians should screen for fear and phobias as a routine part of every appointment.

CLIENT EDUCATION

- Most behavioral conditions are due to chemical and functional abnormalities of the brain (areas of the limbic system and prefrontal cortex) and therefore are not willful acts of disobedience by a vengeful pet.
- Treatment of behavioral conditions is an ongoing process, often for the duration of the pet's life. Relapses may occur with treatment discontinuation or with added Stressors.

AUTHOR: SORAYA V. JUARBE-DIAZ

EDITOR: KAREN L. OVERALL

Pheochromocytoma

BASIC INFORMATION

DEFINITION

Catecholamine-producing tumors derived from chromaffin cells of the adrenal medulla (most common) or from extraadrenal sympathetic ganglia (paragangliomas)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: uncommon; middle-aged/old (mean, 11 years; range, 1-18 years)
- Cats: rare; old (mean, 14.5 years)

ASSOCIATED CONDITIONS & DISORDERS: May occur as part of multiple endocrine neoplasia syndrome

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Ante-mortem diagnosis is challenging because clinical signs are variable, intermittent, and fairly nonspecific.

Dogs:

- Intermittent weakness and collapse are most common. Other clinical signs may include panting/tachypnea, agitation, polyuria and polydipsia (PU/PD), lethargy, vomiting, diarrhea, inappetence/anorexia, sudden blindness, seizures, or sudden death.
- Signs are often episodic and complicated by the high incidence of concurrent disease.
- Many animals show no clinical signs, and the diagnosis is made incidentally during abdominal ultrasonography or necropsy.

Cats:

- PU/PD, lethargy, and anorexia are most common.

PHYSICAL EXAM FINDINGS

- The physical examination is commonly unremarkable.
- When present, abnormalities may include tachypnea, generalized weakness (often episodic), tachycardia and/or cardiac arrhythmias, and pale mucous membranes; epistaxis, muscle tremors, blindness, retinal hemorrhage/detachment, and signs of abdominal pain are also possible.
- An abdominal mass is not usually palpable.

ETIOLOGY AND PATHOPHYSIOLOGY

- Usually solitary, slow-growing, highly vascular tumors. Rare bilateral pheochromocytomas or adrenal pheochromocytomas with a contralateral adrenocortical tumor have been reported.
- Considered malignant, with local invasion (e.g., caudal vena cava) and metastasis to liver and regional lymph nodes most common.
- Clinical signs result from sporadic oversecretion of catecholamines or local tumor invasion and metastasis.
- Excess catecholamines cause arteriolar vasoconstriction and systemic hypertension, cardiac arrhythmias, mydriasis, increased smooth muscle sphincter tone, and increased hepatic gluconeogenesis and glycogenolysis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A presumptive diagnosis rests on identification of an adrenal mass and concurrent, often transient cardiovascular abnormalities (persistent sinus tachycardia; premature ventricular complexes; systemic hypertension; syncope; pulmonary thromboembolism) in the

affected patient. Definitive diagnosis requires histopathologic examination of the excised adrenal gland.

DIFFERENTIAL DIAGNOSIS

- Adrenal mass:
  - Nonfunctional adrenal mass
  - Adrenocortical neoplasia
- Systemic hypertension—other causes such as kidney, cardiac, hyperadrenocorticism may need to be investigated
- Collapse/weakness; other causes such as hypoglycemia, cardiac or respiratory disease may need to be investigated.
- Sinus tachycardia; other causes such as cardiac disease may need to be investigated.

INITIAL DATABASE

- Diagnosis requires a high index of suspicion because clinical signs are usually episodic and nonspecific; often not suspected until an adrenal mass is found on ultrasound exam or during necropsy.
- CBC, serum biochemical profile, and urinalysis: normal or may show nonspecific changes (mild nonregenerative anemia, mature neutrophilia, increased liver enzymes, hypercholesterolemia, proteinuria).
- Multiple arterial blood pressure (BP) measurements: hypertension (sustained systolic pressure >160 mm Hg and/or diastolic pressure > 100 mm Hg) is well recognized (40% of cases), but normotension does not rule out a pheochromocytoma because tumor catecholamine release is intermittent.
- Abdominal radiographs: low sensitivity for detecting a pheochromocytoma but may reveal a pedrenal mass ± mineralization. May aid in assessment of local extension of the tumor.
- Thoracic radiographs: may show pulmonary metastasis (10% of dogs), cardiomegaly, or pulmonary edema or congestion (rare). Pulmonary thromboembolism (see p. 940) is well recognized with pheochromocytoma and may cause acute cor pulmonale and/or right-sided congestive heart failure.
- Electrocardiogram (ECG): intermittent or sustained tachycardias (sinus tachycardia, ventricular arrhythmias) are common. A 24-hour period of Holter monitoring (see p. 1287) may be needed to document intermittent arrhythmias.
- Abdominal ultrasonography: usually unilateral adrenomegaly with normal-size contralateral adrenal gland; may also identify intraabdominal metastasis or tumor invasion of adjacent structures (see p. 42). Careful evaluation of the regional vena cava using Doppler ultrasound is important to identify any tumor thrombi (basis for anticoagulation; prognosis more guarded); large thrombi are possible.
- Tests for hyperadrenocorticism (see p. 548) should be normal, ruling out adrenocortical tumor.

ADVANCED OR CONFIRMATORY TESTING

- Contrast radiography (nonselective venography or excretory urography) for evaluating tumor invasion of the caudal vena cava or kidney, respectively.
- Abdominal CT or MRI with or without contrast: useful for surgical planning; usually shows an adrenal mass and helps identify any local invasion or distant metastasis.
- Increased serum and urine catecholamines and urinary catecholamine metabolites (e.g., vanillylmandelic acid): confirmatory in humans, but use is limited in veterinary medicine by assay availability, lack of established reference ranges, and expense and inconvenience of 24-hour urine collection. Stress associated with hospitalization has been shown to increase urine catecholamine excretion, so urine collection from dogs and cats with suspected pheochromocytomas should preferably occur at home following a few days of adaptation to the sampling procedure.
- Histopathologic examination and positive immunohistochemical staining for chromaffin granules of the excised tumor: required for definitive antemortem diagnosis.

TREATMENT

TREATMENT OVERVIEW

Initially, medical stabilization of the patient is often necessary, involving judicious blood pressure control and cardiac rate/rhythm management (including into general anesthesia). Surgical excision of the tumor is the treatment of choice for cases where unresectable metastasis is not evident. Concurrent vena caval venotomy is required when caudal vena caval invasion is diagnosed.

ACUTE GENERAL TREATMENT

- An alpha1-antagonist: phenoxybenzamine (0.25 mg/kg PO q 12 h initially, then increased every few days until hypertension controlled); maximum dosage of 1.5 mg/kg PO q 12 h in dogs (cats, maximum 0.5 mg/kg PO q 12 h) can be reached. Treat the animal for 1-3 weeks prior to surgery. Potential side effects may include hypotension (seen clinically as lethargy, weakness, syncope) or adverse drug reactions (e.g., vomiting). Prazosin or amlodipine are alternative treatments.
- Beta-blocker drugs (e.g., atenolol, beginning at 0.5 mg/kg PO q 12 h and titrating up to 1 mg/kg PO q 12 h if needed) may be

used for controlling sinus tachycardia but only after alpha1-adrenergic blockade has been initiated.

CHRONIC TREATMENT

- Careful anesthetic selection is needed to minimize intraoperative complications; isoflurane or sevoflurane are typically used for maintenance. Direct arterial BP and ECG should be monitored during surgery and for at least 24 hours postoperatively.
- If surgical resection is incomplete or not possible, long-term treatment with an alpha1-antagonist is required.

DRUG INTERACTIONS

Avoid administering monoamine oxidase inhibitors and metoclopramide, as both may lead to hypertension in these patients.

POSSIBLE COMPLICATIONS

- Sudden blindness, seizures, or even death from a hypertensive crisis
- Perioperative complications are common and include hypertension, hypotension, arrhythmias, respiratory distress, and hemorrhage. Most animals become normotensive 24-48 hours following surgery.

RECOMMENDED MONITORING

- In hospital: monitor BP and central venous pressure perioperatively.
- After discharge: assess BP and ECG monthly.

PROGNOSIS AND OUTCOME

- Prognosis depends on tumor size, metastasis or local tumor invasion, perioperative complications, and the presence of concurrent diseases, which is common (older animals).
- Animals with a surgically excisable tumor have a guarded to good prognosis. If animals survive the immediate postoperative period, a survival time of 18-24 months is possible.

PEARLS & CONSIDERATIONS

COMMENTS

These tumors are difficult to diagnose antemortem, and perioperative management is complex. Consider referral.

TECHNICIAN TIP

Both preoperatively and immediately postoperatively, these patients may have marked fluctuations in blood pressure and heart rhythm. Close monitoring and preparation for treatment when necessary (monitoring parameters/guidelines should be made clear) are essential.

Phenobarbital: Adverse Effects/Toxicoses

BASIC INFORMATION

DEFINITION

Adverse, unintended effects resulting from repeated therapeutic doses of phenobarbital (chronic exposure) or from an excessively high dose of phenobarbital (acute exposure caused by accidental ingestion/injection of a prescription drug or a dosage miscalculation). Additional information regarding acute barbiturates toxicosis can be found in the online chapter: Barbiturates Toxicosis.

EPIDEMIOLOGY

SPECIES, AGE, SEX: All species and ages; both sexes

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Chronic exposure:
  - Central nervous system (CNS) effects: sedation, lethargy, ataxia; hyperactivity, nervousness
  - Polyuria and polydipsia (PU/PD)
  - Polyphagia, weight gain, indiscriminate ingestions
  - Increased serum liver-associated enzymes without clinical signs of liver disease
  - Decreased serum thyroxine (T4) and free T4; ± mildly increased serum thyroid-stimulating hormone (TSH)
  - Hepatotoxicity
  - Blood dyscrasias (anemia, thrombocytopenia, neutropenia)
  - Superficial necrolytic dermatitis
  - Physical dependency
  - Pancreatitis
  - Generalized hypersensitivity reaction
  - Hyperlipidemia
- Acute overdose: adverse CNS effects (coma, hypothermia, respiratory depression)

HISTORY, CHIEF COMPLAINT: Prescription of or possibility of accidental exposure to phenobarbital. Abnormalities involving any organ system can be caused by phenobarbital.

PHYSICAL EXAM FINDINGS

- Chronic/repeated exposure: one or more of the following may be present:
  - Sedation, ataxia
  - Hyperactivity, nervousness
  - Lethargy, depression
  - Anorexia, vomiting
  - Abdominal pain
  - Icterus, ascites
  - Infection
  - Skin erythema, vesicles, crusted erosions, hyperkeratosis; especially affects footpads; painful
  - Ecchymoses
  - Ulcerations of mouth, mucocutaneous junctions; ear lesions; facial rash; pruritus; swelling of feet and limbs
  - Generalized lymphadenopathy
- Acute overdose
  - Acute onset of CNS depression, ataxia, weakness, hypothermia, hyporeflexia, respiratory depression, cardiac arrhythmias, hypotension, coma, death
    - Time to onset of signs: 15 min to 2 hr. Duration of signs: 24 hr to 8 days or longer (dose-dependent)

ETIOLOGY AND PATHOPHYSIOLOGY

- Sedation, PU/PD, polyphagia: direct CNS effects; common after start of drug and often improves within weeks. Sedation is also common with high serum drug concentrations.

- Hyperactivity, nervousness: often associated with low serum drug concentrations
- Increased serum liver-associated enzymes without clinical liver disease: elevated alkaline phosphatase (ALP) in 50% of dogs; elevated alanine amino-transferase (ALT) in 25% of dogs; can occur within weeks to months. Other liver enzymes are less commonly elevated. Elevated ALP may be due either to liver abnormalities or to benign induction; elevated ALT most likely due to early liver injury.
- Decreased serum T4: occurs in 40% of dogs and is likely due to increased metabolism and excretion of T4; can occur within weeks. Generally not associated with clinical signs of hypothyroidism.
- Hepatotoxicity: uncommon but potentially fatal; occurs in dogs (suspected in cats but not documented) and is unpredictable. Usually associated with long-term treatment (months to years) and high serum drug concentrations (>40 mcg/mL). Unknown if dose dependent or idiosyncratic; histopathologic examination reveals hepatic cirrhosis.
- Blood dyscrasias: uncommon reaction; neutropenia, thrombocytopenia, and/or anemia that often occur within weeks; likely an idiosyncratic or hypersensitivity reaction
- Hypersensitivity reaction: especially in cats, immunologic mechanism; can affect many organs and often occurs within weeks
- Physical dependency: can occur within weeks; abrupt discontinuation of drug can precipitate withdrawal seizures
- Pancreatitis: increased risk with phenobarbital/bromide combination
- Acute overdose: signs are dose dependent (ASPCA Animal Poison Control Center information) as shown in table. Note that any dose leading to coma can cause respiratory failure and death if the animal is not treated intensively.

Signs of Acute Phenobarbital Overdose According to Amount of Drug Intake

Sedation, ataxia	1-2 mg/kg orally (dogs, cats); any dose IV (dogs, cats)
Recumbent	12 mg/kg orally (dogs)
Severe CNS signs	20 mg/kg orally (dogs)
Unconsciousness	65 mg/kg orally (dogs); 6-10 mg/kg IV (dogs; expect cats similar)
Lethal dose	110 mg/kg orally (dogs); 125 mg/kg orally (cats)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Chronic/repeated exposures: monitor for evidence of liver disease, blood dyscrasias, pancreatitis, and inappropriate serum drug concentrations. Suspect acute overdose if there is history/evidence of excessive exposure and rapid onset of ataxia, sedation, coma, and hyporeflexia.

DIFFERENTIAL DIAGNOSIS

Dependent on adverse effects

INITIAL DATABASE

- Serum biochemical profile, CBC
- Serum phenobarbital concentration

ADVANCED OR CONFIRMATORY TESTING

- Hepatotoxicity: abdominal radiography/ultrasonography; preprandial and postprandial bile acids; coagulation profile; histopathologic evaluation of biopsy
- Decreased T4: serum TSH concentration
- Pancreatitis: abdominal radiography/ultrasonography; pancreas-specific lipase immunoreactivity
- Blood dyscrasias: bone marrow aspirate
- Dermatopathy: dermatohistopathologic examination
- Acute overdose: analysis of blood, stomach contents, urine, feces for drug

TREATMENT

TREATMENT OVERVIEW

For chronic exposures, if adverse effects are sufficiently severe to warrant treatment, a decrease in drug dosage or discontinuation of

the drug as well as supportive care for the patient will be needed. For acute overdoses situations, patient stabilization, decontamination, and supportive care are the cornerstones of treatment.

ACUTE GENERAL TREATMENT

- Chronic/repeated exposure:
  - Sedation, PU/PD, polyphagia: if serum drug concentration is excessive, decrease drug dosage.
  - Hyperactivity, nervousness: if drug concentration is low, increase drug dosage.
  - Increased serum liver-associated enzymes without clinical liver disease:
    - If ALP is elevated but other liver-associated enzymes, albumin, and blood urea nitrogen (BUN) are normal and serum phenobarbital concentration is not excessive, elevation may be due to benign enzyme induction. Monitor animal and serum biochemical profile frequently as well as rule out other causes of elevated ALP (e.g., hyperadrenocorticism, corticosteroids).
    - If ALT is > two times the upper limit of normal, consider decreasing drug dosage and monitor ALT, or can discontinue phenobarbital and initiate alternative anticonvulsant. Discontinue phenobarbital gradually over several weeks to avoid withdrawal-induced seizures. Loading dosages of alternative anticonvulsant may be necessary.
    - If ALT is elevated and BUN and/or albumin are decreased, liver damage is likely. Pursue further diagnostics and discontinue phenobarbital as previously described.
  - Decreased serum T4: initiate supplemental T4 only if the animal has clinical signs of hypothyroidism.
  - Hepatotoxicity: discontinue phenobarbital and initiate alternative anticonvulsant. Rapidity of phenobarbital discontinuation depends on severity of liver disease. If the liver is functional and metabolizing phenobarbital, reduce the dose over several weeks. If the liver is severely affected, causing elevated serum drug concentration due to impaired metabolism, phenobarbital may be abruptly discontinued and an alternative anticonvulsant initiated. Monitor the animal's serum phenobarbital concentration daily and treat liver disease.
  - Blood dyscrasias, hypersensitivity reactions, hepatocutaneous syndrome: discontinue phenobarbital as previously described and initiate alternative anticonvulsant. Treat signs associated with dyscrasia, hypersensitivity, or dermatitis.
  - Pancreatitis: discontinue the combination of phenobarbital and bromide, then initiate monotherapy with phenobarbital or bromide or an alternative anticonvulsant. Treat pancreatitis.
- Acute overdose:
  - Treatment: See online chapter: Barbiturate Toxicoses
  - No specific antidote is available

DRUG INTERACTIONS

Drugs that inhibit drug-metabolizing enzymes (e.g., chloramphenicol, cimetidine) can elevate serum phenobarbital concentration and lead to toxicity. Phenobarbital use may decrease the effect of a number of drugs by inducing enzymes involved in drug metabolism and clearance.

RECOMMENDED MONITORING

- CBC, serum biochemical profile before starting phenobarbital; repeat these tests after 1-2 months and every 6-12 months or when the animal is ill.
- Monitor the serum phenobarbital concentration 2 weeks after the start of drug and every 6-12 months or when the animal is ill or has recurrence of seizures.

PROGNOSIS AND OUTCOME

- With milder adverse effects, prognosis is generally good.
- With serious adverse effects (hepatotoxicity, blood dyscrasias), prognosis can be good if phenobarbital is discontinued early; otherwise, the condition can be fatal.
- Hypersensitivity reactions can resolve within days to weeks of discontinuing the drug.

PEARLS & CONSIDERATIONS

COMMENTS

- Liver failure can cause a rapid rise in serum phenobarbital concentration secondary to impaired drug metabolism.
- Serum liver-associated enzymes can increase transiently after seizure activity.

TECHNICIAN TIPS

Hyperlipidemia is common in patients receiving phenobarbital, and it can interfere with several serum biochemical analyses and drug analyses. Animals should ideally be fasted for at least 12 hours prior to blood collection. Some animals receiving phenobarbital will have a persistent hyperlipidemia, and longer fasting periods may be needed. Alert the attending veterinarian if serum sample is lipemic.

PREVENTION

- Maintain serum phenobarbital concentration within the therapeutic range to decrease the risk of adverse effects (dogs 15-40 mcg/mL; cats 23-30 mcg/mL). Multiply mcg/mL by 4.31 to convert to µmol/L.
- Base drug dosage alterations on serum drug concentration. Variation in metabolism of phenobarbital exists between individual animals, resulting in poor correlations between oral dosage of drug and serum drug concentration.

AUTHOR: CYNTHIA GASKILL

EDITOR: SAFDAR A. KHAN

Petroleum Distillates/Turpentine Toxicosis

BASIC INFORMATION

DEFINITION

- Toxicosis caused by any of a number of hydrogen- and carbon-containing (HC) chemicals originating from distillation of crude oil/petroleum; a few compounds originate from steam distillation of plants.
- Toxicosis is usually due to accidental dermal or oral exposure to HC-containing products and is manifested by repeated vomiting, retching, vocalization, lethargy, salivation, anorexia, ataxia, and signs of aspiration pneumonia (wheezing, coughing, dyspnea, panting).

SYNONYMS

- Petroleum hydrocarbons toxicosis
- Examples of hydrocarbon-containing products: naphtha, gasoline, kerosene, paint thinners/strippers, engine cleaners/degreasers, diesel fuel, heating fuels, lamp and furniture oils, waxes, lubricating oils, grease, paraffin wax, tar, asphalt
- Plant distillate examples: turpentine, linseed oil

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs are more commonly exposed than cats.
- Because of grooming behavior, topical exposure in cats can lead to clinically significant oral exposure.

RISK FACTORS

- Free-roaming animals are at higher risk for accidental exposures (open garage, workshop, shed, or construction area).
- Fenced dogs may chew into charcoal lighter fluid containers or lick hydrocarbon spills from a garage floor or work area.

GEOGRAPHY AND SEASONALITY: Warmer months involve an increased use of hydrocarbon distillate-containing products outdoors, with increased opportunities for exposure.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Evidence or suspicion of exposure to hydrocarbon-containing product
- Onset of clinical signs generally <1-3 hours after exposure
- Owner may note salivation, vomiting, retching, excessive licking motions, and coughing.

PHYSICAL EXAM FINDINGS

- Presence of product on the feet, muzzle, or on the trunk
- Hydrocarbon/distillate smell on the coat or breath
- Dermal discomfort (tender and inflamed interdigital skin or other exposed areas)
- Hyperirritability, agitation, pacing, and crying/whimpering
- Oral exposure: hypersalivation, vomiting, excessive licking motions, hacking, retching, panting, wheezing, coughing, crackling lung sounds
- Ocular: blepharospasm, blepharitis

ETIOLOGY AND PATHOPHYSIOLOGY

- The physical and chemical properties of a particular hydrocarbon determine its toxicity. Hydrocarbons with lower boiling points (more flammable), lower viscosities (“thinner”), and lower surface tensions are more dangerous owing to an increased ability to penetrate lipid membranes (increased systemic absorption) and increased ability to spread over larger surface areas (providing an increased risk of aspiration).

- Volatile hydrocarbons damage nerve endings and solubilize subdermal/submucosal fat, resulting in acute, generalized pain and discomfort. Systemic absorption can result in dissolution of cellular lipids and cell necrosis with generalized systemic inflammation and congestion. Some specific hydrocarbons can cause more direct organ damage (e.g., benzene causes bone marrow toxicity).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

History (known or suspected exposure) and clinical signs, particularly when a volatile scent of petroleum distillates is present, are the major components of the diagnosis. If the patient vomits, the simple spot test can confirm ingestion of petroleum distillates.

DIFFERENTIAL DIAGNOSIS

- Acute gastrointestinal (GI) viral and bacterial diseases
- Acute upper and lower respiratory infections (respiratory toxicosis)
- Allergic or other dermatitides (topical toxicosis)
- Organophosphate or carbamate insecticides, zinc phosphide

INITIAL DATABASE

- CBC: leukocytosis, neutrophilia; possibly septic changes if pneumonia complication; possible hemoconcentration
- Serum biochemistry profile: hypoglycemia possible
- Urinalysis: unremarkable
- Baseline chest radiograph if respiratory involvement (aspiration)
- Pulse oximetry or arterial blood gas measurement if respiratory involvement (aspiration)

ADVANCED OR CONFIRMATORY TESTING

- Simple spot test: vigorously mix warm water and vomitus; distillates will come to the surface; clinicians will note characteristic odor of volatile distillates (e.g., gasoline, charcoal lighter fluid).
- Confirmatory analysis of the distillate is possible but is usually of academic interest and not useful in terms of clinical management; collect samples in airtight containers and refrigerate.

TREATMENT

TREATMENT OVERVIEW

Do not induce vomiting or give activated charcoal; risk of aspiration outweighs benefit. Dermal decontamination (bathing the animal with a dishwashing liquid) is important to decrease continued exposure. Treat pain (especially with skin lesions) and aspiration as needed.

ACUTE GENERAL TREATMENT

- Emesis, gastric lavage, and administration of activated charcoal are contraindicated; increased risk of aspiration.
- Oxygen supplementation (see p. 1318) if the animal is showing respiratory distress
- Mechanical ventilation may be necessary, depending on oxygen concentration and delivery (see p. 1362).
- IV fluid support (may begin with 0.9% NaCl; adjustment based on electrolytes, hydration, etc.) to maintain hydration and perfusion; forced diuresis is not effective at eliminating toxins more rapidly.
- Pain control if needed (opioids such as buprenorphine, 0.005-0.02 mg/kg IM, SQ, IV, or fentanyl patch) because dermal exposure in particular can be painful.
- Corticosteroids: controversial; sometimes considered in aspiration pneumonia, but there is an increased risk of infection; avoid prolonged use.
- Early prophylactic antibiotic use is controversial; hydrocarbon pneumonitis has been reported to be of low risk for bacterial pneumonia complication.
- Broad-spectrum antibiotics: amoxicillin with clavulanate, 12-20 mg/kg PO q 12 h; second- or third-generation cephalosporins (e.g., cefoxitin, 30 mg/kg IV q 8 h to q 6 h); or fluoroquinolones (e.g., enrofloxacin, 5 mg/kg IM or diluted 1:1 in saline and given slowly IV q 12 h or q 24 h in cats) for secondary bacterial pneumonia
- Dermal decontamination, which consists of bathing (including haircoat and feet) with a mild liquid dishwashing detergent solution and rinsing thoroughly.

CHRONIC TREATMENT

If aspiration pneumonitis: oxygen supplementation, mechanical ventilation as necessary.

POSSIBLE COMPLICATIONS

Aspiration and chemical pneumonitis

RECOMMENDED MONITORING

- Chest radiographs as needed
- Arterial blood gas and Pao2 monitoring in animals that are compromised
- CBC and serum biochemistry profile
- In animals with a pulmonary condition, tracheal aspirate for Gram stain and/or culture can assist with antibiotic selection.

PROGNOSIS AND OUTCOME

- Good for cases in which no aspiration pneumonitis/pneumonia develops
- Guarded if aspiration occurs; update as needed

PEARLS & CONSIDERATIONS

COMMENTS

- Most commercial or industrial products containing a petroleum distillate carry a rather stern warning: “May be harmful or fatal if swallowed.” This warning is not specific to the individual product and does not automatically imply a poor prognosis. It is more useful to consider the volatility of the product when reasoning out the relative clinical risk to the animal, with greater volatility carrying a higher risk.
- Risk of aspiration pneumonitis/pneumonia from viscous or solid petroleum distillates including motor oil, transmission oil, waxes, other lubricating oils, grease, paraffin wax, and asphalt is very low. Most of these exposures result in mild self-limiting vomiting, lethargy, and diarrhea.
- Petroleum distillates are listed here in terms of their volatility: tar (least volatile); paraffin wax, lubricating oil, fuel oil, mineral seal oil, kerosene (intermediate); mineral spirits, gasoline, petroleum naphtha, petroleum ether (most volatile).

TECHNICIAN TIP

With petroleum distillates intoxications, “routine” decontamination measures (emesis, charcoal, gastric lavage) are contraindicated.

CLIENT EDUCATION

Owners should keep all products under lock and key and out of reach of pets. Childproof containers are not animal proof.

SUGGESTED READING

Raisbeck MF, Dailey RN: Petroleum hydrocarbons. In Peterson ME, Talcott PA, editors: Small animal toxicology, ed 2, St Louis, 2006, Saunders Elsevier, pp 986–995.

1ST EDITION AUTHOR: MICHAEL KNIGHT

Petechiae and Ecchymoses

BASIC INFORMATION

DEFINITION

Manifestations of disorders of the platelet and/or blood vessel wall (primary hemostasis) that can result in bleeding in the skin or mucous membranes to a degree that is out of proportion to the trauma. Petechiae are pinpoint hemonhages, whereas an ecchymosis is a large area of hemorrhage that a layperson would describe as a bruise.

SYNONYMS

Bruising, hemorrhagic diathesis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dependent on underlying cause:

- Young, purebred animals: von Willebrand disease, thrombasthenia, thrombopathia
- Young to middle-aged animals: infectious diseases, trauma
- Middle-aged animals: acquired immune-mediated diseases
- Older animals: neoplasia

GENETICS & BREED PREDISPOSITION

- von Willebrand disease (Doberman pinscher, Airedale, German shepherd, Scottish terrier, Chesapeake Bay retriever, and many other breeds; cats: Himalayan)
- Thrombopathia: basset hounds
- Thrombasthenia: otterhounds
- More common in dogs than in cats

RISK FACTORS

- Thrombocytopenia:
  - Immune-mediated disease: young to middle-aged, small to medium female dogs
  - Rickettsial disease: dogs living in or traveling to endemic areas
  - Bone marrow disease
- Thrombopathia/thrombasthenia:
  - Previous/current administration of nonsteroidal antiinflammatory drugs (NSAIDs)
  - Metabolic diseases: uremia, liver disease, paraproteinemia/hyper-globulinemia
- Vascular disease:
  - Hyperadrenocorticism
  - Drug reaction
  - Rocky Mountain spotted fever

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Nasal hemorrhage
- Pinpoint to large areas of bleeding on skin and mucous membranes
- Bruising
- Melena
- Hematuria

PHYSICAL EXAM FINDINGS

- Epistaxis
- Melena: from swallowing blood

- Petechiae, ecchymoses, hematochezia, and hematuria

ETIOLOGY AND PATHOPHYSIOLOGY

The conditions described will all cause capillary hemonhage and, unlike clotting factor defects, will result in frank hemorrhage:

- Thrombocytopenia:
  - Immune-mediated disease: idiopathic disease, systemic lupus erythematosus (SLE), drug reaction
  - Rickettsial disease: ehrlichiosis, Rocky Mountain spotted fever
  - Bone marrow disease: neoplasia, aplastic anemia, infectious (fungal, rickettsial, or viral)
  - Disseminated intravascular coagulation (DIC)
- Thrombopathia:
  - Congenital: von Willebrand disease, thrombasthenia, thrombopathia
  - Acquired: NSAIDs, hyperglobulinemia (ehrlichiosis, multiple myeloma), uremia, DIC
- Vascular disease:
  - Vasculitis: immune-mediated and rickettsial diseases
  - Vascular hemostatic defect:
    - Heightened permeability: hyperadrenocorticism
    - Reduced vessel strength: Ehlers-Danlos syndrome
    - Lack of contraction

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Barring severe trauma, petechiae or ecchymoses indicate a vascular wall, platelet, or severe coagulation factor problem leading to excessive bleeding. The history should seek to identify causes (e.g., intoxication), and the physical exam is essential for triage (to determine whether internal bleeding may be placing vital structures at risk). A platelet count is always indicated and a coagulation profile should be performed.

DIFFERENTIAL DIAGNOSIS

- Trauma resulting in areas of bruising
- Hemolytic uremic syndrome
- Cutaneous vasculopathy of greyhounds
- Cutaneous hemangioma or hemangiosarcoma

INITIAL DATABASE

- CBC:
  - Anemia if sufficient hemorrhage has occurred
  - RBC fragmentation suggests DIC or other vascular disease.
  - Thrombocytopenia
  - Neutrophilia: nonspecific stress, infection, neoplasia
  - Pancytopenia: bone marrow disease
- Urinalysis (avoid cystocentesis until coagulation status is known):
  - Usually normal
  - Isosthenuria with kidney disease
  - Hematuria
  - Proteinuria (e.g., with ehrlichiosis)
- Serum biochemistry profile:
  - Hypoproteinemia: if enough hemorrhage has occurred
  - Elevated urea with normal creatinine: gastrointestinal (GI) bleeding
  - Azotemia with renal disease or prerenal causes
  - Hyperglobulinemia with ehrlichiosis, multiple myeloma
  - Elevated alkaline phosphatase (ALP) activity with hyperadrenocorticism

ADVANCED OR CONFIRMATORY TESTING

- Other laboratory tests:
  - Coagulation profile: prolonged times with DIC; normal with thrombocytopenia and thrombopathia
  - von Willebrand factor analysis

- Buccal mucosal bleeding time (see p. 1222)
- Antinuclear antibody test for SLE
- Platelet function testing
- *Ehrlichia* and Rocky Mountain spotted fever titers, PCR

- Other diagnostic procedures:
  - Bone marrow aspiration biopsy: with pancytopenia
  - Skin biopsy: vascular disease, cutaneous lesions

TREATMENT

TREATMENT OVERVIEW

Treatment of the primary cause and support (e.g., blood transfusions) if necessary until treatment response

ACUTE GENERAL TREATMENT

- Restriction of patient's activity or stimuli that precipitate hemorrhage episodes
- Discontinuation of any medications that may alter platelet function
- Blood or platelet transfusions with severe anemia

CHRONIC TREATMENT

- Immunosuppressive therapy for immune-mediated thrombocytopenia
- von Willebrand disease: plasma or cryoprecipitate for acute bleeding
- Hyperglobulinemia: plasmapheresis
- Vasculitis: doxycycline for rickettsial disease; prednisone for primary immune-mediated diseases

POSSIBLE COMPLICATIONS

- Anemia and collapse state
- Hemorrhage into vital organs

RECOMMENDED MONITORING

- Platelet count with thrombocytopenia
- Clinical signs

PROGNOSIS AND OUTCOME

Dependent on cause

PEARLS & CONSIDERATIONS

COMMENTS

- Petechial hemorrhage is not a diagnosis but a clinical sign. Its presence should prompt a diagnostic workup early on to avoid catastrophic hemorrhage if the underlying cause is left unchecked.
- Pure secondary hemostatic defects (e.g., coagulation factor deficiency) do not typically cause spontaneous petechiae/ecchymoses, but venipuncture and other manipulations can allow subcutaneous bleeding, causing iatrogenic ecchymoses in these cases.

CLIENT EDUCATION

Recurrence of clinical signs

SUGGESTED READING

Callan MB: Epistaxis and hemoptysis. In Ettinger SJ, Feldman EC, editors: Textbook of veterinary internal medicine, ed 6,

Philadelphia, 2005, WB Saunders, pp 232–235.

AUTHOR: REMO LOBETTI

EDITOR: ETIENNE CÔTÉ

Persistent Müllerian Duct Syndrome

BASIC INFORMATION

DEFINITION

Persistent Müllerian duct syndrome (PMDS) is an uncommon condition characterized by the presence of paired uterine tubes, uterine horns, uterine body, cervix, and cranial vagina in a male dog or cat.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats; present at birth

GENETICS & BREED PREDISPOSITION: Miniature Schnauzers, basset hounds, and Persian cats. PMDS is an autosomal recessive condition.

ASSOCIATED CONDITIONS & DISORDERS: Urinary tract infections, prostatitis, fever of unknown origin, pyometra

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Affected animals may show no clinical signs; persistence of female tubular reproductive tract may be an incidental finding during ultrasound examination or exploratory surgery in a male animal. PMDS may also be associated with urinary tract infection, prostatitis, or fever of unknown origin due to pyometra or infected uterus masculinus.

PHYSICAL EXAM FINDINGS: Normal external male genitalia; 50% are cryptorchid.

ETIOLOGY AND PATHOPHYSIOLOGY

Normally, Müllerian inhibitory substance (MIS) secreted by embryonic testes prevents the development of the Müllerian ducts into uterine tubes, uterus, cervix, and cranial vagina. PMDS patients are genetically (XY) male but lack MIS receptors, so embryonic regression of the müllerian duct system does not occur.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Definitive diagnosis of PMDS requires karyotype and abdominal ultrasonography and/or exploratory surgery to confirm that the patient is genetically male with bilateral testes and retention of all Müllerian duct-derived organs.

DIFFERENTIAL DIAGNOSIS

Cystitis, prostatitis, fever of unknown origin, male pseudohermaphrodite

INITIAL DATABASE

CBC only; chemistry panel if clinical signs are present

ADVANCED OR CONFIRMATORY TESTING

Karyotype, abdominal ultrasound, abdominal exploratory surgery

TREATMENT

TREATMENT OVERVIEW

Treatment of PMDS depends on the clinical signs produced by the retention of Müllerian duct-derived organs. If the retained uterus is infected, it must be treated as a pyometra (see p. 954).

ACUTE GENERAL TREATMENT

Affected animals should undergo simultaneous castration and hysterectomy.

PROGNOSIS AND OUTCOME

Prognosis is good for normal lifespan after castration and hysterectomy.

PEARLS & CONSIDERATIONS

PREVENTION

PMDS is a hereditary autosomal recessive trait. Affected animals should be castrated. Parents and male and female siblings of affected animals can be latent carriers and should be eliminated from breeding stock.

CLIENT EDUCATION

As for Prevention, above

EDITOR: MICHELLE A. KUTZLER

Persistent Frenulum

BASIC INFORMATION

DEFINITION

Persistence of a thin membrane of tissue between the ventral tip of the penis and the corpus of the penis or the inner prepuce

SYNONYMS

Ventral deviation of the penis (phallo-campus), balanopreputial fold

EPIDEMIOLOGY

SPECIES, AGE, SEX: Male dogs and cats; the condition is present at birth.

GENETICS & BREED PREDISPOSITION: Cocker spaniels may be predisposed.

RISK FACTORS: Prepubertal castration (see Etiology)

ASSOCIATED CONDITIONS & DISORDERS: Posthitis, infertility (intromission failure)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Spontaneous
- Iatrogenic

HISTORY, CHIEF COMPLAINT: Licking at the penis, inguinal urine scalding due to urine dripping, painful erection, difficulty breeding

PHYSICAL EXAM FINDINGS: Ventral curvature of the distal penis, with the presence of a thin band of tissue between the ventral tip of the penis and the corpus of the penis or the inner fold of the prepuce (dogs). In cats, the remnant is ringlike rather than a band, since the penis separates from the prepuce (during embryonic growth) in a circumferential manner rather than a linear, longitudinal manner like the dog.

ETIOLOGY AND PATHOPHYSIOLOGY

The frenulum is a remnant of the balanopreputial fold, which normally dissolves during postnatal development under the influence of androgens (near puberty). Prepubertal (early age) castration will prevent or diminish the dissolution of this attachment.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Most cases of persistent frenulum go undiagnosed or are incidental findings during urethral catheterization.

DIFFERENTIAL DIAGNOSIS

Preputial adhesion secondary to trauma or infection

INITIAL DATABASE

Physical examination of the penis following complete preputial retraction

TREATMENT

TREATMENT OVERVIEW

Treatment is necessary if there is urine dribbling, balanoposthitis (inflammation of the penis and prepuce), or if the animal is intended for breeding.

ACUTE GENERAL TREATMENT

The ventral band (dog) or circumferential attachment (cat) is resected with surgical scissors while the patient is under sedation or light general anesthesia.

CHRONIC TREATMENT

Postoperatively the prepuce may need to be retracted daily to prevent readherence.

BEHAVIOR/EXERCISE

The male should be sexually rested until the mucosal defect is completely healed.

POSSIBLE COMPLICATIONS

Balanoposthitis may develop secondary to the persistent frenulum or following resection of the attachment.

RECOMMENDED MONITORING

Monitor for hemorrhage or purulent preputial discharge.

PROGNOSIS AND OUTCOME

Very good prognosis after resection

PEARLS & CONSIDERATIONS

COMMENTS

The heritability of penile frenulum is unknown in the dog and cat but is heritable in other species (bovine, ovine, caprine, porcine).

PREVENTION

If appropriate, delay castration in nonbreeding animals until after puberty (>6 months).

TECHNICIAN TIPS

Difficulty may be encountered during penile exposure for urethral catheterization when a penile frenulum is present.

CLIENT EDUCATION

Delaying castration in nonbreeding animals until after puberty (>6 months) will prevent the iatrogenic occurrence of a persistent frenulum.

AUTHOR: JAMES FLANDERS

EDITOR: MICHELLE A. KUTZLER

Peritonitis, Septic

BASIC INFORMATION

DEFINITION

Peritonitis is the local or generalized inflammation of the peritoneum; a diagnosis of septic peritonitis is based on identification of toxic neutrophils with intracellular bacteria within abdominal fluid.

EPIDEMIOLOGY

SPECIES, AGE, SEX: There is no species or sex predilection; younger animals that are prone to ingesting foreign material and older animals with gastrointestinal (GI) masses that can perforate are predisposed.

RISK FACTORS: Gastrointestinal surgery, gastric dilation and volvulus with gastric resection

ASSOCIATED CONDITIONS & DISORDERS: Neoplasia, linear foreign body, gastric dilation and volvulus

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPE

- GI perforation
- Non-GI perforation of an abdominal organ (e.g., pyometra, prostatic abscesses, hepatic abscess)

HISTORY, CHIEF COMPLAINT

- Lethargy
- Collapse
- Vomiting

PHYSICAL EXAM FINDINGS

- Tachycardia and signs of hypovolemic or septic shock
- Signs of abdominal pain (may be disproportionately subtle for the degree of inflammation or conversely may be mimicked by apprehension and abdominal guarding when no pain is there)
- Ascites
- Fever
- Altered mentation
- Injected mucous membranes/hyperemia

ETIOLOGY AND PATHOPHYSIOLOGY

- Bacteria gain access to the abdominal cavity. This occurs most frequently via perforation of the intestinal tract, although other internal sources (genitourinary tract, liver) and external sources (penetrating trauma) are possible.
- Infection within the abdominal cavity causes localized inflammation, with cellular inflammation and fibrin production.
- The peritoneum responds with increased vascular permeability, cellular infiltration with leukocytes and macrophages, and fibrin deposition.
- With increases in vascular permeability, interstitial fluid may accumulate rapidly.
- Substantial quantities of electrolytes, plasma proteins, and red blood cells (RBCs) may extravasate and be lost through third spacing in the abdominal cavity.
- This loss may progress to the point of causing hypovolemia, dehydration, severe hemoconcentration, septicemia, and metabolic alterations.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of septic peritonitis, regardless of the underlying cause, is based upon demonstration—typically via cytologic evaluation of fluid obtained by abdominocentesis—of intraperitoneal toxic degenerative neutrophils containing intracellular bacteria.

DIFFERENTIAL DIAGNOSIS

Differentiation from other causes of abdominal pain or distension (e.g., acute abdomen [see p. 28], sterile ascites, neoplasia, sterile pancreatitis)

INITIAL DATABASE

- CBC, serum chemistry panel, urinalysis with culture
  - Urine sample obtained by urethral catheterization if possible; cystocentesis may inadvertently retrieve septic ascitic fluid.
- Abdominal radiographs: may document free intraabdominal air
  - Highly suggestive/specific for septic peritonitis unless air is result of prior abdominal surgery in the preceding week
- Abdominal ultrasound
- Abdominocentesis with fluid analysis, cytologic examination, and culture and sensitivity (C&S; both aerobic and anaerobic)

ADVANCED OR CONFIRMATORY TESTING

- Clotting profiles (prothrombin time and activated partial thromboplastin time) are useful because many animals with septic peritonitis are septic and thus have coagulopathy.
- Abdominocentesis (see p. 1193) and diagnostic peritoneal lavage (see online chapter: Diagnostic Peritoneal Lavage) have been shown to be safe and reliable in evaluating a septic peritonitis:
  - Abdominocentesis: see p. 1193
  - Diagnostic peritoneal lavage: aseptic placement of a large-bore (12- to 14-G) 5¼-inch (12 cm) catheter with additional side holes into the abdomen, followed by instillation of 20 mL/kg body weight of warm (body temperature) sterile saline into the peritoneum using an IV administration set, allowing the fluid to flow with gravity. The patient is then carefully rolled from side to side to mix the fluid. Finally, a sample is recovered for cytologic examination and C&S.
- The diagnosis of bacterial peritonitis is based on the presence of toxic degenerate neutrophils with intracellular bacteria in the abdominal fluid.
  - In most cases, the glucose level of the abdominal fluid is at least 20 mg/dL (1.1 mmol/L) lower than that of the peripheral blood glucose level.

TREATMENT

TREATMENT OVERVIEW

- Patient stabilization
- Identification and correction of underlying cause

ACUTE GENERAL TREATMENT

- Initial treatment must be directed toward stabilization of the metabolic consequences of peritonitis.
- IV crystalloid fluids (60-90 mL/kg), plasma (10-15 mL/kg), or whole blood may be necessary to maintain cardiac output.
  - Hematocrit to be maintained above 21%
- Exploratory laparotomy is warranted as soon as possible.
  - Stabilization of the patient as much as possible preoperatively
  - Repair of the lesion
  - Biopsy of affected tissues and intraoperative cultures
  - Lavage
  - Closed-suction drainage (warranted in almost all cases)
  - Open abdominal drainage if extensive contamination is present
- Broad-spectrum antimicrobial therapy; recommendations include:
  - Ampicillin, 22 mg/kg IV q 6 h; + gentamicin, 6 mg/kg IV q 24 h
    - Gentamicin q 24 h is less nephrotoxic than q 12 h or q 8 h.
    - Gentamicin should not be initiated until the animal is both hydrated and producing urine.
  - Ampicillin, 22 mg/kg IV q 6 h; + enrofloxacin, 10 mg/kg IV q 24 h
    - Enrofloxacin IV should be diluted in saline; use is off label.
    - Avoid enrofloxacin at this dose in cats (permanent retinopathy possible).
  - Cefazolin, 22 mg/kg IV q 8 h; + gentamicin or enrofloxacin (according to dosage just presented); + metronidazole, 10 mg/kg IV q 8 h

- Hospital-acquired infections (e.g., dehiscence of enterotomy sites) should be treated based on the sensitivity pattern of the hospital's pathogenic flora.

POSSIBLE COMPLICATIONS

- Sepsis
- Multiple organ dysfunction syndrome
- Dehiscence at site of prior repair
- Hypoalbuminemia

RECOMMENDED MONITORING

- Hydration status
- Serum total protein and albumin levels
- Serum electrolytes
- Serum/blood glucose level
- Blood pressure
- Renal function/urine output
- Central venous pressure
- Adequacy of pain control

PROGNOSIS AND OUTCOME

The reported mortality rate for dogs and cats with septic peritonitis ranges from 20%-70%. The clinician should inform the owner of the mortality rate prior to surgery.

PEARLS & CONSIDERATIONS

COMMENTS

- Gastric perforations may result in a large amount of free intraabdominal air without fluid.
- Linear foreign bodies are particularly prone to perforation.

PREVENTION

Good surgical technique is required for abdominal surgery.

Peritonitis (General)

BASIC INFORMATION

DEFINITION

Inflammation of the peritoneum

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Any species, breed, age, or sex
- Cat: feline infectious peritonitis (FIP)

RISK FACTORS

- Abdominal trauma:
  - Blunt
  - Penetrating
- Intraabdominal surgery:
  - Gastrointestinal (GI) procedures
- Inflammatory/infectious disease of abdominal organ(s):
  - Cholecystitis/cholangiohepatitis
  - Prostatitis/prostatic abscess
  - Pancreatitis
  - Pyometra
- Cat:
  - Environment conducive to transmission of FIP

CONTAGION & ZOONOSIS: Cat: transmission of coronavirus FIP is mainly fecal-oral; mutation of coronavirus from less pathogenic form to FIP variant is necessary to cause clinical FIP.

ASSOCIATED CONDITIONS & DISORDERS

- Sepsis/septic shock
- Coagulopathy/disseminated intravascular coagulation (DIC)
- Systemic inflammatory response syndrome
- Acute respiratory distress syndrome
- Multiple organ dysfunction

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES:

Primary versus secondary:

- Primary:
  - Peritoneal inflammation or infection without preexisting intraabdominal condition:
    - FIP
    - Rare occurrence of bacterial (mycobacteria) and protozoal primary infections
- Secondary:
  - Peritoneal inflammation or infection caused by intraabdominal pathologic condition:
    - Disruption of hollow viscus
    - Penetrating trauma
    - Organ inflammation/ischemia
    - Iatrogenically induced

Nonseptic versus Septic:

- Nonseptic:
  - Peritoneal inflammation caused by mechanical trauma:
    - Intraabdominal surgery
  - Sterile foreign material:
    - Urine
    - Bile
    - Iatrogenically introduced (e.g., surgical sponge)
- Septic:
  - Contamination and subsequent infection of the peritoneal cavity by an infectious agent:
    - Bacteria; most common cause in dog and cat
    - Virus
    - Protozoa

HISTORY, CHIEF COMPLAINT: History variable depending on underlying cause of peritonitis; may include:

- Known traumatic event
- Ingestion of a foreign object
- Previous abdominal surgery
- Ongoing or recent treatment for intraabdominal organ disease
- Problems urinating or defecating
- Heat cycle in previous month

Chief complaint(s) variable depending on underlying cause of peritonitis; may include:

- Nonspecific complaints:
  - Lethargy, fever, anorexia, vomiting, decreased/no fecal production, diarrhea
- Complaints related to cause of peritonitis:
  - Wound(s) in abdominal area
- Urination:
  - Straining to urinate
  - Decreased/no urine production
  - Blood in urine
  - Developing jaundice
  - Vaginal discharge
- Complaints related to developing peritonitis:
  - Abdominal discomfort:
    - Reluctance to lie down or uncomfortable when lying down
    - “Praying posture”
    - Pain on handling/touching abdomen:
      - May only be subtle (especially in cats)
      - Abdominal distension

PHYSICAL EXAM FINDINGS: Findings related to peritoneal inflammation:

- Nonspecific findings:
  - Lethargy, fever, dehydration
- Specific findings:
  - Pain on abdominal palpation:
    - Localize to specific region of abdomen if possible
    - May be absent or not dramatic:
      - Even in face of significant peritoneal inflammation
      - Especially in the cat
  - Abdominal distension:
    - Fluid
    - Mass

Findings related to underlying cause of peritonitis:

- Evidence of abdominal trauma:
  - Wound(s)
  - Contusions
  - Disruption of the abdominal wall
  - Linear foreign body (see p. 407) caught around tongue base. Clinicians should apply dorsal pressure with thumb externally between mandibles to raise tongue for proper sublingual examination.

- Incision line from previous abdominal surgery
- Icterus
- Hematuria, pyuria
- Purulent or hemorrhagic vaginal discharge
- Findings related to developing sepsis
- Hyperemia or injected mucous membranes
- Increased or decreased capillary refill time
- Tachycardia, tachypnea
- Hyperdynamic or hypodynamic pulse

ETIOLOGY AND PATHOPHYSIOLOGY

- Peritoneal inflammation; vasculitis, increased capillary permeability
- Movement of large volumes of fluid into peritoneal cavity:
  - Severe hypovolemia or hypovolemic shock
  - Accompanying loss of protein and electrolytes
- Development of coagulation abnormalities due to release of inflammatory mediators and cytokines:
  - Hypercoagulable or hypocoagulable state
  - DIC
- If septic, bacterial translocation into the bloodstream:
  - Bacteremia
  - Sepsis or septic shock

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is suspected based on presenting history and physical examination findings. Confirmation requires demonstration of inflammation in intraabdominal fluid and evaluation of the fluid to determine the cause of the peritonitis.

DIFFERENTIAL DIAGNOSIS

- Pain, abdominal; need to rule out nonperitonitis causes:
  - Organ enlargement
  - Organ inflammation
- Pain, nonabdominal; need to rule out:
  - Spinal:
    - Intervertebral disk disease
    - Trauma
  - Pelvic:
    - Fracture/dislocation
  - Thoracic:
    - Trauma related: rib fractures, diaphragmatic hernia
    - Intrathoracic disease: pleural pain
  - Limbs:
    - Joint pain/polyarthritis
- Abdominal distention, fluid:
  - Associated with peritonitis:
    - Refer to fluid analysis for an animal with peritonitis.
  - Not associated with peritonitis:
    - Transudate; modified transudate; hemorrhage
- Abdominal distension, mass:
  - Nonperitonitis causes of abdominal mass:
    - Organ enlargement: hepatomegaly, splenomegaly
    - Cyst formation: paraprostatic cyst

INITIAL DATABASE

- CBC, evidence of:
  - Regenerative left shift: inflammation
  - Degenerative left shift: sepsis
- Serum biochemistry profile:

- Evidence of cause of peritonitis:
  - Azotemia: uroabdomen versus dehydration (postrenal versus prerenal, respectively)
  - Hyperbilirubinemia: bile peritonitis
- Assessment of organ function and pathophysiologic effects of the peritonitis:
  - Electrolyte imbalance:
    - Hypokalemia: fluid loss, no intake
    - Hyperkalemia: uroabdomen, anuria, acidosis
  - Hypoproteinemia:
    - Leakage into peritoneal cavity
    - Decreased production
  - Altered blood glucose concentration:
    - Hypoglycemia or hyperglycemia
    - Blood/peritoneal fluid concentration: blood glucose = 20 mg/dL higher than peritoneal fluid glucose may be predictive of septic peritonitis
  - Lactate:
    - Blood/peritoneal fluid lactate concentration difference >2 mmol/L may be predictive of septic peritonitis in the dog
  - Hyperbilirubinemia:
    - Bile leakage: bile peritonitis

- Urinalysis:
  - Avoid cystocentesis in animals with peritonitis; catheter preferable (indwelling may be desired for monitoring critical cases; contrast cystography for uroperitoneum, etc.)
- Whole-abdomen clipping of hair: if possibility of penetrating wound with (e.g., stick, projectile) or without (e.g., tooth, claw) retention of penetrating object
- Survey abdominal radiographs:
  - Findings suggestive of peritonitis:
    - Fluid, causing loss of serosal detail
    - Free gas:
      - Mottling throughout viscera or “gas cap effect” (clearest with horizontal beam radiograph)
    - Ileus
    - Mass(es)
- Ultrasound examination:
  - Integrity of organs
  - Evaluate mass(es)
  - Confirm presence of fluid and obtain sample for analysis (see below)
- Abdominal fluid analysis:
  - Obtain by ultrasound guidance:
    - Preferable to blind abdominocentesis or diagnostic peritoneal lavage
  - Analysis:
    - Glucose, lactate concentrations (see previous)
    - Urea nitrogen, creatinine concentrations:
      - Fluid/blood creatinine concentration ratio = 2:1 highly predictive of uroabdomen in the dog
    - Bilirubin concentration:
      - Compare to serum: fluid bilirubin concentration > serum concentration highly suggestive of bile peritonitis
    - Electrolytes:
      - Fluid/blood potassium concentration ratio = 1.4:1 highly predictive of uroabdomen in the dog
  - Cytologic examination:
    - Neutrophils:
      - Inflammation: increased count, nondegenerative, no intracellular bacteria
      - Septic peritonitis: increased count, toxic changes, intracellular bacteria
    - Plant material: GI leakage
    - Bacteria: Gram stain to aid choice of antibiotic therapy pending culture results
  - Microbiologic culture and sensitivity (C&S) testing:
    - Aerobic and anaerobic

ADVANCED OR CONFIRMATORY TESTING

- Contrast radiographic studies:
  - Uroabdomen: cystography (lower urinary tract) or excretory urography (upper urinary tract; less commonly indicated) to confirm site of disruption prior to surgery
- Coagulation profile: DIC

TREATMENT

TREATMENT OVERVIEW

- Patients with primary peritonitis (e.g., FIP) require supportive care and specific medical treatment of the underlying cause.
- Patients with secondary peritonitis require surgical exploration of the abdomen with:
  - Surgical correction of the cause
  - Peritoneal lavage and possible drainage
  - Intensive postoperative care
- Some cases (e.g., severe pancreatitis) may have elements both favoring and disfavoring surgical exploration, and consultation with an internist and a surgeon should be considered for optimal planning.

ACUTE AND CHRONIC TREATMENT

- Correction of fluid and electrolyte abnormalities:
  - Hypovolemia
  - Hypokalemia or hyperkalemia:
    - Uroabdomen, hyperkalemia:
      - Potassium-free fluids: 0.9% NaCl (seep. 55)
- Blood products if necessary (see p. 1111):
  - Whole blood (if anemia or bleeding disorder)
  - Packed red cells (if anemia)
  - Fresh frozen plasma (if hypoproteinemia or coagulopathy)
- Appropriate antimicrobial therapy if septic:
  - Empirical therapy (aerobic and anaerobic coverage):
    - Second-generation cephalosporin:
      - Cefoxitin, 22 mg/kg IV q 2 h during the perioperative period, then q 6 h
    - Combination therapy:
      - Metronidazole, 10-15 mg/kg IV q 12 h; enrofloxacin, 2.5-5 mg/kg (diluted 1:1 in sterile saline and given via slow IV q 12 h); and ampicillin, 22 mg/kg IV q 6 h
  - Ultimately based on culture results
- Surgical exploration of abdomen to identify and correct underlying cause of peritonitis if appropriate (e.g., evidence of septic peritonitis; hemorrhage in the absence of systemic bleeding disorder)
  - Thorough lavage of the abdominal cavity
- Consideration of need for postoperative drainage of the abdominal cavity:
  - Specific sites within the abdomen; drain placement:
    - Pancreatic abscess
    - Prostatic abscess
    - Necrotizing cholecystitis
  - Entire abdominal cavity:
    - Open abdominal drainage
    - Closed suction drainage
- Postoperative intensive care with continuous monitoring of animal until peritonitis has resolved

NUTRITION/DIET

- Feeding tue placement if anorexia (seepp. 1267 ,)
- Coax-feeding (see p. 1377)

POSSIBLE COMPLICATIONS

See Peritonitis, Septic, ; Feline Infectious Peritonitis, p. 383; other relevant topics

RECOMMENDED MONITORING

Dependent on cause of peritonitis; see Peritonitis, Septic, ; Sepsis and Septic Shock,p. 1014; Systemic Inflammatory Response Syndrome, ; Multiple Organ Dysfunction Syndrome,p. 732.

PROGNOSIS AND OUTCOME

Variable; dependent on underlying cause

PEARLS & CONSIDERATIONS

TECHNICIAN TIPS

Peritonitis patients (septic) are often in a critical state and require intensive care. Technicians treating and caring for these patients should be familiar with and competent in a number of intensive patient care techniques:

- Fluid and blood component therapy
- Intensive patient monitoring including blood pressure, CBC and serum biochemistry profile, blood gases, urine output
- Nutritional support
- Analgesia

1ST EDITION AUTHOR: ELLEN DAVIDSON DOMNICK

Peritoneopericardial Diaphragmatic Hernia

BASIC INFORMATION

DEFINITION

- Embryologic malformation of the diaphragm, resulting in communication between peritoneal and pericardial cavities and allowing herniation of cranial abdominal organs and omentum into the pericardial space (from most to least common: liver, gallbladder, small intestine, spleen, stomach)
- Can result in vascular compromise or obstruction of herniated organs and (rarely) cardiac tamponade

SYNONYMS

Pericardioperitoneal diaphragmatic hernia, pericardial diaphragmatic hernia, PPDH

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats
- Age at diagnosis highly variable (30% diagnosed at >4 years of age)
- No sex predilection

GENETICS & BREED PREDISPOSITION

- Not known if hereditary but reported in littermates
- Predisposed breeds: weimaraners, cocker spaniels; Persians, Himalayans, domestic longhair cats

RISK FACTORS: Prenatal injury, possibly systemic illness or toxin exposure affecting pregnant dam

ASSOCIATED CONDITIONS & DISORDERS

- Cranioventral abdominal hernias
- Caudal sternal abnormalities (pectus excavatum, malformed or absent sternebrae)
- Ventricular or atrial septal defects, pulmonic stenosis, pericardial cysts
- Polycystic kidney disease in cats

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Often incidental finding with no clinical signs
- Nonspecific signs (lethargy, anorexia, pyrexia, weight loss)
- Respiratory signs (dyspnea, tachypnea, coughing)
- Gastrointestinal (GI) signs (vomiting, diarrhea)
- Rarely, signs of cardiac tamponade and right heart failure (weakness, collapse, ascites)

PHYSICAL EXAM FINDINGS

- May be normal
- Displaced or absent apical cardiac impulse on thorax
- Muffled or displaced heart sounds
- Cardiac murmur if congenital cardiac defect is also present
- Palpable sternal or cranial abdominal defects
- Inability to palpate cranial abdominal organs if herniated into pericardial space
- Borborygmi (GI sounds) over heart

ETIOLOGY AND PATHOPHYSIOLOGY

- Abnormal development of septum transversum (forms ventral portion of the diaphragm) ± pleuroperitoneal folds (form dorsolateral diaphragm), resulting in an hourglass-like shape of the joined peritoneal and pericardial cavities (that should instead be separate body cavities)
- PPDH is always a congenital abnormality, not an acquired one.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Definitive diagnosis can be made on the basis of history, physical exam, and thoracic radiographs alone if characteristic radiographic findings are seen, including heterogeneous radiopacities (gas and/or fat) within an enlarged cardiac silhouette and concurrent loss of distinct diaphragmatic border.

DIFFERENTIAL DIAGNOSIS

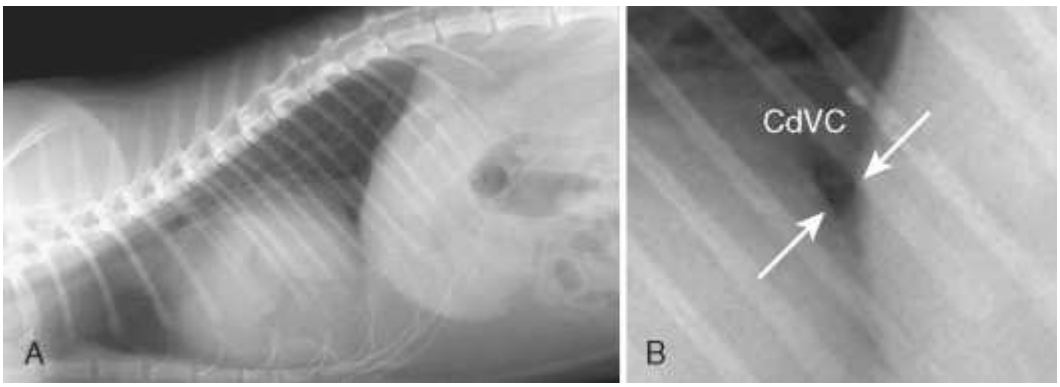
- Other causes of generalized cardiomegaly:
  - Pericardial effusion
  - Congenital or acquired cardiac diseases
- True diaphragmatic hernias do not involve the presence of abdominal viscera in the pericardial space.

INITIAL DATABASE

- CBC and serum biochemistry panel: no characteristic abnormalities
- Thoracic radiographs: o Cardiomegaly
  - Silhouetting of the caudal cardiac border with the diaphragm
  - Discontinuity of the diaphragm
  - Presence of irregular and heterogeneous radiopacities (soft tissue, fat, gas) within cardiac silhouette
  - Dorsal mesothelial remnant on lateral view in cats: curvilinear soft-tissue opacity ventral to caudal vena cava, representing dorsal aspect of hernia
  - Sternal deformities
- Abdominal radiographs:
  - Small or absent liver
  - Cranial displacement or absence of stomach or spleen
  - GI gas pattern extending from abdomen into pericardial space

ADVANCED OR CONFIRMATORY TESTING

- Ultrasound: fat or abdominal organs within the pericardial sac, ± small amount of pericardial effusion and discontinuity of diaphragm
  - Consolidation of the accessory lung lobe can be an extremely misleading impostor for PPDH ultrasonographically; fluid-filled bronchi appear identical to portal veins, and atelectatic lung mimics liver parenchyma. If any uncertainty exists (e.g., clinical features inconsistent with PPDH, such as previously normal thoracic radiographs), a radiologist's evaluation of the thoracic radiographs is strongly recommended.
- Upper GI barium series: may confirm presence of GI segments in pericardial space; often not required for diagnosis
- Positive contrast peritoneography: 2 mL/kg of water-soluble, iodinated radiopaque contrast agent such as iohexol injected aseptically into peritoneal cavity, followed by elevation of the animal's caudal end and thoracic radiography (contrast may flow into pericardial cavity). Often not required for diagnosis; many false negatives (omental/visceral plugging of the hernia).



PERITONEOPERICARDIAL DIAPHRAGMATIC HERNIA A, Lateral radiograph of thorax and cranial abdomen of a cat with

peritoneopericardial diaphragmatic hernia (PPDH). Note cardiomegaly, irregular soft-tissue and fat opacities over the heart, indistinct ventral diaphragm, and small liver. **B**, Magnified view of **A**, showing dorsal mesothelial remnant *(between the arrows),* which is characteristic of PPDH. *CdVC,* Caudal vena cava.

(Courtesy Dr. Stephanie Nykamp.)

TREATMENT

TREATMENT OVERVIEW

Surgical correction is generally indicated to eliminate clinical signs and prevent vascular compromise or obstruction of organs.

ACUTE GENERAL TREATMENT

- Oxygen supplementation if the patient is dyspneic
- Surgical correction via laparotomy: return of all abdominal organs to correct location and closure of the diaphragmatic defect
- Assessment of liver function prior to general anesthesia in order to choose anesthetic protocol accordingly
- It may be appropriate not to pursue surgical repair in some cases (e.g., geriatric animal without clinical signs, small incidentally discovered PPDH).

POSSIBLE COMPLICATIONS

- If the PPDH is left uncorrected, the risk of hepatic or splenic incarceration, bowel obstruction, or (rarely) cardiac tamponade, and right heart failure persists.
- Surgical complications: difficulty ventilating, hypotension, reexpansion pulmonary edema

PROGNOSIS AND OUTCOME

- Excellent prognosis with surgical correction
- Left with an uncorrected PPDH, the patient may remain free of clinical signs, but there is always a risk of complications as listed above.

PEARLS & CONSIDERATIONS

COMMENTS

- PPDH is the most common congenital pericardial disorder in dogs and cats.
- PPDH is a congenital defect (failure of complete separation of the pericardial and abdominal cavities) in contrast to a true diaphragmatic hernia, which is almost always acquired as a result of trauma.
- PPDH is an important rule-out for cardiomegaly and in young animals with cranial abdominal or sternal defects.

AUTHOR: M. LYNNE O'SULLIVAN

EDITOR: ETIENNE CÔTÉ

Perirenal Pseudocysts

BASIC INFORMATION

DEFINITION

Collection of fluid (usually transudate, but sometimes urine) between the renal capsule and kidney that is rare in cats and extremely rare in dogs. Pseudocysts may be unilateral or bilateral.

SYNONYMS

Perinephric pseudocyst, capsulogenic renal cyst, capsular cyst, pararenal pseudocyst, capsular hydronephrosis, pseudohydronephrosis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Rare in cats, extremely rare in dogs
- Older cats; some reports have shown male cats to be overrepresented.

RISK FACTORS

- Chronic kidney disease (transudative pseudocysts)
- Trauma, obstruction, neoplasia of renal pelvis or ureter, causing urine leakage (uriniferous pseudocysts)

ASSOCIATED CONDITIONS & DISORDERS

- Chronic kidney disease
- Urinary tract infection

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Usually abdominal enlargement/abdominal mass (noted by owner or incidental finding during exam)
- Less frequently: weight loss, vomiting, anorexia, polyuria, and polydipsia

PHYSICAL EXAM FINDINGS: Palpable abdominal mass (renomegaly; common but depends on size of cyst) ± thin body condition

ETIOLOGY AND PATHOPHYSIOLOGY

- Incompletely understood pathophysiology
- Lack of epithelial lining in fibrous sacs means that these are not true cysts.
- Renal interstitial fibrosis may impair venous and lymphatic drainage, causing transudate to escape the renal parenchyma and accumulate under the capsule, forming a transudative pseudocyst.
- Uriniferous pseudocysts may form when damage to the renal parenchyma, pelvis, or ureter allows urine to leak between the renal capsule and renal parenchyma.
- The distinction between transudative and uriniferous pseudocysts may be useful with respect to initial management. Transudative pseudocysts suggest chronic kidney disease (International Renal Interest Society [IRIS] stage 2-4, consider appropriate treatment), whereas uriniferous pseudocysts suggest physical disruption of the integrity of the kidney or proximal ureter (identify and correct source of leakage).

DIAGNOSIS

DIAGNOSTIC OVERVEIW

Ultrasonographic identification of hypoechoic fluid between the renal capsule and parenchyma strongly supports the diagnosis but does not usually identify a cause.

DIFFERENTIAL DIAGNOSIS

For enlarged kidneys: perinephric abscess, renal lymphoma or other neoplasia, ureteral obstruction with hydronephrosis, feline infectious peritonitis, hematoma, polycystic kidney disease, and compensatory hypertrophy (Note: abscess, other neoplasia, ureteral obstruction, hematoma, and compensatory hypertrophy: more commonly unilateral than bilateral)

INITIAL DATABASE

- CBC: possibly nonregenerative anemia of chronic kidney disease
- Serum biochemistry profile: usually evidence of mild to moderate renal failure (e.g., azotemia, hyperphosphatemia)
- Urinalysis: isosthenuric or minimally concentrated urine specific gravity
- Urine culture: often positive even in the absence of pyuria
- Abdominal radiographs: unilateral or bilateral renomegaly

ADVANCED OR CONFIRMATORY TESTING

- Abdominal ultrasound: method of choice to confirm diagnosis. Transudative and uriniferous pseudocysts are characterized by an accumulation of completely anechoic fluid between renal parenchyma and capsule. Septations, particulate matter in the perirenal fluid, and other variations suggest a diagnosis other than perirenal pseudocysts.
- Excretory urography if ultrasound unavailable. Decreased renal function may result in poor contrast study. Small risk of contrast-induced renal failure.
- If the diagnosis remains in question after ultrasound, aspiration of anechoic/hypoechoic region for cytologic analysis can differentiate pseudocyst from perinephric abscess, hematoma, or lymphoma.
- Concentration of creatinine will be higher in fluid from uriniferous pseudocysts than concurrent serum creatinine concentration.

TREATMENT

TREATMENT OVERVIEW

Transudative pseudocysts may be managed conservatively, with the goal of preventing renal and ureteral compression. Uriniferous pseudocysts may require surgical intervention.

ACUTE GENERAL TREATMENT

- If transudative pseudocyst, percutaneous drainage or surgical intervention
- If uriniferous, identify (i.e., via excretory urography) and correct source of urine leakage.

CHRONIC TREATMENT

- Repeated percutaneous drainage of transudative pseudocysts
- Surgical resection of pseudocyst ± omentopexy
- Treat existing bacterial cystitis, if present (see p. 276).
- With transudative pseudocysts: treat appropriately for chronic kidney disease (see pp. 205 and <207).
- With uriniferous pseudocysts: surgical intervention
- Nephrectomy should be avoided if possible when renal function is compromised. May become necessary if persistent ascites develops after surgical resection of pseudocyst or if there is reason to believe neoplasia is causative (e.g., thick, irregular capsule on one kidney).

NUTRITION/DIET

For animals with chronic kidney disease, a protein-restricted renal diet is appropriate (see pp. 205 and 207).

POSSIBLE COMPLICATIONS

- Urinary tract infection
- Ascites may be a complication of pseudocyst removal, occasionally necessitating nephrectomy.
- Hydrothorax due to pseudocyst has been reported in a single cat.

RECOMMENDED MONITORING

- Monitor as for chronic kidney disease (see pp. 205 and 207).
- Repeat ultrasound examination periodically after percutaneous drainage or surgical pseudocyst removal. Frequency of repeat ultrasound depends on rapidity of fluid reaccumulation.

PROGNOSIS AND OUTCOME

- Prognosis variable, generally in the range of months to years
- Prognosis better if associated chronic kidney disease is IRIS stage 1 or 2, worse if stage 3 or 4.
- Median survival after surgery (capsulectomy): 9 months, with wide range
- Prognosis apparently worse in cats treated with nephrectomy
- No clear generalization regarding prognosis in transudative versus uriniferous pseudocysts

PEARLS & CONSIDERATIONS

COMMENTS

- The choice between surgical removal of transudative pseudocysts and repeated percutaneous drainage depends on severity of underlying kidney disease, concurrent disease, age of the cat, and cost to owner. Cats with severe azotemia, another disease process that makes them a poor anesthetic/surgical candidate, advanced age, or where cost is an issue may be best managed via repeated percutaneous drainage.
- Nephrectomy may result in worsened azotemia in cats and should be reserved for cats that develop persistent ascites after removal of the pseudocyst. Ideally, renal scintigraphy should precede the decision for nephrectomy to determine contribution of kidney to be removed to total glomerular filtration capacity.

Periodontal Disease

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Plaque-induced inflammation and infection of the gingiva, periodontal ligament, and alveolar bone

SYNONYMS

Gingivitis (inflammation of gingiva), gum disease, periodontitis (inflammation of the periodontium, which includes gingiva, alveolar bone, periodontal ligament, and cementum)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Most common disease in companion animals; affects all breeds
- Tends to be more common and severe in toy and small-breed dogs
- Occurs in dogs and cats of any age, although the condition is more severe with increasing age

GENETICS & BREED PREDISPOSITION: Toy and small breed dogs are particularly prone to severe alveolar bone loss (relatively large teeth compared to small size of jaws, causing crowding of teeth).

RISK FACTORS: Soft-food diets; lack of dietary abrasion permits rapid accumulation of plaque and calculus.

CONTAGION & ZOONOSIS: Periodontal disease is an infectious disease; however, all clinically normal animals carry the putative causative organisms in their mouths. There is no evidence of dog/cat-to-dog/cat or dog/cat-to-human spread.

GEOGRAPHY AND SEASONALITY: Dogs and cats in less developed parts of the world are less prone to develop severe periodontal disease, because they have a more varied diet that encourages natural chewing activity.

ASSOCIATED CONDITIONS & DISORDERS: Coexists with many other oral conditions and may mask appearance of diseases with a worse prognosis, such as oral neoplasms. Found in almost every animal with stomatitis (see p. 1428). Masks and is masked by gingival hyperplasia.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Severity of inflammation varies relative to extent of plaque and calculus accumulation and to local and general immunologic health. Maxillary fourth premolar and first molar teeth are often the most severely affected teeth.

HISTORY, CHIEF COMPLAINT: Halitosis, teeth stained by calculus; gingiva may be swollen, bleeding, or ulcerated.

PHYSICAL EXAM FINDINGS: There is often a wide variation in the severity of the disease, which may be apparent when comparing one part of the mouth with another in the same animal.

- Halitosis, plaque, and calculus formation
- Gingivitis, gingival bleeding (on probing or spontaneous), gingival recession (root exposure)
- Involvement of furcation (space between roots of multirooted teeth), periodontal pocket formation
- Horizontal or vertical alveolar bone loss on radiographs
- Perio-endodontic disease on radiographs (extension of periodontal disease to the apical periodontium and pulp involvement)
- Mobile, displaced, and missing teeth
- Pathologic jaw fracture

ETIOLOGY AND PATHOPHYSIOLOGY

- Caused by bacteria in dental plaque at the gingival margin (primarily gramnegative anaerobic rods and spirochetes); exacerbated by accumulation of calculus on the surface of teeth
- Gingival inflammation leads to destruction of the periodontal ligament and resorption of adjacent alveolar bone, causing gradual loss of attachment of the tooth to the jaw.
- Gingiva may recede in step with worsening bone loss, or remain in place with a deepening pocket between the gingiva and

root as bone loss worsens.
- Local disease resolves once the teeth are no longer present (but no regrowth of lost alveolar bone).

PERIODONTAL DISEASE A, Clinical photograph of a dog with severe periodontal disease; note generalized extensive plaque and calculus accumulation. **B**, Radiograph of upper jaw in same patient (labial mounting: rostral is at bottom of image, patient's left is on right of image). Note extensive calculus accumulation *(asterisks)* at the left maxillary teeth (calculus had already been grossly removed on the contralateral side) and generalized alveolar bone loss (particularly visible in the incisor region).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Physical examination of the awake patient provides an initial diagnosis. Full extent of the disease becomes apparent when radiographs are taken and/or on periodontal probing.

DIFFERENTIAL DIAGNOSIS

- Any other oral disease; periodontal disease is almost always present when other oral diseases are present.
- Oral tumors (see pp. 786 and 788) may appear as ulcerated gingival lesions, but unlike tumors, periodontal disease is typically symmetric, and teeth with greater amounts of plaque and calculus deposition are more severely affected.
- Familial gingival hyperplasia of bulldogs, boxers, collies, and some other medium-large dogs; gingiva is firm and symmetric, often irregular in surface contour and may partly or completely cover the tooth crowns. Usually not inflamed or ulcerated (except where extent of overgrowth results in physical injury of gingiva during chewing).
- The abnormalities in periodontal disease are limited to gingiva and alveolar bone in almost all cases; exceptions are considered to be stomatitis cases (see p. 1051). If there is doubt about whether a case is stomatitis or simply a severe case of periodontal disease, a practical approach is to anesthetize the patient, extract severely affected teeth, scale and polish the remaining teeth, and reexamine the animal in 2-3 weeks. If inflammation or ulceration returns, the case is considered to be a stomatitis case.

INITIAL DATABASE

- Awake oral examination. Is the extent of periodontal disease appropriate for the age and diet of the animal? If the extent of inflammation is more severe than would be expected, distant organ or immune disease may be exacerbating the periodontal disease.
- A general physical examination and CBC, serum chemistry profile, and urinalysis are warranted to ensure that the animal is sufficiently healthy to undergo general anesthesia and to rule out distant organ disease (renal, hepatic) that may be exacerbating the oral disease.

ADVANCED OR CONFIRMATORY TESTING

While the animal is under anesthesia, a detailed oral examination is indicated:

- Visual examination of location, color, and swelling of gingiva
- Gentle insertion of a periodontal probe between the gingiva and crown or exposed root to assess the periodontal pocket depth (distance between gingival margin and bottom of pocket normally no more than 3 mm in a dog and 0.5 mm in a cat) and attachment loss (distance between cementoenamel junction and bottom of pocket). Note: Because of gingival recession occurring as part of periodontal tissue loss, the measured pocket depth may substantially underestimate the quantity of attachment loss.
- Pressure against the side of the tooth determines mobility (assessed on a 0 to 3 [least to most] mobility index)
- Dental radiographs are indicated to ensure that remaining bone is healthy, especially when advanced therapy of severely involved teeth is under consideration.

TREATMENT

TREATMENT OVERVIEW

- Removal of the cause: accumulated dental plaque and calculus
- For severely affected teeth: diagnosis and triage of the extent of disease followed by addressing abnormalities of surrounding bone to stabilize the tooth (if owner is willing to provide long-term home oral hygiene following treatment) or extract the tooth
- Prevention of subsequent accumulation of dental plaque and calculus to avoid progression of periodontal disease around remaining teeth

ACUTE GENERAL TREATMENT

- Scaling and polishing of all teeth, accompanied by examination of every tooth to assess extent of bone loss and gingiva present
- For severely affected but retainable teeth (those with periodontal pockets deeper than 5 to 6 mm and mobility of 1 to 2), many procedures are available. Which procedure is selected depends on whether the gingival cuff around the tooth is intact, whether the furcation is exposed, extent of bone surrounding the root, and experience of and equipment and materials available to the veterinarian. Options include periodontal flaps or gingival grafts to enhance the gingiva around the tooth and various bone augmentation techniques.
- When more than 50% of the root length (in a single-rooted tooth) or more than 60% of any root in a multirooted tooth is no longer attached to the surrounding alveolar bone or mobility is 2, scaling and polishing are unlikely to provide effective removal of calculus attached to root surfaces; involved therapy or extraction is indicated. When mobility index for a tooth is 3, extraction is the only practical treatment.
- The only guaranteed effective treatment for the animal is extraction; dogs and cats manage very well without teeth.

CHRONIC TREATMENT

Home oral hygiene (tooth brushing, oral rinses, appropriate chewing toys and treats, dry food) to prevent further development of periodontal disease

DRUG INTERACTIONS

Gingival hyperplasia can result from long-term phenytoin or cyclosporine therapy.

POSSIBLE COMPLICATIONS

- Traumatic lesions (typically chronic granulomatous areas) of the caudal buccal mucosa or sublingual tissue, resulting from abnormal chewing patterns; the lesions may need to be excised as part of comprehensive periodontal treatment.
- Distant organ disease from periodontitis-related bacteremia or systemic release of inflammatory or bacterial degradation products
- Pathologic mandibular fracture due to extensive bone loss around teeth in toy breed dogs
- Damage to adjacent organs (jaw, eye, tongue) during extraction procedures
- Oronasal fistula (see p. 795)

RECOMMENDED MONITORING

Periodic reexaminations:

- 1 month and 2 to 3 months following involved periodontal surgical procedures to ensure that tissues are responding as expected and that home oral hygiene performed by owner is effective (if not, rescaling of teeth and adjustments in homecare regimen should be considered).
- There is a recommended maximum of 6 months between reexaminations following less involved periodontal surgery, and a

maximum of 1 year between reexaminations following scaling and polishing.

PROGNOSIS AND OUTCOME

- Prevention of periodontal disease by plaque and calculus control is very effective.
- Treatment of severe lesions is more problematic as severity of bone loss around the root increases; it is very difficult to create new bone once resorption has occurred, and a tooth that is unstable (mobile) because of insufficient bone surrounding the root(s) will lose more bone as the pressure from the angled, mobile tooth is concentrated on specific areas of bone. Very mobile teeth should always be extracted.
- If teeth have been lost or are extracted because of severe periodontal disease, the tooth that would normally occlude against the missing tooth will be more at risk of plaque and calculus accumulation than teeth with occluding partners present.

PEARLS & CONSIDERATIONS

COMMENTS

- This is a preventable disease if the patient is started on a home oral hygiene program following eruption of permanent teeth.
- The importance of periodontal disease as an insult to the rest of the body is a topic of research; an association has been proven, and the hypothesized cause and effect relationship are under study.
- Meanwhile, an effective prevention program should be built into every animal's wellness program from a young age.
- Oral examination, including assessment of areas of the mouth most severely affected by periodontal disease (maxillary fourth premolars and first molars), does not take much time. Clinicians should perform this examination whenever an animal is brought for a veterinary appointment for any reason.
- The Veterinary Oral Health Council (VOHC) provides a standard for efficacy of products marketed as controlling plaque and calculus accumulation and awards its seal of acceptance to products that have been shown to meet its standards.

PREVENTION

Home oral hygiene (see p. 1243): owner education about the combination of brushing or rubbing the tooth surfaces, the use of oral health care products, and offering pets nutritionally complete diets formulated to reduce plaque and calculus accumulation.

TECHNICIAN TIPS

Proper tooth brushing can easily be demonstrated to owners and is a vital part of long-term maintenance of oral health.

CLIENT EDUCATION

Clinicians should teach owners about methods of prevention, as described previously.

EDITOR: ALEXANDER M. REITER

Perineal Hernia

BASIC INFORMATION

DEFINITION

Weakness and separation of the muscles of the pelvic diaphragm allowing prolapse of tissue/organs

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Primarily dogs; highest incidence in middle-aged and geriatric intact male dogs
- Rare in cats

GENETICS & BREED PREDISPOSITION

- Dogs: reported in many different breeds and mixed breeds
- Cats: possible history of megacolon, feline lower urinary tract signs/disease (FLUTS/D, FUS), or previous perineal surgery

RISK FACTORS

- Older, intact, male, dog
- Any condition that causes tenesmus:
    - Prostatomegaly
    - Constipation

ASSOCIATED CONDITIONS & DISORDERS

- Prostatomegaly
- Constipation

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Tenesmus, constipation
- Unilateral or bilateral perineal swelling lateral to the anus
- Dysuria:
    - Bladder entrapment

PHYSICAL EXAM FINDINGS

- Unilateral or bilateral swelling in perineal region, lateral and possibly ventral to the anus; may contain:
    - Rectal sacculation packed with feces o Prostate
    - Bladder
    - Fat
- Rectal palpation: diagnostic test of choice
    - Defect or separation in muscles of the pelvic diaphragm on affected side(s)
    - Rectal sacculation

ETIOLOGY AND PATHOPHYSIOLOGY

- Unknown; possible association with:
    - Tenesmus
        - Constipation, obstipation
        - Prostatomegaly
        - Rectal abnormalities
    - Stranguria

- Congenital or acquired weakness of the muscles of the pelvic diaphragm
  - Effect of androgens on muscles
- Neurogenic atrophy of the muscles of the pelvic diaphragm

PERINEAL HERNIA Soft tissue swelling immediately to the right of the anus in a young shar-pei dog; characteristic of a perineal hernia.

(Courtesy Dr. Richard Walshaw.)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Perineal hernia may be suspected based on history or incidental finding of a subcutaneous perianal protrusion. Confirmation is obtained on rectal palpation.

DIFFERENTIAL DIAGNOSIS

- Colorectal mass
- Pelvic neoplasia
- Prostatic cyst/abscess
- Perianal neoplasia

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis:
  - Presurgical screening
  - Bladder entrapped in hernia (postrenal azotemia)
  - Elevated white blood cell count, ± left shift if abscess, cellulitis, strangulation/ischemia of entrapped organs
- External perineal and rectal palpation:
  - Unilateral versus bilateral
  - Contents of hernia:
    - Fecal-filled rectal sacculation
    - Fat

        - Pelvic/abdominal organ (prostate, bladder)
    - Important to rule out neoplasia, prostatic cyst/abscess

ADVANCED OR CONFIRMATORY TESTING

- Survey abdominal and pelvic radiographs:
    - Position and size of bladder and prostate
    - Contents of hernia
- Ultrasound examination:
    - Position and morphology of bladder and prostate:
        - Underlying prostatic disease

TREATMENT

TREATMENT OVERVIEW

Surgical repair of the perineal hernia (perineal herniorrhaphy) is necessary to achieve a good functional outcome. Therapeutic goals are:

- Repositioning of herniated organs
- Reconstructing pelvic diaphragm:
    - Often a bilateral problem requiring bilateral herniorrhaphy:
        - One side often more obvious than other, but on careful palpation, clinician may note weakening of the pelvic diaphragm.
        - The internal obturator flap technique is the recommended surgical procedure for repair of perineal hernia (high success rate, low rate of recurrence).
- Preventing recurrence by resolution of underlying causes of tenesmus:
    - Castration to decrease size of prostate

ACUTE GENERAL TREATMENT

- Emergency treatment to relieve urinary obstruction caused by a retroflexed urinary bladder:
    - Perineal cystocentesis
    - Indwelling catheter
- Relief of constipation:
    - Manual evacuation of rectal sacculation
    - Stool softeners/dietary management

CHRONIC TREATMENT

- Prevention of postoperative tenesmus
    - Dietary management
    - Stool softeners
- Identification of cause of constipation; appropriate treatment
- Identification of cause of prostatomegaly; appropriate treatment
- Cystopexy may be needed to maintain position of bladder in abdomen.

NUTRITION/DIET

Postoperatively:

- Prevent tenesmus, constipation, and diarrhea
- Gastrointestinal diet to produce formed but soft stool
- Stool softener (psyllium mucilloid) as needed for pain-free defecation and no tenesmus

POSSIBLE COMPLICATIONS

- Complications associated with perineal hernia:
    - Urinary obstruction
        - Retroflexed bladder
    - Urinary incontinence or bladder atony
        - Damage to pelvic nerves/detrusor muscle

    - Constipation/obstipation
        - Rectal sacculation
- Complications associated with perineal herniorrhaphy:
    - Recurrence (10%)
    - Incisional dehiscence and infection (6%-26%)
    - Sciatic nerve entrapment (rare)
    - Tenesmus or rectal prolapse
        - Compression of rectal sacculation (8%-13%)

RECOMMENDED MONITORING

History and physical examination findings consistent with recurrence: perineal swelling, tenesmus, and dysuria

PROGNOSIS AND OUTCOME

- Good to excellent outcome with successful herniorrhaphy and no other concurrent diseases
- Fair to poor if the patient cannot undergo surgical correction, if there is recurrence after appropriate surgical correction, and/or if cannot resolve cause of tenesmus/dysuria

PEARLS & CONSIDERATIONS

COMMENTS

- Perineal hernia may be a hormonally related disease in the male dog.
- Herniorrhaphy plus castration is the treatment of choice.
- Diagnosis and elimination of underlying causes of tenesmus are important for a successful outcome.

PREVENTION

- Prevention of tenesmus plays a role in retarding the development or progression of perineal hernia.
- Castration reduces or eliminates the risk of benign prostatomegaly.
- Appropriate diets with increased fiber may help manage constipation.

TECHNICIAN TIPS

Important points regarding postoperative care:

- Maintain appropriate level of analgesia/sedation:
    - Pain control
    - Prevention of tenesmus: undue strain on surgical repair
- Perianal/perineal hygiene:
    - Maintain clean surgical site to decrease risk of wound infection.
    - Especially after defecation
    - Hot pack the area to decrease swelling and ease discomfort.

CLIENT EDUCATION

- Prevention and control of risk factors such as constipation, prostatomegaly, and colitis
- Surgery is the definitive treatment for perineal hernia.

AUTHOR: JOSEPH G. HAUPTMAN

EDITOR: RICHARD WALSHAW

1ST EDITION AUTHOR: ELLEN DAVIDSON DOMNICK

Pericarditis

BASIC INFORMATION

DEFINITION

Non-neoplastic inflammation of the parietal or visceral pericardium; produces either fibrosis and fusion of the two layers, resulting in pericardial thickening, or adherence to the epicardium, causing constriction or increased intrapericardial fluid formation (effusion) that leads to cardiac tamponade. See also p. 855 and online chapter: Pericarditis, Infectious

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Species: dog ≫ cat
- Idiopathic benign pericarditis is the second most common cause of pericardial effusion in the dog (after hemangiosarcoma).

GENETICS & BREED DISPOSITION: Dogs: golden retriever, German shepherd, Saint Bernard, Great Pyrenees, bull mastiff, Lhasa apso, shih tzu

RISK FACTORS

- Dog: thoracic infections, bacteremia, viral diseases, fungal diseases, trauma, migrating foreign bodies (porcupine quills, foxtail plant awns)
- Cat: FIP virus, *Bartonella* spp. infections, trauma, fungal disease

CONTAGION & ZOONOSIS: FIP transmission cat to cat; systemic mycoses: common-source infection, including zoonoses

ASSOCIATED CONDITIONS & DISORDERS: Idiopathic benign pericarditis: associated with immune complex diseases, chronic inflammatory diseases

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Chronic loss of stamina
- Acute cardiac tamponade
- Recurrent fever
- Development of ascites or pleural effusion

HISTORY, CHIEF COMPLAINT

- Exercise intolerance, weight loss, episodic weakness, lethargy, anorexia, dyspnea, acute collapse, ascites
- Associated with gradual accumulation of pericardial fluid or constriction (restriction) of cardiac filling, leading to tamponade

PHYSICAL EXAM FINDINGS

- Tachycardia, muffled heart sounds, thready/weak pulse, abdominal distension
- In some cases: jugular distension, pulsus paradoxus, positive hepatojugular reflux
- Recurrent fever, pleural effusion

ETIOLOGY AND PATHOPHYSIOLOGY

Idiopathic Benign Pericardial Effusion:

- Unknown etiology
- Generally associated with increasing amounts of sanguineous, inflammatory fluid from damaged blood vessels, lymphatics, mesothelial cells, and microvilli of the serosal layer of the pericardial sac
- The pericardial sac gradually becomes distended.

- When intrapericardial pressures exceed right atrial filling pressures, tamponade develops, which in turn usually produces overt clinical signs.

Infectious Pericarditis:

- Associated with multiple bacterial, fungal, or viral diseases resulting in inflammation, fibrosis, thickening of the pericardium, and epicarditis, with or without accompanying effusion, resulting in either pericardial effusion and tamponade or constrictive pericarditis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Echocardiography is indispensable, particularly in cases of pericarditis with little or no effusive component to create radiographic changes in size or shape of the cardiac silhouette.

DIFFERENTIAL DIAGNOSIS

Idiopathic Benign Pericardial Effusion:

- Major differential is cardiac hemangiosarcoma
- Other forms of pericardial disease causing effusion

Infectious Pericarditis:

- Major differentials are other forms of pericardial effusion, including idiopathic benign pericardial effusion, hypoalbuminemia, and CHF (especially in the cat).
- Major differentials in the constrictive form are other causes of pleural effusion and ascites. Constrictive pericardial disease is a frequent sequela to idiopathic pleural effusion in the cat.

INITIAL DATABASE

- CBC: may show mild anemia, monocytosis, lymphocytosis, mild neutrophilia
- Serum biochemistry profile: usually unremarkable
- Should screen for immune-mediated disease (antinuclear antibody, rheumatoid factor, Coombs' test, thyroid profile, serum protein electrophoresis)
- Electrocardiogram (ECG): electrical alternans (25% of the time), diminished R-wave amplitudes (50% of the time)
- Thoracic/abdominal radiographs: enlarged globoid cardiac silhouette possible (80% of time), caudal vena caval distension, hepatomegaly, ascites, pleural effusion
- Constrictive pericarditis may not influence the size or shape of the cardiac silhouette.
- Echocardiography: anechoic fluid surrounding heart; may see fibrin tags in fluid, thickened pericardial sac (occasionally), no tumor mass seen

ADVANCED OR CONFIRMATORY TESTING

- Pericardial fluid cytologic examination:
  - Especially to exclude infectious pericardial effusion and lymphoma
  - Cytologic examination alone is highly unreliable: 74% of malignancies are not detected, and 13% of benign cases are wrongly identified as malignant.
- Pericardial fluid pH: controversial. One study indicated pericardial pH = 7.0 as highly indicative of neoplasia and pericardial pH < 7.0 as highly indicative of benign effusion; another study showed no statistical ability to differentiate etiology on basis of pH of pericardial fluid.
- Elevated serum troponin-I concentration is inconsistent with benign disease and rather suggests hemangiosarcoma. This blood test may be performed locally at a human hospital (human assay is accurate in dogs) or may be performed in referral veterinary laboratories.
- Lack of evidence for neoplasia of liver or spleen on abdominal ultrasound
- Contrast CT scan and cardiac MRI: investigational

TREATMENT

TREATMENT OVERVIEW

If pericardial effusion is present echocardiographically, cytologic analysis of the effusion, bacterial culture, fungal serology, and PCR testing when appropriate should be performed prior to considering subtotal (hemi-) pericardectomy. If constrictive pericarditis is present (minimal to no effusion, structurally normal heart, normal vena caval structure without thrombi, and right-sided congestive heart failure all coexisting), medical treatment alone is seldom effective, and subtotal pericardectomy including histopathologic evaluation of excised pericardium should be pursued (elevated risks).

ACUTE GENERAL TREATMENT

- Pericardiocentesis (seep. 1325)
- Diuretics are contraindicated in acute pericardial effusion/cardiac tamponade.
- If an infectious etiology has been ruled out (effusion cytologic examination ± culture): corticosteroids, initially at immunosuppressive doses, taper to antiinflammatory dosage in 2 weeks.
- Treat primary infection when identified.
- Surgical subtotal pericardectomy for constrictive pericarditis when confirmed

CHRONIC TREATMENT

- Repeat pericardiocentesis
- Subtotal pericardectomy with histopathologic examination

POSSIBLE COMPLICATIONS

- Effusive forms may progress to constrictive pericarditis.
- Extension of the disease process to the thorax
- Failure to recognize or resolve systemic disease

RECOMMENDED MONITORING

Follow-up echocardiography 24 hours after initial pericardiocentesis and monthly thereafter

PROGNOSIS AND OUTCOME

Idiopathic Benign Pericardial Effusion:

- Often favorable with initial pericardiocentesis and corticosteroid therapy
- Usually favorable following subtotal pericardectomy

Infective Pericarditis:

- Often poor, especially if evidence of disease beyond the pericardium
- Difficult removal of the pericardium if epicardial adhesions present

PEARLS & CONSIDERATIONS

COMMENTS

- Echocardiography is the cornerstone of diagnosis of pericardial effusion; cytologic analysis of centesed effusion is the determining test for identifying infectious versus noninfectious pericardial disease.
- Subtotal pericardectomy may lead to development of pleural effusion; initially, postsurgical management may require chest drainage/thoracocentesis.
- Following initial pericardiocentesis, monthly follow-up echocardiograms are advised to evaluate resolution of effusion or subsequent visualization of tumor mass not seen on initial evaluation.
- If effusion/tamponade returns following initial pericardiocentesis, subtotal pericardectomy (either by thoracotomy or thoracoscopy [seep. 1340]) can yield results that are superior long term compared to repeated pericardiocentesis.
- Differentiation from mesothelioma may be extremely difficult until late in the course or without pericardial tissue histopathologic examination.
- Serum cardiac troponin-I concentrations are easily assessed at many local human hospitals (human assay is valid in the dog).

- Follow-up echocardiography is important in management of constrictive forms.
- Effusive bacterial forms may benefit from intrapericardial antibiotics.

CLIENT EDUCATION

- Clinicians should inform clients that the condition may spontaneously recur after apparent cure.
- Some animals require long-term steroid therapy, risking complications such as iatrogenic hyperadrenocorticism.

AUTHOR: N. JOEL EDWARDS

EDITOR: ETIENNE CÔTÉ

Pericarditis, Infectious

BASIC INFORMATION

DEFINITION

Inflammation of the parietal and visceral layers of the pericardium due to infectious agent(s); relatively uncommon condition

SYNONYM

Infective pericarditis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- No reported age or sex predilection
- Dogs: causative etiology has been identified in 2% of cases diagnosed with pericardial effusion.
- Cats: causative etiology has been identified in 14% of cases diagnosed with pericardial effusion.

RISK FACTORS

- Local infection (pleural or pulmonary)
- Penetrating trauma
- Migrating foreign body
- Open wounds
- Bacteremia
- Viral infection

CONTAGION & ZOONOSIS

- Feline infectious peritonitis (FIP), cat to cat
- Tuberculous pericarditis, while uncommon, has been reported (postmortem risk for transmitting the disease from dog to human).
- *Coccidioides immitis* (postmortem risk for transmitting the disease from dog to human)

GEOGRAPHY AND SEASONALITY

- *C. immitis* in the southwestern part of the United States
- Grass awn migration in the western part of the United States

ASSOCIATED CONDITIONS & DISORDERS

- Pericardial effusion
- Effusive-constrictive pericarditis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Virulence of the infectious agent and rate and magnitude of fluid accumulation determine the clinical signs.

HISTORY, CHIEF COMPLAINT

- Weight loss
- Lethargy, weakness
- Dyspnea
- Ascites
- Fever (inconsistent finding)

PHYSICAL EXAM FINDINGS: Reflective of secondary cardiac tamponade or effusive-constrictive pericarditis:

- Jugular vein distension or pulsation
- Weak arterial pulses
- Muffled heart and lung sounds
- Ballotable abdominal fluid wave
- Pale mucous membranes

ETIOLOGY AND PATHOPHYSIOLOGY

- Reported organisms or diseases:
  - *Actinomyces*
  - *Nocardia*
  - *Mycobacterium*
  - *Pasteurella multocida*
  - *C. immitis*
  - *Acremonium*
  - *Leishmania*
  - Tuberculosis
  - Leptospirosis
  - *Streptococcus canis*
  - *Citrobacter* spp.
  - *Pseudomonas* spp.
  - α-hemolytic streptococci
  - Canine distemper virus
- Mixed bacterial infections are common.
- Pathophysiologic examination reflects secondary cardiac tamponade or effusive-constrictive pericarditis:
  - Effusion becomes extensive, and intrapericardial pressure rises.
  - Intrapericardial pressure exceeds intracardiac diastolic pressures, and filling is impaired.
  - Stroke volume is reduced.
  - Central venous pressure increases, and venous return to the right atrium is impaired.
  - Increased venous pressure leads to pleural effusion and ascites. Therefore, pleural effusion or ascites may be due to increased venous pressure or to concurrent infection in those body cavities (cytologic examination to differentiate).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in an animal that is systemically ill (i.e., weight loss, lethargy) with pericardial effusion +/− right heart failure (pleural effusion and/or ascites); pericardiocentesis with fluid and cytologic analysis and culture and susceptibility are required for confirmation.

DIFFERENTIAL DIAGNOSIS

- Radiographic:
  - Cardiac enlargement from other types of heart disease
  - Normal variation
- Echocardiographic:
  - Pericardial effusion due to other etiology (i.e., neoplastic, idiopathic)
  - Pleural effusion: many causes (see p. 882)

INITIAL DATABASE

- CBC: ± anemia, ± inflammatory leukogram, ± degenerative left shift
- Serum biochemistry panel: elevated liver enzymes, elevated creatine kinase (CK), decreased albumin
- Thoracic radiographs: mildly to severely enlarged, round cardiac silhouette; caudal vena cava distention; pleural effusion; ± abnormal pulmonary parenchyma if source of infection
- Echocardiogram: pericardial effusion which may be hyperechoic, ± thickened pericardium, fibrin, ± hyperechoic densities within pericardial space
- Electrocardiogram (ECG): changes may be present if effusion is severe: low-voltage complexes, electrical alternans, ST-segment changes.

ADVANCED OR CONFIRMATORY TESTING

- Cytologic analysis of the effusion:
  - Serosanguineous or bloody
  - Modified transudate or exudates
  - Protein content is >2.5 mg/dL; often >3.5 mg/dL
  - Neutrophils and erythrocytes are predominant cell types.
  - Others: macrophages, reactive mesothelial cells, degenerative neutrophils, etiologic agent
- Microbial culture of the effusion:
  - Always do both aerobic and anaerobic cultures.
  - Secondary invaders are common with aerobic cultures.
- Histopathologic examination:
  - Lesions dependent on etiology

TREATMENT

TREATMENT OVERVIEW

Treatment consists of pericardiocentesis if pericardial effusion is causing cardiac tamponade, with the goal of delaying or eliminating recurrent effusion. Antibiotic therapy is ideally based on culture and susceptibility results. Aggressive therapy such as continuous chest drainage may be indicated in chronic cases where pericardiectomy +/− epicardial stripping has been performed.

ACUTE GENERAL TREATMENT

- Pericardiocentesis (see p. 1325) if cardiac tamponade is present
- Thoracocentesis (see p. 1338) if respiratory compromise
- Abdominocentesis (see p. 1193):
  - Usually unnecessary
  - Can be performed if ascites is causing discomfort and/or respiratory compromise

CHRONIC TREATMENT

- Subtotal pericardiectomy:
  - Pericardial window not recommended
  - May require epicardial stripping if pericardium is severely thickened
- Continuous chest drainage after the pericardiectomy
- Aggressive antibiotic therapy based on culture and susceptibility

BEHAVIOR/EXERCISE

- Animals will naturally limit their own activity if pericardial effusion with cardiac tamponade is present. Weakness and/or collapse may be observed.

DRUG INTERACTIONS

Diuretics contraindicated if cardiac tamponade is present:

- Contract intravascular volume
- Reduce venous filling pressure and stroke volume

POSSIBLE COMPLICATIONS

- Infectious effusion can lead to constrictive pericarditis.
- Dyspnea due to pleural effusion or ascites

RECOMMENDED MONITORING

- Follow-up exam and echocardiography 24 hours after the pericardiocentesis or sooner if poor perfusion
- Periodic reassessment for recurrent effusion

PROGNOSIS AND OUTCOME

- If treated aggressively with pericardiectomy, continuous chest drainage, and appropriate antibiotics, prognosis is good in acute phase.
- If the animal is systemically ill and treatment is not aggressive, prognosis is poor.

PEARLS & CONSIDERATIONS

COMMENTS

- Infectious pericarditis is a rare cause of pericardial effusion in dogs and cats.
- A normal cardiac silhouette on radiographs, a negative culture, and the absence of fever may exist in patients with infectious pericarditis.
- Some antibiotics achieve high concentrations well in pericardial fluid.

PREVENTION

- Minimize foreign body exposure.
- Treat local infections, wounds, and bacteremia aggressively.
- Minimize viral exposure.

TECHNICIAN TIPS

If heart sounds are difficult to auscultate, pulses are weak and/or variable, and/or mucous membrane color is pale during status checks, alert the attending veterinarian; pericardial disease could be the cause.

CLIENT EDUCATION

- If this disorder is treated aggressively with pericardiectomy, continuous chest drainage, and appropriate antibiotics, prognosis is good in early stages.
- Prognosis worsens with time and degree of fibrosis (pericardial and epicardial scarring).

AUTHOR: SARAH J. MILLER

EDITOR: ETIENNE CÔTÉ

Pericarditis, Idiopathic Sterile

BASIC INFORMATION

DEFINITION

Non-neoplastic inflammatory pericardial effusion of undetermined etiology; frequently accompanied by thickening of the pericardium, epicardial fibrin formation, and adhesions between the serosal layer of the pericardial sac and the epicardium

SYNONYMS

Benign pericardial effusion, idiopathic sterile pericarditis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Canine, more common in males, middle aged and older

GENETICS & BREED DISPOSITION: Dogs: golden retrievers, German shepherd, St. Bernard, Great Pyrenees, mastiff, Lhasa apso, shih tzu.

RISK FACTORS: Associated with immune complex diseases, chronic inflammatory diseases; idiopathic second most common cause of pericardial effusion in the dog

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Chronic loss of stamina, acute cardiac tamponade

HISTORY, CHIEF COMPLAINT

- Exercise intolerance, episodic weakness, dyspnea, acute collapse, ascites
- Associated with gradual accumulation of pericardial fluid leading to tamponade

PHYSICAL EXAM FINDINGS: Tachycardia, muffled heart sounds, thready pulses, jugular distension, pulsus paradoxus, positive hepatojugular reflux, abdominal distension

ETIOLOGY AND PATHOPHYSIOLOGY

- Unknown etiology, may be several causes
- Generally associated with increasing amounts of sanguineous, inflammatory fluid by damaged blood vessels, lymphatics, mesothelial cells, and microvilli of the serosal layer of the pericardial sac
- Gradually the pericardial sac becomes distended; when intrapericardial pressures exceed right atrial (RA) and RA filling pressures, tamponade develops.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on presenting physical signs and confirmation of pericardial effusion with echocardiography. The definitive confirmation of benign disease can be extremely challenging, as cytologic analysis of fluid is often misleading (both false positives and false negatives for malignancy). Some malignancies, particularly mesothelioma and small hemangiosarcoma masses that bleed vigorously, mimic idiopathic benign pericarditis on echocardiographs: hemorrhagic pericardial effusion with no visible mass. In many cases, idiopathic benign pericarditis is either a histologic diagnosis when recurrent effusion prompts subtotal pericardiectomy, or a presumptive diagnosis (albeit imperfect) based on self-resolution of pericardial effusion after one or two centesis procedures.

DIFFERENTIAL DIAGNOSIS

- Major differential is cardiac hemangiosarcoma

- Other forms of pericardial disease
- Often a diagnosis by exclusion where no specific cause of the effusion can be identified.

INITIAL DATABASE

- CBC: may be mild anemia, monocytosis, lymphocytosis, mild neutrophilia
- Serum chemistry: usually unremarkable
- Should screen for immune-mediated disease (ANA, RF, Coombs, thyroid profile, serum protein electrophoresis)
- Electrocardiography (ECG): electrical alternans (25% of cases), diminished amplitudes (50% of cases)
- Thoracic/abdominal radiographs: enlarged globoid cardiac silhouette, vena caval distension, hepatomegaly, ascites, pleural effusion
- Echocardiography: anechoic fluid surrounding heart; may see fibrin tags in fluid, thickened pericardial sac (occasionally), no tumor mass seen

ADVANCED OR CONFIRMATORY TESTING

- Pericardiocentesis: for cytologic analysis and pH (see and ; difficult differentiation from malignancy)
- Lack of evidence of neoplasia of liver, spleen on abdominal ultrasound
- Lack of evidence of thoracic neoplasia on thoracic ultrasound and radiography

TREATMENT

TREATMENT OVERVIEW

Therapeutic goal is relief of effusion/tamponade.

ACUTE GENERAL TREATMENT

- Pericardiocentesis (see p. 1325): fluid is sanguineous, nonclotting, and may contain small fragments of fibrin.
- Verify complete drainage and resolution of tamponade by echocardiography.
- Corticosteroids, initially at immunosuppressive doses (e.g., prednisone, 2-4 mg/kg PO q 24 h), taper to antiinflammatory dose (1-2 mg/kg PO q 24 h) in 2 weeks.

CHRONIC TREATMENT

- Repeat pericardiocentesis
- Partial pericardial fenestration using balloon technique to allow drainage into pleural space
- Subtotal pericardectomy with histopathologic confirmation of inflammation; preferred procedure if more than two repeat pericardiocentesis procedures required

POSSIBLE COMPLICATIONS

May progress to constrictive pericarditis

RECOMMENDED MONITORING

Follow-up echocardiography 24 hours after initial pericardiocentesis and monthly thereafter

PROGNOSIS AND OUTCOME

- Often favorable with initial pericardiocentesis and corticosteroid therapy
- Usually favorable following subtotal pericardectomy

PEARLS & CONSIDERATIONS

COMMENTS

- Subtotal pericardectomy may lead to development of pleural effusion, pleural thickening, and compartmentalization of lung

lobes
- Initial postsurgical management may require chest drainage.
- Following initial pericardiocentesis, monthly follow-up echocardiograms advised to evaluate resolution of effusion or subsequent visualization of tumor mass not seen on initial evaluation
- If effusion/tamponade returns following initial pericardiocentesis, consider subtotal pericardectomy rather than repeated attempts at pericardiocentesis where surgery is an appropriate option, either by thoracotomy or thoracoscopy.
- Differentiation from mesothelioma maybe extremely difficult until late in the course or without pericardial tissue histopathology, as reactive mesothelial cells are a common cytological finding on fluid analysis.

CLIENT EDUCATION

- May spontaneously recur after apparent cure
- Some patients require long-term steroid therapy, leading to development of iatrogenic hyperadrenocorticism

Pericardial Effusion

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Pathologic accumulation of fluid (blood, plasma, neoplastic cells, pus, chyle, or combinations) in the pericardial space

SYNONYM

Pericardial fluid accumulation

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dependent on underlying cause; dogs: older adults (neoplastic, idiopathic)

GENETICS & BREED PREDISPOSITION

- Dogs: golden retrievers, Labrador retrievers, German shepherds, other large breeds (hemangiosarcoma, mesothelioma); boxers, bulldogs (and other brachycephalics), terriers (chemodectoma)
- Cats: rare predispositions. Asian breeds, feline infectious peritonitis (FIP)

RISK FACTORS

- Dogs: mesothelioma associated with asbestosis; speculative link between lymphoma and exposure to volatile chemicals
- Cats: multicat household, FIP

CONTAGION & ZOONOSIS: Cats: FIP (cat-to-cat only)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Incidental/unexpected finding; no clinical signs caused by pericardial effusion:
  - During echocardiography
  - Cardiomegaly on radiographs
  - Electrocardiogram (ECG) changes: electrical alternans or small QRS complexes
- Cardiac tamponade: pericardial effusion is causing overt signs.

HISTORY, CHIEF COMPLAINT

- Acute collapse, usually without loss of consciousness
- Exercise intolerance/episodic weakness
- Abdominal distension
- General discomfort, with or without dyspnea
- Pale mucous membranes

PHYSICAL EXAM FINDINGS

- Tachycardia
- Soft or muffled heart sounds
- Weak pulse
- Abdominal distension possible
- Dyspnea/attenuated lung sounds possible if pleural effusion

ETIOLOGY AND PATHOPHYSIOLOGY

Etiology:

- Primary:
  - Neoplasia (hemangiosarcoma [dogs], heart base tumors [chemodectoma, ectopic thyroid carcinoma], mesothelioma, lymphoma)
  - Idiopathic pericardial effusion (dogs)
  - Left atrial rupture
- Systemic:
  - Congestive heart failure (effusion volume usually very small)
  - Infectious (FIP [cats], bacterial [very uncommon])
  - Anticoagulant intoxication
  - Uremia

Mechanism:

- Rate and volume of fluid accumulation and pericardial distensibility determine onset of clinical signs.
- When overt signs are present as a result of pericardial effusion, cardiac tamponade exists.
- In general, pericardial effusions caused by systemic processes rarely produce cardiac tamponade (exception: anticoagulant intoxication), whereas pericardial effusions caused by primary lesions within the pericardial space commonly produce cardiac tamponade.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Pericardial effusion is suspected in one of two very different contexts: either as an incidental finding during diagnostic testing (typically small volume, no overt clinical signs of right-sided congestive heart failure) or as the cause of clinical signs of cardiac tamponade. Confirmation requires echocardiography; thoracic radiographs, abdominal sonography, and routine complete blood and urine testing are typically necessary to investigate the underlying cause.

DIFFERENTIAL DIAGNOSIS

- Physical:
  - Hypovolemia
  - Hypotension
  - Causes of ascites (seep. 93)
  - Causes of pleural effusion (see p. 882)
- Radiographic:
  - Cardiac enlargement from heart disease
  - Expiratory radiograph
  - Normal variation
- Echocardiographic:
  - Pleural effusion
  - Oblique views
- Specific causes can be determined by etiology (previously described)

INITIAL DATABASE

- Echocardiogram: confirmation of the diagnosis and investigation for right atrial/ventricular (hemangiosarcoma) or periaortic (heart base) masses. Right ventricular diastolic collapse is highly indicative of severe cardiac tamponade; right atrial collapse is less specific.
- Thoracic radiographs: large cardiac silhouette (80% of cases), globoid cardiac silhouette (60% of cases), caudal vena cava enlargement; metastatic lesions, pleural effusion
- CBC, serum biochemistry panel, and urinalysis are usually unremarkable except with systemic disorders.
- ECG: Electrical alternans is unreliable and only found in 50% of dogs with pericardial effusion.
- Prothrombin time if anticoagulant intoxication is suspected

ADVANCED OR CONFIRMATORY TESTING

- Pericardial effusion cytologic examination: useful for lymphoma, infectious causes; otherwise, malignant versus benign is totally unreliable with Cytologie examination.
- Pericardial effusion pH: generally unreliable, much overlap between benign and malignant
- Transesophageal echocardiography
- Serum cardiac troponin-I level: elevation is suggestive of hemangiosarcoma.

- Effusion vascular endothelial growth factor (VEGF) concentration: nondiagnostic

TREATMENT

TREATMENT OVERVIEW

- Removal of pericardial effusion if causing cardiac tamponade
- Delaying or eliminating recurrent effusion is a long-term goal, including correction of the underlying cause of the effusion if possible.

ACUTE GENERAL TREATMENT

- Pericardiocentesis (see p. 1325): if cardiac tamponade is present; contraindicated if coagulopathy is a cause of effusion, unless there are critical circulatory effects (severe/periterminal tamponade).
- Abdominal drainage is usually unnecessary if ascites is secondary to congestion (resorbs in 24-48 hours).
- Treatment of underlying cause if systemic disorder
- Diuretics contract intravascular volume and therefore are contraindicated in treating cardiac tamponade acutely.

CHRONIC TREATMENT

- Management/resolution of systemic disorder if present
- Recurrent pericardiocentesis if needed
- Pericardiectomy if recurrent effusion occurs secondary to idiopathic pericarditis or heart base mass
- Diuretics are indicated if the animal has congestive heart failure (and secondary pericardial effusion) due to myocardial or valvular heart disease; otherwise, chronic diuretic treatment for delaying recurrence of primary pericardial effusion is controversial.

POSSIBLE COMPLICATIONS

- Recurrent effusion; follow-up echocardiography to assess need for recentesis ± pericardiectomy
- Dyspnea from severe pleural effusion or ascites
- Pericardiocentesis-related (seep. 1325)

RECOMMENDED MONITORING

- Follow-up exam and echocardiography 24 hours after the pericardiocentesis (sooner if poor perfusión): assessment for recurrent effusion
- Follow-up exam and echocardiography 2-4 weeks after the pericardiocentesis
- Serial echocardiography and thoracic radiographs as dictated by recurrence

PROGNOSIS AND OUTCOME

- Guarded (average: days to months) with hemangiosarcoma; worse if a mass is seen on the right atrium or if pulmonary metastases exist, but better if nonhemorrhagic ascites is present
- Guarded to fair with heart base tumors, better if pericardiectomy
- Guarded to fair with mesothelioma (months to a year or more)
- Guarded to fair with idiopathic (risk of constrictive pericarditis or of mesothelioma)
- Hemorrhagic effusion that recurs in hours to 1 to 2 days after the pericardiocentesis is rarely benign; prognosis is worse.

PEARLS & CONSIDERATIONS

COMMENTS

- Grossly malignant pericardial effusions and benign pericardial effusions can both appear equally hemorrhagic.
- Normal-looking heart on radiographs does not rule out pericardial effusion.
- If a weak pulse, tachycardia, and muffled heart sounds are all present, pericardial effusion is possible, and an echocardiogram is warranted.

CLIENT EDUCATION

- Clients need to monitor for recurrence of presenting signs as described previously.
- Rapid deterioration is possible; re-checks are necessary.

AUTHOR & EDITOR: ETIENNE CÔTÉ

Perianal Fistula

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A chronic inflammatory disease of the tissues surrounding the anus in the dog. The lesions are painful, ulcerative, with sometimes deep, draining tracts adjacent to the anus. The anus itself is not usually involved.

SYNONYM

Anal furunculosis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs, usually >5 years old; males may be overrepresented.

GENETICS & BREED PREDISPOSITION: German shepherds are by far the most common breed affected. Irish setters may be predisposed. Any breed may be affected.

RISK FACTORS: Possibly broad-based tail, low tail carriage, and increased density of apocrine sweat glands in the perianal region

ASSOCIATED CONDITIONS & DISORDERS: Food allergy has been theorized to be a causative or associated condition resulting in inflammation of the colon or pruritus of the perineum.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Initially the owners may notice a foul odor or observe the dog licking the perianal region excessively. As the lesions progress, the dog may have dyschezia, hematochezia, tenesmus, and fecal incontinence; the dog may engage in self-mutilation. In the severe cases, inappetence, lethargy, and weight loss are also possible.

PHYSICAL EXAM FINDINGS

- In mild to moderate cases, physical examination abnormalities are confined to the perianal region. In more severe cases, the dog may also be in poor body condition. Examination of the perianal region may be very difficult in some patients due to pain, and sedation is often necessary. Visual and digital rectal exams are indicated.
- Visually, the lesions appear as multiple ulcerated, draining tracts that may be superficial or extend deeply into the perianal tissues. The lesions may extend 360° around the anus and involve the ventrum of the tail base.
- Upon rectal palpation, rectal strictures, loss of anal tone, anal sac rupture or abscessation, and/or roughened rectal mucosa may also be found.

ETIOLOGY AND PATHOPHYSIOLOGY

- An immunologic basis is suspected based on clinical improvement with immunosuppressive medications, as well as a few pathologic studies identifying sterile chronic inflammatory changes.
- Secondary bacterial infection is common, often due to fecal microflora or skin contaminants.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

In general, a diagnosis can be made with history and physical examination, including visual examination of the perianal region.

DIFFERENTIAL DIAGNOSIS

- Perianal neoplasia (anal sac adenocarcinoma)
- Anal sac abscessation/rupture
- Trauma, bite wounds

- Perianal hernia (early phase of fistula, prior to ulcerated lesions)

INITIAL DATABASE

- CBC, serum chemistry panel, and urinalysis are often unremarkable; may occasionally have a mature neutrophilia.
- Abdominal radiographs may show evidence of constipation.

ADVANCED OR CONFIRMATORY TESTING

- Colonoscopy may reveal inflammatory colitis (usually lymphoplasmacytic), rectal strictures.
    - Occasionally, rectal balloon dilation or surgery may be needed if the stricture is severe.

TREATMENT

TREATMENT OVERVIEW

Goals of treatment include reducing the size and number of strictures (often to the point of no visible lesions), control of infection, and treatment of colitis if present or rectal stricture if present.

ACUTE GENERAL TREATMENT

- Under sedation or general anesthesia, the hair in the area should be clipped, feces and debris removed, and surrounding tissues cleansed.
- Enemas may be needed if constipation is present.
- Antibiotics (cephalexin, 22 mg/kg PO q 8-12 h for at least 2 weeks) can be helpful to treat secondary infections.

CHRONIC TREATMENT

- Immunosuppression is the initial therapy of choice. Cyclosporine results in a reported 90% success rate. This can be expensive in larger dogs. Starting dose using the emulsion form (Atopica, Neoral, cyclosporine modified generic) is 3-5 mg/kg PO q 12 h for 16 weeks. Ideally, whole-blood trough cyclosporine levels should be run and maintained at 400-600 ng/mL. Adding ketoconazole at 10 mg/kg PO q 24 h allows a reduction in cyclosporine dose to 1 mg/kg PO q 12 h, while achieving similar cyclosporine levels.
- Azathioprine 2 mg/kg PO q 24 h for 2-4 weeks, then tapered, may be an effective alternative in some dogs.
- Prednisone alone may be effective in about 33% of dogs. A starting dose of 2 mg/kg PO q 24 h for 2-4 weeks followed by a taper is recommended. The dose should be tapered to 0.5 mg/kg q 48 h.
- Tacrolimus 0.1% topical applied q 12-24 h resulted in resolution of lesions in 50% of dogs with mild to moderate lesions.
- Stool softeners such as lactulose at 0.25-0.5 mL/kg PO q 12 h are indicated to prevent constipation, assist defecation if strictures are present, and keep stool soft when defecation is painful.
- If appropriate medical management does not resolve the lesions to an acceptable degree, surgery can be considered. Nd: YAG laser and cryotherapy as well as en bloc resection have been reported with variable success rates. Surgical procedures that may be needed include anal sacculectomy, removal of skin overlying the tracts, débridement of diseased tissue, and rectal pull-through for rectal strictures.
- Balloon dilation is recommended as first line of therapy for rectal strictures, because surgical removal of strictures may result in fecal incontinence.

NUTRITION/DIET

Dietary therapy has been used in conjunction with immunosuppression. Novel antigen diets have been recommended because there is a suspected association with food hypersensitivity. Most important, animals should avoid high-fiber (bulking) foods/diets, and owners should feed highly digestible diets that will result in a softer, smaller stool (low-residue diets).

DRUG INTERACTIONS

Ketoconazole decreases metabolism of cyclosporine and can be given for this purpose.

POSSIBLE COMPLICATIONS

- Recurrence of fistulae with discontinuation of immunosuppressive drugs
- Rectal strictures secondary to chronic inflammation
- Constipation secondary to pain or rectal strictures
- Fecal incontinence secondary to chronicity or surgery

RECOMMENDED MONITORING

- Follow-up examinations of the perianal region every 2 weeks until healed, then periodically thereafter to check for recurrence
- Whole-blood trough cyclosporine levels at 2 weeks, then monthly
- CBC when azathioprine is being used

PROGNOSIS AND OUTCOME

- Fair to good prognosis with early treatment
- Long-term prognosis may be guarded with more severe lesions and the need for indefinite medical therapy.

PEARLS & CONSIDERATIONS

COMMENTS

- Improvement on cyclosporine will usually be seen within 4 weeks. If the signs recur once the drug is discontinued, long-term therapy may be needed, with the lowest effective dose determined with a taper.
- Most dogs will respond to medical management but may also require long-term therapy to maintain remission.

PREVENTION

- Recurrent cases may need long-term medications or novel protein diet to prevent recurrences.
- Keeping lesions under control with immunosuppressive medications and diet can help prevent infections, rectal strictures, and constipation.

TECHNICIAN TIPS

These lesions may be painful, and a gentle approach to any manipulation of the anal region (e.g., rectal temperature) is important.

CLIENT EDUCATION

Advise clients on the clinical signs and lesions that warrant early intervention if lesions recur.

AUTHOR: LISA MOORE

EDITOR: DEBRA L. ZORAN

Pemphigus Complex

Additional Images Available on Website

BASIC INFORMATION

DEFINITION

A group of autoimmune blistering diseases of the skin and/or mucous membranes characterized by keratinocyte acantholysis (separation from cell-cell detachment), producing varying degrees and depth of cutaneous ulceration, pustules, vesicles, and crusting. Subsets of pemphigus are classified based on the level of blistering in the epidermis. Spontaneous, drug-induced, and paraneoplastic forms are reported. The most common type in dogs and cats is pemphigus foliaceus.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Seen in dogs and cats; more common in middle-aged animals (average age of onset is 5 to 6 years, with a range of 0.5-16 years).

GENETICS & BREED PREDISPOSITION

- Pemphigus foliaceus (PF): Akita, Australian shepherd, chow chow, cocker spaniel, dachshund, Doberman pinscher, Finnish spitz, schipperke (drug-induced PF in Doberman pinscher and Labrador retriever)
- Pemphigus erythematosus (PE): collie and German shepherd
- Canine benign familial chronic pemphigus has been reported in English setters and their crosses and appears inherited (autosomal dominant)

RISK FACTORS: PF and PE may be aggravated by sunlight. Some cases of pemphigus are triggered by drug reactions. Paraneoplastic pemphigus (PNP) in dogs has been associated with underlying lymphoma, thymoma, and (in one case) Sertoli-cell tumor.

GEOGRAPHY AND SEASONALITY: A lower incidence of canine PF exists in the northeastern United States, and a higher prevalence exists in warmer regions. Seasonal exacerbation of lesions may occur during months of increased sunlight exposure.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Subsets of pemphigus are described and listed in decreasing order of frequency:

- Superficial pemphigus complex: PF, PE (a possible local and milder variant of PF), panepidermal pustular pemphigus (PPP; possibly a more extensive subtype of PF).
- Deep variants: pemphigus vulgaris (PV), pemphigus vegetans (PVg), and PNP. A few cases of benign familial pemphigus have also been reported in dogs.

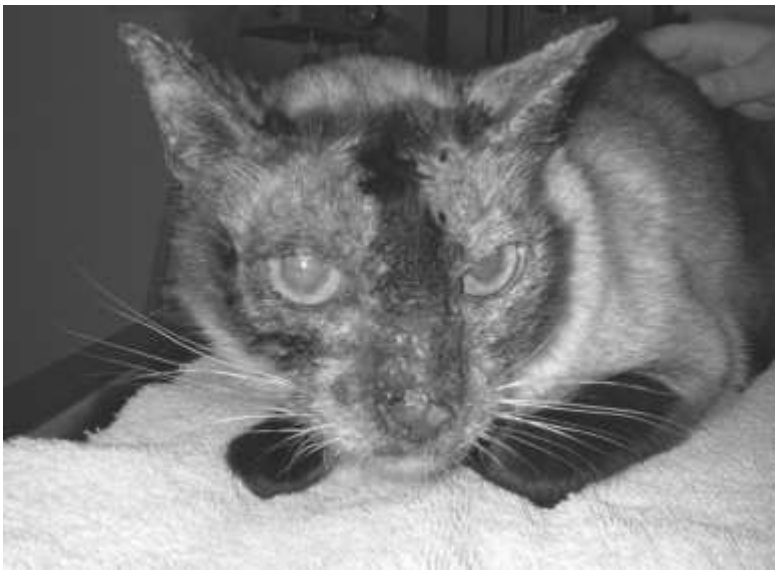
HISTORY, CHIEF COMPLAINT

- PF: progressive multifocal or generalized skin disease, often with facial and footpad involvement. Degree of pain appears to be variable. Pruritus is noted in 30%-50% of the cases. The initial complaint can be lameness due to footpad disease.
- With PV and PNP, disease of the oral cavity is common, and presenting signs include hypersalivation, halitosis, anorexia, and weight loss.
- Fever, anorexia, lethargy, and limb edema are reported in severe cases of pemphigus.

PHYSICAL EXAM FINDINGS

- **PF:** a pustular and crusting dermatitis, with crusts on the trunk and/or the facial area being the most common lesion. Inner pinnae and dorsal muzzle are often the first areas affected, and the disease can stay restricted to the head and face. Other commonly involved areas are the feet, footpads, and nail beds (nail beds are affected more often in cats; it is sometimes the only physical exam abnormality). The disease progresses and becomes generalized or multifocal in most cases. Range of lesions noted includes erythema, pustules, dry honey-colored crusts, scales, alopecia, and erosions bordered by collarettes. Secondary bacterial pyoderma (a third of PF cases) and peripheral lymphadenopathy are common.
- **PE:** a milder form of PF with crusts, erosions, alopecia, and scales restricted to the face
- **PV:** a deep and severe form of pemphigus, presenting with transient flaccid vesicles rapidly replaced by large erosions and ulcers of the mucosal surfaces and mucocutaneous junctions. Affected areas include oral cavity (>70% of cases), inner pinnae, nasal planum, lip margins, genitalia, and anus. Erosions of the nail beds are reported in 14% of cases. A milder form

of PV is reported where lesions are restricted to one body area (nail beds, nasal planum, oral cavity).
- **PVg and PPP:** Severe erosions and ulcerations of the oral cavity, nose, vulva, and haired skin



PEMPHIGUS COMPLEX A 5-year-old male castrated Siamese cat with pemphigus foliaceus affecting the face and pinnae.

(Courtesy Dr. Caroline de Jaham.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Intraepithelial acantholysis (loss of intercellular cohesion between keratinocytes) leading to vesicles/pustules formation due to antikeratinocyte autoantibodies (IgG) binding to components of desmosome complex.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of PF, the most common form of pemphigus, is suspected in a middle-aged dog or cat presented for evaluation of a progressive crusting and pustular dermatitis that does not typically respond to appropriate systemic antibiotic therapy. The definitive diagnosis requires skin biopsies showing histopathologic changes of acantholysis.

DIFFERENTIAL DIAGNOSIS

- **PF, PE, and PNP:** bacterial folliculitis, demodicosis, dermatophytosis, eosinophilic folliculitis and furunculosis, cornification disorders, cutaneous (discoid) and systemic lupus erythematosus, drug eruptions
- **PV and PPP:** bullous pemphigoid, epidermolysis bullosa acquisita, erythema multiforme, toxic epidermal necrolysis, Stevens-Johnson syndrome, epitheliotropic lymphoma, ulcerative stomatitis, vesicular cutaneous lupus erythematosus, systemic lupus erythematosus.

INITIAL DATABASE

- Cytologic examination of content of intact pustules or of exudate under a crust may strongly suggest pemphigus: intact neutrophils, varying number of eosinophils, and clusters of acantholytic keratinocytes can be seen in most cases, but biopsies are still required because other disorders may present similar findings.
- CBC, serum biochemistry profile: nonspecific changes, mild to moderate leukocytosis with neutrophilia, mild nonregenerative anemia, and hypoalbuminemia

ADVANCED OR CONFIRMATORY TESTING

- Skin biopsies: confirmatory test. Histopathologic findings of acantholysis with pustule formation are diagnostic. Lesional epidermal location is related to depth of autoantibody deposition: subcorneal and intragranular layers in PF and PE; suprabasilar level in PV and PPP; panepithelial in PNP.
- Immunohistochemical and immuno-fluorescent analysis of skin biopsies or serum may be helpful but depends on the

sensitivity of the methods being used; not routinely performed.

TREATMENT

TREATMENT OVERVIEW

The treatment goal is to implement immunosuppressive therapy that will induce and maintain remission of skin lesions without significant or life quality-altering side effects. The therapeutic modalities and response to treatment will vary with the type of pemphigus and the species treated. Cases refractory to initial systemic glucocorticoids should be referred to a dermatologist.

ACUTE TREATMENT

Systemic glucocorticoids alone induce remission in most cases of PE and in a third to half of cases of PF in dogs and in most cats. Other forms of pemphigus are more refractory. Response should be seen within 10-14 days.

- Dogs (initially):
  - Prednisone/prednisolone: 2-4 mg/kg PO q 24 h; *or*
  - Dexamethasone: 0.2-0.4 mg/kg PO q 24 h for more refractory cases
- Cats (initially):
  - Prednisone/prednisolone: 4-8 mg/kg PO q 24 h (prednisolone is preferred in cats); *or*
  - Dexamethasone: 0.2-0.4 mg/kg PO q 24 h; *or*
  - Triamcinolone: 1-2 mg/kg PO q 24 h
- High (shock) dosages of glucocorticoid used in the acute phase in severe cases of PF or PV. Prednisolone sodium succinate, 10 mg/kg IV over 4 hours; or prednisone, 10 mg/kg PO given 1-3 days consecutively. Potential side effects such as gastrointestinal ulceration are increased.

CHRONIC TREATMENT

- The dose of glucocorticoid is slowly reduced on a daily basis over 30-40 days once remission of active skin lesions is attained (2-4 weeks). Lowering to an alternate-day regimen with an ideal maintenance dose of 1 mg/kg q 48 h of prednisone/prednisolone or less is the ultimate goal.
- Concurrent immunosuppressive drugs are used initially in conjunction or added later to glucocorticoids to enhance or maintain adequate immune suppression to induce or maintain remission with fewest/no glucocorticoid adverse effects.
  - Azathioprine: 2.2 mg/kg PO q 24-48 h in conjunction with prednisone/prednisolone; first choice in dogs, contraindicated in cats; *or*
  - Chlorambucil: 0.1-0.2 mg/kg PO q 24-48 h in conjunction with prednisone/prednisolone; first choice in cats; *or*
  - Cyclosporine: 5-10 mg/kg PO q 24 h has shown good effectiveness with prednisone/prednisolone for PF in dogs and cats.
- Alternative immunosuppressive drugs:
  - Tetracycline and niacinamide: milder or localized cases of PF and PE (250 mg of each PO q 8 h for dogs <10 kg; 500 mg of each PO q 8 h for dogs >10 kg) for 2-3 months to achieve remission then gradually decrease to q 12-24 h or alternate days if remission is maintained.
- Topical therapy is indicated as a sole treatment in some localized forms of PF and PE and in conjunction with systemic therapy on persistent focal lesions that remain active despite satisfactory control of the overall disease. Person applying treatment must wear gloves.
  - Potent topical glucocorticoid initially: fluocinolone acetonide, triamcinolone, betamethasone valerate; when adequate response, treatment is changed to l%-2% hydrocortisone for maintenance.
  - Tacrolimus 0.1%: has shown efficacy for treating both PE and PF.

POSSIBLE COMPLICATIONS

- Recurrence of skin lesions with discontinuation of immunosuppressive drugs
- Side effects are common with long-term oral glucocorticoid therapy (signs of iatrogenic hyperadrenocorticism, urinary tract infections, pyoderma).
- Persistent use (daily for >14 days) of potent topical glucocorticoids can create skin atrophy, alopecia, and comedone formation.

DRUG INTERACTIONS

- Ketoconazole potentiates cyclosporine activity; adjust dosage accordingly and monitor serum cyclosporine levels.
- Azathioprine is contraindicated in cats because of a profound myelosuppressive effect in this species.

RECOMMENDED MONITORING

- Semiannual CBC, serum biochemistry profiles, urinalysis, and urine cultures for all patients receiving long-term oral glucocorticoids
- Azathioprine, chlorambucil: CBC monitoring for cytopenias every 2-3 weeks for the first 3 months then q 3-6 months. For azathioprine, also monitor liver and pancreatic enzyme activity.

PROGNOSIS AND OUTCOME

- PF: fair to good prognosis with the majority achieving partial or complete remission with oral glucocorticoid +/− other immunosuppressive drugs. Time to improvement with therapy is 2-6 weeks; time to complete remission is 3-9 months. Mortality (euthanasia) rate in dogs with PF averages 20%-30% within the first year owing to lack of response or adverse effects of treatment, notably glucocorticoids (implying a need to use combination therapy prior to triggering adverse effects that are unacceptable to the owner, deleterious to the patient, or both). Mortality rate in cats with PF: <10% first 6 months of therapy. Persistence of long-term remission of PF after discontinuation of therapy has been reported in 7%-22% of cases.
- PV: 39% mortality (death or euthanasia). Milder variants have better prognosis.
- PNP: poor prognosis

PEARLS & CONSIDERATIONS

COMMENTS

- Response to treatment and prognosis vary with the forms of pemphigus. It is therefore essential to make a specific diagnosis.
- Although acantholytic keratinocytes and neutrophils on skin cytology exams are highly suggestive of pemphigus, clinicians may also see these cells in cases of pustular dermatophytosis *(Trichophyton* spp.) and in some cases of canine pyoderma. Biopsies are indicated for confirmation.
- Clinicians should consider prophylactic antibiotic treatment during initial immunosuppression or (in milder cases) prior to starting immunosuppressive therapy.
- Combination therapy (prednisone and either azathioprine or cyclosporine) as the initial therapy in PF can decrease the maintenance dose of glucocorticoids and reduce side effects.

TECHNICIAN TIPS

Gentle bathing or whirlpool bathing for 10-20 minutes in lukewarm water will help soften the cutaneous crusts, clean and débride the skin, and improve healing in animals afflicted with generalized forms of pemphigus.

CLIENT EDUCATION

Owners of dogs with pemphigus must be well informed of the chronic and typically incurable nature of the disease as well as the potential side effects of immunosuppressive drug therapy.

AUTHOR: CAROLINE DE JAHAM

EDITOR: MANON PARADIS

Pediculosis

BASIC INFORMATION

DEFINITION

Infestation with lice

EPIDEMIOLOGY

SPECIES, AGE, SEX: Affects animals of any age, but young patients are predisposed.

RISK FACTORS: Neglect, overcrowding, poor sanitation

CONTAGION & ZOONOSIS

- Contagious to animals of the same species
- Transmitted by direct contact, grooming instruments, bedding
- Lice are not zoonotic

GEOGRAPHY AND SEASONALITY: Possibly more common in winter. Rare in areas where flea control is routine, fairly common in some areas where fleas are rare (e.g., parts of Canada, Sweden).

ASSOCIATED CONDITIONS & DISORDERS

- Acute moist dermatitis (hot spots)
- Pyoderma
- Anemia, debilitation (young puppies)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Biting versus sucking lice: differentiation is possible via microscopic examination; clinical signs also may be suggestive (e.g., signs of anemia with sucking but not biting lice infestations).

HISTORY, CHIEF COMPLAINT

- Pruritus may be severe and affect several animals.
- Lice or nits (ova) may be seen by owners.
- Weakness (puppies with sucking lice)

PHYSICAL EXAM FINDINGS

- Unless lice or nits are seen, examination findings are nonspecific.
- Lice accumulate around ears and body openings.
- Lice are smaller than fleas but visible to the naked eye.
- More frequently, small white eggs (nits) are seen on hairs.
- Excoriations, scaling, matted hair, alopecia, and:
    - In dogs, secondary pyoderma and pyotraumatic dermatitis (hot spots)
    - In cats, miliary dermatitis
- Occasionally weakness, pale mucous membranes in puppies (sucking lice)

ETIOLOGY AND PATHOPHYSIOLOGY

- Pediculosis is caused by insects of the suborder Anoplura (sucking lice, which suck host's blood) or Mallophaga (biting lice, which feed on skin debris and hair)
- Dogs: sucking louse *Linognathus setosus* and biting louse *Trichodectes canis*
- Cats: biting louse *Felicola subrostratus*
- Rarely, other louse species
- Lice have a 2-4 week life cycle spent entirely on the host, survive only 2-3 days off host

- Lice may be capable of transmission of *Bartonella* and *Rickettsia* spp. in some animals, but the importance of their role as vectors in dogs and cats is not known

PEDICULOSIS Louse nits attached to hairs on a black dog.

(Courtesy Dr. Kinga Gortel.)

PEDICULOSIS Microscopic examination of dog hair with attached louse nit.

(Courtesy Dr. Kinga Gortel.)

T. canis can act as the intermediate host of the dog tapeworm, *Dipylidium caninum*

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Pediculosis is diagnosed by finding lice or nits on direct physical and microscopic examinations.

DIFFERENTIAL DIAGNOSIS

- Other ectoparasite infestations, particularly fleas, *Sarcoptes, Cheyletiella*
- Various hypersensitivity disorders

INITIAL DATABASE

- Attempt to find and identify ectoparasites, including lice, in pruritic cats and dogs. See p. 1248.
- Direct examination of skin and hair can reveal lice and nits. Aided by adequate lighting and magnification (e.g., loupe).
- Skin scrapings
- Clear tape preparations can trap surface-dwelling ectoparasites: press tape repeatedly onto skin surface, place on a drop of mineral oil and examine like a skin scraping.
- Hair clippings or plucks from areas with suspected nits should be examined microscopically to confirm the diagnosis (see figure).
- Hair and surface samples may be collected using a flea comb and similarly examined.

ADVANCED OR CONFIRMATORY TESTING

Response to therapy can be used but is not specific for pediculosis.

TREATMENT

TREATMENT OVERVIEW

The goals of therapy are eradication of lice from the patient and in-contact animals, and amelioration of associated clinical signs.

ACUTE GENERAL TREATMENT

- Treat the affected pet and same-species in-contact animals.
- Wash the premises, bedding, collars, and grooming equipment at least once.
- Clip matted hair.
- Treat secondary pyoderma (see p. 951).
- Pruritus is reduced in 2-4 weeks; if it is severe, coadministration of antiinflammatory doses of corticosteroids for 1-3 weeks should not interfere with parasiticidal therapy.
- Lice succumb to many parasiticides, some after a single application.
- Nits are more resistant, so repeating treatment after 2-4 weeks is recommended for products without residual efficacy. May not be necessary using some modern topical flea-control preparations.
- All treatments are off label.
- Treatments considered effective for lice (and species studied) include:
    - Fipronil spray and spot-on (biting lice; cats and dogs)
    - Imidacloprid spot-on (biting and sucking lice; dogs)
    - Selamectin spot-on (sucking lice; dogs)
    - Various pyrethrin, carbamate, and (for dogs only) permethrin preparations
    - Lime sulfur dip
    - Ivermectin, 0.2 mg/kg PO or SQ every 2-4 weeks; no longer routinely recommended, as safer alternatives exist
- Follow-up is recommended to ensure complete eradication of lice.
- In weak, anemic puppies, additional supportive care (including blood transfusion) as needed

RECOMMENDED MONITORING

Recheck patients after 4-6 weeks.

PROGNOSIS AND OUTCOME

The prognosis for pets with pediculosis, with the exception of severely anemic or debilitated animals, is excellent.

PEARLS & CONSIDERATIONS

COMMENTS

- Nits attached to hairs may be mistaken for skin scales. Unlike scales, nits are of uniform size and almost impossible to

remove from hair shafts.
- Nits are harder to see on light coats.
- Microscopically, *Cheyletiella* ova may also be seen in association with hair shafts, but they are attached much more loosely.

PREVENTION

Pets regularly receiving topical flea control products are protected from lice. In areas where fleas are not endemic, consider protecting dogs attending grooming, boarding, dog shows, or dog daycare facilities.

TECHNICIAN TIPS

- Clients become understandably concerned about a diagnosis of lice in their pet. They may also inquire whether a household pet could be the source of a human infestation (no). Counsel clients about the highly host-specific nature of this parasite.
- Stress the importance of follow-up to assess efficacy, since all treatments used for pediculosis are administered off label.

AUTHOR: KINGA GORTEL

EDITOR: MANON PARADIS

Pectus Excavatum

BASIC INFORMATION

DEFINITION

Congenital dorsoventral narrowing of the thorax or depression of the sternum dorsally into the thoracic cavity; can cause malpositioning or compression of heart and lungs

SYNONYMS

Chondrosternal depression, funnel chest

EPIDEMIOLOGY

SPECIES, AGE, SEX

- More common in cats than dogs
- No sex predilection
- Defect is present at birth, but affected animals may not present with clinical complications until secondary disease (e.g., acquired heart disease) develops later in life.

GENETICS & BREED PREDISPOSITION: The defect is congenital and can be inherited. Brachycephalic dogs are more commonly affected.

ASSOCIATED CONDITIONS & DISORDERS

- Other congenital defects, such as cardiac defects
- Stunted growth
- Hypoplastic trachea
- “Swimmer's syndrome” (laterally splayed legs as neonate)
- Pneumonia
- Recurrent respiratory infections

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Presentation of defect ranges from mild to severe. Severity of thoracic defect does not always correlate to severity of clinical signs, which may be more a reflection of concurrent defects (e.g., cardiac, respiratory).
- Simple cases of pectus excavatum occur in the absence of other congenital anomalies.

HISTORY, CHIEF COMPLAINT

- In many animals, pectus excavatum is found incidentally, and no clinical signs are present.
- Owners may palpate the defect and seek veterinary advice despite lack of clinical signs.
- When signs occur, they can include:
    - Exercise intolerance
    - Dyspnea
    - Cyanosis
    - Poor growth
    - Cough
    - Inappetence
    - Cachexia
    - Lethargy
    - Weakness
    - Vomiting

PHYSICAL EXAM FINDINGS

- Palpable dorsal defect of caudal sternum, creating sternal concavity
- Dyspnea, tachypnea, and shallow respirations may be evident at rest or with excitement and minimal exertion.
- Auscultation of a heart murmur or muffled heart and breath sounds are possible.
- Affected animals may be small in stature for age or smaller than their littermates and exhibit poor condition.

ETIOLOGY AND PATHOPHYSIOLOGY

Congenital malformation of the sternum and costochondral cartilages causes deformation of the thorax and malpositioning of thoracic organs. The exact etiology is unknown.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is usually straightforward and typically based on physical examination identification of palpable dorsal defect of the caudal sternum that creates sternal concavity. Thoracic radiographs and echocardiography may provide additional details.

DIFFERENTIAL DIAGNOSIS

- Trauma
- Lordosis of thoracic or thoracolumbar spine
- Differentials must include those for associated abnormalities:
    - Cardiac murmurs indicating cardiac defects must be differentiated from murmurs generated through malpositioning of the heart and great vessels.

INITIAL DATABASE

Thoracic radiographs; possible findings include:

- Elevated sternum in caudal thorax
- Malformation of sternum and costochondral cartilages
- Decreased thoracic volume
- Displacement of heart and other structures:
    - The heart may falsely appear enlarged because of abnormal positioning and must be differentiated from other causes of true cardiomegaly. Consultation with a radiologist is often warranted.
    - Complete diaphragm may be difficult to confirm.

ADVANCED OR CONFIRMATORY TESTING

Echocardiography to identify cardiac defects and assess possibility of pleuroperitoneal/pericardioperitoneal hernia; may be very challenging owing to chest malformation

TREATMENT

TREATMENT OVERVIEW

Treatment is aimed at supportive care and manual compressions for young, nonsurgical cases and surgical correction for moderate to severe cases. Goals are maximizing thoracic cavity capacity to allow normal function and activity, treatment of respiratory infections if present, improvement of growth by increasing nutritional plane/assimilation, and identification and management of concurrent defects.

ACUTE GENERAL TREATMENT

- No treatment may be needed for animals without concurrent defects and for whom pectus excavatum is an incidental finding (no clinical signs).
- For severely compromised animals or acute complications:
    - Oxygen supplementation (see p. 1318)
    - Avoidance of exertion, excitement, and stress
    - Treatment with antibiotics if pneumonia or other infections are suspected or confirmed

CHRONIC TREATMENT

- Incidental/mild cases: daily gentle, manual, lateral-to-medial chest compressions until the animal is mature (about 9 months of age) to help flatten the chest as the animal grows. An external compressing stent may be applied. Chest contour may normalize with growth.
    - The benefits of surgical correction in animals with moderate or severe pectus excavatum and no clinical signs have not been established.
- Moderate/severe clinical signs: surgical application of an external splint. Correction in young animals is generally more successful because the costal cartilages and sternum remain pliable, allowing the thorax to reshape.
    - Optimal age for surgery is variable; a minimum of 8 weeks of age has been recommended.
    - Anesthetic management requires the utmost attention and monitoring.
    - Prevention of hypothermia and hypoglycemia in young animals
    - Positive-pressure ventilation
    - Theoretically, reduction of risk for reexpansion pulmonary edema with slow reexpansion of atelectatic lung; often not practical intraoperatively.
    - Avoiding chamber or mask induction if animal is dyspneic

NUTRITION/DIET

High-quality nutritional augmentation benefits animals with poor growth until correction or improvement of the defect.

POSSIBLE COMPLICATIONS

- Surgical complications
- Pneumothorax
- Hemothorax
- Infection
- Reexpansion pulmonary edema

RECOMMENDED MONITORING

- Postoperative monitoring for intrathoracic hemorrhage; immediate postoperative monitoring for pneumothorax
- Monitoring for signs of respiratory infections in untreated or conservatively treated animals

PROGNOSIS AND OUTCOME

- Mild cases without overt clinical signs: excellent prognosis if no other defects are present
- Prognosis of more severe cases depends on nature of concurrent defects.
- Long-term prognosis is excellent in animals that show clinical signs but have no other defects, provided surgery is performed at a young age. Surgery of older animals may require partial sternectomy.

PEARLS & CONSIDERATIONS

COMMENTS

- Severity of signs at maturity is difficult to predict. If corrective surgery is not possible (cost, unavailability), signs may still lessen spontaneously with growth. Thus, euthanasia should be only considered in the most severe cases when surgery is not possible.
- Puppies and kittens with swimmer's syndrome can benefit from early physical therapy.
- The opposite of pectus excavatum is pectus carinatum (protruding sternum).

PREVENTION

- Spaying or neutering of affected animals once they are stable for elective surgery
- Avoidance of breeding animals with pectus excavatum or the relatives of animals with pectus excavatum

TECHNICIAN TIPS

Small-gauge (22 or 23 G) butterfly needles and 3-way stopcocks attached to a syringe are often useful for acute management of pneumothorax or hemothorax if such complications develop postoperatively.

CLIENT EDUCATION

If corrective surgery is not an option, thoracic volume may improve as the animal grows. Outcome is highly variable, and even animals with severe deformities may thrive.

EDITOR: RANCE K. SELLON

Pattern Alopecia, Canine

BASIC INFORMATION

DEFINITION

Canine pattern alopecia is a relatively common, likely heritable, noninflammatory alopecic disorder of specific breeds. It encompasses several distinct syndromes.

SYNONYMS

CPA, canine pattern baldness

EPIDEMIOLOGY

SPECIES, AGE, SEX

- These disorders affect dogs of either sex and of any reproductive status.
- Early onset (usually before 1 year of age)

GENETICS & BREED PREDISPOSITION

- CPA, ventral type is seen in dogs with fine, short coats such as dachshunds, Chihuahuas, miniature pinschers, whippets, greyhounds, Boston terriers, and boxers.
- CPA, pinnal type is seen mainly in dachshunds.
- Alopecia and melanoderma of Yorkshire terriers is breed specific.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- The two main forms of CPA are the ventral type, the most common syndrome, and the pinnal type.
- Alopecia and melanoderma of Yorkshire terriers is clinically very similar to CPA, pinnal type, and it is most likely the same disorder.

HISTORY, CHIEF COMPLAINT: Dogs born with a normal hair coat are presented for evaluation of a gradual thinning of the coat in specific body areas.

PHYSICAL EXAM FINDINGS

- CPA, ventral type: progressive alopecia developing along the ventral neck, chest, and abdomen, caudomedial aspect of thighs, perineum, and post-auricular regions (base of the ear pinnae)
- CPA, pinnal type: progressive alopecia of the convex aspect of the ear pinnae, starting around 6 months of age
- Alopecia and melanoderma of Yorkshire terriers: alopecia and hyperpig-mentation of the convex aspect of the ear pinnae and the bridge of the nose

ETIOLOGY AND PATHOPHYSIOLOGY

CPA may be an overshoot reaction to artificial selection pressure favoring the fine, delicate coat sought by breeders. Over the last decades, smooth-hair dachshund breeders have been able to significantly decrease the incidence of CPA, ventral type by selective breeding but with the result of dogs generally having a coarser hair coat.

PATTERN ALOPECIA Pattern alopecia (ventral type) in a 2-year-old neutered male Boston terrier. Note loss of hair on ventral neck and chest.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is based on history, dermatologic exam, and exclusion of endocrinopathies and inflammatory diseases such as alopecia areata. The early onset, breed predisposition, and absence of inflammation and pruritus are distinctive.

DIFFERENTIAL DIAGNOSIS

- Endocrinopathies (hypothyroidism, hyperadrenocorticism, hyperestrogenism)
- Follicular dysplasias
- Alopecia areata
- Infectious process (pyoderma, demodicosis, dermatophytosis) in some clinical presentations

INITIAL DATABASE

- History and physical exam findings are generally sufficient.
- Ruling out other differentials may involve thyroid testing, adrenal function testing, and dermatologic diagnostic tests such as skin scraping based on lesion distribution and appearance.

ADVANCED OR CONFIRMATORY TESTING

Skin biopsies: changes are characterized by miniaturization of anagen hair follicles. Biopsies are rarely performed, because biopsy sites often require general anesthesia, biopsy healing may lead to permanent visible scarring, and histopathologic changes can be subtle and wrongly suggestive of endocrinopathies.

TREATMENT

TREATMENT OVERVIEW

The goal is to try to promote hair regrowth if this is the desire of the owner; it may protect the dog from cold climate.

ACUTE GENERAL TREATMENT

Anecdotal evidence exists for the efficacy of melatonin at 3-6 mg/dog PO q 8-12 h for 1-2 months to stimulate hair growth.

PROGNOSIS AND OUTCOME

- Dogs affected by this genetically based dermatosis are healthy otherwise.
- It is not known if dogs initially responding to melatonin will eventually become refractory to this form of treatment.

PEARLS & CONSIDERATIONS

COMMENTS

- The early onset, pattern-linked alopecia, and breed predisposition make the diagnosis straightforward in many cases.
- The main impact of this disorder is usually cosmetic rather than medical.

Paradis M, Cerundolo R: Genodermatosis: alopecia and hypotrichosis. In Hillier A, Foster AP, Kwochka KW, editors: Advances in veterinary dermatology, Vol 5. Ames, IA, 2005, Blackwell publishing, p 360.

AUTHOR & EDITOR: MANON PARADIS

Patent Ductus Arteriosus

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

An arterial shunt between the aorta and pulmonary artery that is normally present in fetuses but should constrict and close within 24 hours after birth. Incomplete closure (patency) results in a variably sized channel whose minimum diameter determines the amount and direction of blood flow through the shunt and hence determines the impact on the patient. It is the most common congenital heart defect in dogs, occurring in 1/1000. It is rare in cats.

SYNONYM

PDA

EPIDEMIOLOGY

SPECIES, AGE, SEX

- All species and any age
- Recognized most frequently in young animals
- Moderate predominance in females
- Occurs much less frequently in cats

GENETICS & BREED PREDISPOSITION

- Any breed
- Sporadic or heritable defect occurring most frequently in small, relatively nonmuscular dog breeds such as Maltese, Pomeranians, Yorkshire terriers, Shetland sheepdogs, and toy and miniature poodles

RISK FACTORS: Inbreeding

GEOGRAPHY AND SEASONALITY:

Breed predispositions may vary due to regional differences in the gene pool.

ASSOCIATED CONDITIONS & DISORDERS

- Arrhythmias
- Congestive heart failure
- Pulmonary hypertension
- Polycythemia

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Type 1: small patent ductus arteriosus (PDA)
- Type 2: medium PDA
- Type 3A: large PDA
- Type 3B: large PDA with congestive heart failure
- Type 4: large PDA with pulmonary hypertension and right-to-left or bidirectional shunt
- An angiographic classification scheme also exists for dogs, wherein PDAs are categorized according to morphology: type I (5%) = gradual tapering from aorta to pulmonary artery; type IIa (most common; 54.5%) = walls of PDA taper gradually until abrupt tapering at pulmonary arterial insertion; type IIb (32.5%) = walls of PDA abrupt tapering at pulmonary arterial insertion; type III (8%) = walls of PDA are parallel for the length of the PDA (tubular).

HISTORY, CHIEF COMPLAINT

- Varies with PDA diameter and age
- Most often recognized as an incidental heart murmur in a young animal presented for vaccination and not showing overt clinical signs
- When clinical signs are present, they include exercise intolerance, failure to thrive, and signs of congestive heart failure.

PHYSICAL EXAM FINDINGS: Vary with PDA diameter:

- Type 1, small:
  - Characteristic focal continuous murmur at left heart base
- Type 2, medium:
  - Type 1 signs

    - Continuous murmur audible at apex
    - Precordial thrill at left heart base
- Type 3A, large:
    - Types 1 and 2 signs
    - Bounding pulses
    - Prominent cardiac impulse at left apex
    - Systolic murmur of mitral regurgitation at left apex
- Type 3B, large with congestive heart failure:
    - Types 1, 2, and 3A signs
    - Dyspnea
    - Pulmonary crackles
    - Ascites (occasionally)
    - Arrhythmias, especially atrial fibrillation, possible
- Type 4, large PDA with pulmonary hypertension:
    - No heart murmur
    - Prominent right apical impulse
    - Split second heart sound
    - Caudal cyanosis
    - Hind limb collapse with exercise

ETIOLOGY AND PATHOPHYSIOLOGY

- The principal cause of PDA in dogs is site-specific hypoplasia of ductus smooth muscle, coupled with reciprocal excess elastic tissue in the wall of the ductus. In varying degree, the hypoplastic smooth muscle does not encircle the lumen, and muscle contraction does not completely constrict the lumen postpartum.
- Typically, pulmonary vascular resistance decreases after birth and postnatal blood flow through the PDA is from the aorta to the pulmonary artery (“left-to-right type”), causing increased flow through the pulmonary circulation, left atrium, left ventricle, and ascending aorta, resulting in enlargement of these chambers and left ventricular hypertrophy. Established left-to-right types very rarely develop enough pulmonary hypertension to cause reversed PDA flow (“right-to-left type”).
- In animals with a large PDA and pulmonary hypertension (type 4, persistent fetal circulation), there is right ventricular hypertrophy; blood flows through the ductus predominantly from the pulmonary artery to the aorta, resulting in caudal cyanosis and secondary polycythemia.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

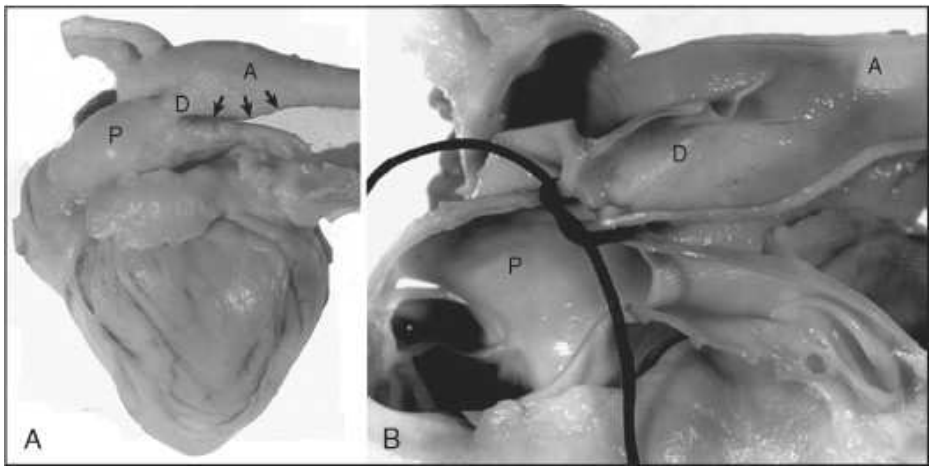
The diagnosis is made easily by palpating a precordial thrill and auscultating a continuous murmur over the left heart base (types 1-3). Chest radiographs reveal the degree of cardiomegaly and the urgency of PDA closure.

DIFFERENTIAL DIAGNOSIS

- Combined abnormalities producing systolic and diastolic heart murmurs, such as a ventricular septal defect and aortic insufficiency due to an unsupported aortic valve cusp
- Aorticopulmonary window
- Arteriovenous fistula
- Bronchial artery flow in chronic heart-worm cor pulmonale
- Tortuous collateral arteries in aortic coarctation or interruption

INITIAL DATABASE

- Thoracic radiographs to assess heart and lung vessel size and lung parenchyma
- Electrocardiogram (ECG) to identify ventricular hypertrophy and arrhythmias
- Packed cell volume to determine presence of anemia or polycythemia



PATENT DUCTUS ARTERIOSUS A, Photograph of heart, aorta *(A),* and pulmonary artery *(P)* in a 4-month-old dog with a PDA *(D)* and ductal-aortic aneurysm *(arrows).***B**, Sagittal section photograph of great vessels and a ligature demonstrating PDA ligation at surgery. Most of the PDA lies within the wall of the aorta in dogs and constitutes a ductal-aortic aneurysm commonly referred to as a *ductus diverticulum.* Typical ridge at pulmonary artery opening limits PDA diameter and determines blood flow through PDA.

(Courtesy Dr. James W. Buchanan, Philadelphia, Pennsylvania.)

ADVANCED OR CONFIRMATORY TESTING

These tests are optional:

- Two-dimensional echocardiography to determine chamber sizes, wall thickness, and contractility and to identify any concurrent cardiac defects
- Color Doppler echocardiography to verify turbulent blood flow in the pulmonary artery
- Spectral Doppler echocardiography to determine flow velocity in the PDA and estimate the aorta/pulmonary artery pressure gradient. If tricuspid and pulmonic insufficiencies are present, respective estimates of right ventricular systolic and pulmonary artery diastolic pressures can be made.

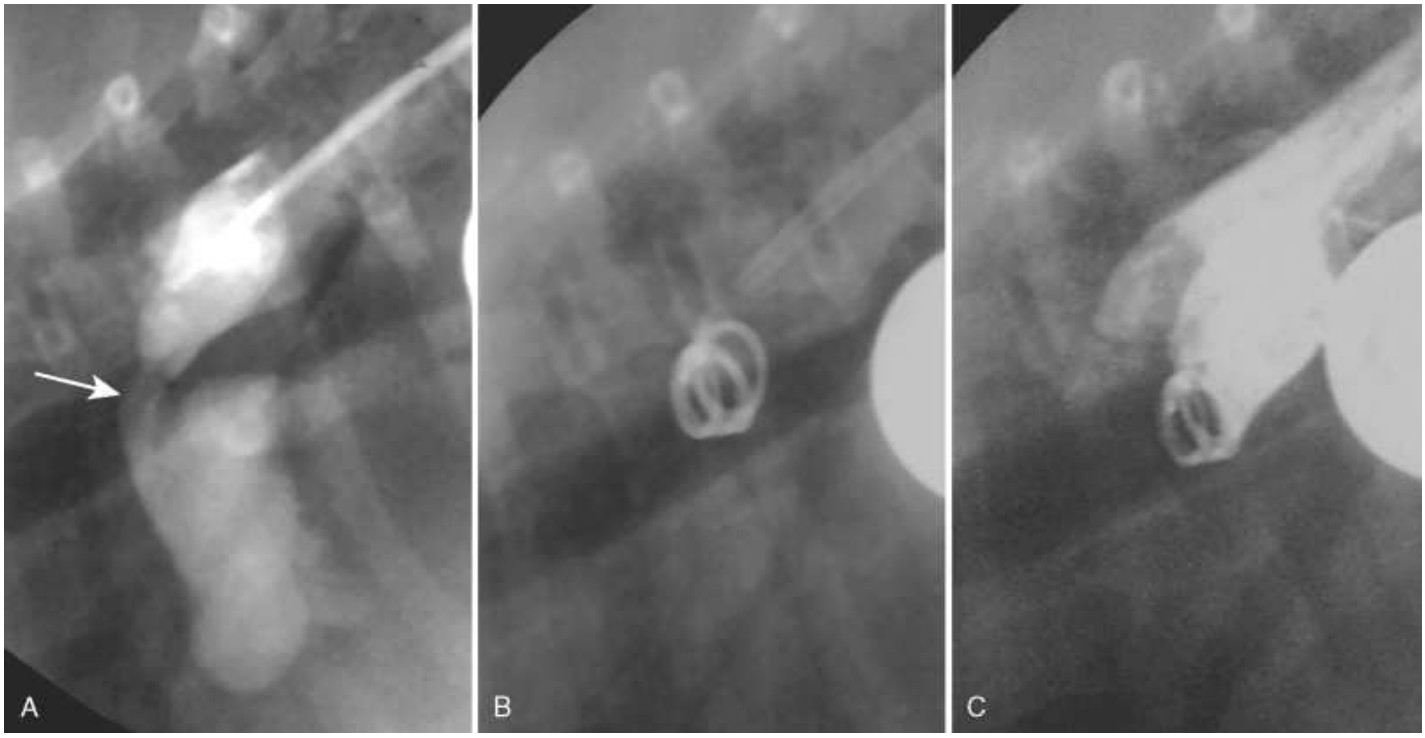
TREATMENT

TREATMENT OVERVIEW

PDA closure is recommended for all left-to-right cases (types 1-3) but contraindicated in right-to-left cases (type 4). In type 4 cases, phlebotomy and/or chemotherapy reduce and maintain hematocrit at 60%-65%, which improves blood flow characteristics.

ACUTE GENERAL TREATMENT

- Type 3B: For large PDA, preoperative diuretic and cage rest to alleviate congestive heart failure, then occlusion of PDA are indicated.
- Types 1-3: surgery or transarterial coil or Amplatz duct occluder to occlude PDA
- Type 4: phlebotomy to reduce polycythemia



PATENT DUCTUS ARTERIOSUS Aortic injection angiograms in a 6-month-old dog with PDA before **(A)** and after **(C)** PDA occlusion with a transarterial coil **(B)**. The *arrow* (panel **A**) indicates the narrowest part of the PDA; a properly deployed coil should be placed on the aortic side of this point (as shown in panels **B** and **C**).

(Courtesy Dr. James W. Buchanan, Philadelphia, Pennsylvania.)

Mortality	<2%	<1%	Transvascular device

CHRONIC TREATMENT

Type 4: hydroxyurea to suppress bone marrow, 20-25 mg/kg PO q 12 h every other day; titrated downward as needed based on resulting hematocrit

POSSIBLE COMPLICATIONS

- Refractory congestive heart failure
- Refractory arrhythmias
- Iatrogenic surgical hemorrhage

- Coil or occludar device embolization into pulmonary artery branch
- Hematoma at transarterial site
- Persistent polycythemia in type 4

RECOMMENDED MONITORING

Nonspecific

PROGNOSIS AND OUTCOME

- Types 1-3A: 98% successful correction and normal lifespan
- Type 3B: 98% initially successful if heart failure and arrhythmia are controlled preoperatively; animal can live for years, but lifespan is usually shortened.
- Type 4: may live for years if polycythemia is controlled

PEARLS & CONSIDERATIONS

PREVENTION

Owners should avoid breeding affected animals.

Patellar Luxation

BASIC INFORMATION

DEFINITION

Medial or lateral displacement of the patella from the femoral trochlear sulcus or groove. Medial patellar luxation is more common in dogs and cats.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Primarily seen in dogs; less frequently in cats
- All ages affected; more common in the young dog

GENETICS & BREED PREDISPOSITION

- Most dog breeds affected; more common in the toy and miniature canine breeds and Newfoundland dogs
- Heritability has been established in toy/miniature poodles and toy spaniels.
- Some reports of increased incidence in Maine coon, Persian, Devon rex and Abyssinian cats

RISK FACTORS

- Malalignment of the quadriceps mechanism (hereditary and developmental causes)
- Trauma to the bone or soft tissues of the hind limb, or neurogenic muscle contracture
- Previous stifle surgery that included lateral arthrotomy with patellar luxation

ASSOCIATED CONDITIONS & DISORDERS

- Cranial cruciate ligament instability (present in 15%-20% of stifles with chronic patellar luxation)
- Hip dysplasia in large dogs

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Medial patellar luxation (MPL): the most common form of PL in dogs and cats
- Lateral patellar luxation (LPL): uncommon. Seen in all breeds; large and giant canine breeds most commonly affected.
- Traumatic luxation: uncommon. Usually the patella displaces medially following retinacular injury.

HISTORY, CHIEF COMPLAINT

- Intermittent, partial to non-weight-bearing lameness of one or both hind limbs
- Transient “skipping” gait (holding hindlimb flexed and nonweightbearing for a few steps at a time) when walking or running with low-grade luxation
- Mechanical lameness due to secondary limb deformity with high-grade luxation
- Weakness in jumping or reluctance to jump
- Sudden lameness or increase in lameness in a stifle with chronic PL suggests recent cranial cruciate ligament rupture.

PHYSICAL EXAM FINDINGS: Grading system:

- Normal:
  - Patella cannot be manually luxated
  - Normal gait
- Grade I:
  - Patella can be luxated manually but spontaneously reduces.
  - No clinical signs of lameness, or occasional “skipping” lameness
- Grade II:

- Spontaneous luxation and reduction of the patella occurs.
- Intermittent “skipping” lameness, or persistent weight-bearing lameness
- Mild to moderate internal (MPL) or external (LPL) tibial torsion
- Mild to moderate medial (MPL) or lateral (LPL) deviation of the tibial crest

- Grade III:
  - Patella remains luxated but can be manually reduced with stifle extension.
  - Persistently abnormal gait: externally rotated stifle, internally rotated pes (bowlegged and pigeon-toed) with MPL, valgus deformity of stifle, external rotation of pes (knock-kneed and cow-hocked) with LPL
  - Moderate to severe tibial torsion and tibial crest deviation
  - Shallow distal femoral trochlear groove may be palpable.
- Grade IV:
  - Patella is permanently luxated and cannot be manually reduced. o Non-weight-bearing hind limb lameness or ambulation in a “crouched” position (inability to fully extend the stifles)
  - Severe internal (MPL) or external (LPL) tibial torsion
  - Severe medial (MPL) or lateral (LPL) deviation of the tibial crest
  - Distal femoral trochlear groove is shallow or absent.

ETIOLOGY AND PATHOPHYSIOLOGY

- Hereditary and developmental skeletal changes that lead to malalignment of the quadriceps mechanism. Which deformity comes first is unknown because many of the changes in high-grade MPL and LPL result from the abnormal directional pull of the quadriceps.
  - Medial patellar luxation:
    - Coxa vara (decreased femoral neck angle)
    - Distal femoral varus
    - Tibial internal torsion
    - Shallow femoral trochlear sulcus
    - Tight, thick medial retinaculum, loose, thin lateral retinaculum
  - Lateral patellar luxation:
    - Coxa valga (increased angle of inclination of the femoral neck)
    - Distal femoral valgus
    - External tibial torsion
    - Tight, thick lateral retinaculum; loose, thin medial retinaculum

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

Diagnosis of patellar luxation is based on physical examination. Radiographs may be normal if taken when the patellas are in place, but they are useful for planning surgical intervention and identifying changes present with concurrent cranial cruciate ligament rupture. However, interpretation of apparent angular and torsional deformities must be done with caution, since natural curvatures of the femur and tibia can give the impression of abnormal conformation.

DIFFERENTIAL DIAGNOSIS

- Aseptic necrosis of the femoral head (Legg-Calvé-Perthes disease): young, small dogs only
- Coxofemoral luxation
- Cranial cruciate ligament rupture
- Osteochondrosis of the stifle
- Immune-mediated polyarthritis
- Lumbosacral compressive disease

INITIAL DATABASE

- Palpation of the stifle joints for patellar instability and cranial cruciate ligament rupture
- Radiographs to characterize the femoral and tibial conformation and joint condition:
  - Lateral and craniocaudal radiographs of the femur, stifle, and tibia
  - Need to include the hip and tarsal joints in higher grades of luxation to better assess angular and torsional deformities. Caution should be taken with positioning (it is often best to take craniocaudal views with the dog held sitting upright and the hind limbs extended, stifles pointed directly upward with no splay), as slight variations from the ideal can cause the femurs to appear falsely angled.

ADVANCED OR CONFIRMATORY TESTING

- Calculation of femoral neck inclination and anteversion angles for LPL in large-breed dogs
- CT scan with three-dimensional reconstruction

TREATMENT

TREATMENT OVERVIEW

- Only animals showing overt clinical signs should have surgery. Patellar luxation usually produces surprisingly little osteoarthritis, which is typically slow to progress.
- In all but very young puppies and kittens, correction of bone deformities, in addition to soft-tissue repairs, will be necessary. A soft-tissue repair that feels stable on the operating table usually allows patellar reluxation by 3 weeks after surgery.
- Concurrent cranial cruciate rupture must be addressed during the PL operation, since cruciate ligament rupture is frequently the chief source of the lameness being treated.

ACUTE GENERAL TREATMENT

- Medical management:
  - Nonsteroidal antiinflammatory, drugs (NSAIDs) in dogs:
    - Carprofen: 2 mg/kg PO q 12 h, *or*
    - Etodolac: 10-15 mg/kg PO q 24 h, *or*
    - Deracoxib: 1-2 mg/kg PO q 24 h (may use 3-4 mg/kg PO q 24 h for first 7 days only), *or*
    - Meloxicam: 0.1 mg/kg PO q 24 h, *or*
    - Tepoxalin: 10 mg/kg PO q 24 h, *or*
    - Other drugs
- Physical rehabilitation for mild patellar luxations (grade I, ± grade II)
  - Exercises to strengthen quadriceps muscle function
- Surgical management
  - Soft-tissue reconstruction:
    - Imbrication of loose and release of tight pericapsular tissues based on direction of luxation; release of the rectus femoris or sartorius muscle for MPL
    - Derotational suture from fabella to patella or tibial tuberosity
  - Trochleoplasty to deepen the femoral trochlear groove:
    - Trochlear chondroplasty in immature dogs
    - Trochlear abrasion sulcoplasty
    - Trochlear recession sulcoplasty (using a wedge or a block technique)
  - Tibial tubercle transposition opposite to direction of luxation
  - Femoral or tibial correctional osteotomies: usually performed when angular deformity is severe (>15○ varus for the distal femur in MPL).
  - Stifle arthrodesis may be performed as a salvage procedure for severe luxations not amenable to other treatments.
  - Concurrent cranial cruciate ligament rupture should be treated along with the MPL; osteotomy techniques such as tibial plateau-leveling osteotomy (TPLO) or tibial tuberosity advancement (TTA) can be modified so that the tibial osteotomy also transposes the tibial tuberosity.

CHRONIC TREATMENT

- Same as in acute cases but may require long-term medical management for the treatment of osteoarthritis
- One of these chondroprotective agents can be used:
  - Polysulfated glycosaminoglycan, 5 mg/kg IM once weekly for 4-6 weeks
  - Pentosan polysulfate, 3 mg/kg SQ once weekly
  - Oral formulations (glucosamine. chondroitin sulfate, hyaluronan, avocado soy unsaponifiables): according to formulation/labeled instructions

NUTRITION/DIET

Weight control

POSSIBLE COMPLICATIONS

- Medical management:
  - Gastrointestinal (GI), hepatic, renal, or other systemic reactions from NSAIDs

    - Continued progression of degenerative joint disease
    - Failure of medical management to control pain
- Surgical management:
    - Patellar reluxation (occurs in 10%-30% of cases, especially if tibial tuberosity transposition has not been done)
    - Implant failure/tibial tuberosity avulsion

RECOMMENDED MONITORING

- Basic laboratory monitoring of animals on NSAID therapy
- Weight, exercise levels, and clinical signs as dictated by the patient
- Postoperative rehabilitation enhances clinical recovery.

PROGNOSIS AND OUTCOME 

- Generally good to excellent for return to normal limb function if appropriate techniques are utilized
- Degenerative joint disease progresses (radiographically, not necessarily symptomatically) despite treatment.

PEARLS & CONSIDERATIONS 

COMMENTS

- Severity of lameness may not correlate with grade of patellar luxation. Animals with grade 2 luxation are often the most painful, as their patellas are repeatedly grinding across the trochlear ridges. Animals with higher-grade luxations are not painful, but rather impeded by joint misalignment.
- Patellar luxation is usually a developmental condition, and the grade of luxation may increase as the animal matures.
- In bilateral luxations, the grade of patellar instability may differ between stifles.
- Soft-tissue stabilization techniques alone are not sufficient to stabilize moderate or severe luxations.
- Trochlear recession sulcoplasty (wedge or block) is the preferred method to deepen the femoral trochlear groove, because it preserves the articular cartilage.
- In older animals with chronic patellar instability and acutely worsening lameness, always rule out concomitant cranial cruciate ligament rupture.

PREVENTION

Screening and control of breeding animals for prevention of patellar luxation

Parvoviral Enteritis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A viral infection that destroys the crypt cells of the villous epithelium of the small intestine together with lymphocyte depletion and neutropenia, leading to severe enteritis, anorexia, vomiting, hemorrhagic diarrhea, and shock

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs only; parvoviral enteritis almost exclusively affects puppies (<8 months old) and unvaccinated adults. In cats, parvovirus-induced disease is called *panleukopenia* (see p. 822).

GENETICS & BREED PREDISPOSITION:

Suspected predisposition for Doberman pinscher, rottweiler, pit bull, German shepherd, and dachshund breeds; toy poodles and cocker spaniels have below-normal degree of risk.

RISK FACTORS

- Unvaccinated puppies or pups less than 7 weeks of age with poor maternal immunity; unvaccinated dogs are 12.7 times more likely than vaccinated dogs to develop parvoviral enteritis.
- Exposure to high viral loads
- Immunosuppression (systemic illness, cancer chemotherapy)

CONTAGION & ZOONOSIS

- Extremely resistant virus (parvovirus 1 and 2) that can survive more than 7 months in the environment (longer if frozen over winter months) and is resistant to most disinfectants
    - Diluted bleach (1:32 bleach/water) and quaternary ammonium disinfectants (Parvosol, Roccal-D, quats, and others) effectively kill parvovirus.
- Highly contagious to other dogs via the fecal-oral route
    - Fecal shedding begins 4-5 days after exposure (i.e., before the onset of overt clinical illness, which occurs 6-10 days after exposure).
    - Shedding generally occurs for a total of 7-10 days, usually ending by day 14 after exposure.
    - An animal that is discharged after successful treatment of parvoviral enteritis has a low risk of contagion to other dogs through feces it passes, but there is a high risk of contagion through fecal staining on the hair-coat or in feces or vomit produced at home immediately prior to hospitalization.
- Shedding of vaccine-source (attenuated live) parvovirus occurs for several days after vaccination; there is no contagion risk, but the shedding may produce a false-positive reaction on fecal ELISA testing for parvovirus.
- Species-specific; no clinically relevant transmission to cats or other species, and no zoonotic transmission

GEOGRAPHY AND SEASONALITY: Occurs worldwide and year round but is more common in warmer, wetter seasons. Most commonly seen in spring when the majority of puppies are born. However, in a Canadian study, dogs were three times more likely to be admitted with parvoviral enteritis in July, August, or September compared with the rest of the year.

ASSOCIATED CONDITIONS & DISORDERS

- Helminthiasis, giardiasis, coccidiosis, and coronavirus infections may occur concurrently.
- Sepsis likely is prevalent in parvoviral enteritis cases because bacteremia is common: in 90% of dogs that died of parvoviral enteritis, microbial liver or lung cultures revealed growth of *Escherichia coli.*

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Subclinical, mild, moderate, and severe enteritis

HISTORY, CHIEF COMPLAINT

- Onset of signs 3-14 days after exposure (if known)

- Acute onset of lethargy (often first sign), anorexia, vomiting, and diarrhea (often hemorrhagic)

PHYSICAL EXAM FINDINGS

- Mild cases may be unremarkable.
- Moderate and severely affected puppies are typically lethargic, dehydrated (tacky oral mucous membranes), with palpably fluid-filled intestines; abdominal palpation may induce vomiting or retching, and fever and tachycardia are common.
- Severely affected puppies may present in hypovolemic shock, with altered mentation (may be due to septic shock, hypoglycemia) and hypothermia.

ETIOLOGY AND PATHOPHYSIOLOGY

- Exposure is followed by a 3-to 14-day incubation period
- Parvoviral predilection for rapidly dividing cells
- Destruction of intestinal crypt epithelium, causing sloughing of intestinal mucosa, vomiting, diarrhea, and sepsis from translocation of enteric bacteria into the portal circulation
- Lymphocyte depletion and neutropenia
- Glucose and potassium depletion/loss
- Dehydration and sepsis

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on the presence of anorexia, vomiting, diarrhea, lethargy, or a combination of these, typically in a young and usually unvaccinated dog; confirmation requires fecal assay such as a parvovirus ELISA snap test.

DIFFERENTIAL DIAGNOSIS

- Any severe acute gastroenteritis
- Distemper
- Salmonellosis
- Coronaviral enteritis
- Foreign body/intussusception

INITIAL DATABASE

- ELISA test for parvovirus in feces: diagnostic test of choice
  - Sensitive and specific
  - False-positive result possible with recent vaccination (beginning 5 days after vaccination and continuing for 1 week)
  - False-negative result possible with fecal sample obtained outside period of shedding or profusely hemorrhagic diarrhea (diluted or complexed antigen fails to react with test antibody)
- Fecal flotation and fecal wet preparation: concurrent helminthiasis is common.
- CBC: leukopenia (neutropenia) is common and supports the need for broad-spectrum antibiotic treatment. If financial restrictions: hematocrit, total solids, and blood smear as a minimum for hematologic examination.
- Serum biochemistry panel: hypokalemia, hypoalbuminemia, and hypoglycemia are common correctable secondary effects of parvoviral enteritis. Azotemia (often prerenal) and liver enzyme elevations are common. If severe financial restrictions: serum potassium, albumin, and glucose as a minimum for serum biochemistry.
- Urinalysis: generally unremarkable; specific gravity > 1.035 confirms prerenal source of azotemia.
- Abdominal radiography: to avoid misdiagnosis (e.g., identify foreign body) and detect abnormalities secondary to parvoviral enteritis (e.g., obstruction due to intussusception).

ADVANCED OR CONFIRMATORY TESTING

Financial considerations often result in empirical therapy without comprehensive evaluation beyond confirming the diagnosis. In cases of financial restriction, it is considered more important to direct veterinary costs toward treating the pup rather than performing exhaustive diagnostic testing. While doing so carries a risk of missing important information, which the owner must accept, most puppies will recover with supportive care; without treatment, the mortality rate is high.

TREATMENT

TREATMENT OVERVIEW

Treatment goals are rehydration, treatment or prevention of sepsis, correction of potassium and glucose levels, normalization of blood pressure (BP), cessation of vomiting, pain control, + enteral nutrition, and voiding iatrogenic complications (e.g., risk of abscess formation with subcutaneous injections in parvovirus cases [especially with neutropenia]).

ACUTE GENERAL TREATMENT

See table below.

Initial Treatment of Parvoviral Enteritis in Puppies

At admission	• Place IV catheter, administer IV antibiotics (cefazolin, 22 mg/kg IV q 8 h; or ampicillin, 22 mg/kg IV q 6 h). If leukopenia: add enrofloxacin, 7.5-10 mg/kg slow IV q 24 h; or once patient is rehydrated, gentamicin, 6 mg/kg IV q 24 h. Aminoglycosides are contraindicated in hypovolemia/dehydration. • Test: hematocrit/total protein/glucose • crystalloid fluid bolus (e.g., lactated Ringer's solution 60 mL/kg) if hypovolemic shock
First 2 hours	• Calculate fluid needs (i.e., sum of: rehydration + maintenance + ongoing losses for first 12 hours). Note: rehydration (mL) = % dehydration (expressed as a percent [7% is 7]) × body weight in kg × 10. • Maintenance is 65 mL/kg/d (30 mL/lb/d) • Give ¼ to ½ of amount over first 2 hours to correct intravascular volume and blood pressure (warm fluids to body temperature). • Colloids can be used at 10-20 mL/kg IV over 1-4 hours if shock is present or if albumin is low. Recall additional cost of colloids.
After first 2 hours	• Give rest of fluid allotment over next 10 hours. • Test hematocrit + total protein + serum potassium + serum/blood glucose. • Warm patient on heating pad at this point if needed (not before; doing so may dilate peripheral vasculature). • Add glucose to fluids if needed (50 mL of 50% dextrose in 1 liter bag = 2.5% or 100 mL of 50% dextrose in 1 liter bag = 5%). • Plasma or polymerized hemoglobin (Oxyglobin) can be administered as an immunotherapy (plasma) and for oncotic pressure; potentially indicated if plasma albumin < 1.5 mg/dL. • Blood transfusion or polymerized hemoglobin indicated if status worsening and hematocrit < 20%
Approximately 2-3 hours	• Metoclopramide IV constant rate infusion (CRI), 1-2 mg/kg/d, to treat ileus and/or vomiting • Pain control: e.g., buprenorphine, 0.01 mg/kg IV q 6 h • Amikacin/gentamicin IV if not already administered and blood pressure has improved, or enrofloxacin if a concern persists regarding nephrotoxicity • Test: blood pressure, palpate for urine in bladder, confirm capillary refill time < 2 seconds.
Approximately 4-5 hours	• Start to feed (aim for at least ⅓ of requirements over next 24 hours). Some clinicians will advocate feeding despite vomiting. • Calculate energy requirements with formula: kcal = [(body weight (kg) × 30) + 70] × illness factor (1.25-1.5) • See main text for added control of vomiting and diet.
Approximately 12 hours	• Reassess hydration (weigh patient often): continue rehydration as needed. • In pups with large ongoing losses, fluid rates may be very high (5-10 mL/kg/h). Titrate fluid rate to hydration, perfusion, and clinical signs (vomiting and diarrhea).

CHRONIC TREATMENT

- Continuation of IV fluids, antibiotic therapy, pain control, antiemetic treatment, and nutrition as described in table
- Repeated blood, plasma, or synthetic colloid transfusions as often as needed
- To control vomiting after ensuring no obstruction (e.g., intussusception):
    - Step 1: continuous rate infusion (CRI) metoclopramide (as previously described)
    - Step 2: maropitant (Cerenia), 1 mg/kg SQ q 24 h
    - Step 3: add ondansetron, 0.5-1 mg/kg PO or IV q 12-24 h; or dolasetron, 0.6 mg/kg IV q 24 h.
    - Step 4: add prochlorperazine (often given as a suppository).
- Deworming:

- Fenbendazole 50 mg/kg PO q 24 h, 3-5 days (if > 12 weeks old); *or* ○ Ivermectin 0.2 mg/kg SQ once

NUTRITION/DIET

- High-protein, high-calorie foods (e.g., Eukanuba Max Calorie, Hill's Science Diet A/D) diluted with as little water as possible
- It is the author's opinion that a small volume of food is far more important than a low-fat content.

DRUG INTERACTIONS

- Flunixin meglumine is nephrotoxic and gastric ulcerogenic and should be avoided in animals that are hypovolemic.
- Fluoroquinolones (5 mg/kg q 24 h) used for 5-8 days should be safe and *not* cause cartilage problems.
- Ivermectin deworming is not advised in debilitated patients.

POSSIBLE COMPLICATIONS

- Intussusception or rectal prolapse
- Septic arthritis or endocarditis
- Acute respiratory distress syndrome
- Pneumonia (embolic, aspiration, or opportunistic [e.g., canine distemper])

RECOMMENDED MONITORING

- Clinicians should monitor the following at admission, after 2 hours of fluid therapy, and then at least on a daily basis in patients that are still ill:
  - Body weight
  - Blood glucose
  - Hematocrit and total solids
  - Serum potassium
- Pediatric sampling tubes and very small quantities of blood should be used. Once the puppy is eating, monitoring should be curtailed or stopped to avoid overinterpretation of results in an animal that is improving.

PROGNOSIS AND OUTCOME

Good with correct therapy. Following the treatment protocol, a 93%-95% success rate is expected with severely ill, confirmed cases of parvoviral enteritis.

PEARLS & CONSIDERATIONS

COMMENTS

Essential aspects of management include:

- Normalize hydration, potassium, and glucose.
- Control vomiting.
- Control pain.
- Feed early.

TECHNICIAN TIPS

- Become familiar with estimating the volume of fluid on a surface such as the cage floor. This helps in calculating daily fluid requirements.
- Wear gloves and use strict hygiene when handling these patients, not only for contagion prevention but because of their immunocompromised state (often leukopenic); this applies to doctors and anyone else in contact as well.

PREVENTION

- Ensure adequate vaccination status.
- Owners should limit environmental access for puppies until they are fully vaccinated.
- Dogs that survive parvoviral enteritis generally have immunity to reinfection (lifelong).

CLIENT EDUCATION

- Parvovirus remains in the environment for up to 7 months or more. Indoor surfaces should be cleaned and then disinfected with diluted bleach, and only vaccinated adult dogs should be allowed in the dog's immediate environment.
- Serial vaccination of all puppies until at least 12 weeks of age is essential; typical protocols involve vaccination at age 6, 9, 12, and possibly 16 weeks, the latter being for breeds at risk.
- Annual re vaccination of adult, and especially geriatric, dogs with a complete history of vaccinations is controversial, since titers remain high for more than 1 year. The debate over the appropriate interval of vaccination interval in adult dogs remains unresolved, with a recent advisory board recommending vaccination every 3 years.

AUTHOR: DAVID MILLER

EDITOR: ELIZABETH ROZANSKI

Parturition, Normal

BASIC INFORMATION

DEFINITION

The act or process of giving birth to puppies or kittens

SYNONYMS

- Queening: parturition in the queen (female cat)
- Whelping: parturition in the bitch

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats: adult, female

CONTAGION & ZOONOSIS: *Brucella canis* (see p. 162) and canine herpesvirus 1 (see p. 525) can be shed in lochia (parturient uterine fluids) during term parturition, preterm parturition, and/or abortion.

GEOGRAPHY AND SEASONALITY

- With the exception of the basenji, bitches are nonseasonal, meaning that parturition occurs year round. However, in the basenji, ovulation only occurs in October, and parturition associated with a resulting pregnancy only occurs in December.
- By contrast, queens are seasonal, long-day breeders; estrous cycles cease during October-December (Northern Hemisphere) unless they are exposed to 14 hours of light (natural and artificial). Parturition associated with any resulting pregnancy could be expected about 65 days from breeding (February-December).

ASSOCIATED CONDITIONS & DISORDERS

- Dystocia
- Premature parturition
- Abortion

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Bitch or queen uncomfortable about 60 days after breeding, may have a vaginal discharge

PHYSICAL EXAM FINDINGS

- In the bitch, rectal temperature is normal to low normal (98°F-100°F; 36°C-37°C) in the hours before parturition and increases to normal or slightly higher than normal during parturition. In the queen, rectal temperature is normal to low normal (100.5°F-102.5°F; 37.8°C-39.3°C), with additional variation based on environment, body condition, and other factors.
- Respiration and heart rates are slightly increased to normal.
- Uterine contractions may be visible through the abdominal wall.
- Examiner may be able to palpate fetuses transabdominally.

ETIOLOGY AND PATHOPHYSIOLOGY

- Three stages of labor:
  - Stage 1: cervical dilation, 3-6 hours
  - Stage 2: fetal expulsion, 3-6 hours (depends upon litter size)
  - Stage 3: placental expulsion, occurs at the same time or within minutes of each fetal expulsion (however, two fetuses and then two placentas may be delivered).
- Dystocia may occur for a variety of reasons (see p. 329).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Parturition is identified when a gravid dam is at term gestation and is showing clinical signs of labor or has began delivering fetuses.

DIFFERENTIAL DIAGNOSIS

- Abortion
- Dystocia
- Pseudopregnancy
- Premature birth
- Pyometra

INITIAL DATABASE

- Pups or kittens are present on abdominal palpation
- Confirmation of fetal skeletons in the normal position and not too large for dam's bony pelvis: abdominal radiography after 42 days' gestation
- Evaluation of fetal distress: see p. 162

ADVANCED OR CONFIRMATORY TESTING

Tocodynamometry can be used for monitoring uterine contractility (see p. 162)

PARTURITION, NORMAL A tocodynamometer used for monitoring uterine contractility in bitches.

TREATMENT

TREATMENT OVERVIEW

- Goal: delivery of healthy puppies or kittens without compromising mother's health
- Bitches and queens with normal parturition do not require any treatment.

ACUTE GENERAL TREATMENT

- In normal parturition, treatment is not needed.
- If parturition is not normal, see p. 329.

NUTRITION/DIET

Administration of a calcium carbonate tablet (e.g., Tums) at the onset of parturition may increase the strength of uterine contractions and prevent dystocia secondary to uterine inertia. However, administration of any calcium supplementation prior to parturition is contraindicated.

BEHAVIOR/EXERCISE

Dams can have unrestricted exercise before and during parturition.

POSSIBLE COMPLICATIONS

If the bitch or queen has prolonged abdominal contractions without delivery of a fetus, or appears to be in constant intense pain, she should be evaluated by a clinician (see p. 162).

RECOMMENDED MONITORING

- Clinicians can monitor the puppy or kitten delivery and be available to assist if needed (e.g., if dystocia occurs, if puppies experience distress).
- Clinicians should make sure a placenta is delivered following each fetus.

PROGNOSIS AND OUTCOME

- Good if parturition is normal
- Fair to guarded in cases of dystocia

PEARLS & CONSIDERATIONS

COMMENTS

- As parturition is a normal process, many animal owners and breeders prefer that the female deliver pups or kittens at home in familiar surroundings.
- Oxytocin treatment should be used only if the cervix is open (see p. 162).
- Dark-green colored lochia or postpartum vaginal discharge before the delivery of any pups in the bitch is an indication of premature placental separation. The bitch should be evaluated for fetal viability by abdominal ultrasonography and may require a caesarean section to remove the fetuses.

PREVENTION

Ovariohysterectomy

TECHNICIAN TIP

- Technicians involved in whelping/queening should be familiar with
  - Basic asepsis and hygiene of neonates
  - Normal neonatal responses that indicate viability (versus signs of distress)
  - Normal maternal behavior
  - Neonatal resuscitation

CLIENT EDUCATION

For prepartum bitches, the client should monitor the rectal temperature two to three times daily beginning at 56 days postbreeding. Rectal temperature decreases by 1°F-2°F (0.5-1°C) about 8-12 hours before whelping.

SUGGESTED READING

AUTHORS: MUSHTAQ A. MEMON, MICHELLE A. KUTZLER

EDITOR: MICHELLE A. KUTZLER

Paresis, Hind Limb

BASIC INFORMATION

DEFINITION

Paraparesis is defined as partial loss of motor function to the pelvic limbs. Para-paralysis or paraplegia is a complete loss of voluntary motor function to the pelvic limbs.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Any species, age, or sex can be affected.

GENETICS & BREED PREDISPOSITION

- Young to middle-aged chondrodystrophoid dogs (e.g., basset hounds, dachshunds, beagles) are predisposed to intervertebral disk disease (IVDD), especially Hansen type I.
- Middle-aged to older nonchondrodystrophoid dogs (e.g., German shepherds) are predisposed to IVDD, especially Hansen type II.
- German shepherds (geriatric) are over-represented in degenerative myelopathy.

CONTAGION & ZOONOSIS: In some cases where underlying etiology is infectious (e.g., rabies)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Hind limb paresis or paralysis can present as difficulty or inability to use the hind limbs due to weakness, ataxia (incoordination), or spasticity (limb stiffness caused by a neurologic lesion). Weakness suggests a lower motor neuron or neuromuscular lesion, whereas spasticity and ataxia suggest an upper motor neuron lesion.

HISTORY, CHIEF COMPLAINT: Inability to walk on the hind leg(s)

PHYSICAL EXAM FINDINGS

- Assessment of the femoral pulse; if absent, consider aortic thromboembolism as a diagnosis.
- Palpation of the bones of limbs, pelvis (including rectal exam in dogs), and vertebral column for fractures/luxations
- Fundic exam: for evidence of multifocal/diffuse central nervous system (CNS) inflammation
- Neurologic injuries: physical findings depend on severity of lesion.
- Gait varies from mild hind limb ataxia to a nonambulatory status without deep pain perception.
- Spinal reflexes (e.g., patellar):
  - Hyporeflexia: lesion in L4-S2 spinal cord segments
  - Hyperreflexia: lesion in T3-L3 spinal cord segments
- Spinal hyperpathia (back pain on palpation):
  - Presence: may indicate IVDD, neoplasia, or trauma
  - Absence: may indicate embolism or degenerative cord process
- Muscle tone:
  - Increased (spasticity): lesion in T3-L3 spinal cord segments
  - Decreased: lesion in L4-S2 spinal cord segments

ETIOLOGY AND PATHOPHYSIOLOGY

- IVDD (see p. 1571):
  - Degenerative disk changes lead to herniation of the nucleus pulposus into the spinal canal.
    - Hansen type I disk rupture: focal, acute myelopathy
    - Hansen type II disk rupture: chronic, progressive disk (annulus) bulging into the spinal canal; chronic, slowly progressive myelopathy
    - Concussive type III disk rupture: high velocity rupture that leaves little residual compression
- Fibrocartilaginous embolization (see p. 392):
  - Herniation of disk material into vertebral body and entrance into the venous plexus
- Degenerative myelopathies (see p. 286:
  - Progressive, diffuse degeneration of spinal cord myelin and axons

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Patients with weakness or motor dysfunction confined to the pelvic limbs most likely have neurologic or orthopedic disease. Definitive diagnosis begins with neurologic and orthopedic exams and usually requires advanced spinal cord imaging (myelogram, CT, MRI)

DIFFERENTIAL DIAGNOSIS

- Acute, nonprogressive: orthopedic intervertebral disk rupture, fracture/luxation, fibrocartilaginous embolism, aortic thromboembolism
- Acute progressive: intervertebral disk rupture (type I), hemorrhagic myelomalacia, neoplasia, infectious/inflammatory (distemper myelitis; bacterial, protozoal, or fungal myelitis; granulomatous meningoencephalitis; feline infectious peritonitis; diskospondylitis)
- Chronic progressive: IVDD (type II), degenerative myelopathies, neoplasia, infectious/inflammatory (as previously stated)

INITIAL DATABASE

- CBC, serum biochemistry panel, urinalysis: may reflect stress or underlying infectious cause (less common)
- Complete orthopedic (see p. 1315), neurologic (see p. 1311) and cardiovascular evaluation to rule out concurrent disease
- Spinal radiographs to evaluate animal for bony lesions such as fracture, neoplasm, or infection

ADVANCED OR CONFIRMATORY TESTING

- Myelogram, CT, or MRI (seepp. 1306 ,1233 , and 1302): spinal cord compression secondary to IVDD or neoplasia or changes consistent with infection
- Cerebrospinal fluid (CSF) analysis (): evidence of infection, inflammation, exfoliating neoplasia
- Serum or CSF titers: to assess for infectious etiologies, especially if initial CSF analysis suggests active inflammation
- CSF culture if indicated by cytologic examination report

TREATMENT

TREATMENT OVERVIEW

Treatment should address the underlying cause: surgical decompression if a compressive lesion is found (IVDD, neoplasia, granuloma, etc.) or medical management as indicated (antibiotics, antiinflammatory medication, antifungal medication). The main goal of treatment is pain relief and resolution of neurologic dysfunction.

ACUTE GENERAL TREATMENT

- Acute traumatic spinal cord injuries (no spinal cord compression): consider initial methylprednisolone (30 mg/kg IV, then 15 mg/kg IV 2 and 4 hours later; if no improvement, consider surgical intervention).
  - Must be given within the first 8 hours to be effective
  - Further evaluation to determine need for surgery
  - Dexamethasone is contraindicated, as there is no evidence of efficacy, and gastrointestinal side effects can be severe.
- Pain secondary to intervertebral disk rupture with no neurologic deficits: consider nonsteroidal antiinflammatory drug (NSAID) at appropriate dose OR tapering course of prednisone (start at 0.5 mg/kg PO q 12 h and decrease by 50% every 5 days) and methocarbamol (20 mg/kg PO q 8 h) for 2 weeks and strict cage confinement for 4 weeks.
- Animals that have neurologic deficits should be evaluated with advanced imaging (myelogram, CT, MRI), followed by surgical decompression if indicated; referral to veterinary surgeon or neurosurgeon is recommended.

CHRONIC TREATMENT

Nursing care:

- Preventing pressure sores, urinary tract infections, muscle atrophy
- Hygiene: providing clean, dry, well-padded bedding
- Performing manual urinary bladder expression or catheterization if not voiding normally
- Performing physical rehabilitation exercises as indicated (seep. 1329)

POSSIBLE COMPLICATIONS

- Methylprednisolone may cause gastrointestinal (GI) ulceration.
- Ascending myelomalacia from severe cord injury is somewhat unpredictable and has a grave prognosis.

RECOMMENDED MONITORING

- Reevaluation of animal's neurologic function at 4-week intervals; duration of reevaluation is based on the animal's progress.
- If the dog remains nonambulatory after weeks or months, without signs of improvement in limb function, a canine cart is an option.

PROGNOSIS AND OUTCOME 

- Based on preoperative neurologic exam and underlying disease
- Acute spinal lesion in an animal with good deep pain perception: fair to excellent for return to near-normal neurologic function with surgery
- If deep pain perception is not present: prognosis is guarded to poor if surgical lesion is addressed in the first 8 hours and poor to grave if after 8 hours.
- Chronic spinal cord compression in an animal with good deep pain perception: guarded to good prognosis, depending on number of lesions and duration of clinical signs, with a prospect of a longer recovery with surgical decompression.
- Nonsurgical spinal cord disease has a variable prognosis depending on underlying etiology.

PEARLS & CONSIDERATIONS 

COMMENTS

Immediate referral to a surgeon or neurosurgeon is warranted for an animal that is decompensating neurologically.

TECHNICIAN TIPS

Care should be taken when moving these patients, especially if clinical signs are acute and history of trauma is unknown.

Two technicians per patient and/or rigid support are recommended.

CLIENT EDUCATION

- Prognosis often guarded, depending on preoperative neurologic examination; potential for prolonged postoperative nursing care.
- It is essential to respect a recommendation of a period of cage rest/confinement.

AUTHOR: SHARON L. SHIELDS

EDITOR: ETIENNE CÔTÉ

Paresis, Forelimb

BASIC INFORMATION

DEFINITION

- Monoparesis: partial loss of motor function to one limb; voluntary movement but will not initiate gait and unable to support weight
- Monoplegia/paralysis: complete loss of motor function to one limb
- Mononeuropathy: disease or injury of a peripheral nerve or its nerve roots

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Weakness, lameness, or inability to use a forelimb

ASSOCIATED DISEASES & DISORDERS

- Horner's syndrome
- Loss of ipsilateral cutaneous trunci (panniculus) reflex
- Self-mutilation/trauma to affected limb

PHYSICAL EXAM FINDINGS

- Lower motor neuron (LMN) signs to the affected limb: weakness and decreased muscle tone
- Variable degree: mild forelimb lameness to complete loss of sensory and motor function
- Denervation atrophy of forelimb musculature, usually within 7-10 days of nerve injury. Differentiate from disuse atrophy, which is slower to develop and generally less severe.
- Nerve root signature: lameness and pain of affected forelimb caused by entrapment of a nerve root within the brachial plexus (see pp. 149 and)
- Suspicion of neoplasia if chronic progressive monoparesis, nerve root signature, and denervation atrophy
- Variable exam findings also may include:
    - Horner's syndrome (ipsilateral); common with traumatic injuries to the brachial plexus
    - Loss of cutaneous trunci (panniculus) reflex (ipsilateral); may be seen with brachial plexus injuries
    - Palpable mass in axilla; uncommon
    - Dysesthesia/paresthesia of limb and secondary self-trauma
    - Traumatic injury/fracture

ETIOLOGY AND PATHOPHYSIOLOGY

- Central nervous system (CNS):
    - Lesions affecting spinal cord segments C6-T2 can cause LMN forelimb signs.
    - Flaccid forelimb monoparesis
    - Basis: injury to LMN cell bodies that innervate forelimb musculature
    - Usually associated with upper motor neuron signs to ipsilateral pelvic limb
- Peripheral nervous system:
    - Spinal/peripheral nerve disorders cause sensory and motor dysfunction distal to the lesion (permanent nerve damage or temporary, self-resolving trauma called neurapraxia).
        - Trauma: brachial plexus avulsion and radial nerve injury as examples
        - Neoplasia: commonly affected are brachial plexus and dorsal nerve roots
- Cervicothoracic spinal cord, nerve roots, sympathetic trunk: Horner's syndrome (ipsilateral)
- Lateral thoracic nerve (C8, T1) disruption causes ipsilateral loss of the panniculus reflex.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A complete orthopedic and neurologic exam (including distribution of sensory loss) is the best means of differentiating musculoskeletal disease from neural involvement. Electromyography and nerve conduction can also aid in confirming the diagnosis

of a nerve injury, determining the distribution, estimating the prognosis and monitoring recovery, though these procedures are uncommonly performed. Advanced imaging (MRI, CT) and/or surgical exploration and biopsy may be necessary to achieve a definitive diagnosis.

DIFFERENTIAL DIAGNOSIS

- CNS
  - Trauma
  - Vascular
  - Neoplasia
  - Infectious
  - Inflammatory
- Peripheral nervous system
  - Trauma
  - Vascular
  - Neoplasia
  - Inflammatory

INITIAL DATABASE

- CBC, serum biochemistry panel, urinalysis: generally unremarkable
- Orthopedic (see p. 1315) and cardiovascular evaluation: rule out concurrent diseases
- Neurologic exam (gait, posture, spinal reflexes; seep. 1311)
  - Distribution and severity of sensory loss aids in localizing the injury to a particular nerve or within 2-3 spinal cord segments: most important test for establishing prognosis for peripheral nerve injuries.
- Forelimb, spinal radiographs (bone fractures, luxations, neoplasia, or infection)

ADVANCED OR CONFIRMATORY TESTING

- Myelogram (see p. 1306) or MRI (see p. 1302) to localize unilateral spinal cord compression (intervertebral disk disease [IVDD] or neoplasia)
- MRI or CT scan to evaluate for nerve/nerve sheath tumors
- Electrodiagnostics (electromyography [EMG], motor nerve conduction [see online chapter: Electromyography and Nerve Conduction Velocity]) to localize the dysfunctional spinal cord segment, nerve root, or peripheral nerve
  - EMG used for determining if LMN, myelin, or muscle fibers are the site of the lesion. Fibrillation potentials, positive sharp waves, and fasciculations can be seen beginning 5 days after denervation.
  - Nerve conduction will be polyphasic and prolonged with LMN disease (with severe loss of myelin sheath) and absent with avulsion injury (or injury resulting in wallerian degeneration).
- Surgical exploration (based on imaging results):
  - Biopsy, histopathologic examination for suspected neoplasia o Evaluation of type, extent, and severity of nerve injury

TREATMENT

TREATMENT OVERVIEW

- Short-term treatment is dictated by the etiology, anatomic localization, and severity of the lesion/injury. Long-term treatment may involve appropriate medications, physical rehabilitation, protection of affected limb from trauma, and an adequate duration of supportive care to allow for recovery/reinnervation.

ACUTE GENERAL TREATMENT

- CNS
  - Trauma; intervertebral disk herniation (see pp. 1039 and)
  - Vascular (see p. 392)
  - Neoplasia; treatment based on tumor type, location, and invasiveness
  - Infectious (e.g., diskospondylitis [])
- Peripheral nervous system
  - Trauma (see pp. 149 and 1016)
  - Surgical management: referral to neurosurgeon for primary nerve repair (lacerated/entrapped nerve). Carpal arthrodesis or transposition of a flexor tendon may be helpful in radial nerve injury.
  - Vascular: ischemic thromboembolic neuromyopathy involving the subclavian or brachial artery
    - Pain management, anticoagulation therapy, treatment of underlying heart disease

- Neoplasia: surgical recommendations depend on the type, location, and invasiveness of the tumor.
- Inflammatory: brachial plexus neuritis (hypertrophic, chronic or idiopathic). Medical management may include prednisolone, chlorambucil versus supportive care only.

CHRONIC TREATMENT

- Physical rehabilitation (see p. 1329); the animal should continue treatment for 3-6 months or until it shows signs of reinnervation.
- Adequate protection of an affected limb to prevent secondary trauma and self-mutilation

POSSIBLE COMPLICATIONS

- Failure to regain adequate function of affected limb
- Local recurrence of nerve root tumors
- Persistent trauma, self-mutilation, or contracture of paretic limb, necessitating amputation

RECOMMENDED MONITORING

- Monitoring of limb daily for signs of trauma or self-mutilation
- Serial neurologic examinations for up to 6 months to evaluate limb for reinnervation
- Serial electrodiagnostics to monitor recovery
- Monitoring for evidence of recurrence of nerve root tumor by physical exam and MRI or CT scan if indicated

PROGNOSIS AND OUTCOME

- Largely depends on the neurologic exam at presentation and response to treatment
- Central
  - Intervertebral disk herniation:
    - Fair to excellent if good deep pain perception
    - Guarded to poor with poor deep pain sensation if addressed within 8 hours
    - Poor to grave if poor deep pain sensation and addressed after 8 hours
  - FCE:
    - Approximately 50% chance for return to function of limb
  - Neoplasia:
    - Guarded to poor based on surgical accessibility and follow-up care
- Peripheral
  - Brachial plexus avulsion:
    - Generally poor; often requires amputation
    - Guarded to fair if deep pain sensation is present
  - Brachial plexus neuritis:
    - Guarded but recovery is possible
  - Peripheral nerve injuries:
    - Fair to good for mild neurologic deficits, sharp lacerations with prompt surgical repair and short distance from site of injury to end organ
    - Guarded to poor for severe neurologic deficits; stretching, crushing, and avulsion injuries; contaminated wounds with delayed surgical repair; and large distance from site of injury to end organ (>12 inches/>30 cm)
  - Ischemic thromboembolic neuromyopathy
    - Prognosis more favorable for forelimb emboli
  - Nerve sheath tumors:
    - Guarded to poor because local recurrence is common

PEARLS & CONSIDERATIONS

COMMENTS

Brachial plexus avulsions with severe traction on the nerve roots may cause damage to the spinal pathways, resulting in pelvic limb deficits that are generally ipsilateral but can be bilateral.

TECHNICIAN TIPS

Fractures or luxations can cause damage to peripheral or spinal nerves. Use caution when manipulating a patient that has suspected fractures or luxations so as to avoid secondary nerve injuries.

CLIENT EDUCATION

- Clinicians should inform clients of prognosis, expected duration of forelimb paresis, and potential for failure to regain adequate function of limb, which necessitates amputation.
- Clinicians should perform or recommend physical rehabilitation techniques.

Paraquat and Diquat Toxicoses

BASIC INFORMATION

DEFINITION

Paraquat and diquat are herbicides with corrosive properties, causing acute gastrointestinal (GI) signs, abdominal pain, and oral mucosal ulcerations when ingested. Delayed pulmonary toxicity (pulmonary fibrosis) occurs with paraquat toxicosis, and central nervous system (CNS) effects can occur with diquat.

SYNONYMS

Paraquat: 1,1′-dimethyl-4,4′-bipyridinium or N,N′-dimethyldipyridyl dichloride

Diquat: 9,10-dihydro-8a,10a-diazoniaphenanthrene dibromide or ethylene dipyridylium dibromide

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs are more commonly involved than cats.

GEOGRAPHY AND SEASONALITY: Accidental poisonings are more common during growing seasons; paraquat has been used year round for malicious poisonings in dogs.

CONTAGION/ZOONOSIS: Paraquat penetrates transcutaneously in animals and humans; users and veterinary personnel should wear gloves and protective clothing.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Known/suspected exposure to paraquat or diquat herbicide
- Clinical signs within hours to days after exposure; with acute ingestions, neurologic signs may occur within 2-6 hours, whereas the respiratory effects are seen in 3-5 days
- Paraquat: vomiting (all cases), lethargy, anorexia, diarrhea, ataxia; eventually, tachypnea and respiratory distress are apparent.
- Diquat: vomiting, lethargy, anorexia, diarrhea, ataxia

PHYSICAL EXAM FINDINGS

- Paraquat: initially, patient may experience oral, esophageal, and gastric irritation leading to ulceration; abdominal pain; dermatitis if topical contact. Patient may then experience hypotension, arrhythmias, weakness, and disorientation/depression due to cerebral edema. Onset of cough, dyspnea, and hemoptysis may occur 3-14 days after ingestion.
- Diquat: oral/pharyngeal mucosal ulceration, oliguria/anuria, dermal irritation/burns, weakness, coma; rarely, arrhythmias, seizures, and dyspnea due to noncardiogenic pulmonary edema.

ETIOLOGY AND PATHOPHYSIOLOGY

- Paraquat concentrates in lung tissue (type I and II pneumocytes). Free radicals are produced, causing cellular injury (especially pulmonary, GI, renal, and erythrocytic). Cell wall injury leads to mononuclear macrophage activation and, notably, pulmonary fibrosis, which can be fatal 3-14 days after ingestion. Paraquat is a restricted-use pesticide (RUP) owing to its toxicity; only certified applicators can purchase and use the product.
- The mechanism of diquat toxicity is similar, but diquat does not accumulate in the lungs (no pulmonary fibrosis); instead, diquat may cause cerebral hemorrhage, coma, and renal failure.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The clinical diagnosis is made from history and physical exam: observed or suspected exposure, typically in a patient with fresh oral ulcers. Delayed pulmonary effects (3-5 days from paraquat) and CNS signs (hours after exposure to diquat) help support the diagnosis during/after treatment. Definitive diagnosis is possible through toxicologic analysis of vomitus, bait, blood, plasma, or other tissues (liver) within 48 hours of exposure.

DIFFERENTIAL DIAGNOSIS

- Toxicosis involving any caustic or corrosive agent (acids, alkali, cationic detergents, potpourri)
- Kidney disease/renal failure (uremic ulcers)

INITIAL DATABASE

- Paraquat:
  - CBC: neutrophilia, monocytosis, lymphopenia
  - Serum biochemistry panel: moderate increases in blood urea nitrogen (BUN), aspartate aminotransferase, and alanine aminotransferase in 24-96 hours and slight increases in total protein, creatinine, cholesterol, and bilirubin
  - Urinalysis: myoglobinuria (from rhabdomyolysis); proteinuria, hematuria (acute renal injury)
  - Thoracic radiographs: initially normal, progressing to noncardiogenic pulmonary edema (marked interstitial lung pattern); pneumomediastinum is a common, early finding.
- Diquat: serum biochemistry panel shows BUN, creatinine elevations (within 24-96 hours) and liver enzyme elevations

ADVANCED OR CONFIRMATORY TESTING

- Analysis of vomitus, bait, plasma, blood, tissues, urine: samples must be obtained within 48 hours of exposure, because initial excretion is rapid; contact the laboratory first.
- Histopathologic lesions:
  - Paraquat: marked pulmonary edema, hemorrhage, congestion, eventually fibrosis; mild hepatic congestion, degeneration; mild renal tubular degeneration, glomerulonephritis
  - Diquat: myocardial necrosis, cerebral hemorrhages, renal tubular damage

TREATMENT

TREATMENT OVERVIEW

Since no antidote exists for either substance, treatment is general and supportive.

ACUTE AND CHRONIC TREATMENT

- Decontamination of the animal:
  - Paraquat:
    - Emesis: induction of vomiting (see p. 1364) as soon as possible after ingestion, even though paraquat can be irritating or corrosive to the esophagus; the possible benefits of early removal outweigh the potential risks.
    - Fuller's earth or bentonite (either is a preferred choice over activated charcoal, because they bind paraquat/diquat more effectively, but most clinics do not carry them) or activated charcoal (1-4 g/kg q 4-8 h) can be used as an adsorbent and are most useful if given PO within 4 hours of exposure. Multiple doses are recommended.
    - Clinicians should bathe the entire patient if there is any dermal exposure. Paraquat is absorbed well through abraded or injured skin (wear protective clothing).
    - With ocular exposures, irrigate eyes with copious amounts of tepid water for at least 15 to 30 minutes (see p. 250).
  - Diquat
    - Induction of vomiting is usually not recommended unless the patient has been exposed to a very large dose of the toxin.
    - Activated charcoal, bentonite clay, or Fuller's earth: same dosage as for paraquat
    - With dermal exposure, the animal's skin should be immediately washed with soap and water. Diquat can be absorbed through damaged or injured skin, resulting in systemic poisoning. Absorption through intact skin is minimal.
    - Ocular exposures: same treatment as for paraquat
- Supportive care:
  - IV fluids as indicated to correct hypovolemia, electrolyte changes associated with vomiting
  - Control pain as needed (e.g., for dogs/cats: buprenorphine, 0.005-0.03 mg/kg IV, IM, or SQ q 6-12 h; or fentanyl patch).

- Ascorbic acid (antioxidant), 20-30 mg/kg IM, IV, or PO q 8 h, may be useful.
- Avoid supplemental oxygen therapy because it increases the formation of superoxide free radicals.
- Control vomiting as needed with maropitant, 1 mg/kg SQ q 24 h; or metoclopramide, 0.1-0.4 mg/kg SQ or IM q 6 h.
- Treatment of ventricular arrhythmias (see p. 1165), seizures (see p. 1009), secondary infections, oral ulcers (see), gastric ulcers (see), and renal complications (see p. 31) as needed.
- Positive-pressure ventilation (see p. 1362) may be used, but lung lesion may become (or may already be) irreversible.

POSSIBLE COMPLICATIONS

- Paraquat: pneumothorax, pneumopericardium, and subcutaneous emphysema
- Diquat: pneumonia, renal failure

RECOMMENDED MONITORING

- Paraquat: baseline thoracic radiographs and blood gases and serial monitoring for several days (CBC and renal and liver panels)
- Diquat: renal values (monitor for 3-4 days with large ingestions) and monitor CBC, liver enzymes, and electrolytes.

PROGNOSIS AND OUTCOME

- Paraquat: outcome appears to be related to dose and early intervention (decontamination of animal); poor prognosis for affected animals showing any clinical signs; those that survive the acute toxicosis often succumb to chronic pulmonary fibrosis.
- Diquat: good prognosis with early and aggressive treatment

PEARLS & CONSIDERATIONS

COMMENTS

- Paraquat LD50 (dogs, oral) 25-50 mg/kg
- Diquat LD50 (dogs, oral) 100 mg/kg
- Concentration of diquat in most ready-to-use weed and grass killer products is <1%. Systemic effects from these products is highly unlikely with casual exposure (e.g., dog walking through the sprayed area when it was still wet or dog licking the grass after spray) unless large amounts have been ingested from the container.

TECHNICIAN TIP

As with most ingestions of toxic material, knowing which toxin is involved allows for accurate treatment and prognostication. Therefore, clients telephoning because their dogs or cats have ingested a foreign substance should be encouraged to bring the container or label along with the patient.

PREVENTION

Keep animals away from all herbicides until dry; dipyridyl herbicides are rapidly and completely inactivated in the soil.

CLIENT EDUCATION

Follow label directions on all herbicides.

AUTHOR: HANY YOUSSEF

EDITOR: SAFDAR A. KHAN

1ST EDITION AUTHOR: TINA WISMER

Paraphimosis

BASIC INFORMATION

DEFINITION

Inability to retract the penis into the prepuce

SYNONYM

Penile protrusion

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Young, intact male dogs > castrated male dogs; rare in cats
- 4 months to 13 years of age (average: 2.9 years)

GENETICS & BREED PREDISPOSITION

- Boxer, Chihuahua, cocker spaniel, Doberman, German shepherd, German short-haired pointer, Great Pyrenees, Labrador retriever, poodle, and mixed-breed dogs
- Boxers (n = 4), poodles (n = 2), and mixed-breed dogs (n = 12) have had more than one case reported.

RISK FACTORS

- Developmental preputial anomalies (e.g., small preputial opening, aplastic or hypoplastic prepuce, hypospadias [urethra opening is on the ventral penis or perineum], male pseudohermaphroditism)
- Infectious (e.g., transmissible venereal tumor, balanoposthitis)
- Neurologic deficits associated with posterior paresis (e.g., intervertebral disk disease [IVDD], spinal tumors)
- Trauma (e.g., os penis fracture)

CONTAGION & ZOONOSIS

Transmissible venereal tumor preventing penile retraction

ASSOCIATED CONDITIONS & DISORDERS

- Balanoposthitis: inflammation of the glans penis (balanitis) and preputial mucosa (posthitis)
- Phimosis: inability to extrude the penis from the prepuce (paraphimosis occurs 14 times more frequently than phimosis in the dog)
- Priapism: prolonged penile erection with or without sexual arousal

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Acute paraphimosis usually resolves within 12 hours; chronic paraphimosis may be intermittent or continuous.

HISTORY, CHIEF COMPLAINT: History may include recent mating, penile or preputial trauma, masturbation, balanoposthitis, neurologic disease, and/or promazine tranquilizer administration.

PHYSICAL EXAM FINDINGS

- Protrusion of the penis from the prepuce: extent of penile protrusion can vary from only the apex to the entire length of the penis.
- Penile mucosa may be erythematous, dry, inflamed, edematous, ischemic, and painful, which may lead to self-mutilation. Chronic protrusion of the penis may lead to excoriation and subsequent cornification of the mucosa.

ETIOLOGY AND PATHOPHYSIOLOGY

- Most commonly associated with a relatively stenotic preputial orifice or with ineffective preputial musculature that cannot effectively retract the penis into the prepuce; hair ring or scar tissue also possible.
    - Following sexual excitement or copulation, the engorged penis may become entrapped outside the prepuce, causing penile strangulation, congestion, and paraphimosis.
    - Cranial preputial muscles (paired muscles originating from the cutaneous trunci) draw the prepuce cranially, normally about 1 cm beyond the tip of the penis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Paraphimosis is diagnosed conclusively on physical exam alone. Additional testing may help elucidate the cause, although in dogs roughly 30% of cases are idiopathic.

DIFFERENTIAL DIAGNOSIS

- Balanoposthitis
- Phimosis
- Priapism

INITIAL DATABASE

Neurologic exam (see p. 1311) with specific attention to posterior peripheral motor and sensory function.

ADVANCED OR CONFIRMATORY TESTING

- Electromyographic testing and/or histopathologic evaluation of cranial preputial muscles: to identify abnormal function or cellular architecture; rarely necessary
- Radiographs: to identify concomitant os penis fracture

TREATMENT

TREATMENT OVERVIEW

Paraphimosis is an emergency condition. Immediate treatment should protect the penile mucosa, prevent additional swelling (edema, inflammation) and trauma, and return the penis within the prepuce as quickly as possible. The underlying cause is then addressed to reduce the risk of recurrence.

ACUTE GENERAL TREATMENT

- Conservative: reduction of penis size via topical cold compresses, topical hyperosmotic solutions (e.g., sugar, honey), and systemic antiinflammatory therapy (e.g., prednisolone sodium succinate [SoluDeltaCortef] 10 mg/kg slow IV bolus)
- Passage of urinary catheter: to ensure patency of urethra
- If paraphimosis occurred secondarily to promazine-induced priapism, benztropine mesylate (0.015 mg/kg IV) should be administered as soon as possible (i.e., within 6 hours of onset of clinical signs).
- Removal of hair from around the preputial orifice
- Manual replacement of the penis in the preputial sheath using lubrication and gentle digital pressure. If unsuccessful, emergency surgical intervention is required.

CHRONIC TREATMENT

Surgical intervention:

- Attempt manual reduction under general anesthesia.
- If unsuccessful, incisional enlargement of preputial orifice and retraction of penis within prepuce
- Options for preserving reduction: purse-string suture at the preputial orifice, preputial orifice narrowing, preputial lengthening (preputioplasty), preputial advancement, preputial muscle myorrhaphy, and phallopexy. None entirely eliminates the possibility of recurrence.

- Chronic paraphimosis can be eliminated with amputation of the penis and concurrent scrotal urethrostomy.
- Castration is often performed in conjunction with surgical correction of paraphimosis, but castration alone is not successful in correcting paraphimosis.

BEHAVIOR/EXERCISE

Affected intact males should be separated from estrous females for at least 4 weeks afterward. Efforts should be made to prevent excessive licking of the penile and prepuce that may result in self-mutilation.

POSSIBLE COMPLICATIONS

- Erection and ejaculation may be impaired following longstanding paraphimosis.
- Balanoposthitis secondary to phimosis may occur following surgical retention of the penis within the preputial cavity.
- Urethral stricture formation and recurrent urinary tract infections may result following penile amputation.

PROGNOSIS AND OUTCOME

The prognosis is good to guarded for the resolution of paraphimosis, depending on the severity and duration of clinical signs.

PEARLS & CONSIDERATIONS

COMMENTS

Dogs with developmental preputial conditions associated with paraphimosis should not be used for breeding.

PREVENTION

- Hairs around the preputial orifice should be kept short in long-haired dogs.
- Following mating or semen collection, application of a topical lubricant to penile mucosa around the preputial opening will prevent inversion of the prepuce during detumescence (natural resolution of erection and penile retraction).

PARAPHIMOSIS Ventral caudal abdomen of a longhaired male dog; cranial is to the top of the image. Following semen collection for an infertility evaluation, this dog developed paraphimosis secondary to inversion of the prepuce during detumescence. This was resolved quickly with application of a topical lubricant to penile mucosa near the preputial opening and gently sliding the prepuce over the swollen glans penis.

CLIENT EDUCATION

Paraphimosis may occur as a learned behavior secondary to penile licking (masturbation). Owners should be cautioned not to promote paraphimosis by positive behavioral reinforcement.

SUGGESTED READING

Paraneoplastic Syndromes

BASIC INFORMATION

DEFINITION

Pathologic change in structure or function which develops secondary to and distant from a primary neoplasm. Certain paraneoplastic syndromes (PNS) occur very frequently, whereas others are rare. PNS mostly commonly arise secondary to hormonal or other cytokine factors produced by the tumor. In some instances, the PNS can be more harmful than the physical tumor.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Both canine and feline patients may experience PNS. In most cases, there is no sex predilection, with few exceptions (e.g., feline acromegaly in association with pituitary adenomas occurs more commonly in males).

GENETICS & BREED PREDISPOSITION

- PNS are rarely directly induced by genetic factors, with occasional exceptions (e.g., nodular dermatofibrosis associated with autosomal dominant heritable mutation of Birt-Hogg-Dube gene in German Shepherds). Affected dogs commonly develop bilateral renal cysts or cystadenocarcinomas. Female dogs may also develop uterine leiomyoma.
- Certain purebreds are predisposed to individual cancers, so incidence of PNS will be relatively higher (e.g., boxer has higher incidence of T-cell lymphoma; boxer, pug, Labrador retriever have higher incidence of mast cell tumors).

RISK FACTORS: Individual PNS associated with specific tumors:

- Hypercalcemia: T-cell lymphoma, anal sac apocrine gland adenocarcinoma, and parathyroid adenoma most common. Also reported sporadically with malignant melanoma, squamous cell carcinoma, mammary adenocarcinoma, thyroid carcinoma, bronchoalveolar carcinoma, multiple myeloma, and others.
- Cachexia: multiple tumor types
- Hypoglycemia: beta-cell tumor (insulinoma), gastrointestinal leiomyosarcoma, hepatocellular carcinoma most common; others sporadically
- Gastroduodenal ulceration: mast cell tumor (MCT), pancreatic gastrinoma (Zollinger-Ellison syndrome)
- Erythrocytosis: renal tumors, nasal fibrosarcoma
- Disseminated intravascular coagulopathy: hemangiosarcoma, acute leukemia, lymphoma
- Hyperviscosity syndrome: multiple myeloma, lymphoma, leukemia, primary polycythemia
- Hyperadrenocorticism: pituitary adenoma, primary adrenocortical adenoma/carcinoma
- Cardiac arrhythmias/altered blood pressure: pheochromocytoma, hemangiosarcoma
- Anemia: hemangiosarcoma, lymphoma, leukemia, multiple myeloma, estrogen-producing tumors (Sertoli cell), other chronic neoplasia
- Thrombocytopenia: lymphoma, leukemia, multiple myeloma, hemangiosarcoma
- Leukocytosis: lung tumor, renal transitional cell carcinoma (TCC)
- Peripheral neuropathy: many tumors
- Alopecia: pancreatic carcinoma
- Hypertrophic osteopathy: lung tumor (primary or metastatic), Sertoli cell tumor, renal TCC, nephroblastoma, adrenocortical carcinoma
- Myasthenia gravis: thymoma
- Acromegaly: pituitary adenoma (cats), mammary adenocarcinoma (dogs)
- Superficial necrolytic dermatitis (hepatocutaneous syndrome): glucagonoma

ASSOCIATED CONDITIONS & DISORDERS

- Chronic hypercalcemia can result in renal failure via tubular mineralization and ischemic damage.
- Hyperglobulinemia/hyperviscosity syndrome can lead to coagulopathy and hypertension, resulting in retinal detachment, seizures, renal infarction, cerebral/pulmonary thromboembolism, congestive heart failure.
- Hypoglycemia usually causes depression, ataxia, and seizures.
- Gastroduodenal ulceration from excessive histamine-induced gastric hydrochloric acid (HCl) production results in melena, hematemesis, and anemia.
- Pancytopenia predisposes patients to opportunistic infections and spontaneous hemorrhage.
- Myasthenia gravis-induced megaesophagus predisposes to aspiration pneumonia.
- Hypertrophic osteopathy causes fever and lameness.

- Hyperadrenocorticism may predispose to thromboembolism.
- Acromegaly commonly causes insulin resistance, hypertrophic cardiomyopathy, and renal failure.
- Hepatocutaneous syndrome results in superficial necrolytic dermatitis of skin, paw pads.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Hypercalcemia: most common clinical signs include polyuria and polydipsia (PU/PD). Patients may also be lethargic with inappetence, vomiting from renal failure.
- Cachexia: patient has profound loss of lean body mass, often despite normal appetite.
- Hyperviscosity syndrome: presenting clinical signs depend on organ system(s) affected: seizures, blindness, syncope, dyspnea.
- Hypoglycemia: depression, ataxia, and seizures
- Gastroduodenal ulceration: anorexia, melena, hematemesis
- Myasthenia gravis: regurgitation, dyspnea, weakness/collapse
- Hypertrophic osteopathy: lameness, lethargy
- Hyperadrenocorticism: PU/PD, polyphagia, bilaterally symmetric hair loss, muscle wasting, pot-bellied appearance, comedones
- Acromegaly: PU/PD, weight gain, enlarged head and limbs
- Peripheral neuropathy: cranial nerve deficits, altered proprioception, urinary/fecal incontinence
- Superficial necrolytic dermatitis: ulcerated cutaneous lesions, cracked/painful paw pads

PHYSICAL EXAM FINDINGS: Dependent on tumor type; see History, Chief Complaint

ETIOLOGY AND PATHOPHYSIOLOGY

- Hypercalcemia: due to excessive parathyroid hormone (PTH) production by parathyroid adenomas or humoral production of PTH-related peptide (PTHrp) and other cytokines (interleukin [IL]-1, transforming growth factor [TGF]-β), prostaglandins, and receptor activator of nuclear factor κB ligand (RANKL)
- Cachexia: complex metabolic derangement due to altered cytokine milieu (especially increased IL-1β, IL-6, tumor necrosis factor [TNF]-a), increased anaerobic glycolysis, and misappropriation of nutrients
- Hypoglycemia: due to excessive insulin or insulin-like growth factor 1 (IGF-1) production
- Gastroduodenal ulceration: most commonly result of hyperhistaminemia leading to excessive gastric acid in mast cell tumors and rarely hypergastrinemia in pancreatic gastrinoma
- Erythrocytosis: due to excessive production of erythropoietin (Epo)
- Bleeding disorder: due to antibody coating of platelets, platelet loss/sequestration/consumption, or inappropriate activation of the secondary coagulation cascade
- Hyperviscosity syndrome: due to excessive immunoglobulin production and subsequent antibody coating of red blood cells, leading to aggregation
- Hyperadrenocorticism: due to excessive cortisol production in adrenal glands; most commonly due to excessive ACTH release from pituitary tumors but may also be primarily produced by adrenal tumors, or rarely ectopically
- Cardiac arrhythmias/altered blood pressure: due to excessive catecholamine production, hypoxia, sepsis
- Cytopenias: due to hemorrhage, chronic inflammation, immune-mediated hemolysis, hormone-induced suppression, myelophthisis
- Leukocytosis: due to excessive production of granulocyte-macrophage colony stimulating factor (GM-CSF) or G-CSF
- Myasthenia gravis: due to antibody production targeted against acetylcholine receptors at neuromuscular junctions
- Acromegaly: due to excessive growth hormone (GH) production

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Definitive diagnosis of PNS requires observation of associated clinical signs, documentation of syndrome with laboratory testing when applicable, and confirmation of underlying cancer.

DIFFERENTIAL DIAGNOSIS

- Hypercalcemia: granulomatous disease, hypoadrenocorticism, renal secondary hyperparathyroidism, hypervitaminosis D, young/growing, spurious, osteogenic disease
- Cachexia: intestinal parasites, poor-quality diet, inadequate feeding, malabsorptive/maldigestive disorder
- Hypoglycemia: sepsis, iatrogenic (insulin overdose), spurious/old sample

- Gastroduodenal ulceration: nonsteroidal antiinflammatory medications (NSAIDs), corticosteroids, foreign body, toxin ingestion
- Erythrocytosis: hemoconcentration, breed-related variation (greyhounds, sled dogs)
- Bleeding disorder: anticoagulant rodenticide ingestion, sepsis, idiopathic immune-mediated thrombocytopenia
- Hyperadrenocorticism: iatrogenic (corticosteroid administration)
- Cardiac arrhythmias/altered blood pressure: primary cardiac disease, renal failure
- Cytopenias: infectious disease (especially *Rickettsiae)*
- Myasthenia gravis: hypothyroidism, hypoadrenocorticism, lead intoxication, esophagitis, idiopathic

INITIAL DATABASE

CBC, serum chemistry panel, urinalysis, coagulation profile, thoracic radiographs, abdominal ultrasound, tumor aspiration/biopsy to confirm neoplasia

ADVANCED OR CONFIRMATORY TESTING

- Hypercalcemia: measure PTH/PTHrp and ionized calcium to identify inappropriate function of hormone axis; parathyroid gland ultrasound to identify tumor; bone marrow aspiration to identify sequestered neoplasia.
- Hypoglycemia: measure serum insulin. Concentration should be below reference range; if level is high or within reference range with concurrent hypoglycemia, this suggests inappropriate function of the hormonal feedback axis.
- Pancytopenia: bone marrow aspiration to evaluate for infiltrative disease versus maturation arrest of cell lines
- Hyperviscosity syndrome: serum/urine protein electrophoresis to document monoclonal gammopathy
- Hyperadrenocorticism: urine cortisol/creatinine ratio, ACTH stimulation test, dexamethasone suppression test, endogenous ACTH to identify inappropriate function of pituitary-adrenal hormone axis.
- Myasthenia gravis: measure serum acetylcholine receptor antibody titer to prove autoimmunity.
- Acromegaly: measure serum GH, IGF-1 to confirm inappropriate hormone secretion.

TREATMENT

TREATMENT OVERVIEW

The severity of a PNS tends to parallel the status of the neoplasm. Direct treatment of the primary tumor (surgical excision, chemotherapy, or radiation therapy) should be the ultimate goal and usually causes resolution of the PNS. However, in some cases, the patient may be debilitated by the PNS and initially unable to undergo definitive therapy. Other supportive measures include the following:

- Hypercalcemia: saline diuresis, loop diuretics, corticosteroids, bisphosphonates, calcitonin to reduce serum calcium to normal range and/or to alleviate clinical signs
- Hyperviscosity syndrome: phlebotomy, plasmapheresis to reduce serum globulins to normal range
- Gastroduodenal ulceration: gastroprotectants (histamine receptor antagonists, proton pump inhibitors, coating agents, prostaglandin analogues) to reduce gastric HCl production; antiemetics, antidiarrheals as needed
- Myasthenia gravis: cholinesterase inhibitors and/or immunosuppressive therapy to improve esophageal muscular tone; upright feedings versus permanent gastrostomy tube to reduce risk of aspiration
- Cytopenias: blood product transfusion as needed; prophylactic antibiotics to prevent opportunistic infection in neutropenic patients
- Hypoglycemia: dextrose, corticosteroids, and diazoxide to increase serum glucose concentration; small frequent meals with complex carbohydrates to prevent spikes in serum glucose
- Seizures: anticonvulsant medications, corticosteroids, and mannitol as needed for increased intracranial pressure
- Hypertrophic osteopathy: analgesic medications such as NSAIDs, opioids, bisphosphonates as needed

PROGNOSIS AND OUTCOME

Usually dependent on individual tumor type, although some PNS influence long-term prognosis:

- Hypercalcemia shortens survival in lymphoma +/− anal sac apocrine gland adenocarcinoma.
- Myasthenia gravis: megaesophagus shortens survival in thymoma.
- Gastroduodenal ulceration: patients with MCT and clinical signs have shorter survival.

PEARLS & CONSIDERATIONS

COMMENTS

- Recrudescence of a PNS can indicate cancer relapse.
- If cause for hypercalcemia cannot be determined based on history and baseline diagnostic testing, consider bone marrow aspiration to investigate occult neoplasia.

TECHNICIAN TIPS

- PNS can cause clinical signs not typically associated with individual cancer types.
- Understanding the dynamic behavior of PNS can be helpful in distinguishing recurrence of cancer from treatment-related complications.

Paraneoplastic Syndromes, Cutaneous

BASIC INFORMATION

DEFINITION

Uncommon non-neoplastic skin lesions that serve as markers for internal neoplasia

SYNONYMS

Exfoliative dermatitis, nodular dermatofibrosis, paraneoplastic alopecia, paraneoplastic pemphigus

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Paraneoplastic alopecia: older cats (7-16 years)
- Exfoliative dermatitis: middle-aged to old cats
- Nodular dermatofibrosis: middle-aged dogs (3-9 years)
- Paraneoplastic pemphigus: dogs

GENETICS & BREED PREDISPOSITION: Nodular dermatofibrosis: German shepherds, autosomal dominant inheritance

ASSOCIATED CONDITIONS & DISORDERS

- Paraneoplastic alopecia (cats): pancreatic carcinoma, bile duct carcinoma, hepatocellular carcinoma
- Exfoliative dermatitis (cats): thymoma
- Nodular dermatofibrosis (dogs): renal cystadenocarcinomas/cystadenomas, polycystic kidneys, concurrent uterine leiomyoma
- Paraneoplastic pemphigus (dogs): lymphoma, Sertoli cell tumor, mammary carcinoma

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Paraneoplastic alopecia: progressive alopecia, weight loss, lethargy, excessive grooming. The alopecia may be noted as the first manifestation (harbinger) of internal neoplasia. Internal disease is often advanced at the time of presentation, but the chief complaint commonly relates to alopecia.
- Exfoliative dermatitis: scaling dermatitis; alopecia; brown, waxy deposits noted on the skin
- Nodular dermatofibrosis: cutaneous nodules on the limbs, head
- Paraneoplastic pemphigus: anorexia, ptyalism, erosive/ulcerative skin and mucosal lesions

PHYSICAL EXAM FINDINGS

- Paraneoplastic alopecia: nonpruritic symmetric alopecia on ventrum, legs, face, and neck; glistening skin; fur epilates easily; dry, fissured footpads; erythema; scale; + dehydration, emaciation
- Exfoliative dermatitis: nonpruritic scaling dermatitis on pinnae, head, generalized; variable alopecia; brown, waxy deposits around mucocutaneous areas, nail beds; variable erythema
- Nodular dermatofibrosis: nonpainful, firm cutaneous nodules on extremities; also present on the head, neck, ventral trunk
- Paraneoplastic pemphigus: depressed attitude; ulcers and erosions of the oral mucosa, mucocutaneous junctions

PARANEOPLASTIC SYNDROMES, CUTANEOUS Paraneoplastic alopecia in a 14-year-old cat with pancreatic adenocarcinoma.

(Copyright Dr. Manon Paradis.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Paraneoplastic alopecia: pathogenesis may involve cytokine production, leading to atrophy of hair follicles.
- Exfoliative dermatosis: a tumor-induced immune-mediated process has been suggested.
- Nodular dermatofibrosis: collagen production within the skin may be stimulated by growth factors produced by the renal tumors; lesions develop separately through a common genetic abnormality, or simultaneous fibrosis of the skin and kidneys results in collagenous nevi and renal outflow obstruction.
- Paraneoplastic pemphigus: cross-reactivity between tumor antigen and self-antigen or secretion of excessive immunostimulatory cytokines may be involved.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The association between cutaneous lesions and internal neoplasia should be remembered (but not overinterpreted) to avoid under-and overdiagnosis of these syndromes. Diagnosis of the different cutaneous paraneoplastic syndromes is confirmed with skin biopsy and dermatohistopathologic evaluation. The histologic diagnosis of the skin lesions then suggests which underlying metabolic derangement or internal neoplasm to pursue as the cause of the paraneoplastic disorder.

DIFFERENTIAL DIAGNOSIS

- Paraneoplastic alopecia: demodicosis, dermatophytosis, endocrine (hyperadrenocorticism, hyperthyroidism, hypothyroidism), immune-mediated (alopecia areata), neoplasia, telogen effluvium
- Exfoliative dermatosis: demodicosis, infectious agents (dermatophytosis, bacterial infections, feline leukemia virus [FeLV] infection), hypersensitivities, cutaneous drug reactions, autoimmune disorders, neoplasia (cutaneous lymphoma)
- Nodular dermatofibrosis: primary cutaneous neoplasms
- Paraneoplastic pemphigus: pemphigus vulgaris, bullous pemphigoid, systemic lupus erythematosus, erythema multiforme, toxic epidermal necrolysis, cutaneous lymphoma

INITIAL DATABASE

- CBC, serum biochemical panel, and urinalysis. Nonspecific changes may be noted.
- FeLV and feline immunodeficiency virus (FIV) serologic examination is indicated in all cats, but these neoplasms are not expected to be associated with seropositive status.
- Paraneoplastic alopecia:
    - Dermatohistopathologic examination: hair follicle atrophy, telogenization, hyperkeratosis, or hypokeratosis
    - Abdominal ultrasonography: liver or pancreatic lesions due to neoplasia
- Exfoliative dermatosis:
    - Dermatohistopathologic examination: cell-poor interface dermatitis with apoptotic keratinocytes in the stratum basal and stratum spinosum layers
    - Thoracic radiographs/ultrasound: mediastinal mass

- Nodular dermatofibrosis:
  - Dermatohistopathologic examination: nodular areas of collagenous hyperplasia
  - Abdominal imaging: renal cysts, renal masses (neoplasms), or uterine masses (neoplasms)
- Paraneoplastic pemphigus:
  - Dermatohistopathologic examination: intraepithelial acantholysis, apoptotic keratinocytes, vacuolar interface dermatitis
  - Abdominal and thoracic imaging: masses (primary neoplasm, metastases)

ADVANCED OR CONFIRMATORY TESTING

- Paraneoplastic alopecia:
  - Exploratory laparotomy with pancreatic, liver or biliary tract biopsies
- Exfoliative dermatosis:
  - Fine-needle aspiration of the mediastinal mass and cytologic examination
  - Core biopsies of the mediastinal mass
- Nodular dermatofibrosis:
  - Biopsy of renal masses
- Paraneoplastic pemphigus:
  - Biopsy of tumor
  - Indirect immunofluorescence testing: Positive on stratified and nonstratified squamous epithelia
  - Western blot analysis; target antigen proteins include envoplakin (210 kD), periplakin (190 kD), desmoglein lll (130 kD), and an unidentified antigen (170 kD)

TREATMENT

TREATMENT OVERVIEW

The goal of treatment is to resolve the primary neoplasm if possible, since control or resolution of the cutaneous lesions is ultimately dependent on control or resolution of the underlying internal neoplasm. Palliative care for dermatologic lesions should be provided.

ACUTE GENERAL TREATMENT

- Paraneoplastic alopecia: surgical excision of neoplasm, if possible
- Exfoliative dermatosis: surgical excision of thymoma
- Nodular dermatofibrosis: unilateral nephrectomy is rarely curative but is indicated if renal cysts are severe; bilateral renal disease is common.
- Paraneoplastic pemphigus: none reported

CHRONIC TREATMENT

Nodular dermatofibrosis: surgical excision of collagenous nevi until end-stage renal failure develops

PROGNOSIS AND OUTCOME

- Paraneoplastic alopecia: grave; euthanasia due to advanced disease
- Exfoliative dermatosis: guarded; outcome depends on complete thymoma removal
- Nodular dermatofibrosis: poor for long-term survival; slowly progressive renal disease; average lifespan: 9 years of age
- Paraneoplastic pemphigus: grave unless neoplasm can be removed; euthanasia for failure to respond to immunosuppression

PEARLS & CONSIDERATIONS

COMMENTS

- Cutaneous clinical signs represent the “tip of the iceberg.”
- Internal disease is often advanced at the time of presentation.
- Earlier recognition may improve outcome in some cases (at least in thymoma).
- Nodular dermatofibrosis may precede clinical signs of renal disease by 3-5 years and does not warrant immediate consideration of euthanasia.

AUTHOR: STEPHANIE R. BRUNER

EDITOR: MANON PARADIS

Papillomas, Oral and Cutaneous

BASIC INFORMATION

DEFINITION

Benign tumors of the skin and oral cavity caused by site-specific papilloma viruses (see p. 786)

SYNONYMS

Lentiginosis profuse, papillomas, pigmented epidermal nevi, verrucae, warts

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Young dogs (6 months to 4 years) or immunocompromised adults
- Cutaneous papillomas are more often seen in males, likely due to their aggressive interactive behavior.

GENETICS & BREED PREDISPOSITION

- Cutaneous papillomas: cocker spaniels, Kerry blue terriers
- Pigmented sessile papillomas: miniature Schnauzers and pugs

RISK FACTORS

- Young and immunologically naive individuals with damaged skin or mucous membranes
- Immunosuppressed individuals (chronic use of glucocorticoids and/or oral cyclosporine)

CONTAGION & ZOONOSIS: Contagious to other dogs via direct and indirect (fomite) contact but not to humans or cats

ASSOCIATED CONDITIONS & DISORDERS

- Hyperadrenocorticism
- Squamous cell carcinoma (SCC)
- Bowen's disease (SCC in situ, cats)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Oral: owner-observed intraoral nodule(s); oral discomfort, dysphagia, halitosis, and ptyalism
- Cutaneous: owner-observed cutaneous growth that often involves a distal extremity and may bleed if scratched or chewed upon; occasional lameness (footpad)

PHYSICAL EXAM FINDINGS

- Canine oral papilloma virus (COPV) presents with multiple growths in the oral cavity (a few millimeters to 1 cm in diameter). Initially develop as smooth white nodules before progressing to gray pedunculated masses with fronds.
- In contrast, cutaneous lesions are normally solitary and can either present as:
    - Pedunculated growth with multiple fronds; found anywhere on the body (head, eyelids, and feet most commonly affected); rarely >1 cm diameter
    - Inverted papilloma with a small pore opening (ventral trunk and abdomen most common); typically 1-2 cm diameter
    - Pigmented sessile plaques/nevi/lentigines dispersed in numbers from 3 or 4 up to 80, involving the ventral neck, trunk, and medial surfaces of limbs of pugs and miniature schnauzers (autosomal dominant inheritance)
    - Multiple papillomas affecting the footpads of dogs (digital keratomas). Firm, hyperkeratotic, hornlike growths that occur on multiple footpads, sometimes resulting in lameness as the primary presenting complaint.

PAPILLOMAS, ORAL AND CUTANEOUS Multiple papilloma on the lips and oral cavity in a weimaraner.

(Copyright Dr. Manon Paradis.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Papilloma viruses (PV) are host specific and fairly site specific, nonenveloped, double-stranded DNA viruses that induce proliferative cutaneous and mucosal tumors in dogs.
- Infection requires inoculation via breaks in the epidermal or mucosal barrier by means of direct contact with other infected dogs or iatrogenic transmission through use of contaminated instruments.
- Replication: PV attaches to cell receptors and undergoes endocytosis. Viral DNA (vDNA) makes its way to the nucleus and establishes a pool of vDNA in basal cells. Amplification of vDNA in differentiated cells and virion maturation in nucleus and infected cells are immortalized by PV infection. Reactivation of the latent PV occurs if the patient is immunocompromised naturally or iatrogenically. Early genes stimulate cell hyperplasia followed by benign tumor formation showing as warts.
- Incubation period is 1-8 weeks; regression typically occurs in 1-5 months, and lesions may persist for 24 months or more.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is primarily visual, at least for the oral papillomas. Biopsy and histopathologic examination may be necessary for diagnostic confirmation of cutaneous papillomas.

DIFFERENTIAL DIAGNOSIS

- Oral papilloma:
  - Fibromatous epulis
  - Transmissible venereal tumor
  - SCC, especially if ulcerated
- Cutaneous papilloma:
  - Pedunculated with fronds: sebaceous adenoma/hyperplasia
  - Pigmented: melanomas
  - Inverted: intracutaneous cornifying epitheliomas

INITIAL DATABASE

- Oral papillomatosis: clinical appearance is characteristic, followed by biopsy for dermatohistopathologic examination if a definitive diagnosis is desired (uncommon).
- Cutaneous papillomatosis is not as clinically evident and thus requires dermatohistopathologic examination to diagnose the lesion.
- Cytologic evaluation of smears may identify koilocytes, a type of dysplastic squamous cell found in potentially precancerous lesions with the following characteristics: nuclear enlargement (two to three times normal size), irregularity in the nuclear contour (occasionally), hyperchromasia, perinuclear clearing.
- Dermatohistopathologic evaluation of biopsies reveals fingerlike projections into the dermis and parakeratotic hyperkeratosis, inclusion bodies in keratinocytes.

ADVANCED OR CONFIRMATORY TESTING

- Virtually never needed in the clinical setting
- Immunohistochemistry: avidinbiotin complex method to detect papilloma virus group-specific antigen in tissue
- PCR to identify cutaneous papillomas
- Electron microscopy is the gold standard for diagnosis but is primarily used for research or publication purposes.

TREATMENT 

TREATMENT OVERVIEW

Because of frequent spontaneous regression, benign neglect can be an option in mild and early cases. In face of persistent or numerous lesions, various treatment options are available. Clinicians should also identify and correct any underlying cause of immunosuppression.

ACUTE GENERAL TREATMENT

- Lesions may regress spontaneously within 1-2 months.
- Some reports claim that crushing of 5 to 15 tumors may induce spontaneous regression.
- Azithromycin (suspension, tablet, and injectable), 10 mg/kg, q 24 h for 10 days, has been recently reported to result in clinical remission within 10-15 days, possibly as a result of an antiviral essential factor binding and/or immunomodulatory components.
- Surgical removal: especially if compromising normal body function (e.g., airway obstruction, dysphagia) using CO^2 laser ablation, excision, cryosurgery, or electrosurgery.
- Discontinue use of systemic glucocorticoids or cyclosporine, particularly if oral or cutaneous disease recurs or persists.

CHRONIC TREATMENT

- Interferon (IFN), either at immunostimulatory low doses of 30,000 IU/mL-0.1 mL (3000 IU) PO q 24 h OR high doses given at 1-1.5 million IU/m^2 SQ q 48-72 h for 4-8 weeks pending response
- Imiquimod 5% (Aldara) is a topically applied, human-approved immunomodulator that activates toll-like receptors and upregulates interleukin (IL)-6, IL-12, tumor necrosis factor (TNF)-α, IFN-α and IFN-γ. Also activates Langerhans cells and provides antiproliferative and antiviral effects at an application rate of two to three times weekly to affected areas; irritation is anticipated as part of the immune response against the virus and can sometimes be difficult to differentiate from resolving lesions.
- Vaccines (autologous, fractional) are currently experimental. Contact your local veterinary dermatologist for updates regarding this option.

RECOMMENDED MONITORING

- If benign neglect is chosen, clinicians should monitor lesions for ulceration, purulent exudation, and proliferation of growths, any of which might mandate intervention.
- Clinicians should monitor for abnormal persistence (e.g., development into large, ulcerated mass), which could warrant biopsy because of the potential for malignant transformation of affected cells to SCC.

PROGNOSIS AND OUTCOME 

- Prognosis usually good

- Spontaneous regression is likely, with subsequent lifelong immunity.

PEARLS & CONSIDERATIONS

COMMENTS

Once thought to be more of a nuisance often treated by benign neglect with spontaneous regression, persistent lesions should be addressed sooner to minimize the potential metaplasia to SCC.

PREVENTION

Owners should separate dogs with oral papillomatosis from other susceptible individuals.

CLIENT EDUCATION

Contagious to other dogs but not to humans and cats

Yağci BB, Ural K, Ocal N, Haydardedeoğlu AE: Azithromycin therapy of papillomatosis in dogs: a prospective, randomized, doubleblinded, placebo-controlled clinical trial, Vet Dermatol 19:194–198, 2008.

AUTHOR: ANTHONY YU

EDITOR: MANON PARADIS

Panting

BASIC INFORMATION

DEFINITION

- Rapid, shallow breathing with a small tidal volume, usually with the mouth open
- It is a normal and very common thermoregulatory mechanism in dogs, and rare in cats.
- Excessive panting occurs with elevated ambient temperature, exercise, or anxiety (e.g., a visit to the veterinarian's office) in dogs or in the absence of severe ambient temperature elevations in cats.

SYNONYMS

Hyperpnea, hyperventilation, polypnea, tachypnea

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dependent on underlying cause
- Common in normal dogs (thermoregulation, anxiety) but rare in normal cats, except in stressful situations (e.g., car ride)
- Older cats (hyperthyroidism)
- Middle-aged to older dogs, with mild female predominance (hyperadrenocorticism)

RISK FACTORS: Common and physiologic condition with emotional stress in both dogs and cats

GEOGRAPHY AND SEASONALITY: Summer (normal thermoregulation in dogs)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Normal panting due to elevated ambient temperature or anxiety versus inappropriate panting due to underlying disease

HISTORY, CHIEF COMPLAINT

- Increased amount of panting or panting at inappropriate times
- Increased with elevated environmental temperatures and/or humidity
- Perceived evidence of pain
- Glucocorticosteroid or narcotic drug administration
- Polyuria, polydipsia, polyphagia, weight gain (canine hyperadrenocorticism)
- Polyphagia, weight loss, hyperactivity (feline hyperthyroidism)
- Seizures, abnormal mentation (brain disease)
- Exercise intolerance, lethargy, coughing, dyspnea (cardiac or respiratory disease)

PHYSICAL EXAM FINDINGS

- Rapid (200-400 breaths/min), shallow breathing without evidence of respiratory distress
- Elevated body temperature if fever or hyperthermia
- Signs of pain
- Truncal hair loss, pot-bellied appearance, hepatomegaly (canine hyperadrenocorticism)
- Enlarged thyroid, tachycardia, heart murmur, or gallop heart sound (feline hyperthyroidism)
- Neurologic deficits (brain disease)
- Heart murmur, tachyarrhythmia (cardiac disease)
- Harsh lung sounds, wheezing (bronchial disease)
- Obesity

ETIOLOGY AND PATHOPHYSIOLOGY

- Primary means of thermoregulation in dogs via evaporative cooling within the mouth and nasal passages; passage of air,

blood flow, and secretions are increased in these areas during panting.
- Muscular work of breathing is minimally increased during panting.
- Causes respiratory alkalosis only if prolonged or severe.
- Hyperthyroidism rarely causes panting at rest but commonly with any stress. Possible reasons include respiratory muscle weakness, increased carbon dioxide production, and chemical thermogenesis.
- Hyperadrenocorticism and glucocorticosteroid administration may cause panting because of respiratory muscle weakness, muscle wasting, hepatomegaly, and abdominal fat deposition.
- Pure agonist narcotics commonly cause dose-dependent panting that is independent of route of administration.
- Cardiac disease and tachyarrhythmias may lead to panting due to anxiety or angina.
- Animals with pheochromocytoma may pant because of epinephrine induced chemical thermogenesis.
    - A similar mechanism may be inferred for anxiety-associated panting.
- Hypocalcemia may lead to panting, most likely because of anxiety and pain caused by tetany.
- Obese animals fail to lose as much heat through evaporation and radiation, which increases the need for heat loss through panting. Furthermore, the tidal volume may be reduced due to fat deposition in the thorax, further increasing the respiratory rate.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Complete history and physical examination findings can help determine whether panting is normal (thermoregulation or anxiety) or a sign of disease, and aid in ranking the importance of additional tests, which can be varied and extensive.

DIFFERENTIAL DIAGNOSIS

- Elevated ambient temperature, hyperthermia
- Fever
- Anxiety, nervousness
- Pain
- Narcotic administration
- Glucocorticosteroid therapy
- Hyperadrenocorticism
- Hyperthyroidism
- Hypocalcemia
- Pheochromocytoma
- Cardiac disease, tachyarrhythmia
- Feline bronchial disease
- Brain disease
- Obesity

INITIAL DATABASE

- Blood pressure: moderate-severe hypertension possible with hyperthyroidism or pheochromocytoma; mild hypertension possible with severe anxiety
- CBC: possible erythrocytosis, thrombocytosis, leukocytosis, lymphopenia, and eosinopenia in dogs with hyperadrenocorticism
- Serum biochemical profile: elevated alkaline phosphatase (ALP) and cholesterol in dogs with hyperadrenocorticism; elevated liver enzymes in cats with hyperthyroidism; hypocalcemia
- Urinalysis: low specific gravity and/or proteinuria in dogs with hyperadrenocorticism
- Serum T^4: elevated in cats with hyperthyroidism
- Thoracic radiographs: heart enlargement + pulmonary edema, pleural effusion with cardiac disease; bronchiolar lung pattern, lung hyperinflation in feline asthma

ADVANCED OR CONFIRMATORY TESTING

- Arterial blood gas may show respiratory alkalosis (diminished carbon dioxide, elevated pH) in animals with severe panting.
- Hyperadrenocorticism screening via urine protein/creatinine ratio, adrenocorticotropic hormone (ACTH) stimulation, or low-dose dexamethasone suppression tests if history and initial database are suggestive
- Abdominal ultrasound to locate adrenal mass(es)
- Electrocardiogram and echocardiogram to confirm cardiac disease
- Bronchial wash cytologic evaluation to confirm feline asthma
- Brain CT scan or MRI

TREATMENT

TREATMENT OVERVIEW

Clinicians should treat the underlying condition to eliminate excessive panting.

ACUTE GENERAL TREATMENT

Clinicians should:

- Reduce anxiety.
- Control pain if present.
- Decrease ambient temperature if elevated.
- Ensure adequate hydration in animals with elevated body temperature and provide external cooling (e.g., cool water bath, fan, cool water enema, or gastric lavage) in animals with a body temperature above 106○F (41.1○C).
- Discontinue or decrease dose of narcotic or glucocorticosteroid therapy if possible.
- Manage underlying cause (± antiarrhythmic therapy) for tachyarrhythmias.
- Administer calcium supplementation for hypocalcemic animals.
- Manage underlying cause (± antihypertensive medication) for hypertensive animals with hyperthyroidism or pheochromocytoma.
- Eliminate or control underlying trigger (± glucocorticosteroid and bronchodilator therapy) for feline bronchial disease.

CHRONIC TREATMENT

Clinicians should:

- Start cats with hyperthyroidism on oral or topical methimazole and/or schedule them for radioactive iodine therapy.
- Treat hyperadrenocorticism with mitotane, trilostane, or adrenalectomy.
- Perform an adrenalectomy for animals with pheochromocytoma.

NUTRITION/DIET

Initiate program for weight loss if the animal is obese.

POSSIBLE COMPLICATIONS

Bronchodilator therapy may worsen primary cardiac disease.

PROGNOSIS AND OUTCOME

Highly variable, owing to range of severity of underlying causes

PEARLS & CONSIDERATIONS

COMMENTS

Any panting cat should be evaluated for underlying disease. An exception is cats that only pant under predictable conditions of stress (e.g., car ride), the panting has not progressed in severity to resting dyspnea, and an initial physical exam has revealed no abnormalities.

TECHNICIAN TIPS

Obtaining complete historical and physical examination information can assist in determining whether a patient is panting because of normal reasons (thermoregulation, anxiety) or because of underlying illness.

Panosteitis

BASIC INFORMATION

DEFINITION

A spontaneous, self-limiting painful condition of diaphyseal and metaphyseal portions of long bones commonly diagnosed in young, large breed dogs

SYNONYMS

Enostosis, juvenile osteodystrophy, eosinophilic osteomyelitis, eosinophilic panosteitis, juvenile osteomyelitis, osteomyelitis of young German shepherd dogs

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Young (5 months to 2 years), medium-and large-breed dogs
- Occasionally seen in younger or older dogs and in small breeds
- More common in males than females

GENETICS & BREED PREDISPOSITION

- German shepherds have been reported to be at highest risk.
- Basset hounds may be overrepresented.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- The hallmark chief complaint is acute, shifting limb lameness of variable severity that typically lasts 1-3 weeks (each leg).
- Systemic signs (e.g., anorexia, lethargy) occasionally can be severe and may require nutritional and physical support.

PHYSICAL EXAM FINDINGS

- Orthopedic examination demonstrates pain on deep palpation/firm digital pressure of the diaphyseal and metaphyseal (midshaft and distal, respectively) portions of affected bones.
- Frequency: ulna (42%), radius (25%), humerus (14%), femur (11%), and tibia (8%)
- Fever, depression, and anorexia can be seen in more severe (unusual) cases.

ETIOLOGY AND PATHOPHYSIOLOGY

- Panosteitis has an unknown etiology.
- Infectious agents (bacteria, canine distemper virus, modified live viral vaccines) have been suspected but never proven to cause panosteitis.
- Other suggested inciting causes include localized vascular congestion, metabolic diseases, genetic diseases, parasitism, hyperestrinism, and hemophilia.
- Panosteitis is associated with excessive bone remodeling after the death of intramedullary adipocytes and hematopoietic cells. Cell death is attributed to vascular congestion, but the true cause remains unknown.
- The necrotic marrow cells are replaced with fibrous tissue. Woven bone is formed within the fibrous tissue. Endosteal bone formation is a prominent histologic finding with panosteitis.
- Periosteal bone formation is occasionally noted.
- Eventually, endosteal bone resorption occurs, and normal vascularity and marrow adipose tissue are reestablished.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Panosteitis is typically a mild, self-limiting condition and should be a primary consideration in any lame dog < 2 years of age. Panosteitis may occur in a single bone or limb or as a recurrent "shifting leg" lameness. It is suspected from signalment, history, and physical exam, and is confirmed radiographically.

DIFFERENTIAL DIAGNOSIS

Infectious diseases (septic arthritis, osteomyelitis), immune-mediated arthropathies, and other developmental bone diseases (hypertrophic osteodystrophy, ununited anconeal process, osteochondrosis, hip dysplasia, etc.)

INITIAL DATABASE

- Anamnesis and physical examination:
  - Pain during deep palpation of the affected bone (diaphysis or metaphysis)
- Radiography:
  - Diagnostic test of choice
  - Characteristic radiographic lesions:
    - Patchy areas of increased intramedullary opacity
    - Increased radiographic lucency near the nutrient foramen of the bone
    - Increased periosteal bone formation
- Characteristic lesions may not be present during acute phase of the disease.
- Radiographs of other nonpainful limbs may also have characteristic lesions.
- CBC, serum biochemical panel, and urinalysis, as indicated by presence of systemic signs

ADVANCED OR CONFIRMATORY TESTING

Nuclear scintigraphy may be used if radiographs are inconclusive.

TREATMENT

TREATMENT OVERVIEW

Generally, no specific therapy is required, but clinicians should provide analgesia during acute phase of panosteitis to permit the dog to have normal activity with minimal discomfort and maintain appetite.

ACUTE GENERAL TREATMENT

- Supportive care as required; hospitalization is rarely needed.
- Nonsteroidal antiinflammatory drugs (NSAIDs) generally provide adequate analgesic relief for dogs with panosteitis.
  - Carprofen: 2 mg/kg PO q 12 h, *or*
  - Etodolac: 10-15 mg/kg PO q 24 h, or
  - Deracoxib: 1-2 mg/kg PO q 24 h, *or*
  - Meloxicam 0.1 mg/kg PO q 24 h, *or*
  - Firocoxib 5 mg/kg PO q 24 h
  - Misoprostol (synthetic prostaglandin E 1 analog; 2-5 mcg/kg PO q 8-12 h) can be given to decrease the risk of gastrointestinal ulceration.
- There is no indication for the use of glucocorticoids in panosteitis.
- Use of opioid analgesics for discomfort is rarely required but can be considered in patients that have a contraindication to the use of NSAIDs.
  - Butorphanol: 1-4 mg/kg PO q 4-6 h. *or*
  - Tramadol: 1-4 mg/kg PO q 6-8 h

CHRONIC TREATMENT

- Seldom required, since this is a self-limiting condition
- An occasional severe case will require use of stronger analgesics (opioids), nutritional support (i.e., feeding tube placement), or short-term hospitalization.

NUTRITION/DIET

- A well-balanced maintenance diet should be recommended if the patient is not already receiving this.

- Use of additional supplements have not been shown to alter the course of panosteitis and could further complicate the development of other orthopedic conditions.

BEHAVIOR/EXERCISE

Limited activity in patients that are painful

DRUG INTERACTIONS AND CONTRAINDICATIONS

- Gastric ulceration and other side effects may rarely occur with use of NSAIDs; clinicians should be familiar with specific product information and inform owners of possible side effects and actions to be taken if side effects are encountered (i.e., discontinue medication, veterinary evaluation, etc.).
- Corticosteroids should not be used in patients receiving NSAIDS; increases risk of gastric ulceration.

POSSIBLE COMPLICATIONS

- Most complications arise from treatment rather than disease.
- Gastrointestinal (GI) hemorrhage, ulceration, and perforation (NSAIDs).
- Liver toxicity or failure and renal dysfunction are possible with NSAIDs.
- Coagulation abnormalities are rare with most NSAIDs.

RECOMMENDED MONITORING

- Radiographic examination when other legs become affected
- Repeated evaluation in dogs with protracted lameness to rule out other developmental bone diseases
- CBC (blood loss anemia), biochemical profile (changes in liver or renal parameters), and urinalysis (urine specific gravity, sediment for evidence of real casts) are recommended with long-term NSAID usage.

PROGNOSIS AND OUTCOME 

- Disease may last several weeks to months.
- The condition may shift among limbs.
- Long-term prognosis is very good; seldom causes permanent disability.

PEARLS & CONSIDERATIONS 

COMMENTS

- Panosteitis should be a primary differential diagnosis in any young dog with acute onset of lameness.
- Panosteitis is “self-limiting” in most cases.
- Panosteitis may repeatedly flare up over several months.
- Panosteitis is most common in dogs prone to other developmental orthopedic conditions. If the patient does not improve with supportive care, other underlying conditions should be ruled out.
- Nutraceuticals and vitamin supplementation have not been shown to decrease clinical signs, duration, or severity of panosteitis.

CLIENT EDUCATION

- Clients should be reminded that panosteitis is a self-limiting condition and will resolve with minimal treatment in the majority of dogs.
- There are potential side effects of NSAID use in dogs:
    - Long-term use of NSAIDs may require concurrent administration of gastroprotectants.
- Panosteitis can mask other developmental orthopedic conditions.

EDITOR: JOSEPH HARARI

Pannus (Chronic Superficial Keratitis)

BASIC INFORMATION

DEFINITION

A typically bilateral, progressive, immune-mediated, inflammatory disease of the cornea characterized by infiltration of vessels and granulation tissue and/or pigmentation

SYNONYMS

CSK, degenerative pannus, German shepherd pannus, Uberreiter's syndrome

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs only
- Age of onset: 2-5 years of age; depends on breed and altitude

GENETICS & BREED PREDISPOSITION

- Primarily affects large-breed dogs; may occur in any breed
- Breed predisposition: German shepherd, greyhound, Belgian Tervuren, Belgian sheepdog, dachshund, border collie, Shetland sheepdog, Siberian husky, Scotch collie, Australian shepherd, miniature pinscher, pointer, dalmatian, English springer spaniel, Airedale terrier

RISK FACTORS

- Ultraviolet radiation exposure

GEOGRAPHY AND SEASONALITY: Increased incidence and severity of disease in geographic regions with high altitude (i.e., elevation of 4500 feet [1500 m] or higher) and intense sunlight. Dogs that live at lower altitudes respond better to therapy (e.g., dogs living in the southeastern part of the United States are less severely affected and respond better to therapy than dogs living in the Rocky Mountains).

ASSOCIATED CONDITIONS & DISORDERS: Lymphocytic/plasmacytic conjunctivitis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Early chronic superficial keratitis (CSK): lesions occur in the lateral to latero ventral cornea.
- Chronic CSK: entire cornea may be affected
- CSK may present as a:
  - Vascular form
  - Pigmentary form
  - Combination of vascular and pigmentary forms in same eye or between eyes

HISTORY, CHIEF COMPLAINT

- Corneal discoloration: rapidly or slowly progressive; reddish and/or brown film covering surface of the eyes
- Progressive loss of vision

PHYSICAL EXAM FINDINGS

- Typically bilateral; often symmetrical
- Generally nonulcerative, pinkish-red, vascularized, and/or pigmentary superficial corneal lesions commencing in the lateral to ventrolateral cornea; progressively involving the medial, ventral, and dorsal aspects of the cornea, including the central

cornea
- Conjunctivitis present in most cases
- Multifocal white, crystalline lipid deposits often present at the leading edge of the corneal lesions (see p. 245)
- ± Third eyelid involvement as evidenced by pink proliferative lesions and depigmentation along leading edge of third eyelid
- Early CSK:
  - Vascularization and/or pigmentation at lateral to ventrolateral cornea adjacent to limbus
  - Progresses centrally
- Chronic CSK:
  - Fleshy lesion (i.e., granulation tissue) with corneal vascularization and/or pigmentation
  - Entire cornea may be affected, predisposing the animal to blindness

ETIOLOGY AND PATHOPHYSIOLOGY

- Immune-mediated disease
- Ultraviolet radiation exposure at high altitude potentiates the disorder.
- Tissue-specific antigens in the cornea are altered with ultraviolet radiation exposure.
- Dogs with CSK develop a hypersensitivity response to corneal proteins, predisposing them to chronic inflammation.
- CSK is a more rapidly progressive and severe disease in young dogs (<3 years of age).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on the clinical presentation of typically bilateral corneal vascularization and pigmentation in large-breed dogs.

DIFFERENTIAL DIAGNOSIS

Other causes of CSK:

- Corneal vascularization (see p. 254)
- Corneal pigmentation (see p. 246)

INITIAL DATABASE

Complete ophthalmic examination (see p. 1313), including:

- Schirmer tear test (typically normal with CSK)
- Fluorescein dye application (typically no corneal dye retention with CSK, but there may be with secondary corneal ulceration)
- Intraocular pressures normal (15-25 mm Hg) with CSK
- Careful examination of the conjunctiva and cornea

ADVANCED OR CONFIRMATORY TESTING

- Usually not required; CSK is diagnosed by clinical findings, signalment of dog, and ruling out other causes of corneal vascularization and pigmentation.
- Cytologic examination of corneal and conjunctival swabs/scrapings reveals lymphocytes and plasma cells.
- If a keratectomy is performed, histopathologic findings consist of lymphocyte, plasma cell, macrophage, and melanocytic cell infiltrations with corneal vascularization and fibroplasia.

TREATMENT

TREATMENT OVERVIEW

The treatment goal is to suppress the disease process with intensive initial treatment and to keep the disease in remission with maintenance therapy.

ACUTE GENERAL TREATMENT

- Topical corticosteroids (dexamethasone 0.1% solution or ointment, or prednisolone acetate 1% suspension) q 6-8 h for 3 weeks, followed by slow reduction to a maintenance dose

- Cyclosporine-A (CsA) 0.2% ointment or 0.5%-2% solution topically q 12 h; or tacrolimus 0.02%-0.03% ointment or aqueous suspension q 12 h

CHRONIC TREATMENT

- Requires lifelong therapy
- Maintenance therapy consists of topical corticosteroids and/or CsA or tacrolimus once or twice a day.
- Maintenance of remission is possible in some dogs with one daily application of CsA.
- For nonresponsive and severe cases, clinicians can consider:
    - Adjunctive subconjunctival injections of corticosteroids (e.g., methylprednisolone acetate, 4-12 mg; or triamcinolone acetonide, 4-12 mg [dose dependent on size of dog]) q 2-3 weeks
    - Referral to veterinary ophthalmologist for:
        - ß-irradiation (i.e., strontium-90)
        - Superficial keratectomy

POSSIBLE COMPLICATIONS

- Corneal ulceration (see p. 250); if it occurs, clinicians should discontinue corticosteroid for the animal and commence/continue CsA or tacrolimus until corneal ulcer has healed.
- Granuloma at site of subconjunctival corticosteroid injection

RECOMMENDED MONITORING

- Response to therapy is monitored every 3-4 weeks initially then every 4-6 weeks.
- Once stable, the patient is reevaluated every 3-6 months.

PROGNOSIS AND OUTCOME

- CSK is a chronic disorder that typically responds to intensive medical therapy.
- Maintenance therapy is needed to keep the disease in remission.

PEARLS & CONSIDERATIONS

COMMENTS

- A common error in treatment is lack of intensive therapy in the early stages of disease.
- The disease should be treated pro-actively with topical corticosteroids, ± CsA or tacrolimus, and the frequency should be slowly reduced over weeks to reach a maintenance therapy.
- CSK is a chronic disease that requires lifelong treatment.

PREVENTION

- Owners should limit exposure of pets to ultraviolet light.
- They should also avoid breeding affected or closely related dogs.

CLIENT EDUCATION

- CSK is an immune-mediated disease that is manageable but not curable.
- Lifelong treatment is required.

AUTHOR: PHILLIP A. MOORE

EDITOR: CHERYL L. CULLEN

Panniculitis

BASIC INFORMATION

DEFINITION

Inflammation of the subcutaneous adipose tissue. Panniculitis is different from cellulitis, which is an acute, diffuse, and suppurative inflammation of loose connective tissue, particularly the deep subcutaneous tissues, and sometimes muscle, most commonly resulting from infection of a wound, ulcer, or other skin lesion.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Uncommon in dogs and cats

GENETICS & BREED PREDISPOSITION: Sterile nodular panniculitis: dachshunds, golden retrievers, collies, and miniature poodles

RISK FACTORS

- Outdoor pets (penetrating foreign body, bite wound): infectious panniculitis
- Immunocompromised cat (e.g., feline leukemia virus [FeLV], feline immunodeficiency [FIV]) or dog (e.g., iatrogenic hyperadrenocorticism): greater risk of dissemination of infectious organisms
- Unbalanced diets low in antioxidants (e.g., low levels of vitamin E)
- Recurrent pancreatitis: panniculitis and steatitis (inflammation of body fat)
- Pancreatitis or pancreatic carcinomas: mineralizing fat necrosis/panniculitis

CONTAGION & ZOONOSIS

- Dermatophytic granulomatous panniculitis: *Microsporum canis* and *Trichophyton mentagrophytes* are potentially contagious to other animals and are zoonotic.
- Sporotrichosis: risk of cat-to-human transmission is extremely high; dog-to-human transmission not yet reported.
- Blastomycosis, coccidioidomycosis, histoplasmosis: risk of zoonosis by aerosol from culture plates; in-house culture is always contraindicated.

GEOGRAPHY AND SEASONALITY: Sporotrichosis outbreak in Brazil; Blastomycosis, p. 138; Histoplasmosis, p. 538; Coccidioidomycosis, ; Pythiosis and Lagenidiosis, p. 960; Protothecosis, p. 926.

ASSOCIATED CONDITIONS & DISORDERS: Interscapular panniculitis may be a precursor of vaccine-associated fibro-sarcoma in cats.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Acute to chronic onset of single or multiple subcutaneous nodules or draining tracts, potentially with accompanying systemic signs such as anorexia and lethargy.

PHYSICAL EXAM FINDINGS

- Lesions typically involve the trunk and may be single or multifocal.
- Subcutaneous nodules to swellings may become cystic and painful, especially prior to rupturing or developing draining tracts.
- Panniculitis and subsequent fat necrosis are characterized by an oily yellow-brown to blood-tinged discharge.
- Lesions often heal with crusting and scarring.

ETIOLOGY AND PATHOPHYSIOLOGY

- Panniculitis is caused by inflammation and/or infection of the panniculus (subcutaneous fat) with subsequent oxidative damage to the lipocytes.
- Result: release of lipids into subcutis, where the lipids undergo hydrolysis to glycerol and fatty acids
- The fatty acids are potent inflammatory agents, resulting in further inflammation and granulomatous reactions.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Panniculitis has several etiologies but is initially suspected based on physical finding of subcutaneous swellings/nodules that may or may not be painful or have developed draining tracts. Biopsies for histopathologic confirmation and/or bacterial and fungal cultures are generally indicated for diagnosis.

DIFFERENTIAL DIAGNOSIS

- Infectious: bacterial/botryomycosis, actinomycotic, systemic and subcutaneous fungal, dermatophytic pseudomycetomas, feline leprosy, atypical mycobacteria, *Chlamydia* spp., *Bartonella* spp.
- Immune-mediated: lupus profundus, erythema nodosum, drug eruption, insect bite
- Idiopathic: sterile nodular panniculitis
- Trauma with or without foreign body reaction
- Nutritional: vitamin E deficiency (feline nutritional pansteatitis)
- Pancreatitis or pancreatic adenocarcinoma
- Postinjection reaction: corticosteroids, vaccine (rabies)
- Neoplastic: multicentric mast cell tumors, cutaneous lymphoma
- Deep pyoderma/abscess
- Cutaneous cysts
- Drug reaction

INITIAL DATABASE

- Cytologic examination; infectious organisms:
  - Gram-positive branching filamentous organisms: *Actinomyces* sp. (nonacid-fast); *Nocardia* sp. (partially acid-fast)
  - Diff-Quik: fungi possible (systemic mycoses)
  - Acid-fast bacilli: atypical mycobacteria, feline *M. lepraemurium*
  - Organisms may be noted within foamy macrophages.
- Full-thickness (skin plus subcutaneous fat) biopsy, and the panniculus must be included; consider double-punch technique.
- Histopathologic analysis:
  - Identify one of the three possible histopathologic patterns: septal (interlobular connective tissue septa affected; most common in cats); lobular (fat lobules affected); and diffuse (both the lobules and septa involved; most common in dogs).
  - Qualify cellular infiltrate.
  - Identify infectious organisms (special stains).
  - Severity of lesions (necrosis, fibrosis, vasculitis)

ADVANCED OR CONFIRMATORY TESTING

- Clinicians should aseptically submit part of a biopsy specimen for tissue maceration and culture.
- They should also notify the laboratory of suspected organisms (to make adjustments to culture media selection and incubation times and for precautions taken especially with systemic mycoses):
  - Bacterial culture and sensitivity testing
  - Rapid-growing atypical mycobacterial culture
  - Fungal culture (not usually for systemic mycoses; other tests are safer).
  - Negative cultures support a diagnosis of sterile nodular panniculitis, lupus profundus.
- Serologic evaluation: systemic mycoses
- Antinuclear antibody to help rule in lupus profundus
- Direct fluorescent antibody testing for *Sporothrix* antigen
- Abdominal ultrasound: pancreatic diseases may be a contributing factor (rare).

TREATMENT

TREATMENT OVERVIEW

Because panniculitis is caused by a variety of etiologies, selection and duration of treatment are dependent on identification of the specific cause.

ACUTE AND CHRONIC TREATMENT

- Surgical excision of solitary lesions
- Appropriate antifungal, antibacterial, or antimycobacterial treatment if indicated
- Sterile panniculitis (rabies vaccine-induced, sterile nodular, lupus profundus)
    - Vitamin E (10-20 IU/kg PO q 8-12 h) may control mild cases.
    - Tetracycline and niacinamide, 500 mg of each for dogs > 10 kg, or 250 mg of each for dogs < 10 kg, PO q 8 h until improvement (about 2-3 months), then tapering gradually
    - Pentoxifylline, 10-30 mg/kg PO q 8 h until resolved, then tapering gradually
    - Prednisone, 2.2 mg/kg PO q 24 h, or methylprednisolone for dogs, 1.6 mg/kg PO q 24 h; or prednisolone for cats, 4.4 mg/kg PO q 24 h until resolution (about 2-6 weeks), then gradually tapering
    - Azathioprine, 2 mg/kg PO q 24 h (dogs); or chlorambucil, 0.1-0.2 mg/kg PO q 24 h (cats and small dogs): corticosteroid-sparing alternatives for long-term treatment. After a 4-to 8-week lag phase associated with both of these medications, dosage may be q 48 h (or less frequent) on alternate days of glucocorticoid use (if still required).
- Dietary elimination trial: adverse food reaction may be a trigger in immune-mediated panniculitis (rare).

DRUG INTERACTIONS

Clinicians should adjust dosage or minimize combination therapy with drugs that alter cytochrome P450 and/or p-glycoprotein activity (e.g., ketoconazole).

POSSIBLE COMPLICATIONS

Glucocorticoid side effects (iatrogenic hyperadrenocorticism)

RECOMMENDED MONITORING

- Schirmer tear test if long-term use of sulfa-based drugs
- CBC, platelet count, serum chemistry profile, and urinalysis typically after 2-4 weeks (initially) to q 3-6 months (when stable) if using immunosuppressive agents

PROGNOSIS AND OUTCOME 

- Variable, from guarded to good; healed lesions may leave scars.
- Most cases of panniculitis involve lengthy treatment (months).
- Amputation may be a serious consideration to prevent further spread of the disease should traditional therapies provide minimal improvement in a lesion localized to one limb.

PEARLS & CONSIDERATIONS 

COMMENTS

- A complete diagnostic workup to identify the underlying etiology leads to the most appropriate and successful treatment plan and outcome.
- More commonly a medically treated condition rather than a surgically managed disorder
- Clinicians should review the complexity of the differential diagnoses with clients, and ensure they are willing to pursue prolonged treatment before starting extensive diagnostic testing beyond histologic confirmation.
- Clinicians should obtain and freeze extra serum for future diagnostic tests based on histologic findings.

TECHNICIAN TIP

In some cases, a biopsy punch may not reach the hypodermis (subcutaneous fat), impeding proper diagnosis. Therefore, wedge biopsy may be preferred if panniculitis is suspected.

PREVENTION

- Weight loss for obese animals. Reduces amount of fat to which the body can react; may allow medication discontinuation.
- Owners should minimize pets' access to high-risk areas (swamps, riverbeds) and should rinse/bathe the pet after high-risk area exposure.
- Owners can give their pets routine vitamin E antioxidant.

CLIENT EDUCATION

- Extensive diagnostic testing can be involved; need to determine infectious versus immune-mediated cause.
- Treatment is generally lengthy, especially when addressing atypical mycobacteria, *Actinomyces, Nocardia,* and intermediate/systemic fungal infections; but with appropriate therapy, the prognosis in most cases is positive. Healed lesions may leave scars, however.

AUTHOR: ANTHONY YU

EDITOR: MANON PARADIS

Panleukopenia, Cat

BASIC INFORMATION

DEFINITION

Highly contagious parvoviral infection of cats that typically causes severe, sometimes fatal, acute gastroenteritis and leukopenia. No longer common, owing to effective vaccination protocols.

SYNONYMS

Feline infectious enteritis, feline parvovirus (FPV)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- All Felidae: domestic housecats, tigers, lions, cheetahs
- Also affects raccoons, ferrets, mink, civet cats
- Can affect all susceptible cats, primarily kittens <1 year old; most infections (>75%) are subclinical.

RISK FACTORS

- Unvaccinated cats > 6 weeks old
- Vaccinated kittens 8-20 weeks old, when maternal antibodies wane but may still neutralize vaccine-induced antibodies
- Pregnant queens receiving modified live-virus vaccines: risk of kittens with cerebellar hypoplasia
- Diagnosed most frequently in dense feral or shelter populations (frequent new animals, lower vaccination rates)

CONTAGION & ZOONOSIS

- Highly contagious to other cats; quarantine/isolation required
- Virus is shed in all body secretions, primarily feces. Virus extremely stable in the environment (up to 1 year). Susceptible cats infected by exposure to infected feces, secretions, or fomites. Can also be transmitted in utero.
- Does not infect dogs or humans, but cats are susceptible to canine parvovirus 2 (CPV-2) antigenic subtypes, which cause the same clinical course as FPV.

GEOGRAPHY AND SEASONALITY: Worldwide

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Classical feline enteritis: kittens and susceptible adults
- Silent abortion/fetal death: queens (first trimester)
- Central nervous system (CNS) form: kittens infected in utero in second or third trimester or up to 9 days postpartum
    - Virus infects replicating neurons.
    - Neurologic signs are nonprogressive, and affected kittens can still make good pets.

HISTORY, CHIEF COMPLAINT

- Classic enteritis, acute onset:
    - Sudden death, “fading kitten syndrome”
    - Vomiting, anorexia, and/or diarrhea
    - Extreme lethargy or depression, hiding
- In utero infection:
    - Queening of mummified fetuses
    - Ataxia and intention tremors noted once kittens start to walk (10-14 days old)
    - Altered mentation and dullness (usually not noted until several weeks old)
    - Seizures

PHYSICAL EXAM FINDINGS

- Classic enteritis; kitten is infected with FPV:
  - Fever or hypothermia in severe cases
  - Marked dehydration or hypovolemic shock
  - Vomiting, diarrhea
  - Thickened bowel loops, abdominal discomfort
- CNS form; mother was infected with panleukopenia virus when pregnant:
  - Cerebellar ataxia, hypermetria, intention tremors
  - Optic nerve hypoplasia, dark foci/folding/streaking of retina
  - Mental dullness, behavior abnormalities

ETIOLOGY AND PATHOPHYSIOLOGY

- Single-stranded nonenveloped DNA virus
- Replicates in rapidly dividing cells; clinical signs reflect destruction of these cells:
  - Lymphoid tissue: lymphopenia, lymph node necrosis
  - Bone marrow: panleukopenia, occasionally other short-lived cell lines (thrombocytes)
  - Intestinal mucosal crypt cells: damage results in malabsorptive diarrhea, increased permeability, increased risk for bacterial translocation.
  - Nervous system: cerebellar hypoplasia, hydrocephalus, hydranencephaly, retinal dysplasia from destruction of developing neural tissue

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Confirmatory FPV laboratory testing is not readily available; diagnosis is typically based on history, signalment, clinical signs, and initial laboratory findings. Severe gastroenteritis with neutropenia in a 3-to 5-month-old kitten is sufficiently suggestive of FPV infection to proceed with treatment, contagion precautions, and prognostication.

DIFFERENTIAL DIAGNOSIS

- Gastroenteritis:
  - Foreign body
  - Other bacterial or viral infections (coronavirus, *Salmonella* spp., *Clostridium* spp.)
  - Inflammatory bowel disease
  - Neoplasia
  - Toxin ingestion
- Leukopenia:
  - Feline leukemia virus (FeLV)
  - Salmonellosis

INITIAL DATABASE

- CBC: mild anemia unless severe gastrointestinal (GI) bleeding; leukopenia, especially neutropenia, is typical, but normal leukogram does not rule out FPV; thrombocytopenia due to bone marrow suppression or disseminated intravascular coagulation (DIC).
- Serum biochemistry profile: often unremarkable; prerenal azotemia, increases in alanine aminotransferase/aspartate aminotransferase/bilirubin possible
- Coagulation panel: may see evidence of DIC
- Radiographs: typically unremarkable

ADVANCED OR CONFIRMATORY TESTING

- Confirmatory diagnostic tests for enteric FPV exist (e.g., serologic titers, immunofluorescent antibody testing, PCR assay, and virus isolation), but are often labor-or time-intensive, expensive, and not readily available.
- Canine parvoviral fecal ELISA test kits can reliably detect FPV antigen. As with vaccination in puppies, false-positive results can occur within 2 weeks of vaccination with modified live feline panleukopenia vaccine.
- Since definitive antemortern diagnosis of the CNS form is not realistically possible, the practitioner should rely on history, signalment, and neurologic exam to point to in utero or perinatal FPV infection.
- Histologic findings are also similar to those of canine parvovirus.

TREATMENT

TREATMENT OVERVIEW

There is no specific antiviral drug for FPV infection, so comprehensive supportive care is required to carry the patient through the acute episode of enteritis. There is no treatment that will change the course of the neurologic form.

ACUTE GENERAL TREATMENT

Supportive care:

- IV crystalloids/colloids to correct shock, dehydration, and electrolyte abnormalities
- Broad-spectrum antibiotics (e.g., ampicillin, 22 mg/kg IV q 8 h; and gentamicin, 4 mg/kg IV q 24 h, only when hydration is normal) to combat secondary bacterial infections
- Withholding of food/water during acute episode to decrease crypt cell division and subsequent viral replication
- Antiemetics (e.g., metoclopramide 0.2-0.4 mg/kg SQ q 8 h or 1-2 mg/kg/d as an IV contrast rate infusion)

CHRONIC TREATMENT

Cats that recover are immune for life.

NUTRITION/DIET

- Appetite stimulants (cyproheptadine, 2 mg per cat PO q 12 h; or mirtazapine, 3.75 mg PO q 72 h); or enteral tube feeding during recovery period if anorexia persists. Trickle feeding of a liquid diet through a nasogastric tube after acute enterocyte destruction has stopped may improve gut healing and hasten return of appetite.
- Vitamin B^{12}, 0.25 mg IM or SQ per cat once

RECOMMENDED MONITORING

Repeat CBC: rebound leukocytosis (24-48 h). If leukopenia persists, clinicians should rule out other causes (e.g., FeLV).

PROGNOSIS AND OUTCOME

- Guarded (short-term) for acute gastroenteritis
- Guarded to good for kittens with cerebellar hypoplasia, depending on ability to compensate for deficits; neurologic signs are not treatable but are also nonprogressive.
- Grave to poor for kittens with fore-brain signs

PEARLS & CONSIDERATIONS

COMMENTS

- Kittens cannot have both neurologic signs and signs of enteritis simultaneously from panleukopenia, because neurologic signs occur from in utero infection of the dam.
- Routine vaccination has profoundly decreased the incidence of disease. Disease is maintained due to persistence of FPV in the environment and birth of susceptible animals in unvaccinated populations.

PREVENTION

Modified live vaccines (MLV) are preferred because they are rapid and provide more effective immunity. Clinicians should administer the vaccine after the kitten is 8 weeks old to avoid inactivation by maternal antibodies, then 2 and 4 weeks after first vaccination, and again 1 year later. Initial vaccinations probably provide lifelong immunity, but clinicians should revaccinate triennially per American Association of Feline Practitioners. MLV is contraindicated in pregnant queens or kittens < 4 weeks old.

TECHNICIAN TIPS

Because the virus is easily spread via fomites (towels, bowls, shoes) and persists up to 1 year, a strict isolation protocol is essential

in these cases (e.g., disposable gowns, booties, and gloves; monitoring equipment such as stethoscopes and thermometers cannot leave the isolation area). Disinfection of the environment or fomites requires 1:32 diluted sodium hypochlorite (bleach), formaldehyde, or glutaraldehyde.

CLIENT EDUCATION

Breeders should vaccinate new, susceptible cats 1 week prior to introduction to cattery.

Pancreatitis, Dog

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Pancreatitis is an inflammatory condition of the pancreas. It can be acute or chronic, which can only be differentiated histopathologically.

EPIDEMIOLOGY

SPECIES, AGE, SEX: There are no known age or sex predilections.

GENETICS & BREED PREDISPOSITION: Miniature schnauzers appear to be more commonly affected. As in some humans with hereditary pancreatitis, a mutation of the SPINK gene may be responsible.

RISK FACTORS

- Dietary indiscretion
- Blunt abdominal trauma
- Hypercalcemia
- Pancreatic hypoperfusion
- Pharmaceuticals: potassium bromide, phenobarbital, L-asparaginase, azathioprine, trimethoprim-sulfa, and others
    - There is little evidence that corticosteroids cause pancreatitis in dogs, and pancreatitis or a history of pancreatitis are not considered contraindications for corticosteroid use.
- Severe hypertriglyceridemia and disorders of lipid metabolism

ASSOCIATED CONDITIONS & DISORDERS: Peritonitis (in severe cases)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of dietary indiscretion (often high-fat foods)
- Anorexia and vomiting are most common (reported in 91% and 90% of patients in one study, respectively).
- Weakness
- Abdominal pain is reported in more than 50% of dogs with pancreatitis.
- Diarrhea is reported in about 33% of dogs with pancreatitis.

PHYSICAL EXAM FINDINGS

- Abdominal pain
- Dehydration
- Fever
- Possible icterus

ETIOLOGY AND PATHOPHYSIOLOGY

- The cause of pancreatitis is unknown in many dogs.
- There is a common pathogenetic pathway, regardless of the initiating cause. Any number of insults can lead to premature activation of trypsinogen to trypsin. Trypsin, in turn, activates more trypsinogen and other pancreatic zymogens. Prematurely activated pancreatic digestive enzymes lead to local and systemic damage. This process also leads to recruitment of inflammatory cells and cytokine release, causing further systemic changes.
- In general, premature activation of pancreatic digestive enzymes leads to initiation of pancreatitis, while the inflammatory response leads to progression of the disease and systemic complications.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Measurement of serum pancreatic lipase immunoreactivity (now measured by Spec cPL) is the most sensitive and specific laboratory test currently available for pancreatitis, but the diagnosis rests on a combination of clinical signs, diagnostic imaging results, and pancreas-specific serologic tests.

DIFFERENTIAL DIAGNOSIS

- Primary acute or chronic gastrointestinal disorders: infectious, inflammatory, neoplastic, toxic, mechanical, or other
- Acute or chronic metabolic or systemic disorders: hepatic, renal, adrenal, thyroid (less likely), reproductive, or central nervous system (CNS) disease

INITIAL DATABASE

- CBC findings are variable and nonspecific: most commonly observed changes are thrombocytopenia, neutrophilia with a left shift, and anemia.
- Findings on a serum chemistry profile are variable and nonspecific: hypochloremia, hypophosphatemia, elevated hepatic enzyme activities, azotemia, hyperbilirubinemia, hypoalbuminemia, hypoglycemia, or hyperglycemia. Results from a serum chemistry profile are most useful in assessing the patient for systemic complications and ruling out other disorders with overlapping clinical signs.
- Abdominal radiographs are not useful in diagnosing pancreatitis but are useful in ruling out other differential diagnoses of pancreatitis.

ADVANCED OR CONFIRMATORY TESTING

- Abdominal ultrasound is useful for the diagnosis of canine pancreatitis:
  - Diagnostic criteria: enlargement of the pancreas, fluid accumulation around the pancreas, pancreatic mass effect, hypoechoic pancreas (necrosis), hyperechoic peripancreatic fat, or dilated pancreatic duct.
  - Resolution of equipment and operator expertise have increased significantly over the last 2 decades.
  - Clinicians must exercise caution not to overdiagnose pancreatitis.
- Serum amylase and lipase activities have been used for the diagnosis of pancreatitis for several decades.
  - Measurements of serum amylase or serum lipase activities are neither sensitive (approximately 50% sensitivity) nor specific (approximately 50% specificity) for pancreatitis and are thus clinically not very useful.
- SNAP cPL is a patient-side test for immediate rule out of canine pancreatitis. A negative SNAP cPL test should prompt the clinician to evaluate the patient for other differential diagnoses. A positive SNAP cPL should be confirmed by measurement of a Spec cPL test.
- Serum canine pancreatic lipase immunoreactivity (cPLI) concentration (now measured by the Spec cPL assay):0 Measures the concentration of pancreatic lipase in serum (many other lipases contribute to serum lipase activity measurement).
  - Reference range: <200 µg/L
  - Cutoff value for pancreatitis: 400 µg/L
  - Highly specific for exocrine pancreatic function
  - Highly sensitive for both acute and chronic pancreatitis
  - One-time measurement does not allow assessment of disease severity, but serial measurements do allow for monitoring of disease progression in a specific patient.

TREATMENT

TREATMENT OVERVIEW

- Treat the underlying cause if identified.
- Treat clinical signs that cause morbidity (e.g., pain, vomiting, anorexia).
- Identify and treat complications.
- Nutritional support

ACUTE GENERAL TREATMENT

- If the clinician can identify an underlying cause, it should be treated appropriately. For example, the drug history of the animal should be carefully assessed, and if the animal has been treated with any medication that has been implicated in causing pancreatitis, the medication should be discontinued. In addition, medications the animal does not necessarily need should be discontinued or switched to a different class of drug with the same or similar effect.
- The mainstay of pancreatitis therapy is supportive care. This includes aggressive fluid therapy and careful monitoring for any signs of ensuing complications. Once a complication has become established in an animal, treatment of such a complication

becomes increasingly difficult.

- Providing supportive therapy for effects of pancreatitis that cause morbidity is also important. Foremost, analgesia is very important.
  - Abdominal pain is a key clinical sign in people with pancreatitis and should be assumed to be present in any dog with pancreatitis, whether or not this is clinically apparent. Analgesia can be achieved with intermittent dosing or continuous rate infusion. Acceptable options include one of the following:
    - Meperidine: 5-10 mg/kg IM or slow IV as needed (q 1-4 h); short half-life can be limiting.
    - Butorphanol: 0.2-0.7 mg/kg SQ, IM, or IV q 3-6 h
    - Fentanyl: 0.01-0.04 mg/kg SQ, IM, or IV once, then as a constant rate infusion at 0.003-0.006 mg/kg/h; alternatively, may be administered as transdermal patch, which takes >12 hours to be effective.
    - Buprenorphine: 0.01-0.02 mg/kg IM or IV
  - Antiemetic therapy can be important. Metoclopramide antagonizes dopamine at the receptor site, which may have a negative impact on pancreatic perfusion and therefore is not the drug of first choice. Dolasetron and ondansetron are 5-HT^3 serotonergic receptor antagonists that have much stronger antiemetic properties than metoclopramide. Dolasetron and ondansetron can be safely used in the dog. Dolasetron can be used at dosages of 0.3-0.6 mg/kg IV, SQ, or PO q 12-24 h. Maropitant is an NK^1 receptor antagonist which has both peripheral and central antiemetic properties (1 mg/kg SQ q 24 h or 2 mg/kg PO q 24 h). Patients can be treated with a 5 HT^3 and an NK^1 inhibitor simultaneously.
- Dogs with severe pancreatitis (associated with dehydration, electrolyte and acid-base abnormalities, disseminated intravascular coagulation [DIC], and/or other systemic complications) should receive plasma transfusions on a daily basis (10 mL/kg given IV for 1-2 hours). While there is little scientific evidence that plasma administration is clinically useful in human patients with pancreatitis, many veterinary gastroenterologists feel that there appears to be a clinical benefit. One recent retrospective study of dogs with acute pancreatitis showed no benefit from plasma administration.
- Antibiotics have failed to show any benefit in human patients with pancreatitis. In addition, dogs with pancreatitis rarely have the infectious complications of pancreatitis commonly seen in humans with the condition. Thus, antibiotic therapy should only be implemented when there is a specific suspicion for a concurrent infectious disease or an infectious complication of pancreatitis.
- There is no evidence that any other therapeutic strategy is clinically efficacious in dogs with pancreatitis.

CHRONIC TREATMENT

- Dogs with chronic pancreatitis should be evaluated for potential risk factors for pancreatitis. An 18-hour fasting serum triglyceride concentration should be measured, and treatment measures should be employed in hyperlipidemic animals to keep the serum triglyceride concentration below 500 mg/dL (see p. 1398). Also, a serum calcium concentration should be measured and a detailed drug history taken. Dietary measures are important in the successful treatment of dogs with chronic pancreatitis (see below). Antioxidants may also be of benefit.
- Measurement of serum Spec cPL concentration can be used to objectively monitor animals with pancreatitis.

NUTRITION/DIET

- Recommending nothing per os (NPO) for the animal was once standard therapy for dogs with acute pancreatitis. However, nutritional support, preferably enteral nutritional support, can have beneficial effects in animals with pancreatitis. NPO should only be chosen in animals for which vomiting cannot be controlled.
- If the patient vomits and has to be kept NPO for several days, total or partial parenteral nutrition (TPN or PPN; see p. 1322) should be considered for nutritional support. Alternatively, jejunostomy tube placement surgically or via endoscopy (see) can be used for nutritional support.
- Dogs with pancreatitis should be fed an ultra low-fat diet. Care should also be taken to avoid any treats that may be high in fat.

DRUG INTERACTIONS

Any drugs implicated in causing pancreatitis should be avoided. However, corticosteroids, formerly implicated in causing pancreatitis, probably pose little risk of leading to worsening of pancreatitis in the dog.

POSSIBLE COMPLICATIONS

- A pancreatic pseudocyst (an encapsulated fluid collection in the region of the pancreas) rarely develops in dogs with pancreatitis. Little is known about appropriate management in dogs. In humans, pancreatic pseudocysts are carefully monitored and are only drained if they increase in size.
- Pancreatic abscesses have only been reported in approximately 40 dogs. Most of these were not infected. Surgical removal may be the best option. Aggressive antibiotic therapy should be instituted after draining the abscess, at least until culture results show absence of any infectious organisms.
- Pancreatitis can lead to extrahepatic biliary obstruction. In most cases, the obstruction will resolve with supportive care.

However, some patients will need surgery to reroute the bile duct.
- Systemic complications may include DIC, thrombocytopenia, acute renal failure, pleural effusion, pulmonary emboli, myocarditis, peritonitis, and aspiration pneumonia.

RECOMMENDED MONITORING

- Short-term monitoring: CBC, chemistry profile, coagulation panel, Spec cPL
- Ultrasound is of little value in monitoring short-term progress.
- Long-term monitoring: Spec cPL

PROGNOSIS AND OUTCOME

- The prognosis for dogs with pancreatitis is directly related to the severity of disease. Mild disease without pancreatic and systemic complications carries a good prognosis. Severe disease with pancreatic (e.g., pancreatic necrosis, pancreatic pseudocyst, pancreatic abscess, or other) or systemic (e.g., renal failure, pulmonary failure, DIC, or other) complications carries a poor to grave prognosis.
- There is no commonly accepted scoring system that would allow prediction of the outcome of the disease in a specific animal. Such scoring systems are routinely utilized in human patients with pancreatitis.

PEARLS & CONSIDERATIONS

COMMENTS

- Pancreatitis is being diagnosed with increasing frequency in dogs. A recent study has shown histopathologic changes of the exocrine pancreas in most dogs that died for any reason, suggesting that subclinical exocrine pancreatic disease and, more specifically, inflammation are common in dogs. However, at this point, the clinical importance of subclinical pancreatic inflammation in dogs is unknown.

PREVENTION

- Avoiding high-fat foods and treats may prevent pancreatitis, especially in animals that have had previous episodes of pancreatitis.
- Eliminating risk factors will aid in the prevention of pancreatitis.

Pancreatitis, Cat

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Pancreatitis is an inflammatory condition of the pancreas. It can be acute or chronic, which can only be differentiated histopathologically. In contrast to acute pancreatitis, chronic pancreatitis is associated with permanent changes such as pancreatic fibrosis and/or atrophy.

EPIDEMIOLOGY

SPECIES, AGE, SEX: There are no known age or sex predilections for feline pancreatitis.

RISK FACTORS

- Blunt abdominal trauma
- Hypercalcemia
- Pancreatic hypoperfusion
- Pharmaceuticals: organophosphates and others
    - Corticosteroids are no longer implicated in causing pancreatitis in humans, and there is no evidence that they cause pancreatitis in cats.
- Infections: *Toxoplasma gondii,* hepatic fluke infestation *(Amphimerus pseudofelineus),* possibly feline infectious peritonitis (FIP), and others

ASSOCIATED CONDITIONS & DISORDERS

- Feline pancreatitis often concurrently occurs with cholangitis and inflammatory bowel disease (termed “triaditis” when inflammation is present in all three sites), but a cause-and-effect relationship between these conditions has not been demonstrated.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute or chronic
- Mild (not associated with systemic or pancreatic complications) or severe (associated with systemic or pancreatic complications)

HISTORY, CHIEF COMPLAINT: Vague complaints are typical:

- Lethargy
- Anorexia
- Vomiting occurs only in approximately 33% of cases.

PHYSICAL EXAM FINDINGS: Vague findings:

- Lethargy
- Dehydration
- Hypothermia
- Abdominal pain is only reported in approximately 25% of cases.
- Possible icterus

ETIOLOGY AND PATHOPHYSIOLOGY

- The causes for feline pancreatitis are not well defined. Several risk factors (see previous paragraphs) have been identified.
- There is a common pathogenetic pathway regardless of the initiating cause. Any number of insults can lead to premature activation of trypsinogen to trypsin. Trypsin, in turn, activates more trypsinogen and other pancreatic zymogens. Prematurely activated pancreatic digestive enzymes lead to local and systemic damage, which in turn leads to recruitment of inflammatory

cells and cytokine release, leading to further systemic complications.
- In general, premature activation of pancreatic digestive enzymes leads to initiation of pancreatitis, while the inflammatory response leads to progression of the disease and systemic complications.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Serum feline pancreatic lipase immunoreactivity concentration (fPLI), now measured by a commercially available assay, Spec fPL, is the most sensitive and specific laboratory test currently available for feline pancreatitis. However, it should be noted that integration of all clinical data available will afford the most accurate diagnosis.

DIFFERENTIAL DIAGNOSIS

- Primary acute or chronic gastrointestinal (GI) disorders: infectious, inflammatory, neoplastic, toxic, mechanical, or other conditions
- Acute or chronic metabolic or systemic disorders: hepatic, renal, adrenal, thyroid, systemic, or (less likely) central nervous system (CNS) or heart-worm disease

INITIAL DATABASE

- CBC findings are variable and nonspecific: most commonly observed changes are anemia and leukocytosis.
- Findings on a serum chemistry profile are also variable and nonspecific: increased serum hepatic enzyme activities, hyperbilirubinemia, hypercholesterolemia, hyperglycemia, azotemia, hypokalemia, hypocalcemia, and hypoalbuminemia. Results from a serum chemistry profile are very useful in assessing the patient for systemic complications of pancreatitis and ruling out other disorders with overlapping clinical signs.
- Abdominal radiographs are not useful for diagnosing pancreatitis but are useful for ruling out other differential diagnoses of pancreatitis.

ADVANCED OR CONFIRMATORY TESTING

- Abdominal ultrasound is useful for the diagnosis of feline pancreatitis:
    - Diagnostic criteria: enlargement of the pancreas, fluid accumulation around the pancreas, pancreatic mass effect, hypoechoic (necrosis) or, less common, hyperechoic (fibrosis) pancreas, hyperechoic peripancreatic fat, or dilated pancreatic duct
    - Resolution of equipment and operator expertise have increased significantly over the last 2 decades.
    - Clinicians should exercise caution and avoid overdiagnosing pancreatitis.
- Serum amylase and lipase activities are not useful for the diagnosis of feline pancreatitis.
- Serum feline trypsinlike immunoreactivity (fTLI) is highly specific (abnormally high value indicates pancreatitis with a high degree of accuracy) but not very sensitive (only 30%-60% of feline pancreatitis cases have an abnormal fTLI result).
- Serum feline pancreatic lipase immunoreactivity (Spec fPL [Idexx Laboratories, Portland, Maine]) concentration.
    - Measures concentration of pancreatic lipase in serum (many other lipases contribute to total serum lipase activity).
    - Reference range: 0.1-3.5 µg/L
    - Cutoff value for pancreatitis: 5.4 µg/L
    - Highly specific for exocrine pancreatic function
    - Highly sensitive for both acute and chronic pancreatitis
    - One-time measurement does not allow assessment of disease severity, but serial measurements do allow for monitoring of disease progression in a specific animal.

TREATMENT

TREATMENT OVERVIEW

- Treatment of the underlying cause if identified
- Treatment of clinical signs that cause morbidity (e.g., abdominal pain, vomiting)
- Identification and treatment of systemic and pancreatic complications
- Nutritional support

ACUTE GENERAL TREATMENT

- If an underlying cause can be identified, it should be treated accordingly. Examples:
  - The drug history of the animal should be carefully assessed; if the animal has been treated with any medication that has been implicated in causing pancreatitis, the medication should be discontinued.
  - In addition, medications the patient requires for a concurrent condition should be switched to a different class of drug with the same or similar effect.
- The mainstay of pancreatitis therapy is supportive care. This includes intensive but judicious fluid therapy and careful monitoring for any signs of ensuing complications. Once a complication has established itself in a patient, treatment of such a complication becomes increasingly difficult.
- Supportive therapy for signs that cause morbidity is also important. Foremost, analgesia is very important.
- Abdominal pain is a key clinical sign in people with pancreatitis and should be assumed to be present in any cat with pancreatitis, whether the sign is clinically apparent or not. Analgesia can be achieved with intermittent dosing or continuous rate infusion. Acceptable options include one of the following:
  - Meperidine: 2-4 mg/kg IM, as needed; short half-life or adverse effects can be limiting.
  - Butorphanol: 0.1-0.4 mg/kg SQ, IM, or IV
  - Morphine: 0.05-0.2 mg/kg q 2-6 h SQ or IM; may cause dysphoria or nausea
  - Fentanyl: 0.002-0.003 mg/kg IV once, then if needed, as a constant rate infusion: 0.001-0.004 mg/kg/h IV
  - Buprenorphine: 0.005-0.01 mg/kg IM or IV
- Antiemetic therapy can be important. Metoclopramide antagonizes dopamine at the receptor site, which may have a negative impact on pancreatic perfusion and therefore is not the first drug of choice. Dolasetron and ondansetron are 5-HT^3 serotonergic receptor antagonists that have much stronger antiemetic properties than metoclopramide. Dolasetron and ondansetron can be safely used in the cat. Dolasetron can be used at dosages of 0.3-0.6 mg/kg IV, SQ, or PO q 12-24 h. Maropitant is an NK^1 receptor antagonist, which has both peripheral and central antiemetic properties and can be used at 1 mg/kg SQ or PO q 24 h. Patients can be concurrently treated with a 5 HT^3 and an NK^1 inhibitor.
- Recommending nothing per os (NPO), nothing taken orally, was once standard therapy for cats with pancreatitis. However, nutritional support, preferably enteral nutritional support, can have beneficial effects in animals with pancreatitis. Thus, NPO should only be ordered for cats in which vomiting cannot be controlled. In animals that are eating and not vomiting, a low-fat diet should be offered in small amounts and given multiple times a day. If the animal vomits and has to be kept NPO, total or partial parenteral nutrition (TPN or PPN; see p. 1322) should be considered for nutritional support. If the animal is not vomiting but has prolonged anorexia, tube feeding (nasogastric, esophagostomy, or percutaneous endoscopic gastrostomy tube; see , , ,) is warranted. Nutritional support is especially important in cats. Many cats with pancreatitis have been partially or fully anorectic for some time before presentation and are thus at increased risk for secondary hepatic lipidosis.
- Antibiotics have failed to show a reproducible benefit in human patients with pancreatitis. In addition, infectious complications, which are a common cause for morbidity and mortality in human patients with severe pancreatitis, are extremely rare in cats with pancreatitis. Thus, antibiotic therapy should only be implemented when there is a specific suspicion for a concurrent infectious disease or an infectious complication of pancreatitis.
- Glucocorticoid therapy may be helpful, especially if there is concurrent histologically confirmed inflammatory bowel disease and/or cholangiohepatitis.
- There is no evidence that any other therapeutic strategy is clinically efficacious in cats with pancreatitis.

CHRONIC TREATMENT

- Cats with chronic pancreatitis often have concurrent inflammatory conditions such as inflammatory bowel disease (IBD) and/or cholangitis (known as “triaditis” when inflammation is present in all three sites). While there is little scientific evidence to suggest that these concurrent conditions cause pancreatitis, oftentimes the overall health of the cat will improve as these conditions are being appropriately diagnosed and managed.
- Serum calcium and fasting triglyceride concentrations should be measured in cats with pancreatitis, and conditions causing abnormalities in these parameters should be managed if present.
- While there is little evidence that high-fat diets are a cause of pancreatitis in cats, it still seems prudent to place cats with pancreatitis on a low-fat diet.
- Measurement of serum fPLI concentrations can be used for objectively monitoring animals with pancreatitis.
- Many cats with chronic pancreatitis have a lymphocytic infiltration of the pancreas. This is similar to humans with autoimmune pancreatitis. Thus, if no risk factors are identified and the patient does not improve spontaneously, a therapeutic trial with corticosteroids can be undertaken. A baseline serum fPLI concentration is measured, and prednisolone, 2 mg/kg PO q 12 h, is then given for 10 days. A second serum fPLI concentration measured at this point indicates whether to stop treatment (fPLI the same or higher) or continue on a tapering schedule based on positive response (fPLI lower).

DRUG INTERACTIONS

Any drugs implicated in causing pancreatitis should be avoided. However, corticosteroids, formerly implicated in causing pancreatitis, probably pose little risk of leading to worsening of pancreatitis in cats.

POSSIBLE COMPLICATIONS

- Pancreatic abscessation has only been reported in a single cat.

- Pancreatitis can lead to extrahepatic biliary obstruction. Most of these obstructions will resolve with supportive care. A small number of these cats need surgery to reroute the bile duct.
- Systemic complications may include disseminated intravascular coagulation (DIC), thrombocytopenia, acute renal failure, pleural effusion, and peritonitis. These are rare in cats.

RECOMMENDED MONITORING

- Short-term monitoring: CBC, chemistry profile, coagulation panel, fPLI
- Ultrasound is of little value in monitoring short-term progress.
- Long-term monitoring: fPLI

PROGNOSIS AND OUTCOME

The prognosis for cats with pancreatitis is directly related to the severity of disease. Mild disease without pancreatic and systemic complications carries a good prognosis. Severe disease with pancreatic (such as pancreatic necrosis, pancreatic pseudocyst, pancreatic abscess, or other) or systemic (such as renal failure, pulmonary failure, DIC, or other) complications carries a poor to grave prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

Pancreatitis is diagnosed with increasing frequency in cats. In addition, autoimmune pancreatitis has been described with increasing frequency in humans. It is intriguing to speculate that at least some cats with chronic pancreatitis have a similar condition and, like humans with autoimmune pancreatitis, may benefit from corticosteroid administration (see above).

PREVENTION

There is no known prevention for pancreatitis in cats.

AUTHOR: JÖRG M. STEINER

EDITOR: KEITH P. RICHTER

Pancreatic Adenocarcinoma

BASIC INFORMATION

DEFINITION

- Most commonly a malignant, highly metastatic epithelial tumor of the pancreas, of ductular or acinar origin

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Uncommon tumor of dogs and cats (<0.5% of all cancers)
- Older dogs and cats (dogs median age 9.2 years; cats 8-18 years)
- More common in female dogs; no gender predilection in cats

GENETICS & BREED PREDISPOSITION

- Airedale terriers and spaniel breeds may be at higher risk.
- No breed predilection in cats

RISK FACTORS

- Unknown
- Experimentally, *N*-ethyl-*N*′-nitro-*N*-nitrosoguanidine administered intraductally has been shown to induce pancreatic adenocarcinoma.

ASSOCIATED CONDITIONS & DISORDERS

- Paraneoplastic alopecia in cats
- Bile duct obstruction
- Secondary pancreatitis
- Carcinomatosis with or without ascites and metastasis to distant sites
- Diabetes mellitus (reported in two cats)
- Exocrine pancreatic insufficiency secondary to pancreatic duct obstruction (rare)
- Superficial necrolytic dermatitis/hepatocutaneous syndrome (in dogs)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Typically vague and nonspecific: anorexia, weight loss, lethargy, vomiting, constipation, diarrhea, abdominal distension (mass, ascites), and paraneoplastic alopecia (cats)
- Owners may note icterus if the neoplasm is occluding the common bile duct.
- Signs related to metastasis: ascites, dyspnea, lameness/bone pain
- Signs related to effects of hepatocutaneous syndrome on paws (dogs): reluctance to walk or signs of paw pain when walking

PHYSICAL EXAM FINDINGS

- Abdominal mass and/or ascites
- Icterus if common bile duct obstruction
- Dyspnea due to pleural effusion or pulmonary metastasis
- Necrolytic pododermatitis due to superficial necrolytic dermatitis (dogs)

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology unknown
- Clinical signs related to local disease (mass), metastatic disease (carcinomatosis and systemic), and metabolic effects

- The majority of cases have already metastasized to regional or distant sites before the diagnosis can be made.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis may be suspected with vague nonspecific clinical signs. In some cases, there is a palpable abdominal mass, ascites (associated with carcinomatosis) and/or icterus (associated with extrahepatic biliary obstruction). Confirmation is based on detection of a pancreatic mass, (usually with ultrasound or at exploratory laparotomy in an older patient) and cytologic or histopathologic examination of smears or tissue specimens, respectively, from the mass.

DIFFERENTIAL DIAGNOSIS

- Pancreatitis: primary pancreatitis or pancreatitis secondary to the tumor
- Pancreatic pseudocyst
- Pancreatic abscess
- Pancreatic nodular hyperplasia
- Other pancreatic tumors (islet cell tumor, adenoma, sarcoma, and lymphoma)

INITIAL DATABASE

- CBC, serum biochemical profile, and urinalysis:
  - Can be unremarkable
  - Variable neutrophilia, anemia, hyper-bilirubinemia, azotemia, hyperglycemia, and elevations in hepatic enzymes
  - Serum lipase activities: marked hyperlipasemia may be a noninvasive indicator and biochemical marker for neoplasia of the pancreas; an activity greater than 25 times normal is probably diagnostic for exocrine pancreatic carcinoma.
- Abdominal radiographs: nonspecific; may reveal cranial abdominal mass effect and/or loss of abdominal organ detail due to ascites
- Thoracic radiographs (three views): to evaluate for pulmonary metastasis
- Abdominal ultrasound (high yield):
  - In most cases, a soft-tissue mass can be identified in the region of the pancreas. It may not be possible to conclusively identify the mass as pancreatic in origin on the ultrasound exam.
  - Benign pancreatic nodular hyperplasia, a common incidental finding in cats, must be considered when pancreatic nodules are identified. There is a tendency for neoplastic lesions to manifest as a single larger lesion and for nodular hyperplasia to manifest as multiple smaller lesions, although there can be overlap of the imaging findings for both entities.
  - Allows identification of metastatic lesions (liver “target lesions,” peritoneal masses, lymphadenopathy) and ascites, but not specific for pancreatic adenocarcinoma
  - Metastases are already present in a majority of cases of pancreatic adenocarcinoma and may be visible ultrasonographically.
  - The presence of gross metastatic disease (e.g., on ultrasound) must not be overinterpreted, because benign lesions such as hepatic nodular regeneration/hyperplasia, accessory splenic tissue, and others can be present and should not be misidentifted as metastases.

ADVANCED OR CONFIRMATORY TESTING

- Cytologie or histologic diagnosis is essential, owing to the inability to differentiate grossly between pancreatic adenocarcinoma, chronic pancreatitis, and pancreatic nodular hyperplasia.
- Cytologie evaluation of ascites may reveal neoplastic cells in some cases (neoplastic cells may not exfoliate).
- Ultrasound-guided percutaneous fine-needle aspirate for Cytologie examination (variable yield; neoplastic cells may not exfoliate; differentiation between neoplastic lesions and nodular hyperplasia may be difficult).
- Ultrasound-guided percutaneous core biopsy, laparoscopic biopsy, or surgical biopsy for histopathologic evaluation of tissue.
- Pancreatic lipase immunoreactivity (PLI): has not been evaluated with pancreatic neoplasia; increased levels would be expected if there is secondary pancreatitis.
- Abdominal CT scan or MRI (surgical planning and staging)

TREATMENT

TREATMENT OVERVIEW

- Surgical excision of the tumor may be palliative but is not indicated if metastasis is present (majority of cases).
- Aggressive surgical procedures (complete pancreatectomy or pancreatico-duodenectomy) have been described, but they carry high operative morbidity and mortality without meaningful cure rates.

ACUTE GENERAL TREATMENT

- Supportive therapy if there is secondary pancreatitis
- Surgery is indicated for solitary masses without evidence of metastasis, although a high metastatic rate makes this situation uncommon.
- Palliative surgery if there is intestinal or biliary obstruction

CHRONIC TREATMENT

- Chemotherapy or radiation therapy: no effective chemotherapy or radiation therapy protocols have been described.
- Gemcitabine (Gemzar) is approved for the treatment of pancreatic adenocarcinoma in people, and although cures are rare, gemcitabine has improved survival times in human patients. A recent case series of cats with pancreatic adenocarcinoma that underwent surgery and/or chemotherapy reported a median survival time of 3.8 months, with a range of 1 day to 17 months.
- Palliation of pain with analgesics

POSSIBLE COMPLICATIONS

Postoperative pancreatitis; preoperative and perioperative octreotide (Sandostatin, Novartis; 5 meg/kg SQ q 8 h) may be protective.

PROGNOSIS AND OUTCOME

- Very poor to grave
- Survival time of more than 1 year is rare.

PEARLS & CONSIDERATIONS

COMMENTS

- Pancreatic adenocarcinoma is an aggressive malignancy with high potential for metastasis and generally no effective treatment.
- Must be differentiated from non-neoplastic pancreatic lesions. It is important to have a Cytologie or histologic diagnosis, because chronic pancreatitis may closely resemble pancreatic adenocarcinoma.
- Animals with solitary masses without evidence of metastasis are candidates for surgery.

Palm (Cycad/Sago) Toxicosis

BASIC INFORMATION

DEFINITION

Acute, potentially fatal toxicosis occurring from ingesting cycad palm leaves, seeds, bark, or roots and characterized by vomiting and diarrhea, anorexia, lethargy, acute liver failure (2-3 days later), coagulopathies, and neurologic signs

SYNONYMS

Cycad palm/plant: sago palm (true synonyms); includes *Zamia floridana, Cycas revoluta,* and *C. circinalis*

EPIDEMIOLOGY

SPECIES, AGE, SEX: All animals are susceptible; most poisoning cases reported in dogs instead of cats.

RISK FACTORS: Presence of palm in the pet's environment.

GEOGRAPHY AND SEASONALITY

- Ornamental plants, indoor; in the southern part of the United States and in Hawaii, sago palms are frequently used for landscaping.
- Intoxication occurs mostly in summer months. Availability of indoor ornamental sago palms makes intoxication possible throughout the year.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Exposure to sago palm (any part of the plant)
- Within 24 hours, onset of vomiting, diarrhea, lethargy, and anorexia; chewed leaves, seeds, plant material may be in vomitus.
- Ataxia, weakness, or seizures
- Occurrence or recurrence of lethargy, anorexia, vomiting 2-3 days after ingestion, due to acute hepatic injury/failure.

PHYSICAL EXAM FINDINGS

- As above (see History, Chief Complaint)
- Signs of abdominal pain
- Weak pulse associated with hypovolemia or dehydration
- Petechiae, ecchymoses
- Hypovolemic shock (depressed mentation, weakness/collapse, poor perfusion)
- Central nervous system (CNS) signs: ataxia, seizures

ETIOLOGY AND PATHOPHYSIOLOGY

- Sago palms (cycad plants) are palmlike plants in the family Cycadaceae. These are woody, coarse plants with leaves originating from a thickened stem and are found in dry sandy soils of tropical and subtropical regions throughout the world.
- *C. revoluta* is the species most commonly involved in poisoning cases.
- Toxins: cycasin and methylazoxymethanol, a neurotoxic amino acid, and an unidentified high molecular-weight compound.
- The glucose molecule on cycasin is hydrolyzed by the gut bacterial enzyme alpha-glycosidase, yielding sugars and methylazoxymethanol, which then alkylates DNA and RNA. This process causes hepatotoxic, teratogenic, carcinogenic, and gastrointestinal (GI) effects.
- Azotemia can occur secondary to decreased renal perfusion resulting from systemic hypotension/hypoperfusion.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on history/evidence of exposure to plant, and presence of vomiting, anorexia, lethargy, and diarrhea within 24 hours. High serum liver enzyme levels 2-3 days after exposure offer further support. There is no definitive diagnostic test.

DIFFERENTIAL DIAGNOSIS

- Mushroom *(Amanita)* poisoning
- Blue-green algae toxicosis
- Idiopathic chronic hepatitis
- Viral hepatitis (canine hepatitis virus)
- Iron toxicosis in dogs

INITIAL DATABASE

- CBC:
  - Leukocytosis (reported: 3500-34,000 cells/µL)
  - Thrombocytopenia: mild and due to blood loss
- Serum biochemistry panel:
  - Increased alanine aminotransferase (ALT; range 128-10,000 IU/L)
  - Increased alkaline phosphatase (ALP; 218-3931 IU/L)
  - Hyperbilirubinemia (reported: 1.03-10 mg/dL; reference range 0-0.3 mg/dL)
  - Hypoproteinemia
  - Azotemia (prerenal and/or renal)
- Coagulation profile: increased pro-thrombin time, partial thromboplastin time due to liver damage
- Urinalysis: glucosuria, bilirubinuria, hematuria possible

ADVANCED OR CONFIRMATORY TESTING

Histopathologic lesions of liver may include marked focal centrolobular and midzonal coagulation necrosis.

TREATMENT

TREATMENT OVERVIEW

In patients showing clinical signs (GI. CNS), initial treatment is aimed at stabilization (seizure control, antiemetics, respectively). Signs of hepatic dysfunction should prompt treatment/prophylaxis for hepatic encephalopathy. Patients who are thought or known to have ingested this plant but where no clinical signs are apparent should undergo decontamination (induction of vomiting and administration of activated charcoal). Goals of treatment are decontamination of the animal as soon as possible, control of CNS and GI signs, treatment of liver injury, and provision of supportive care.

ACUTE GENERAL TREATMENT

- Decontaminating the animal:
  - Emesis (see p. 1364): only in animals not showing clinical signs; may remain effective within a couple of hours of ingestion
  - Gastric lavage (see p. 1281) only if a very large dose has been ingested and emesis cannot be induced (e.g., comatose animal)
  - Activated charcoal 1-4 g/kg PO; airway protected with cuffed endotracheal tube if animal is unconscious
- Controlling CNS and GI signs:
  - Seizures:
    - Diazepam 0.5-2 mg/kg IV as needed
    - Other anticonvulsants if refractory (see p. 1425)
  - Vomiting, gastric ulceration:
    - Control severe vomiting with metoclopramide (0.1-0.4 mg/kg PO, SQ, or IM q 6 h); or with maropitant, 1 mg/kg SQ q 24 h or 2 mg/kg PO q 24 h for up to 5 days
    - GI protectants, such as famotidine (0.5-1 mg/kg IV q 12-24 h) or sucralfate (0.5-1 g for a dog or 125-250 mg for a cat) PO q 8-12 h if evidence of gastric ulceration
- Treating signs of liver damage (see p. 503):
  - Clinicians should monitor and treat secondary effects of acute hepatic failure, such as hepatic encephalopathy (see p. 501), coagulopathy/bleeding tendencies (see), and hypoproteinemia (see).
  - If serum levels of liver enzymes are elevated or signs of liver dysfunction are present, oral antibiotics (e.g., neomycin, 10-20 mg/kg PO q 6-8 h) and lactulose (15-30 mL PO q 6-8 h [dogs]; 0.25-1 mL PO q 8-12 h [cats]) may help reduce the risk of hepatic encephalopathy (see p. 501).

- S-adenosyl-L-methionine (SAM-e), 18 mg/kg PO q 48-72 h
- Vitamin K[1;] 3 mg/kg PO, IM, or SQ, ± blood transfusions if hemorrhage
- Consider using *N*-acetylcysteine (Mucomyst), 140 mg/kg PO or IV (use a 5-micron filter for IV use) followed by 70 mg/kg PO for 5-7 treatments. Efficacy for treating sago palm toxicosis has not been determined.

- Supportive care
  - IV fluids (may require dextrose supplementation if hypoglycemia)

CHRONIC TREATMENT

SAM-e 18 mg/kg PO every other day to third day for 1-3 months if evidence of persistent liver insult (e.g., serum ALT and/or bilirubin elevation)

POSSIBLE COMPLICATIONS

Chronic liver disease (cirrhosis/fibrosis)

RECOMMENDED MONITORING

- CBC
- Serum biochemistry profile, especially liver enzymes (baseline, 24, 48, 72 hours)
- Coagulation panel (prothrombin time [PT], activated partial thromboplastin time [APTT])
- Hematocrit

PROGNOSIS AND OUTCOME

- Poor prognosis if evidence of severe liver injury
- Good prognosis with early and intensive treatment

PEARLS & CONSIDERATIONS

COMMENTS

- All sago palm exposures should be taken seriously because the overall mortality rate in dogs can be 33%.
- All parts are considered toxic, and seeds concentrate more toxins; one to two ingested seeds potentially can be lethal in a medium-sized dog.
- Clinical signs of toxicosis can last from a few days to several weeks depending on the severity of liver injury.

TECHNICIAN TIP

- Be aware of the biphasic nature of this intoxication: initial clinical signs occur within hours of ingestion of the plant, and after initial recovery, a second clinical syndrome (due to liver failure) should be anticipated, monitored, and treated, 2-3 days after the first.

PREVENTION

Owners should keep pets out of areas where sago palm plants are growing.

SUGGESTED READING

Albretsen JC, et al: Cycad palm toxicosis in dogs: 60 cases (1987-1997). J Am Vet Med Assoc 213(1):99–101, 1998.

AUTHOR: MARY SCHELL

EDITOR: SAFDAR A. KHAN

1ST EDITION AUTHOR: SAFDAR A. KHAN

Pallor

BASIC INFORMATION

DEFINITION

Pale mucous membranes

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats of any age and either sex

GENETICS & BREED PREDISPOSITION: Rare hereditary hemolytic anemias in Abyssinian, Siamese, and Somali cats and in poodle, basenji, and beagle dogs CONTAGION & ZOONOSIS: Feline leukemia virus-associated anemia (cat to cat)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Anemia: perfusion is adequate, but circulating red blood cell (RBC) mass is low.
- Shock: perfusion is inadequate, but circulating RBC mass is normal.

HISTORY, CHIEF COMPLAINT

- Weakness
- Tachypnea
- Collapse
- Those due to underlying disease:
    - History of trauma in hypovolemic shock
    - Coughing and dyspnea with cardiogenic shock
    - Lethargy and anorexia with septic shock
- Pale mucous membranes (uncommon as an owner-reported chief complaint)

PHYSICAL EXAM FINDINGS

- Pale mucous membranes of the gingiva, tongue, conjunctiva, anus, penis, and/or vulva
- Tachypnea, cool mucous membranes, tachycardia, and weakness may be seen with either anemia or shock.
- Capillary refill time (CRT):
    - Unless there is severe anemia, CRT should be normal (<2 sec) in an anemic animal that is not in shock.
    - Animals in shock typically have a prolonged CRT.
- Visualization of stool via rectal examination may identify fresh blood or melena in cases with gastrointestinal (GI) hemorrhage.
- Palpation of the extremities (pinnae, paws) reveals a cool temperature with poor perfusion (e.g., shock) but not with anemia alone.

ETIOLOGY AND PATHOPHYSIOLOGY

- Severe blood loss or severe anemia can lead to shock, so both conditions may exist in the same animal.
- Anemia causes pallor due to blood with diminished hemoglobin (i.e., decreased red blood cells) traversing through easily seen capillary beds, creating a pale red color in the mucous membranes.
- Shock leads to poor perfusion of blood through capillary vessels, thus causing pallor. Shock is a peracute condition, but the underlying cause may be chronic in nature.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Initially, distinguishing the cause of pallor between anemia and shock can be completed via physical examination and blood pressure (BP) and packed cell volume (PCV) measurement. Then additional testing can provide a specific diagnosis.

DIFFERENTIAL DIAGNOSIS

There are two major forms of anemia: regenerative and nonregenerative.

- Regenerative anemia:
  - Blood loss/hemorrhage:
    - Trauma
    - Parasitic infestation
    - Coagulopathy
    - GI disease (ulceration, mass, inflammation, infiltration)
    - Abdominal or intrathoracic mass
  - Hemolysis:
    - Primary immune-mediated
    - Fragmentation (disseminated intravascular coagulation [DIC], hemangiosarcoma, heartworm disease, vasculitis)
    - Toxicoses (zinc, acetaminophen, onions)
    - RBC parasites *(Babesia, Bartonella, Cytauxzoon, Mycoplasma* spp.)
    - Hereditary (pyruvate kinase or phosphofructokinase deficiency)
- Nonregenerative anemia:
  - Bone marrow disease (aplastic anemia, myelodysplasia, myelofibrosis, myeloproliferative disorder)
  - Chronic kidney disease
  - Anemia of chronic disease
  - Feline leukemia virus (FeLV) infection

There are four major types of shock:

- Cardiogenic shock:
  - Severe atrioventricular (AV) valvular endocardiosis
  - Cardiac tamponade secondary to pericardial effusion
  - Dilated cardiomyopathy
  - Hypertrophie cardiomyopathy
  - Heartworm disease
  - Severe dysrhythmia
- Hypovolemic shock:
  - Dehydration
  - Blood loss
  - Hypoadrenocorticism
  - Intoxications
- Traumatic shock
- Septic shock

INITIAL DATABASE

- PCV will help differentiate anemia from shock in most cases. Unless the animal was anemic beforehand, cases of acute shock should have a normal PCV, including those with acute blood loss. Anemic animals, by definition, have a diminished PCV.
- BP is usually diminished in cases of shock. Unless the anemia is severe or acute, BP is typically normal in anemic animals.
- CBC, biochemical profile, and urinalysis are warranted in most cases of pallor to assist in determining the underlying cause.

ADVANCED OR CONFIRMATORY TESTING

- Reticulocyte count to characterize type of anemia
- Evidence of saline-diluted RBC agglutination on a slide suggests an immune-mediated hemolytic anemia, as would a positive Coombs' test result.
- Thoracic radiographs to look for evidence of primary heart disease, trauma (e.g., rib fractures, lung contusions), or an infectious focus causing sepsis (e.g., pneumonia)
- Abdominal radiographs and/or ultrasound to visualize fluid (e.g., blood loss, congestive heart failure), neoplasia, and metallic (zinc) objects in the GI tract
- Cytologie and/or histopathologic examination of bone marrow to help characterize the amount of regeneration in persistently anemic animals and look for evidence of primary bone marrow disease (e.g., neoplasia, FeLV).

TREATMENT 

TREATMENT OVERVIEW

Stabilization of the animal (e.g., blood transfusion for severely anemic patients, intravenous fluids for those in shock) while the cause of pallor is determined and corrected if possible.

ACUTE GENERAL TREATMENT

- Determined by the underlying cause
- Patients with severe anemia or acute blood loss may require transfusion of RBC ± plasma (see p. 1347).
- Hypovolemic, traumatic, and septic shock cases are usually treated with vigorous intravenous crystalloids, + colloids (see pp. 1591 and 1592).
- Cardiogenic shock requires supplemental oxygen and attempts to improve perfusion, such as with pericardiocentesis (if cardiac tamponade) and medications (e.g., positive inotropes, antidysrhythmics).

CHRONIC TREATMENT

Depends on the underlying cause

RECOMMENDED MONITORING

- PCV in patients with anemia
- CRT and BP in cases of shock

PROGNOSIS AND OUTCOME

- Determined by the underlying cause
- Many cases of pallor come with a guarded to poor prognosis (e.g., DIC, hemangiosarcoma, FeLV, cardiogenic shock, chronic kidney disease), but others may respond much better with proper therapy (e.g., trauma, parasitic infection, hypoadrenocorticism).

PEARLS & CONSIDERATIONS

COMMENTS

- Because there are many causes of pallor, the clinician especially needs to be aware of the differential diagnoses and methods to distinguish anemia from shock.
- Most causes of pallor are serious, thus requiring timely workup and therapy.

TECHNICIAN TIP

Strive to recognize pallor in hospitalized and outpatient cases, and assist in distinguishing anemia from shock via physical examination, PCV and BP measurement.

EDITOR: ETIENNE CÔTÉ

Pain

BASIC INFORMATION

DEFINITION

An unpleasant sensory or emotional experience associated with actual or potential tissue damage

EPIDEMIOLOGY

SPECIES, AGE, SEX: Animals of any species, age, or sex may experience pain, although pain thresholds and response characteristics may vary.

ASSOCIATED CONDITIONS & DISORDERS: Pain intensity does not always correlate with degree of tissue damage. In some cases, there may be no obvious evidence of tissue disruption, and persistence of pain may indicate abnormal processing of input in the central nervous system (CNS). The following are some associated conditions and disorders:

- Trauma
- Surgery
- Degenerative disease processes
- Inflammatory disease processes
- Neoplasia

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Physiologic versus pathologic
- Acute versus chronic
- Somatic versus visceral versus neuropathic

HISTORY, CHIEF COMPLAINT

- Humans can verbally report pain as their primary complaint, whereas animals cannot.
- An animal's history will vary depending on the type of pain (i.e., acute versus chronic) and may include an inciting injury.

PHYSICAL EXAM FINDINGS

- Behavioral signs of pain vary considerably among individuals. Common pain-related behaviors in dogs and cats include:
  - Postural changes: arched/hunched back, drooped head
  - Temperament changes: aggression, hiding
  - Vocalization: moaning, howling, purring (cats)
  - Locomotor changes: reluctance to move, lameness
  - Others: no interest in food or play, failure to groom
- Physiologic signs associated with stress response (tachycardia, tachypnea, mydriasis, hypertension) may accompany pain but are nonspecific. Clinical signs associated with chronic pain may be very subtle.

ETIOLOGY AND PATHOPHYSIOLOGY

- A noxious stimulus activates specialized nerve endings called *nociceptors.*
- Nociceptors transduce noxious chemical, mechanical, or thermal stimuli into electrochemical potentials that are transmitted via sensory nerves from affected tissue to spinal cord.
- In the spinal cord dorsal horn, incoming first-order peripheral neurons synapse with ascending spinal neurons that extend to the brainstem.
- Incoming noxious input is modulated at the level of the dorsal horn by other incoming sensory information, descending inhibitory nerve impulses, or pharmacologic interventions.
- In the brainstem, incoming second-order neurons synapse with third-order neurons that form tracts extending to numerous locations within the brain where pain perception ultimately occurs.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Since pain is a sensation, animals may experience it without expressing appreciable manifestations of it. Therefore, attentive physical examination and especially repeated evaluations to detect early or subtle changes are cornerstones of diagnosis of pain, especially in stoic animals.

DIFFERENTIAL DIAGNOSIS

- Since animals cannot self-report pain, the veterinarian must accurately identify it when it is present.
- Pain must be differentiated from:
  - Distress associated with other factors (restraint, restrictive bandaging, confinement, separation from owners)
  - Dysphoria associated with drugs used to treat pain (particularly opioids, dissociative agents)
- Once a presumptive diagnosis of pain is made, veterinarians should investigate the underlying cause.
- Differential diagnoses of common causes listed under Associated Conditions and Disorders.

INITIAL DATABASE

- Recognition of pain in animals is subjective.
- Veterinarians should follow a routine for evaluation. The veterinarian should:
  - Evaluate the animal's signalment, history, and previous physical exam findings.
  - Observe the animal's behavior from a distance (preferably unobserved by the animal).
  - Observe the animal's behavior during interaction prior to extensive palpation and examination.
  - Gently palpate the body region of interest and evaluate the animal's response.
- Perform serial evaluations and record findings in the animal's medical record.
- Pain should be evaluated as the fourth vital sign (in addition to temperature, pulse, and respiration).
- No predictable changes in routine laboratory tests specifically indicate pain.

TREATMENT

TREATMENT OVERVIEW

- Improve the animal's quality of life while addressing underlying cause of pain if possible.
- If pain is intractable, euthanasia may be most humane option.

ACUTE GENERAL TREATMENT

- Depends on species, pain intensity, underlying cause
- Acute pain most often is managed pharmacologically.
- Pharmacologic treatment involves one or more of the following:
  - Opioids: morphine, hydromorphone, oxymorphone, fentanyl, buprenorphine, butorphanol
  - Nonsteroidal antiinflammatory agents (NSAIDs): carprofen, meloxicam, deracoxib
  - Local anesthetics (regional anesthesia techniques, see p. 1299), lidocaine, bupivacaine
- Utilize the following treatment strategies: *multimodal analgesia,* which is a combination of multiple analgesic drugs or techniques to target different points along the pain pathway; *preemptive analgesia,* which is the administration of analgesic agent(s) prior to noxious insult (i.e., surgery).

CHRONIC TREATMENT

- Dietary changes and nonpharmacologic treatment (e.g., physiotherapy, acupuncture) may be beneficial.
- Pharmacologic treatment involves one or more of the following given by the oral route:
  - Nonsteroidal antiinflammatory drugs
  - Opioids (doses may need to be increased if pain intensifies)
  - Adjunctive analgesic agents (tramadol, gabapentin, amantadine) may be added if conventional analgesics fail to manage pain adequately.

DRUG INTERACTIONS

- Opioids reduce anesthetic requirements significantly.

- Certain opioids (e.g., meperidine) may interact with monoamine oxidase-B inhibitors (e.g., selegiline [L-deprenyl] or amitraz) and produce “serotonin syndrome.”
- There is a significantly increased risk of gastrointestinal toxicosis possible when NSAIDs and glucocorticoids are administered concurrently.

PROGNOSIS AND OUTCOME

- Acute pain expected to resolve within period of normal tissue healing
- When pain persists beyond normal course, veterinarians should suspect persistent disease, injury, or CNS changes and consult a specialist.

PEARLS & CONSIDERATIONS

COMMENTS

For challenging cases, veterinarians should seek advice from a veterinary pain specialist (i.e., an anesthesiologist, surgeon, oncologist, or internist with advanced training in pain management).

PREVENTION

Veterinarians should institute preemptive analgesic protocols when appropriate.

AUTHOR: LEIGH A. LAMONT

EDITOR: ETIENNE CÔTÉ

Roundworm Infection

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Infection with a small intestinal round-worm *(Toxocara* or *Toxascaris* spp.)

SYNONYMS

Toxocariasis, ascarid infection, infection with *Toxocara cants* (dog) or *T cati* (cat), infection with *T. leonina* (dogs and cats), visceral larva migrans (zoonosis); ascarids

EPIDEMIOLOGY

SPECIES, AGE, SEX: Young puppies and kittens < 6 months old most commonly infected. Clinically significant disease is uncommon in adult dogs and cats. *T. cants* affects dogs, *T. cati* affects cats, and *T. leonina* affects both dogs and cats.

RISK FACTORS: Young animals and pregnant dogs and cats are more susceptible.

CONTAGION & ZOONOSIS: Unembryonated *Toxocara* spp. eggs are passed in the host's feces. Embryonation in the environment produces second-stage larvae in the eggs, which are infective (via ingestion) to humans, dogs, and cats. Infection with *Toxocara* spp. is the most common cause of human visceral and ocular larva migrans. *T leonina* is not zoonotic.

GEOGRAPHY AND SEASONALITY: *Toxocara* spp. are found worldwide, with a higher incidence in lower socio-economic communities.

ASSOCIATED CONDITIONS & DISORDERS: Commonly found in association with other intestinal parasites. Intussusception and, with very large worm burdens, intestinal obstruction are possible.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Intestinal infection is most common.
- Aberrant migration of larvae (visceral, ocular) is rare.

HISTORY, CHIEF COMPLAINT

- Commonly unremarkable; the parasite is discovered incidentally during a routine fecal examination, or infection is never detected.
- Intestinal: in overt cases, presence of worms in feces or diarrhea, a pot-bellied appearance in young puppies or kittens, or occasional vomiting with or without worms may prompt the owner to seek veterinary attention.

PHYSICAL EXAM FINDINGS: Typically, no physical abnormalities are noted, as above. It has been speculated that essentially all puppies have *Toxocara.*

ETIOLOGY AND PATHOPHYSIOLOGY

- *T. cants* transmission: mainly transplacental from dam to puppies
- *T. cants* (puppies) or *T. cati* (kittens): transmammary transmission possible; principal route in cats
- Fecal-oral transmission and ingestion of other paratenic or transport hosts such as rodents: additional routes of infection
- After infection, the parasite may migrate through the liver into the lungs *(T. cants* and *T cati),* within the wall of the gastrointestinal (GI) tract *(T. cants, T cati,* and *T. leonina),* or somatically within the tissues *(T. cants, T cati).* Puppies and kittens may begin to shed eggs within 2.5-3.5 weeks and generally continue to do so until age 4-6 months.
- Eggs are highly resistant and long-lived within the environment. They adhere easily to fomites. Eggs are most susceptible to heat. A 20% bleach solution will decrease the adherence of the eggs but will not kill them.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Roundworm eggs are easily detected in a simple fecal flotation procedure using zinc sulfate flotation media.

DIFFERENTIAL DIAGNOSIS

- Infections with *Ancylostoma caninum* (hookworms), *Trichuris vulpis* (whip-worms), *Giardia intestinalis,* and *Cystoisospora* (coccidia)
- *Campylobacter* enteritis
- Canine parvovirus
- Feline panleukopenia
- Intussusception or foreign body ingestion (if obstruction)

INITIAL DATABASE

Fecal examination should be routinely performed in all puppies and kittens up to 6 months of age.

TREATMENT

TREATMENT OVERVIEW

Owing to their zoonotic significance, these common helminth parasites must be removed from the gastrointestinal tract of both dogs and cats.

ACUTE GENERAL TREATMENT

- The Centers for Disease Control and Prevention (CDC) and Association of Veterinary Parasitologists recommend deworming all puppies beginning at 2 weeks, with additional treatments at 4, 6, and 8 weeks of age. Semimonthly deworming may be continued up to 12 weeks of age. These recommendations aim to reduce zoonotic risk by decreasing environmental parasite burden.
- Deworm kittens at 6 weeks of age and again at 8 and 10 weeks.
- Deworm puppies and kittens monthly after they reach 3 months of age.
- Deworm puppies and kittens even if fecal results are negative, to ensure removal of prepatent worms prior to shedding.
- Treat pregnant bitches to reduce further transplacental transmission: fenbendazole, 50 mg/kg q 24 h for 14 days.
- Treat lactating bitches and queens to prevent further transmammary transmission.
- Most deworming medications are effective against roundworms. Pyrantel pamoate (5-10 mg/kg PO; considered safe during pregnancy) is used most widely. Other anthelmintics (e.g., milbemycin oxime, moxidectin, selamectin) have antiascarid activity but are not used in a 2-week protocol as previously described. Ivermectin at parasiticidal doses may be effective *(T. canis* > *T. leonina),*but alternatives with a wider safety margin are preferred.
- Many products used for heartworm prevention are also effective against roundworms.

CHRONIC TREATMENT

Environmental decontamination should be considered in all animals, especially those with repeated infections or adult animals with infection.

DRUG INTERACTIONS

The parasiticidal dose of ivermectin (200 mcg/kg) should not be used in collies or other susceptible breeds/individuals (see pp. 625 and).

PROGNOSIS AND OUTCOME

Prognosis is excellent for appropriately treated animals.

PEARLS & CONSIDERATIONS

COMMENTS

- All puppies and kittens should be strategically dewormed to prevent environmental contamination and human exposure.
- The zoonotic risk associated with *Toxocara* spp. parasites outweighs their impact on dogs and cats.

PREVENTION

- Treatment of pregnant dogs and cats can decrease the level of transplacental and transmammary infection of puppies and kittens. Common treatment regimes described for dogs include fenbendazole, 50 mg/kg PO q 24 h, from day 40 of gestation to day 14 of lactation; or ivermectin, 200 mcg/kg, once a week from 3 weeks prior to whelping to 3 weeks after whelping.
- Pregnant cats may be treated with topical selamectin, 6 mg/kg, 6 weeks and 2 weeks before parturition and 2 weeks and 6 weeks after parturition.

TECHNICIAN TIPS

Warn all clients of the risks of exposure to *Toxocara,* especially those clients with young children or those who are immunosuppressed.

CLIENT EDUCATION

- Clients should be encouraged to commit to regular deworming of puppies and older dogs.
- Good hygiene is important in kennels and catteries; all feces should be properly removed from the area.

Round Cell Tumors

BASIC INFORMATION

DEFINITION

- Round cell tumors are composed of a homogenous population of cells that have well-defined cytoplasmic margins, are round in shape, and have a round nucleus. Distinct cytologic characteristics of each type of round cell aid in definitive diagnosis.
- Tumor types include lymphoma, mast cell tumor (MCT), transmissible venereal tumor (TVT), histiocytoma, and plasma cell tumor/multiple myeloma. Malignant melanoma is highly variable in appearance and is often classified as a round cell tumor. Each of these is discussed in greater detail in individual chapters.
- Round cell tumors can be either malignant (e.g., lymphoma, grade II or III mast cell tumors) or benign (histiocytoma, grade I mast cell tumor). Most primarily affect the skin (mast cell tumor, histiocytoma, plasma cell tumor, transmissible venereal tumor) and may metastasize internally. Lymphoma primarily affects lymphoid organs and less commonly affects the skin and other organ systems.

SYNONYM

Discrete cell tumors

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dependent on tumor type

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Lymphoma (malignant lymphoma, lymphosarcoma) is seen in dogs and cats of all ages and can affect any organ system. In dogs, the most common form involves generalized lymph node infiltration; in cats, the gastrointestinal form prevails.
- Mast cell tumors (mastocytomas, mast cell sarcomas) are seen in dogs and cats; most common form is skin/subcutaneous mass. In cats, a splenic or visceral form can occur.
- Transmissible venereal tumors (TVT) are transplanted from dog to dog by direct contact. TVT is most commonly seen in intact dogs in the genital regions and oral and nasal cavities.
- Histiocytomas are most commonly seen in young dogs (<3 years age). They are usually small (<2 cm), red, raised, round, and alopecic. They usually spontaneously regress and may become ulcerated/inflamed as they regress.
- Plasma cell tumors (plasmacytomas) most commonly occur in dogs as skin and subcutaneous masses. The systemic form of plasma cell cancer is multiple myeloma. Plasma cell neoplasia is uncommon in cats.
- Melanomas are most commonly seen in the skin, oral cavity, and digits of dogs. They are rare in cats.

HISTORY, CHIEF COMPLAINT: Dependent on tumor type

PHYSICAL EXAM FINDINGS: Dependent on tumor type

ETIOLOGY AND PATHOPHYSIOLOGY

Dependent on tumor type

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Round cell tumors are one of three cellular categories of major tumor types: carcinomas (epithelial tumors), sarcomas (mesenchymal tumors), and round cell tumors. The diagnosis of round cell tumors is generally straightforward with cytologic examination; treatment, staging, and prognosis are dependent on tumor type.

DIFFERENTIAL DIAGNOSIS

Dependent on tumor type (see chapters on specific tumor types)

INITIAL DATABASE

- Cytologic evaluation will confirm the cell type (diagnosis) for many round cell tumors.
- The following cytologic characteristics are commonly seen in these specific cell types:
  - Lymphoma: high nuclear-to-cytoplasmic ratio; multiple nucleoli; thin rim of dark blue cytoplasm; chromatin is clumped; mitotic figures numerous; in large granular lymphocyte lymphoma (uncommon form of lymphoma seen most commonly in the gastrointestinal tract of cats): red to purple granules are present that are larger and less numerous than granules in MCT.
  - Mast cell tumor: low nuclear-to-cytoplasmic ratio; nuclear details obscured by pink to purple intracytoplasmic granules that are present in most MCT (in some poorly differentiated MCT, granules are absent); eosinophils are often present.
  - Transmissible venereal tumor: cytoplasmic vacuolation is common and distinctive; chromatin is coarse; nucleoli are prominent; mitotic figures may be seen; inflammatory cells such as lymphocytes and plasma cells may be seen.
  - Histiocytoma: low to intermediate nuclear-to-cytoplasmic ratio; anisocytosis and anisokaryosis common; the cytoplasm is pale and may contain fine granules; cytoplasmic vacuolation is sometimes seen; mitotic figures are occasionally seen; inflammatory cells are present when tumors are regressing (histiocytomas often spontaneously regress).
  - Plasma cell tumor: perinuclear clear zone adjacent to nucleus; eccentrically positioned nucleus; chromatin is clumped; large amount of dark blue cytoplasm; bi- and tri-nucleation can be seen but does not correlate with the degree of malignancy.
  - Melanoma: can have the appearance of an epithelial, mesenchymal, or round cell tumor; green, brown, or black intracytoplasmic granules often seen but not always present (absence = amelanotic melanoma).

ADVANCED OR CONFIRMATORY TESTING

- In some cases, the tumor type is not readily distinguished cytologically; a biopsy of the lesion should be submitted for histopathologic analysis. If the cell lineage is still not determined, immunohistochemistry or special stains may be performed.
  - Special stains such as toluidine blue or Giemsa can identify granules in MCT.
  - Immunohistochemistry involves the use of antibodies directed against specific cell antigens that are markers of individual cell types. Examples include CD3, CD4, CD8 (T lymphocytes); CD21, CD79a (B lymphocytes); Melan A or S-100 (melanocytes); CD-117 (c-kit) (mast cells).

Root Signature (Nerve)

BASIC INFORMATION

DEFINITION

Non–weight-bearing lameness and pain resulting from disturbances in sensation within a nerve root or sensory nerve of the cervical or lumbosacral intumescence; common with nerve root compression in the cervical or lumbar intumescence

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dependent on underlying cause; dogs, older adults (neoplasia); cats, young adults (lymphoma)

GENETICS & BREED PREDISPOSITION: DOGS: dachshund, cocker spaniel, beagle, other chondrodystrophoid breeds (intervertebral disk disease [IVDD]); German shepherds (degenerative lumbosacral stenosis)

RISK FACTORS: CATS: multicat household (risk of feline leukemia virus [FeLV])

CONTAGION & ZOONOSIS: CATS: FeLV (cat-to-cat)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute (IVDD)
- Chronic, progressive (neoplasia)
- Intermittent (degenerative lumbosacral stenosis)

HISTORY, CHIEF COMPLAINT

- Thoracic limbs > pelvic limbs
- Non–weight-bearing lameness and pain
- Paravertebral pain
- Trauma
- Difficulty rising, reluctance to jump
- Lack of response to non steroidal antiinflammatory medications

PHYSICAL EXAM FINDINGS

- Non–weight-bearing lameness (limb typically held in flexion)
- Often ipsilateral caudal cervical muscle spasms with disk extrusions
- Focal hyperesthesia (pain), typically following the dermatomal distribution of the affected nerve. A hallmark of nerve root signature is pain.
- Paresis and occasionally hypotonia of the affected limb
- +/− Neurogenic muscle atrophy if chronic (>1 week)
- +/− Ipsilateral Horner's syndrome (T1-T3)
- +/− Ipsilateral cutaneous trunci deficit (C8, T1)
- Paraspinal pain, resistance to cervical manipulation
- Axillary or inguinal pain
- Palpable axillary mass (uncommon)
- Paraparesis, hemiparesis, or tetraparesis if involvement of the spinal cord
- Evidence of external trauma

ETIOLOGY AND PATHOPHYSIOLOGY

- Lateralized or foraminal intervertebral disk extrusion
- Neoplasia (peripheral nerve sheath tumors, lymphoma, primary neural tumors, metastatic)
- Trauma
- Degenerative lumbosacral stenosis
- Discospondylitis

- Summary: clinical signs result from a sensory disturbance within the dorsal root or spinal nerve, typically by compression.
- The spinal cord may be affected in all cases, causing long tract signs (e.g., gait deficit distal to the lesion).
- The dorsal longitudinal ligament of the vertebral column is thicker in the cervical region, predisposing animals to lateral disk extrusions at this site.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Nerve root signature is a clinical diagnosis made by distinguishing lameness due to neurogenic pain from orthopedic lameness. Paravertebral pain, muscle atrophy, and neurologic deficits and a normal orthopedic exam are all helpful in identifying nerve root signature.

DIFFERENTIAL DIAGNOSIS

- Orthopedic disorders
- Soft-tissue injury

INITIAL DATABASE

- Complete neurologic (see p. 1311) and orthopedic (see p. 1315) examinations
- Vertebral radiographs: rule out orthopedic causes, bony neoplasia, chronic diskospondylitis; may support a diagnosis of IVDD, degenerative lumbosacral stenosis, or nerve sheath neoplasm (enlarged intervertebral foramen).
- Many animals have orthopedic disease unrelated to the clinical signs.

ADVANCED OR CONFIRMATORY TESTING

- MRI is far superior to all other imaging modalities for ruling out nerve sheath neoplasia and neuritis.
- Myelography and epidurography: useful for IVDD, degenerative lumbosacral stenosis, nerve sheath neoplasm
- CT (see p. 1233) and MRI (see p. 1302): permit evaluation of the nerve roots, location of extruded disk material.
- Electromyography (EMG see online chapter: Electromyography and Nerve Conduction Velocity): changes are present 1 week following denervation of muscle.
- Cerebrospinal fluid (CSF) analysis (see p. 1228)
- Biopsy: allows definitive diagnosis of confirmed mass lesions; benefit must be weighed against risk of procedure.
- Surgical exploration

TREATMENT

TREATMENT OVERVIEW

- Removal of the source of nerve root or spinal nerve impingement
- Provision of the optimal environment for nerve recovery

ACUTE GENERAL TREATMENT

Dependent on underlying cause:

- Surgical decompression for IVDD, degenerative lumbosacral stenosis
- Tumor resection with or without limb amputation and laminectomy for peripheral nerve sheath neoplasm; surgical intervention should be considered early in these cases (reduce extension of tumor/spinal cord involvement).
- Conservative therapy: generally ineffective in relieving pain of cervical IVDD

CHRONIC TREATMENT

- Attempt conservative therapy (protection of the distal limb with a boot, physiotherapy) for traumatic injuries. Amputation should be delayed for 6 months if possible to allow for reinnervation.
- Radiation therapy: nerve sheath tumors
- Lifelong exercise modification: IVDD
- Physiotherapy: if trauma has compromised limb use

POSSIBLE COMPLICATIONS

- Persistent or progressive clinical signs
- Recurrence or acute progression of clinical signs (IVDD)
- Self-mutilation associated with dysesthesia
- Distal limb trauma associated with decreased sensation and normal activity
- Surgical complications

RECOMMENDED MONITORING

Follow-up exam and serial diagnostic studies as directed by the animal's clinical progression

PROGNOSIS AND OUTCOME 

Dependent on underlying cause:

- Good to excellent (according to clinical signs) with IVDD treated with decompression
- Fair to good (according to clinical signs) with degenerative lumbosacral stenosis
- Guarded to fair with traumatic injury
- Poor with nerve sheath neoplasia

PEARLS & CONSIDERATIONS 

COMMENTS

- It can be difficult to distinguish orthopedic from neurologic causes for clinical signs, and both may be present with traumatic injury. Careful examination with particular attention to muscle tone and sensory deficits is important.
- A ruptured cranial cruciate ligament is often mistaken for a lumbar nerve root signature and vice versa.
- Nerve sheath neoplasms are most common in the cervical intumescence (80%).

CLIENT EDUCATION

Monitor for recurrence of clinical signs

Rocky Mountain Spotted Fever

BASIC INFORMATION

DEFINITION

An acute, potentially life-threatening tickborne rickettsial disease affecting dogs and people

EPIDEMIOLOGY

SPECIES, AGE, SEX

- **Species:** dogs and people are primarily affected. Seropositive cats are not clinically ill.
- **Age:** young dogs (<2 years) are at greater risk.

GENETICS & BREED PREDISPOSITION: Dogs: purebred dogs, especially German shepherds, may be predisposed.

RISK FACTORS: Tick exposure

CONTAGION & ZOONOSIS: Direct transmission does not occur from dogs to people. Dogs are short-term reservoirs and sentinels.

GEOGRAPHY AND SEASONALITY: Rocky Mountain spotted fever (RMSF) is found in North, Central, and South America. The majority of cases in the United States occur in the Southeast; disease occurrence is highest from March to October.

ASSOCIATED CONDITIONS & DISORDERS: Coinfection with other tickborne diseases such as ehrlichiosis can occur.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Clinical and subclinical illnesses have been reported.
- Clinical disease can be systemic or more localized to various systems (dermatologic, neurologic, ocular).

HISTORY, CHIEF COMPLAINT

- Incubation is 2-14 days after tick exposure. There is no carrier state.
- Initial signs are usually vague.
- Depression, anorexia, musculoskeletal pain, and vomiting are often noted.
- Varied presentations: epistaxis, head tilt, limb/scrotal edema, stiff gait

PHYSICAL EXAM FINDINGS

- Fever: commonly seen within 2-3 days of exposure
- Pain (arthralgia/myalgia, abdominal pain)
- Dyspnea/cough (interstitial pneumonitis)
- Cutaneous lesions: petechial/ecchymotic hemorrhages (especially on mucous membranes), edema, hyperemia, vesicles, and macules are all possible.
- Ocular (uveitis/chorioretinitis) and/or neurologic abnormalities (e.g., head tilt)
- Splenomegaly, lymphadenomegaly

ETIOLOGY AND PATHOPHYSIOLOGY

- *Rickettsia rickettsii* is an obligate intracellular parasite. Ticks become infected by horizontal transmission, transtadially, or by transovarial passage.
- Vectors: *Dermacentor variabilis* (American dog tick; eastern United States), *D. andersoni* (wood tick; western United States), *Rhipicephalus sanguineas* (brown dog tick; Arizona/California), and *Amblyomma americanum* (lone star tick; North Carolina).
- Transmission to the host requires at least 5-20 hours of tick attachment.
- Vasculitis, local necrosis, thrombosis, and plasma loss occur.
- Thrombocytopenia is due to consumption (vasculitis ± disseminated intravascular coagulation [DIC]), antiplatelet antibodies,

and/or whole blood loss.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Seasonal occurrence, clinicopathologic changes, and response to therapy suggest the diagnosis. Clinical suspicion justifies treatment while confirmation is pending, since a fulminant course may occur in some individuals. Serologic titers are confirmatory 1-3 weeks later.

DIFFERENTIAL DIAGNOSIS

- Acute ehrlichiosis/anaplasmosis (CBC, oculoneural signs, lameness, proteinuria)
- Babesiosis (CBC, neurologic signs, proteinuria)
- Borreliosis (lameness, proteinuria)
- Leptospirosis (CBC; gastrointestinal, renal, ocular, hepatic changes)
- Immune-mediated diseases (e.g., immune-mediated thrombocytopenia, polyarthropathy, glomerulonephritis)
- Canine distemper (ocular, neurologic, respiratory, GI signs)
- Bacterial diskospondylitis, intervertebral disc disease (stiff painful gait)
- Pneumonia (cough/dyspnea)
- Acute renal failure (acute glomerulonephritis and shock)
- Pancreatitis, enterocolitis (vomiting/diarrhea ± hemorrhage)
- Vestibular disease, acute meningoencephalitis (neurologic signs)

INITIAL DATABASE

- CBC: thrombocytopenia most common; leukopenia or leukocytosis (left shift possible, toxic changes); mild to severe anemia
- Serum biochemistry profile: hypoalbuminemia, azotemia, low Na/Cl/K/Ca, increased liver enzymes
- Fluid analysis (joint or cerebrospinal fluid if affected): mild increase in protein and cells, initially neutrophils, then monocytes
- Proteinuria due to vasculitis/glomerulonephritis

ADVANCED OR CONFIRMATORY TESTING

- IFA documentation of fourfold or greater increase between acute/convalescent titers or an acute titer of 1:1024 or greater is confirmatory.
- Latex agglutination (LA) titer of 1:32 is confirmatory.
- Cross-reactivity with nonpathogenic rickettsial organisms may occur. Some “nonpathogenic” rickettsiae may be pathogenic after all, but not all cross-react with RMSF.
- Direct FA testing for antigen (skin/tissue samples)
- PCR testing (blood/tissue) for RMSF and other rickettsiae

TREATMENT

TREATMENT OVERVIEW

Early recognition and prompt institution of appropriate antimicrobial therapy are associated with a good response to treatment and excellent prognosis. Delayed therapy is associated with complications including renal disease, neurologic disease, vasculitis, and coagulopathies and carries a more guarded prognosis.

ACUTE GENERAL TREATMENT

- Doxycycline, 5-10 mg/kg PO, IV q 12 h for 14-21 days; or tetracycline, 22 mg/kg PO, IV q 8 h for 14-21 days); *or*
- Enrofloxacin, 5-10 mg/kg PO, slow IV, IM q 12 h for 14 days; *or*
- Chloramphenicol, 15-30 mg/kg PO, SQ, IV, IM q 8 h for 14 days
- Prednisolone (1-4 mg/kg PO q 24 h) does not potentiate severity in experimental infections and may minimize immune-mediated complications.
- Fluid and supportive therapies to improve perfusion; caution to avoid exacerbating tissue edema

POSSIBLE COMPLICATIONS

Long-term sequelae may include chronic kidney disease due to loss of renal reserve, or scarring from thrombosis and aeral gangrenous necrosis of digits, nasal planum, and other sites.

RECOMMENDED MONITORING

- Cases are often seronegative acutely; repeated serologic testing at least 1 week after initial onset confirms seroconversion or fourfold rise in acute/convalescent titers. Early antibiotics may blunt rise.
- Monitor platelet and coagulation parameters for signs of severe coagulopathy, including DIC.
- Titers decrease after 4-5 months.

PROGNOSIS AND OUTCOME

- With early diagnosis, prognosis is usually excellent.
- Delayed diagnosis, fulminant disease, and the use of ineffective antibiotics (penicillins, cephalosporins, etc.) increase mortality.

PEARLS & CONSIDERATIONS

PREVENTION

- Owners should limit pet's outdoor roaming, especially in wooded areas.
- Adequate tick control is ideal.
- Lifelong immunity may follow treated disease.

CLIENT EDUCATION

- RMSF in dogs is a warning to owners that ticks in their area carry RMSF (dogs and people may be exposed).
- Ticks removed from pets must not be crushed by unprotected fingers, lest owners' cuticles be exposed to infective tick hemolymph/feces.

Right Bundle Branch Block

BASIC INFORMATION

DEFINITION

An intracardiac conduction disturbance involving failure of normal (rapid) conduction from the bundle of His through the right bundle branch to the Purkinje fibers in the right ventricle. The result is a wide, bizarre-appearing QRS complex on the electrocardiogram (ECG). Right bundle branch block (RBBB) has no clinically meaningful hemodynamic effect on patients and is often a variant of normal. Its main clinical importance lies in the fact that it must not be misinterpreted as a ventricular arrhythmia.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs of any age and either sex; less common in cats

GENETICS & BREED PREDISPOSITION: Incomplete RBBB has been recognized in a family of beagles in association with congenital right ventricular structural disease.

ASSOCIATED CONDITIONS & DISORDERS: RBBB often occurs in normal animals; however, it may be associated with underlying structural heart diseases such as:

- Cardiomyopathy
- Congenital heart disease
- Heartworm disease

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

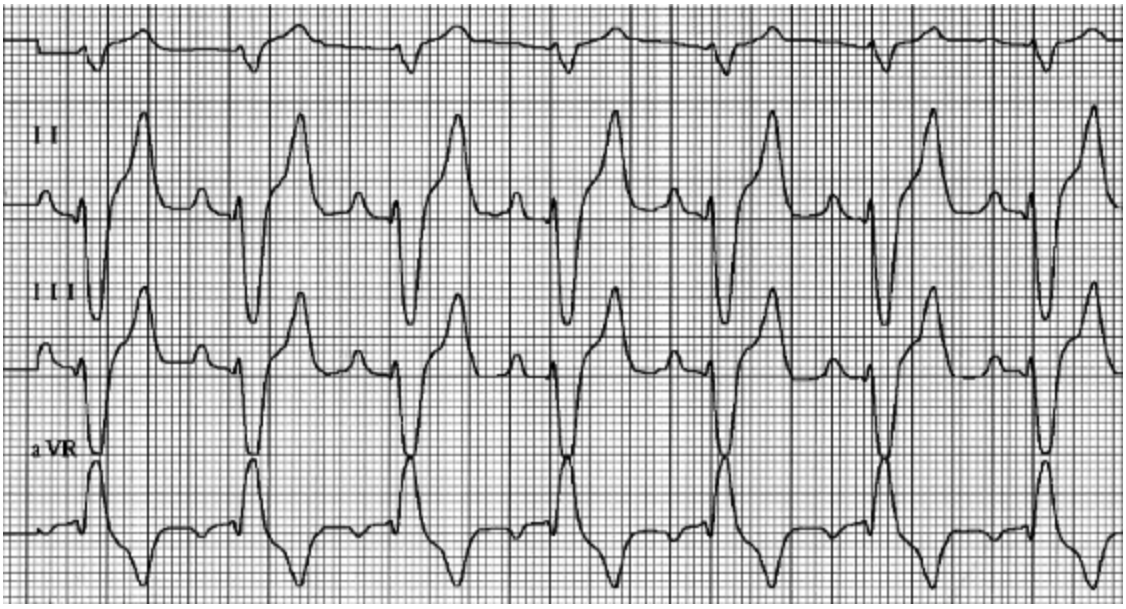
- Incomplete or complete RBBB depending on where the block occurs in the right bundle branch
- Intermittent bundle branch block (left bundle branch block [LBBB] or RBBB) may occur that is heart rate dependent.

HISTORY, CHIEF COMPLAINT: RBBB is an electrocardiogram (ECG) phenomenon only; no overt physical manifestations are expected from RBBB itself.

PHYSICAL EXAM FINDINGS: Typically RBBB is clinically silent, and no clinical signs are observed. However, in some individuals, split heart sounds may be present owing to prolonged right ventricular ejection time and delayed closure of the tricuspid (splitting of the first heart sound) and pulmonic (splitting of the second heart sound) valves. A split second heart sound is most common.

ETIOLOGY AND PATHOPHYSIOLOGY

- With RBBB, impulse formation in the sinoatrial node, atrial depolarization, and passage of the impulse through the AV node all can occur normally, but distribution of the impulse through the Purkinje fibers in the right ventricle is blocked.
- Conduction to the right ventricle still occurs but is very slow because it must travel from muscle cell to muscle cell.
- This results in a marked delay in conduction to the right ventricle, and the QRS complex becomes wide and bizarre on the ECG.
- Additionally, this slow conduction toward the right results in a right axis deviation on the surface ECG.



RIGHT BUNDLE BRANCH BLOCK Four-lead ECG (I, II, III, aVR) showing RBBB. Every QRS complex is preceded by a P wave at a repeatable interval, indicating normal conduction from the atria through the AV node to the ventricles. Rhythm is regular (R-R interval is constant), and heart rate is 150 beats/min. QRS complexes are wide and bizarre. ECG diagnosis is normal sinus rhythm with RBBB. (50 mm/sec, 1 cm = 1 mV.)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is purely electrocardiographic: it is suspected when QRS duration is longer than normal, S waves are present in leads I, II, II, aVF, and the left precordial leads, and the rhythm appears to be supraventricular in origin.

DIFFERENTIAL DIAGNOSIS

- Right ventricular hypertrophy
- Ventricular ectopy
- Ventricular escape rhythm
- Motion artifact

INITIAL DATABASE

By definition, RBBB is an electrocardiographic diagnosis.

- Electrocardiogram characteristics of complete RBBB (see figure):
  - Prolonged QRS complex duration (canine: > 0.07 second; feline: > 0.06 second)
  - Wide and negative QRS complexes with an S wave in leads I, II, III, aVF, and left precordial leads (CV6LL [V2] and CV6LU [V4])
  - Positive QRS complexes in leads aVR, aVL, and CV5RL (V1 or rV2).
- Electrocardiogram characteristics of incomplete RBBB:
  - When the morphology of the QRS complex as described above is noted, but the QRS duration is normal or only slightly prolonged, incomplete RBBB is suspected. It can be very challenging to differentiate this finding from right ventricular hypertrophy, and assessment of the ventricle (e.g., echocardiographically) is usually required. If the ventricle is structurally normal, incomplete RBBB is diagnosed by exclusion.

ADVANCED OR CONFIRMATORY TESTING

- Thoracic radiographs to evaluate for right ventricular enlargement
- Echocardiogram to assess heart structure and function

TREATMENT

TREATMENT OVERVIEW

No specific treatment necessary for RBBB:

- RBBB does not result in clinical or hemodynamic sequelae by itself and therefore does not require treatment.
- The right bundle branch is anatomically vulnerable to injury, and therefore RBBB may be observed in otherwise normal dogs.

POSSIBLE COMPLICATIONS

- Misdiagnosis of RBBB as premature ventricular complexes (PVCs) or ventricular tachycardia can lead to treatment—and toxicosis—with antiarrhythmic drugs.
- Complete block of both the right and left bundle branches produces complete (third-degree) atrioventricular block (rare).

PROGNOSIS AND OUTCOME

RBBB is not a progressive or deleterious entity, so prognosis is good except when associated with structural heart disease, in which case prognosis is the same as that of the underlying disorder.

PEARLS & CONSIDERATIONS

COMMENTS

The bizarre QRS morphology seen with bundle branch block can be confused with ventricular ectopy:

- If P waves are present and the PR interval is consistent, the complex is likely coming from a supraventricular site (and the bizarre QRS morphology is due to BBB rather than ventricular ectopy). However, sometimes P waves are buried and not visible, although the rhythm is supraventricular in origin (particularly with tachycardias). Since most dogs have sinus arrhythmia and some degree of irregularity to the heart rhythm, the regularity of rhythm can be a helpful clue (see pp. 1024 and 1165).
- Supraventricular rhythms (such as sinus rhythm, sinus tachycardia, atrial fibrillation, etc.) respond to vagal maneuvers with slowing of the heart rate, even when RBBB is present. Ventricular arrhythmias do not.

AUTHOR: MEGSLEEPER

EDITOR: ETIENNECÔTÉ

Rhinosporidiosis

BASIC INFORMATION

DEFINITION

A chronic granulomatous disease of humans and animals affecting mucosal surfaces, cutaneous and/or subcutaneous tissues; caused by infection with the microorganism *Rhinosporidium seeberi*. *Rhinosporidium* induces tumor-like growth of epithelial cells, manifesting as single or multiple rhinosporidial polyp-like masses (granulomas).

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Species: occurs sporadically in dogs, extremely rare in cats
- Sex: male dogs > female dogs; male predominance is also evident in humans.
- Age range in dogs: 1.5-13 years (mean 5 years)

GENETICS & BREED PREDISPOSITION: Large-breed dogs most commonly affected

RISK FACTORS

- Wet environment
- Contact with stagnant water
- Nasal mucosal trauma

CONTAGION & ZOONOSIS

- Not contagious; no animal-animal or animal-human transmission reported; humans and animals may become infected from a common environmental source.
- Rhinosporidiosis is primarily a human disease, but it has also been documented in dogs, cats, cattle, horses, mules, goats, buffalo, ducks, swans, and other waterfowl.

GEOGRAPHY AND SEASONALITY: Occurs sporadically in the United States (usually the Southeast) and in other countries (Europe, Africa, Canada); endemic in India and Sri Lanka (over 80% of human cases)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: In people, the disease usually involves nasal and pharyngeal (85% of cases) and/or conjunctival (9% of cases) mucosa, but rarely, cutaneous, subcutaneous, tracheal, genitourinary, and osseous involvement may occur. Disseminated disease with pulmonary involvement has been documented. In dogs and cats, only nasal disease has been reported.

HISTORY, CHIEF COMPLAINT: Presenting complaints are those of nasal disease, including stertor, sneezing, nasal discharge, or epistaxis.

PHYSICAL EXAM FINDINGS

- Nasal discharge
- Epistaxis common
- Nasal polyps are sometimes visible:
    - Fleshy mass evident in the nostril; often ulcerated
    - Rhinosporidial polyp or mass characteristically has miliary, white pinpoint granules (<0.5 mm diameter) visible on surface; these are sporangia (maturing bodies of the organism).

ETIOLOGY AND PATHOPHYSIOLOGY

- This organism was previously classified as a fungus but is presently classified in the protistan class, Mesomycetozoea, at the animal-fungal divergence in the phylogenetic tree.
- Transmission and pathogenesis of rhinosporidiosis largely unknown.

- Infection presumed to occur when spores reach traumatized nasal mucosa. Infection is often associated with contact with stagnant water, but the ocular form predominates in humans living in arid countries, potentially because dust serves as the fomite for inoculation of the organism.
- Once the spore reaches mucosal tissue (usually nose or conjunctiva), it proliferates in epithelial tissue to form sporangia, which can be seen grossly on the polyp surface.
- The organism triggers proliferation of epithelial tissue and a mixed (usually granulomatous) inflammatory response.
- Clinical signs result from obstruction by the proliferative tissue, associated inflammation, and increased nasal secretions and/or ulceration and bleeding from the mass.
- The infection remains localized to the site of inoculation except in rare human cases where dissemination occurs. Autoinoculation (transfer from an initial lesion to a new site by the fingers) is suspected to occur in people and result in multiple lesions.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Rhinosporidium is an uncommon to rare cause of obstructive nasal disease and epistaxis in dogs and cats. In animals with clinical signs, rhinosporidial masses may be characteristically evident at the nares, providing an obvious source of tissue for diagnostic testing.

DIFFERENTIAL DIAGNOSIS

- Nasal tumor
- Nasal foreign body/granuloma
- Nasopharyngeal polyp (cats)
- Other causes of chronic rhinitis: fungal (e.g., aspergillosis, cryptococcosis), lymphoplasmacytic, parasitic (*Pneumonyssoides, Cuterebra*), viral (cats)

INITIAL DATABASE

- Cytologic examination of nasal exudates or of impression smears or fine-needle aspirate samples from nasal masses
  - Granulomatous inflammation (lymphocytes, plasma cells, macrophages) and sporangia (round, thick-walled, 2-8 micron diameter)
  - Important cytologic differential is coccidioidomycosis (sporangium of *R. seeberi* is larger, has thicker walls and larger, more numerous endospores than spherules of *Coccidioides*)
- Nasal imaging: skull radiographs or CT

ADVANCED OR CONFIRMATORY TESTING

Rhinoscopy or rhinotomy

- Nasal biopsy: for definitive diagnosis if cytologic evaluation inconclusive:
  - Diagnosis confirmed by finding sporangia containing endospores; readily identified in affected tissues

TREATMENT

TREATMENT OVERVIEW

Treatment goals are to alleviate nasal obstruction and other clinical signs and to eliminate infective organisms. Most cases are treated by surgical excision alone.

ACUTE GENERAL TREATMENT

- Surgical excision of rhinosporidial masses, preferably by electrocautery, is the treatment of choice, but recurrence is common.
- Drug therapy postoperatively to prevent recurrence or for medical treatment if surgery is not an option is of questionable efficacy:
  - Dapsone is the only drug that has shown some antirhinosporidial effect:
    - Arrests maturation of sporangia, promotes stromal fibrosis
    - Has been used to prevent polyp recurrence after initial surgical excision
    - 1 mg/kg PO q 8 h for 2 weeks, then q 12 h for 4 months

        - Toxicity (see below) may limit use.
    - Ketoconazole; anecdotal efficacy as sole treatment or in preventing recurrence:
        - 8.7 mg/kg PO with food q 8 h for 21 days
- Topical antiseptics (10% povidone-iodine, 1% silver nitrate, 2% chlorhexidine) have been recommended for treatment of the base of the polyp or mass immediately following surgical excision and for disinfection of surgical equipment.
- Inability to establish experimental infection or to culture *Rhinosporidium* in vitro limits ability to study pathogenesis or test efficacy of antimicrobial and antiseptic agents.

CHRONIC TREATMENT

Repeated surgical excision or protracted/repeated medical treatment may be necessary.

DRUG INTERACTIONS

Dapsone and ketoconazole may alter metabolism of drugs that undergo hepatic biotransformation.

POSSIBLE COMPLICATIONS

- Recurrence of rhinosporidial masses (2-12 months after surgery) is the most common complication.
- Dapsone may cause aplastic anemia, agranulocytosis, cutaneous drug eruption, acute gastrointestinal (GI) signs, and hepatic necrosis.
- Ketoconazole may cause hepatic necrosis and GI signs.

RECOMMENDED MONITORING

- Monitor for recurrence of nasal signs.
- With medical treatment, a CBC and serum biochemistry profile (dapsone) or liver enzymes and bilirubin (ketoconazole) should be monitored every 2-4 weeks.

PROGNOSIS AND OUTCOME

Surgery may be curative, especially for a single polyp. However, recurrence is common, especially with broad-based masses or multiple polyps.

PEARLS & CONSIDERATIONS

COMMENTS

- Not contagious
- Most cases are treated by surgical excision alone; radical excision may be necessary.
- Medical management, while reported, is of questionable efficacy.

PREVENTION

No specific prevention is available.

1ST EDITION AUTHOR: JEFFREYSIMMONS

Rhinitis, Lymphoplasmacytic

BASIC INFORMATION

DEFINITION

Chronic, gradually progressive inflammatory nasal disease of unknown etiology characterized by infiltration of the nasal mucosa with lymphocytes and plasma cells. The disorder is recognized with increasing frequency in dogs.

SYNONYMS

Chronic idiopathic rhinitis/rhinosinusitis, chronic inflammatory rhinitis, immune-mediated rhinitis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: any age, although young adult to middle-aged dogs of either sex are considered at risk.
- Cats: young adult to middle-aged cats of either sex

GENETICS & BREED PREDISPOSITION: The disease is seen primarily in large-breed dogs, although dachshunds may be predisposed.

RISK FACTORS

- Diseases causing chronic inflammation with epithelial erosion, turbinate lysis, and remodeling, such as long-standing or recurrent infections (e.g., foreign body, aspergillosis), can provoke lymphoplasmacytic nasal infiltrates.
- The idiopathic disease is not associated with an identifiable underlying cause of inflammation.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: The disease is chronic, sometimes with very mild signs initially, followed by moderate to severe signs.

HISTORY, CHIEF COMPLAINT

- Nasal discharge
- Sneezing
- Stridor
- Reverse sneezing
- Ocular discharge and rubbing at the nose (occasionally)

PHYSICAL EXAM FINDINGS

- Unilateral or bilateral serous, mucoid, or bloody nasal discharge
- Decreased air passage through one or both nares
- Submandibular lymph node enlargement
- General condition is normal

ETIOLOGY AND PATHOPHYSIOLOGY

- Poorly defined, but hypothesized to be either a chronic inflammatory response to an inhaled irritant, pollutant, or allergen or an immune-mediated process
- The local tissue immune response mounted is clearly distinct from that of sinonasal aspergillosis, therefore the disease is not due to undiagnosed sinonasal aspergillosis.
- Chronic inflammation causes loss of epithelium and squamous metaplasia, reduced population of ciliated cells, hyperplasia of subepithelial glands, increased amount of viscid mucus, and impaired ciliary clearance.
- Retention of mucus plugs, inhaled bacteria, and irritable particles maintain and aggravate inflammation.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Lymphoplasmacytic infiltration of nasal mucosa can be observed as a sequela to many chronic nasal diseases, and must be differentiated from the "idiopathic" condition by exclusion of other causes of rhinitis.

DIFFERENTIAL DIAGNOSIS

Other causes of nasal discharge (see p. 746):

- Dogs:
  - Fungal rhinitis
  - Nasal neoplasia
  - Dental disease
  - Foreign bodies
  - Nasal mites
  - Ciliary dyskinesia
- Cats:
  - Chronic viral upper respiratory tract infection
  - Nasopharyngeal polyps
  - Nasopharyngeal stenosis
  - Others as for dogs

INITIAL DATABASE

- Plain radiographs of the nasal cavities, sinuses, and dental roots can help eliminate other structural disorders such as neoplasia, fungal rhinitis, and dental disease but cannot confirm the diagnosis.
- Bacterial cultures can be positive or negative; positive cultures rarely reflect a primary role of bacteria in pathogenesis.
- Results of CBC, biochemistry panel, and urinalysis are usually normal.

ADVANCED OR CONFIRMATORY TESTING

- CT (see p. 1233) and/or MRI (see p. 1302) of the nasal cavities and sinuses can help identify differentials, such as neoplasia, fungal rhinitis, and dental disease, with more accuracy than plain radiographs but cannot confirm the diagnosis.
- Rhinoscopy (see p. 1335) findings are variable and can include:
  - Copious thick mucus or mucopurulent discharge
  - Mucosal hyperemia
  - Proliferative or thickened nasal mucosa
  - Turbinate lysis or remodeling
  - Pseudopolypoid appearance of mucosa
  - Absence of other causes of nasal discharge (aspergillosis, foreign bodies, etc.)
- Histopathologic examination of nasal mucosal biopsies predominantly shows mild to severe lymphoplasmacytic infiltration.

TREATMENT

TREATMENT OVERVIEW

Treatment can be challenging, as there is no primary therapy that has proven consistently effective for all patients.

ACUTE GENERAL TREATMENT

- Antibiotics are of little benefit unless there is a secondary bacterial infection.
- Glucocorticoids at immunosuppressive dosages:
  - Prednisone 1-2 mg/kg PO q 12 h, then gradually tapered to lowest dose that controls clinical signs.
  - Topical (nasal spray, drops, or aerosols) administration of poorly absorbed glucocorticoids (such as fluticasone propionate) may be beneficial without provoking secondary effects of systemic glucocorticoid therapy.
  - Many dogs do not respond to glucocorticoid therapy.
- Other antiinflammatory agents such as piroxicam could potentially have some benefit, but efficacy has not been documented.
- In severe nonresponsive cases, consider additional oral immunosuppressive agents:

- Azathioprine (dogs: 1-2 mg/kg PO q 24 h for 10-14 days, then q 48 h), *or*
- Cyclosporine (3-5 mg/kg PO q 12 h; monitor serum concentrations)

- Mucolytic drugs:
  - *N*-acetylcysteine has a wide therapeutic range, with dosage usually 5-10 mg and up to 100 mg/kg PO q 12 h.
    - Intranasal or aerosol delivery of 5%-20% solution has also been described.
  - Bromhexine hydrochloride (0.5-1 mg/kg PO) or through aerosol delivery

CHRONIC TREATMENT

- Intranasal saline (drops or aerosol delivery)
- Mucolytics (as noted in previous paragraphs)
- Long-term oral glucocorticoids: give the lowest dose at the greatest interval needed to control clinical signs.

POSSIBLE COMPLICATIONS

- Secondary bacterial rhinitis
- Chronic sinusitis

RECOMMENDED MONITORING

Identify and treat episodes of secondary bacterial rhinitis accordingly.

PROGNOSIS AND OUTCOME

- Although clinical signs may appear distressing to owners, and some cases remain refractory to any treatment, the disease is rarely life threatening.
- In the worst cases, maintenance therapy is generally successful in keeping clinical signs mild.
- Treatment must be sustained, since relapses frequently occur.
  - A cure is uncommonly obtained; persistence of mild to moderate clinical signs despite treatment is common.
- Owners should prevent their pets' exposure to potential exacerbating factors (e.g., cigarette smoke, perfumes).

PEARLS & CONSIDERATIONS

COMMENTS

- Definitive diagnosis is established by elimination of other potential causes of chronic lymphoplasmacytic infiltration of the nasal mucosa, such as chronic aspergillosis, chronic or recurrent infection due to dental disease, primary ciliary dyskinesia, or intranasal neoplasia.
- The disease is chronic and progressive, and cure is rarely achieved.
- There is no therapeutic gold standard.

TECHNICIAN TIPS

While of low diagnostic yield, Cytologie examination of nasal exúdate can occasionally identify another underlying cause (e.g., cryptococcosis, rarely nasal neoplasia) of nasal cavity disease.

CLIENT EDUCATION

- Treatment must be sustained, since relapses are common.
- Complete cure is rare, but a normal quality of life is expected in most cases.
- Persistence of some degree of clinical signs is expected despite treatment.
- Potential exacerbating factors should be avoided.

Rhinitis, Bacterial

BASIC INFORMATION

DEFINITION

Inflammation of one or both nasal cavities associated with a bacterial infection that is often secondary to a primary nasal disease

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Rhinitis is possible in dogs and cats of all ages and breeds depending on underlying cause.
- Puppies may develop bacterial rhinitis as a result of congenital abnormalities or immune deficiencies.
- Viral upper respiratory tract infections can lead to rhinitis in cats.
- Kittens are at risk for viral upper airway diseases that predispose to bacterial rhinitis.

GENETICS & BREED PREDISPOSITION: Predisposition reflects susceptibility to primary disease processes:

- Toy breeds are more susceptible to rhinitis associated with dental root infections.
- Dolichocephalic breeds of dogs are at risk for acquiring nasal aspergillosis and neoplasia.

RISK FACTORS: Bacterial rhinitis is most often secondary to a primary nasal disease:

- In dogs, primary disorders include:
  - Foreign body (especially active hunting dogs; plant material as foreign body)
  - Dental root infection
  - Congenital/inherited abnormalities such as primary ciliary dyskinesia and soft palate defects, choanal atresia/stenosis
  - Lymphoplasmacytic rhinitis
  - Fungal rhinitis (aspergillosis)
  - Neoplasia
  - Fracture or osteomyelitis of conchae or facial bones from trauma
- In cats, primary diseases include:
  - Viral or *Mycoplasma* infection (most common)
  - Nasopharyngeal polyps
  - Choanal atresia/stenosis
  - Neoplasia (carcinomas, lymphosarcoma)
  - Fungal rhinitis (cryptococcosis, less commonly aspergillosis)

CONTAGION & ZOONOSIS: Kittens in multiple-cat environments have increased risk of viral infections.

ASSOCIATED CONDITIONS & DISORDERS: Epistaxis and stridor

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Acute or recurrent, depending on primary cause

HISTORY, CHIEF COMPLAINT

- Sneezing
- Nasal discharge
- Sometimes unilateral or bilateral epistaxis
- Head shaking, pawing the nose, snorting (nasal foreign body)
- Halitosis, inappetence (dental disease)

PHYSICAL EXAM FINDINGS

- Unilateral or bilateral mucopurulent nasal discharge
- Decreased (most commonly) or increased air passage through nares

- Enlarged submandibular lymph node(s)
- Evidence of systemic disease is uncommon
- Other signs are possible depending on primary disease

ETIOLOGY AND PATHOPHYSIOLOGY

Nasal turbinates (acting as powerful filters) and mucociliary clearance in the distal third of the nasal cavities are excellent defense mechanisms against infection. Secondary or recurrent bacterial infections develop when a primary nasal disease has impaired these defense mechanisms.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

There are many causes of mucopurulent nasal discharge (see Risk Factors above).

INITIAL DATABASE

- Oral and dental examinations (see p. 1295) to exclude dental disease, palatal and choanal defects
- Plain radiographs of the nasal cavities, sinuses, and dental roots (under general anesthesia) to identify an inciting cause
- Bacteriologic cultures are rarely useful, because the organisms identified are commonly present in normal individuals, and it is the predisposing nasal disease that must be identified and managed.
- Results of CBC, serum biochemistry profile, and urinalysis are often normal.

ADVANCED OR CONFIRMATORY TESTING

Advanced testing is recommended to rule out primary nasal cavity diseases:

- Rhinoscopy (direct and retrograde) (see p. 1335)
- Cytologic or histologic evaluation of nasal mucosal samples
- CT or MRI is superior to standard radiography for imaging the nasal cavity.
- Viral culture or PCR tests for viral infections of cats
- PCR tests for *Mycoplasma/bacterial* infections of cats
- Electron microscopy (primary ciliary dyskinesia)

TREATMENT

TREATMENT OVERVIEW

The key to long-term resolution of bacterial rhinitis in most patients is identification and treatment, whenever possible, of an underlying primary nasal disease.

ACUTE GENERAL TREATMENT

- Broad-spectrum antibiotics: per os, intranasal, or aerosol delivery as appropriate for the animal for short periods of time (1 week is sufficient in most cases). For example, administer amoxicillin, 20 mg/kg PO q 8 h; cefadroxil, 20 mg/kg PO q 8 h; or amoxicillin-clavulanate, 15 mg/kg PO q 12 h.
- Antibiotics need not be selected on the basis of Gram stain or culture and sensitivity (C&S) testing, except in recurrent cases.
- In cats with upper airway disease, amoxicillin, azithromycin, doxycycline, and quinolones have been shown effective.

CHRONIC TREATMENT

- Intranasal administration of sterile physiologic solution several times a day
- Mucolytics:
  - *N*-acetylcysteine has a wide therapeutic range, with dosage usually 5-10 mg/kg and up to 100 mg/kg PO q 12 h.
    - Intranasal or aerosol delivery of 5%-20% solution has also been described.
  - Bromhexine hydrochloride (0.5-1 mg/kg PO) or through aerosol delivery
- Contraindicated treatments: reduction of inflammation with short-acting corticosteroids and attempts to provide relief with decongestants are not indicated.

POSSIBLE COMPLICATIONS

Inflammation and injury to the ciliated nasal epithelium can decrease mucociliary clearance in the distal third of the nasal cavity and cause turbinate lysis or remodeling (especially in young kittens with severe viral infections or dogs with nasal aspergillosis). This will in turn cause mucus to accumulate and further promote bacterial infection.

RECOMMENDED MONITORING

Clinical signs of the condition

PROGNOSIS AND OUTCOME

Prognosis varies depending on the primary cause.

PEARLS & CONSIDERATIONS

COMMENTS

- Most animals with bacterial rhinitis have another primary nasal cavity disease; therefore, failure to achieve a prompt and sustained response to empirical therapy (or spontaneous resolution) should provoke recommendations for advanced testing.
- Obtaining a diagnosis and implementing specific treatment lessen the likelihood of chronic and irreversible epithelial and turbinate lesions that could otherwise predispose the animal to bacterial rhinitis.

TECHNICIAN TIPS

While usually of low diagnostic yield, cytologic examination of nasal exudate is inexpensive and in a few patients, will identify an underlying primary nasal cavity disease (e.g., cryptococcosis, occasionally nasal neoplasia).

CLIENT EDUCATION

Bacterial rhinitis secondary to a viral upper respiratory infection in cats can be difficult to control in the long term without daily medication administration for extended periods of time.

Rheumatoid Arthritis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

An uncommon, progressive, immune-mediated, inflammatory polyarthropathy characterized by erosion of articular cartilage

SYNONYMS

- Canine: immune-mediated erosive polyarthritis
- Greyhounds: erosive polyarthritis of greyhounds (PG)
- Feline: feline chronic progressive polyarthritis (FCPP)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Rheumatoid arthritis (RA): variable: usually young to middle-aged animals
- PG: young greyhounds (3-30 months of age)
- FCPP: cats of any age can be affected: most are young adult males.

GENETICS & BREED PREDISPOSITION

- RA: small breeds commonly affected
- PG: breed specific
- FCPP: domestic short-haired cats, Persians, Siamese cats

ASSOCIATED CONDITIONS & DISORDERS: Dogs:

- Felty's syndrome: RA, splenomegaly, and neutropenia
- Sjögren's syndrome: nonerosive or erosive polyarthritis, keratoconjunctivitis sicca (KCS), xerostomia
- Occasional association of RA with amyloidosis

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Early:
  - Initially indistinguishable from idiopathic polyarthritis (see p. 894)
  - Acute single or multiple leg lameness with anorexia is possible.
  - PG and FCPP: onset often more insidious
- Later: chronic intermittent lameness: angular deformities secondary to ligamentous damage, mostly in the carpus, metacarpus, tarsus, and metatarsus

PHYSICAL EXAM FINDINGS

- Joint pain, soft-tissue swelling, reduced range of motion, joint crepitus; distal joints most severely affected
- Low-grade fever
- Mild generalized lymphadenopathy

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology unknown
- Synovitis arises from a type III (immune complex) hypersensitivity reaction. Synovial lymphocytes and plasma cells produce rheumatoid factors (RFs), immunoglobulin (Ig) M and IgA auto-antibodies directed against altered endogenous IgG.
- Immune complexes activate complement and attract neutrophils (accumulate in the joint fluid).
- Vascular granulation tissue (pannus) erodes the articular cartilage and destroys subchondral bone.
- Inflammation and damage to the joint capsule and collateral ligaments lead to joint instability and angular deformities.

- Electron microscopy has identified distemper viral particles in synovial macrophages.
- FCPP: unknown etiology; association with feline syncytium-forming virus.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A minimum database (CBC, serum biochemistry profile, urinalysis), radiographs of affected joints (erosive changes in all but the early stages), and synovial fluid sampling (cytologic analysis/culture) are indicated in all cases and help distinguish RA/PG/FCPP from other polyarthritides.

DIFFERENTIAL DIAGNOSIS

- Idiopathic nonerosive polyarthritis (see p. 894)
- Bacterial polyarthritis
- Systemic lupus erythematosus
- Reactive polyarthritis
- Neoplasia

INITIAL DATABASE

CBC, serum biochemistry profile, urinalysis: all typically normal; leukocytosis, neutrophilia, hyperglobulinemia, hyperfibrinogenemia, and proteinuria possible.

ADVANCED OR CONFIRMATORY TESTING

- Radiographs of affected joints indicated in all cases. Findings vary with duration of illness.
- Early stage: periarticular swelling; minimal bony changes
- Later: periarticular osteoporosis, subchondral lucencies (“erosive” changes), joint swelling
- Late stage: extensive bone destruction, joint space collapse, subluxations and luxations
- FCPP: marked periosteal new bone; focal erosions, especially hocks and carpi
- Arthrocentesis, synovial fluid analysis indicated in all cases: thin (nonviscous), cloudy, hypercellular (neutrophils predominate); culture negative; mucin clot test negative
- Rheumatoid factor (RF): lacks sensitivity/specificity; positive in 20%-70% of RA dogs; false positives with other inflammatory diseases; IgA RF more specific and more prevalent with severe erosive disease
- Synovial biopsy: proliferative synovitis with lymphocytes, plasma cells, and macrophages

RHEUMATOID ARTHRITIS Radiographic evidence of subchondral bony lysis of the carpal bones *(arrows)* in this dog with rheumatoid arthritis.

(Courtesy LeeAnn Pack, Atlantic Veterinary College, University of Prince Edward Island, Canada.)

TREATMENT

TREATMENT OVERVIEW

A cure is not possible; clinical remission is the goal. Immunosuppressive drugs are the mainstay of treatment.

ACUTE GENERAL TREATMENT

- Nonsteroidal antiinflammatory drugs (NSAIDs) have not proven to be successful. The high doses required for human RA have intolerable gastrointestinal (GI) side effects in dogs.
- Glucocorticoids, in combination with azathioprine, cyclophosphamide, or gold salts, are preferable and often required for remission.
- Prednisone/prednisolone: 1-2 mg/kg PO q 12 h for 2-3 weeks. If lameness and synovial fluid inflammation subside, the dose is reduced gradually over 3-4 months to lowest dose that maintains remission.
- Azathioprine: 2 mg/kg PO q 48 h (dogs)
- Cyclophosphamide: 2 mg/kg PO q 24 h, 4 consecutive days weekly
- Chrysotherapy (gold salts): requires concurrent use of glucocorticoids; two options:
    - Sodium aurothiomalate:
        - 1 mg/kg IM once weekly for 10 weeks or until clinical remission
        - Give a small test dose first.
        - To maintain remission: 1 mg/kg IM q 30 days
    - Auranofin:
        - 0.05-2 mg/kg PO q 12 h (maximum 9 mg/d)
        - Diarrhea common
- FCPP: combination of glucocorticoids and cyclophosphamide may be of benefit in early stages. Gold salts are highly toxic in cats. Combination methotrexate and leflunomide shows promise and requires further study.
- PG: treatment with NSAIDs, glucocorticoids, or cytotoxic drugs has been unrewarding.

NORMAL CARPUS Normal carpus in a healthy dog for comparison.

(Courtesy LeeAnn Pack, Atlantic Veterinary College, University of Prince Edward Island, Canada.)

CHRONIC TREATMENT

- Taper prednisone/prednisolone to lowest dosage that maintains clinical remission (e.g., 1 mg/kg, q 48 h or lower). Continue cytotoxic drug barring adverse effects (e.g., myelosuppression).
- Evaluate the patient's synovial fluid monthly to guide dose reduction.
- Monitor CBC and platelet counts frequently to detect myelosuppression from cytotoxic drugs.

BEHAVIOR/EXERCISE

- Judicious exercise restriction, weight control

POSSIBLE COMPLICATIONS

- Long-term glucocorticoids: hyperadrenocorticism
- Cyclophosphamide: bone marrow suppression, cystitis
- Azathioprine: bone marrow suppression. Occasionally hepatotoxicity, pancreatitis. Avoid use in cats.
- Gold salts: fever, thrombocytopenia, leukopenia, dermatitis, glomerulonephritis, stomatitis
- Avoid administering cytotoxic drugs if the animal has concurrent infections.

RECOMMENDED MONITORING

- Physical exam and joint fluid analysis to assess remission
- CBCs to assess myelosuppression
- Liver panel to assess for hepatotoxicity (azathioprine)

PROGNOSIS AND OUTCOME

- Poor long-term prognosis
- Even with appropriate therapy, the condition of most patients deteriorates over time.

- Joint pain and instability may necessitate arthrodesis (questionable benefits in joints other than carpus).

PEARLS & CONSIDERATIONS

COMMENTS

- RF blood testing is not reliably accurate (positive in only 20%-70% of affected dogs; other factors can cause false-positive results); an accurate diagnosis of RA is multifactorial, involving physical exam, radiographs of affected joints, and arthrocentesis.
- RA may initially resemble idiopathic polyarthritis, but eventually joint destruction becomes apparent.

TECHNICIAN TIPS

- To increase odds of a positive culture (confirming bacterial synovitis rather than RA), it has been suggested to submit cultures in blood culture media.
- Pain associated with arthritis should not be mistaken for reluctance or other behavioral traits; these patients may be too painful to walk, may be more prone to aggression if handled, or both, and should be handled as gently as possible until clinical signs have improved.

CLIENT EDUCATION

Poor prognosis for cure; progressive disease that requires frequent rechecks

Hanna FY: Disease modifying treatment for feline rheumatoid arthritis. Vet Comp Orthop Traumatol1820059499

AUTHOR: LILIANCORNEJO

EDITOR: SUSAN M.COTTER

Rhabdomyosarcoma

BASIC INFORMATION

DEFINITION

A rare primary neoplasm of striated muscle

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Rare in dogs. When affected, dogs often are less than 18 months old, but some cases have been reported in older dogs.
- Rare in cats. There is one report of a rhabdomyosarcoma at an injection site in a cat.

GENETICS & BREED PREDISPOSITION: The young age at diagnosis and occasional presence of more than one tumor suggest a hereditary basis for the disease. However, the low incidence of these tumors makes it difficult to determine genetic or breed predispositions.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Botryoid rhabdomyosarcoma is a rare tumor usually found in the bladder of young, large-breed dogs.
- Other locations reported for rhabdomyosarcoma include the mouth or oropharynx, the tongue, larynx, heart (very rare), and peripheral skeletal muscle.

HISTORY, CHIEF COMPLAINT

- Presenting clinical signs depend on the location of the tumor.
- Dogs with oral and tongue tumors present for evaluation of signs related to an oral mass (halitosis, oral bleeding, discharge, visible mass).
- Dogs with laryngeal tumors may present for evaluation of dysphonia, dysphagia, inspiratory dyspnea, or respiratory distress.
- Tumors in the bladder cause signs attributable to a bladder mass (hematuria, pollakiuria, dysuria).

PHYSICAL EXAM FINDINGS: Physical exam findings vary depending on the location of the primary tumor and are reflected in the presenting complaints.

ETIOLOGY AND PATHOPHYSIOLOGY

- The cell of origin of these tumors is a myocyte in striated muscle.
- Lesions caused by rhabdomyosarcomas depend on the location of the primary tumor and the invasion into and destruction of surrounding normal structures.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Definitive diagnosis can only be confirmed via histopathologic examination. Identification of the primary tumor and subsequent biopsy may be challenging owing to the internal location of many rhabdomyosarcomas (heart, bladder, etc.). Diagnostic imaging can be helpful to identify the extent of the local tumor.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis depends on the location of the primary tumor:

- Bladder: transitional cell carcinoma, other bladder tumors

- Heart: hemangiosarcoma, aortic body tumors, other cardiac tumors
- Oral cavity: melanoma, squamous cell carcinoma, fibrosarcoma

INITIAL DATABASE

- Fine-needle aspirate Cytologie analysis may help identify the tumor type prior to other diagnostics.
- Three-view thoracic radiographs to rule out pulmonary metastases
- Abdominal ultrasound:
  - To rule out abdominal metastases
  - Abdominal ultrasonography and echocardiography generally are the diagnostic tests of choice for identifying masses in the bladder or heart, respectively

ADVANCED OR CONFIRMATORY TESTING

- CT or MRI may be necessary to delineate the local extent of the tumor in some locations (e.g., oropharynx, larynx) and to plan for surgery or radiation therapy.
- Diagnosis is based on histopathologic evaluation of biopsy samples. Special immunohistochemical stains may be necessary to differentiate rhabdomyosarcoma from other soft-tissue sarcomas, especially poorly differentiated tumors.
  - Bladder tumors often require cystotomy to obtain a suitable biopsy and attempt surgical excision. Botryoid ("resembling a cluster of grapes") rhabdomyosarcoma often has a gross appearance that is characteristically multilobulated.

TREATMENT

TREATMENT OVERVIEW

Definitive treatment is based on complete eradication of the primary tumor whenever possible. Palliative treatment options, such as palliative radiation, may help control pain or discomfort in patients with advanced tumors or in patients where definitive treatment cannot be tolerated.

ACUTE AND CHRONIC TREATMENT

- Treatment of the primary tumor usually involves aggressive surgical resection.
- Radiation therapy has not been extensively investigated for treatment of rhabdomyosarcoma. It may be indicated for tumors that cannot be removed with surgery alone. However, the response to radiation is not known.
- Chemotherapy may be indicated for rhabdomyosarcomas. Many cases develop metastases, and chemotherapy may be beneficial, although the response to chemotherapy is not known.
- Peripheral rhabdomyosarcomas arising from skeletal muscle should be approached like other peripheral soft-tissue sarcomas (see p. 1034).

POSSIBLE COMPLICATIONS

Complications of treatment for rhabdomyosarcomas depend on the types of treatments and the location of the primary tumor (see p. 1034).

RECOMMENDED MONITORING

Rhabdomyosarcomas may require more frequent monitoring for metastases (thoracic radiographs, abdominal ultrasound typically q 2-3 months) because of possible high metastatic rates.

PROGNOSIS AND OUTCOME

- Prognosis is guarded to grave for dogs with rhabdomyosarcoma of the bladder, heart, or oral cavity. Many dogs have masses that are not resectable, and metastases are common after treatment of the primary tumor.
- Surgical resection has been reported to result in a fair prognosis in a few cases. These include a dog with a perianal tumor treated with surgery, radiation, and chemotherapy that developed metastasis at 252 days and two dogs treated with laryngectomy and tracheostomy that lived 18 and 22 months after surgery; all three of these dogs developed metastasis.
- Prognosis for rhabdomyosarcoma arising from skeletal muscle is not known.

PEARLS & CONSIDERATIONS

COMMENTS

Young animals that are treated for tumors may be more likely to develop late complications of chemotherapy and radiation (second malignancies, bone necrosis, central nervous system necrosis, radiation-induced tumors). This should be taken into consideration when deciding about treatment for rhabdomyosarcoma in young dogs. However, the poor prognosis for many of these tumors makes late side effects less of a concern.

CLIENT EDUCATION

Clients should be educated to monitor their pets for masses or signs of tumor development, even in young dogs. Early detection may allow for more successful treatment of these tumors.

AUTHOR: JOHNFARRELLY

EDITOR: KENNETH M.RASSNICK

Reverse Sneezing

BASIC INFORMATION

DEFINITION

A paroxysmal and noisy inspiratory effort localized to the nasopharynx, during which the owner commonly thinks the animal is suffocating; commonly encountered in dogs

SYNONYM

Mechanosensitive aspiration reflex

EPIDEMIOLOGY

SPECIES, AGE, SEX: Clinically, reverse sneezing is more commonly seen in dogs of any sex or age, depending on the underlying cause. Reverse sneezing can be experimentally induced in cats.

GENETICS & BREED PREDISPOSITION

- Idiopathic form: any breed of dog can be affected.
- Secondary to nasal mites: primarily large-breed dogs, potentially all types of dogs
- Secondary to nasal neoplasia: primarily dolichocephalic dogs

CONTAGION & ZOONOSIS: Nasal mite *(Pneumonyssoides caninum):* mode of transmission is not well established.

GEOGRAPHY AND SEASONALITY: Nasal mite: exists worldwide but is especially prevalent in the United States and northern European countries (Norway, Sweden, Finland).

ASSOCIATED CONDITIONS & DISORDERS: Reverse sneezing can be a normal occurrence in many dogs but can also be associated with nasal or nasopharyngeal disease (material coming from the nasal cavities, inflammation, abscess, foreign body, tumor, choanal atresia) and nasal mites.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Incidental episodes that do not require any treatment
- Repeated frequent episodes that are associated with other causes of nasal or nasopharyngeal disease

HISTORY, CHIEF COMPLAINT

- Incidental episodes of reverse sneezing are typically short in duration (a few seconds to 1 minute) and are generally self-limiting. Between episodes, the animal is generally normal.
- Frequent episodes of reverse sneezing may be a reflection of underlying disease and thus associated with signs of nasal/nasopharyngeal disease such as sneezing, nasal discharge, epistaxis, stertor, or others according to the etiology.

PHYSICAL EXAM FINDINGS: Incidental episodes of reverse sneezing: normal physical examination. Reverse sneezing associated with:

- Nasal/nasopharyngeal inflammation and bacterial infection of various origins:
  - Unilateral or bilateral serous to bloody discharge
  - Sneezing
  - Stertor
  - Decreased or sometimes increased nasal air passage
  - Systemic signs are rare.
- Nasal tumor:
  - Decreased nasal air passage (unilateral or bilateral)
  - Unilateral or bilateral serous, mucopurulent, or bloody discharge
  - Sneezing

    - Stertor
    - Facial or hard palate deformity (occasionally)
- Nasal aspergillosis:
    - Sneezing
    - Unilateral serous, mucopurulent, or bloody discharge
    - Depigmentation of nasal planum
    - Pain with palpation of facial bones
    - Increased nasal air passage
    - Decreased appetite and poor body condition are possible.
- Nasal mite:
    - Sneezing
    - Reverse sneezing, which may be the only abnormality in some dogs
    - Nasal discharge
    - Facial pruritus and hyposmia

ETIOLOGY AND PATHOPHYSIOLOGY

- Incidental reverse sneezing can be a normal occurrence.
- Receptors and myelinated trigeminal nerve endings situated in the lateral aspects of the nasopharynx respond to local stimulation, implying a reflex pathway. Any local stimulation can activate the reflex, which causes a strong inspiration of material from the nasopharynx to the oropharynx through a decreased nasopharyngeal opening.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is based almost exclusively on history: recognition of the characteristically loud, stertorous inspiratory episode that is sudden in onset and termination and occurs in an animal that is usually otherwise well.

DIFFERENTIAL DIAGNOSIS

When reverse sneezing occurs frequently (daily or several times a day) and/or is accompanied by other clinical signs, nasal or nasopharyngeal disease is possible:

- Nasal or nasopharyngeal tumor
- Cyst
- Foreign body
- Abscess
- Mycotic infection
- Chronic lymphoplasmacytic rhinitis, sinusitis
- Nasopharyngitis
- Nasal mites

INITIAL DATABASE

- Results of CBC, biochemistry panel, and urinalysis are usually unremarkable.
    - Eosinophilia may be present in some cases of nasal mites.
    - Anemia and hypoproteinemia may be present in animals with nasal or nasopharyngeal disorders that cause heavy and/or repeated bloody discharge.
- Nasal radiographs can be useful for the diagnosis of underlying diseases.

ADVANCED OR CONFIRMATORY TESTING

- If the episodes only occur at home (not in the veterinary hospital), and it is unclear whether they are consistent with reverse sneezing, clinicians can make the diagnosis by instructing the owner to videotape the episodes when they occur.
- Direct rhinoscopy and results of culture and cytologic and histopathologic evaluation of nasal samples are useful for the diagnosis of primary nasal diseases, whereas posterior rhinoscopy is needed for the diagnosis of nasopharyngeal diseases.
- CT scans and/or MRIs are useful in the diagnosis of some underlying conditions, such as neoplasia and aspergillosis.

TREATMENT

TREATMENT OVERVIEW

Reduce nasopharyngeal irritation by treating the underlying disorder when possible.

ACUTE GENERAL TREATMENT

Acute episodes of reverse sneezing associated with perceived severe discomfort of the animal can be shortened by opening the dog's mouth and gently pulling on the tongue or giving the animal something to lick or drink.

CHRONIC TREATMENT

- Incidental episodes need no treatment.
- Increased frequency of episodes without any other sign of nasal or nasopharyngeal disease:
    - A short period of nonsteroidal antiinflammatory drug (NSAID) administration (e.g., ketoprofen, 1 mg/kg PO q 24 h) may limit repeated reflex induced by local inflammation.
    - Treatment against the nasal mite if present (ivermectin, 0.1-0.4 mg/kg [100-400 mcg/kg] PO or SQ once every 3 weeks for 3 treatments; or milbemycin oxime, 0.5-1 mg/kg PO once weekly for 3 consecutive weeks)
- Related to nasal or nasopharyngeal disorders: treatment dictated by the underlying condition

PROGNOSIS AND OUTCOME

- Excellent for incidental episodes and when the underlying cause is nasal mite infestation
- Otherwise variable depending on the underlying etiology

PEARLS & CONSIDERATIONS

COMMENTS

The presence of clinical signs that suggest nasal or nasopharyngeal disease in conjunction with reverse sneezing should prompt diagnostic testing to detect underlying diseases.

TECHNICIAN TIPS

Nasal lavage, accomplished either by direct or retrograde methods, in conjunction with examination of nasal lavage fluid, can be helpful to clean the area when occluded as well as provide material for culture, cytologic, and histopathologic examinations.

CLIENT EDUCATION

Clients should learn not to worry during acute episodes of reverse sneezing, since there is in fact no real danger of suffocation.

Retinal Detachment

BASIC INFORMATION

DEFINITION

Separation of the neural retina (inner nine layers) from the underlying retinal pigment epithelium (RPE) as a result of primary inherited retinal disease or secondary to other intraocular disease (acquired); may be focal, multifocal, or complete; extent of retinal involvement determines degree of vision impairment

EPIDEMIOLOGY

SPECIES, AGE, SEX: Affects dogs and cats; age of onset and sex predisposition vary with underlying cause.

- Inherited (dogs):
  - Severe retinal dysplasia: congenital
  - Multifocal retinopathy: nonprogressive multifocal serous retinal detachments that manifest between 3 and 4 months of age
  - Collie eye anomaly (CEA): retinal detachments occur in up to 10% of CEA affected dogs; commonly young pups; may also develop later in life.
- Acquired:
  - Secondary to vitreous degeneration (liquefaction of the vitreous); usually older dogs
  - Systemic hypertension; typically older animals

GENETICS & BREED PREDISPOSITION: Dogs:

- Retinal dysplasia: presumed autosomal recessive in many predisposed breeds, including English springer spaniels, Bedlington terriers, American cocker spaniels, and miniature schnauzers; presumed an incomplete dominant inheritance in breeds with associated skeletal deformities, including Labrador retrievers and Samoyeds
- Multifocal retinopathy: autosomal recessive condition in Cotons de Tulear
- CEA: predisposed breeds include collies, Shetland sheepdogs, border collies, and Australian shepherds.
- Shih tzus are predisposed to vitreous degeneration and rhegmatogenous (retina is torn) retinal detachments.

RISK FACTORS: Acquired:

- Ocular trauma (see p. 249)
- Uveitis (see p. 1151)
- Glaucoma (see p. 448)
- Cataracts (see p. 181)
- Intraocular neoplasia (see p. 620)
- Lens luxation (see p. 644)
- Bleeding disorder (e.g., coagulopathy due to anticoagulant rodenticide intoxication; see p. 493)
- Surgical lens removal (lensectomy)
- Systemic hypertension (see p. 1068)
- Old age

ASSOCIATED CONDITIONS & DISORDERS

- Cataracts
- Hyphema (see p. 571)
- Retinal degeneration (see p. 983)
- Systemic diseases causing uveitis (see p. 1151)
- Diseases causing systemic hypertension (see p. 1068)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Bilateral or unilateral

- Inherited versus acquired
- Rhegmatogenous (retinal tear) versus nonrhegmatogenous
- Focal, multifocal, complete
- Bullous versus flat
- Exudative versus nonexudative
- Tractional

HISTORY, CHIEF COMPLAINT: Similar to retinal degeneration (see p. 983) ± bleeding inside eye

PHYSICAL EXAM FINDINGS: May produce no clinical signs if detachment is focal or multifocal, but typical findings in complete detachment are:

- Pupil(s) dilated or fixed and dilated
- Pupillary light reflex (PLR) decreased (i.e., sluggish and incomplete) or absent
- ± Anisocoria (asymmetric pupil size, especially if unilateral lesion; only pupil of affected eye is dilated).
- Blindness (variable vision impairment if incomplete)
- Gray to white membrane (retina) with blood vessels and/or hemorrhage often visible through pupil behind lens
- With or without signs of:
  - Uveitis (see p. 1151)
  - Hyphema (see p. 571)
  - Glaucoma (see p. 448)
  - Cataracts (see p. 181)
  - Systemic disease (acquired)

ETIOLOGY AND PATHOPHYSIOLOGY

- A potential space exists between the neural retina and the RPE (subretinal space).
- Exudative/nonexudative:
  - Breakdown of the blood-retinal barrier, allowing the following into the subretinal space:
    - Serous fluid ± hemorrhage (e.g., hypertension; hyperviscosity; vasculitis)
    - Exudative fluid (e.g., posterior uveitis due to systemic bacterial or mycotic infection)
- Rhegmatogenous:
  - Tear in retina allows vitreous to enter the subretinal space (e.g., hypermature cataracts, after lensectomy, CEA, old age or breed predisposition to vitreous degeneration/liquefaction, retinal degeneration).
- Tractional:
  - Fibrous or fibrocellular tissue pulling on the retina, with separation of the neural retina from RPE (e.g., ocular trauma resulting in vitreous hemorrhage, posterior uveitis and hyalitis [inflammation of the vitreous])
- Causes: see Risk Factors above.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis rests on examination of the fundus, typically through a complete ophthalmic exam (ocular ultrasound if the ocular medium is opaque [e.g., hyphema or cataract]). Examination of the posterior segment of the eye can be difficult, and making a diagnosis of retinal detachment can be challenging. Prompt referral to a veterinary ophthalmologist is advisable for all cases of vision impairment or blindness of undetermined cause.

DIFFERENTIAL DIAGNOSIS

Other causes of blindness (see p. 141)

INITIAL DATABASE

Complete ophthalmic examination (see p. 1313), including:

- Direct or indirect ophthalmoscopy to assess the posterior segment of the eye, including:
  - Optic nerve (optic disk hidden under membrane of detached retina with complete rhegmatogenous/ “morning glory” form)
  - Tapetum (dorsal reflective mirror; hyporeflective/grayish, dull discoloration ± hemorrhage with most forms of retinal detachment; hyper-reflective/brighter with complete rhegmatogenous form, because retina remains attached at/hangs off optic disk and no longer covers underlying tapetum).
  - Nontapetal fundus (typically pigmented and located ventrally; whitish/gray discoloration ± hemorrhage with retinal

detachment)
- Retinal vasculature: well-focused, small arteries and larger veins normally come from the optic disk and course peripherally. With retinal detachment, blood vessels change their course and become out of focus. With certain forms of retinal detachment, blood vessels may be visualized in the pupil behind the lens.

ADVANCED OR CONFIRMATORY TESTING

- Ocular ultrasound if ocular media opaque, preventing evaluation of deeper ocular structures
- Histopathologic evaluation of eye when eye is blind and painful and enucleation advised
- Referral is advisable for all cases of blindness of undetermined cause for additional workup (see p. 141).

TREATMENT

TREATMENT OVERVIEW

Treat underlying cause and restore vision or preserve remaining vision when possible.

ACUTE GENERAL TREATMENT

- Variable depending on underlying cause, duration, extent, and type of retinal detachment.
- Treat underlying cause, when possible, to prevent progressive retinal detachment.
- Promptly refer animals with acute blindness of undetermined cause to a veterinary ophthalmologist for early diagnosis and treatment (medical and/or surgical).

POSSIBLE COMPLICATIONS

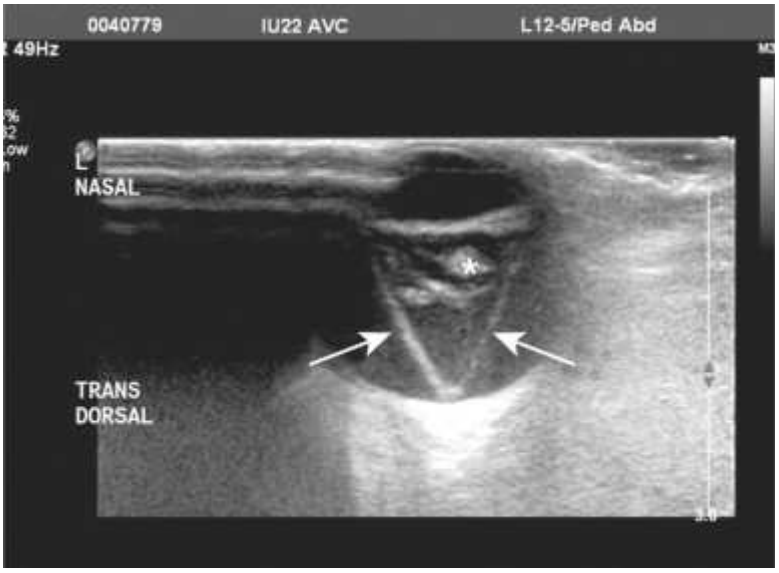
- Permanent blindness
- Cataracts
- Retinal degeneration (see p. 983)
- Hyphema (see p. 571)
- Uveitis ± secondary glaucoma
- Corneal/scleral trauma due to vision impairment (see p. 249)

RECOMMENDED MONITORING

- Variable depending on underlying cause
- Monitor for secondary cataracts and uveitis ± glaucoma

PROGNOSIS AND OUTCOME

- Variable depending on underlying cause, duration, extent, and type of retinal detachment
- Prognosis for vision with focal or multifocal forms is typically good, especially if underlying cause addressed and does not recur.
- Prognosis for vision with complete retinal detachment is typically guarded.



RETINAL DETACHMENT Ultrasound image of an eye (anterior/rostral is at top of image) showing retinal detachment *(arrows).* Note also the globoid hyperechogenicity consistent with vitreous hemorrhage and/or degeneration *(asterisk)* posterior to the misshapen hyperechoic lens compatible with a hypermature cataract.

(Courtesy Dr. Lee Ann Pack, Atlantic Veterinary College, UPEI, Canada.)

RETINAL DETACHMENT Ultrasound image of a normal eye for comparison. Separated, linear echogenicity (retina) seen in the other figure is not apparent in a normal eye.

(Courtesy Dr. Lee Ann Pack, Atlantic Veterinary College, UPEI, Canada.)

PEARLS & CONSIDERATIONS

COMMENTS

Irreversible retinal degeneration occurs quickly following retinal detachment; therefore, prompt diagnosis and treatment of underlying cause (when possible) are crucial.

PREVENTION

Ophthalmic screening of animals used for breeding by a board-certified veterinary ophthalmologist and registration through the Canine Eye Registration Foundation (www.vmdb.org/cerf.html) will help remove animals with inherited forms of retinal detachment from the breeding population.

CLIENT EDUCATION

- Retinal detachment may indicate systemic disease and may or may not be reversible, depending on cause; therefore, diagnostic testing is advised.
- Animals often adjust well to blindness.

AUTHOR & EDITOR: CHERYL L.CULLEN

Retinal Degeneration

BASIC INFORMATION

DEFINITION

Deterioration of the retina due to primary inherited retinal disorders or secondary to other intraocular disease (acquired); may be focal, multifocal, or generalized. Extent of retinal involvement determines degree of vision impairment.

SYNONYM

Retinal atrophy

EPIDEMIOLOGY

SPECIES, AGE, SEX: Affects dogs and cats; age of onset and sex predisposition vary with underlying cause:

- Inherited:
  - Progressive retinal atrophy (PRA): early onset (i.e., dysplasia; 12 weeks of age) and late onset (i.e., degeneration; typically detected by 2 to 5 years of age) in dogs and cats
  - Retinal pigment epithelial dystrophy (RPED); young dogs; uncommon
- Acquired:
  - Sudden acquired retinal degeneration (SARD) typically affects middle-aged to older dogs; females are predisposed.

GENETICS & BREED PREDISPOSITION

- Dogs:
  - PRA: autosomal recessive in most predisposed breeds, including poodles, cocker spaniels, Irish setters, and collies
  - RPED: high frequency in briards
- Cats: PRA is seen in Abyssinians as autosomal dominant (dysplasia) and autosomal recessive (degeneration).

RISK FACTORS

- See Uveitis, p. 1151.
- See Retinal Detachment, p. 985.
- See Glaucoma, p. 448.
- See Intraocular Neoplasia, p. 620.
- Nutritional deficiency (e.g., taurine in cats; vitamin A or E in dogs and cats)
- Toxicosis (e.g., idiosyncratic reaction to enrofloxacin, typically at high doses [>5 mg/kg per day], or griseofulvin in cats)
- Metabolic (e.g., mucopolysaccharidosis, dogs and cats; see p. 1054).

ASSOCIATED CONDITIONS & DISORDERS

- Cataracts
- Retinal detachment
- Systemic diseases causing uveitis (see p. 1151)
- See Hyperadrenocorticism, p. 548, regarding SARD.
- See Taurine Deficiency, p. 1075, regarding taurine deficiency in cats.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Bilateral or unilateral
- Inherited versus acquired
- Acute onset versus progressive
- Focal, multifocal, generalized

HISTORY, CHIEF COMPLAINT: Variable depending on underlying cause; owner may report any or all of the following:

- Acute or progressive vision impairment or blindness
- Red eye and/or other signs of glaucoma (see p. 448) or uveitis (see p. 1151)
- Greenish reflection to eye (tapetal reflection in dilated pupil)
- "Enlarged eye" (illusional due to dilated pupil or caused by buphthalmos; see p. 778)

PHYSICAL EXAM FINDINGS

- May show no clinical signs if focal
- Generalized:
  - Often bilateral
  - Dilated pupils and sluggish to absent pupillary light reflexes (PLRs)
  - Vision disturbances: ranging from impaired night vision (nyctalopia) and/or day vision (hemeralopia) (e.g., PRA) to complete blindness (e.g., SARD; end-stage PRA)
  - With/without signs of:
    - Uveitis (see p. 1151)
    - Glaucoma (see p. 448)
    - Cataracts (see p. 181)
    - Systemic disease (acquired)

ETIOLOGY AND PATHOPHYSIOLOGY

- Inherited:
  - Breed-specific genetic abnormality in photoreceptor metabolism, termed ***PRA:***
    - PRA: always bilateral; variable rate of progression; leads to blindness when both rods and cones affected:
      - Early onset: photoreceptors fail to develop normally (i.e., dysplasia).
      - Late onset: photoreceptors develop normally but degenerate:
        - Typically, rods affected first, causing nyctalopia
        - Eventually cones also affected, resulting in hemeralopia and blindness
  - RPED is a genetic abnormality affecting the RPE layer, with secondary effects on the neural retina (nine inner retinal layers); uncommon.
- Acquired:
  - SARD is idiopathic, always bilateral, dogs only:
    - Sudden blindness within days or 1-2 weeks
    - Normal fundic examination acutely; when disease is end-stage, generalized retinal degeneration is present that is indistinguishable from PRA.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Examination of the posterior segment of the eye (i.e., fundic examination) is the cornerstone of diagnosis but can be difficult, so making a diagnosis of retinal degeneration can be challenging. Prompt referral to a veterinary ophthalmologist is advisable for all cases of vision impairment or blindness of undetermined cause.

DIFFERENTIAL DIAGNOSIS

- Acute, nonred, quiet-eye blindness (e.g., SARD):
  - Optic neuritis
  - Optic chiasmal lesion
  - Postchiasmal/cortical blindness (pupil size and PLRs usually normal)
- Progressive blindness (e.g., PRA):
  - Slowly progressive cataracts
  - Progressive corneal discoloration
- "Red eye" blindness (e.g., glaucoma):
  - Uveitis
  - Cataracts
  - Lens luxation
  - Complex corneal ulceration
- See Blindness, p. 141.

INITIAL DATABASE

Complete ophthalmic examination (see p. 1313); fundic abnormalities may include:

- Optic nerve (pale and small with end-stage retinal degeneration)
- Tapetum (dorsal reflective mirror; hyperreflective/brighter with retinal degeneration)
- Nontapetal fundus (typically pigmented and located ventrally; whitish/gray depigmentation and/or mottled hyperpigmentation with retinal degeneration)
- Retinal vasculature (small arteries and larger veins normally come from the optic disk and course peripherally; with retinal degeneration, the retinal vessels become narrowed and eventually diminish in number; no retinal vessels are discernable with end-stage retinal degeneration).

ADVANCED OR CONFIRMATORY TESTING

- Histopathologic evaluation of eye (when eye blind and painful, enucleation is advised).
- Genetic screening of blood sample for various inherited ocular diseases, including PRA (available for certain breeds).
- ACTH stimulation testing to evaluate cortisol and sex hormones, blood pressure screening (see p. 1209), and urinalysis in cases diagnosed with SARD (see pp. 548 and 6)
- Referral is advisable for all cases of blindness of undetermined cause for additional evaluation:
    - Electroretinography (ERG; see p. 1255) to assess retinal function:
        - Flatline response (i.e., no retinal function) in SARD
        - Variable to flatline response in PRA, depending on stage of disease
        - See Blindness, p. 141.

TREATMENT

TREATMENT OVERVIEW

No treatment exists to regenerate the retina, and the presentation of these patients for vision loss often means the disease process has affected the retina extensively. Therefore, treatment of retinal degeneration consists of controlling or reversing an underlying cause when one can be identified.

ACUTE GENERAL TREATMENT

- Treat underlying cause (e.g., glaucoma, uveitis) when possible, to prevent progression of acquired retinal degeneration.
- Investigational treatments under evaluation include gene therapy and retinal allograft transplantation.

POSSIBLE COMPLICATIONS

- Cataracts
- Retinal detachment ± hyphema
- Uveitis ± secondary glaucoma
- Corneal/scleral trauma (see p. 249) due to vision impairment

RECOMMENDED MONITORING

- Variable depending on underlying
- Clinicians should monitor the animal for secondary cataracts and lens-induced uveitis (see p. 181).
- If SARD is suspected but cannot be confirmed with ERG, repeated fundic examinations at 3, 6, and 12 months are indicated for clinical signs of progressive retinal degeneration.

PROGNOSIS AND OUTCOME

- Permanent blindness with SARD and PRA
- Prognosis is typically good with focal retinal degeneration caused by scarring from previous posterior uveitis and/or retinal detachment, assuming disease process does not recur.

PEARLS & CONSIDERATIONS

COMMENTS

- There is no available treatment to regenerate the retina.
- Avoid enrofloxacin doses greater than 5 mg/kg/d in cats.

PREVENTION

- Ophthalmic screening by a veterinary ophthalmologist of animals used for breeding, and registration through the Canine Eye Registration Foundation (www.vmdb.org/cerf.html), will help remove PRA- and RPED-affected animals from the breeding population.
- Genetic testing of blood samples for breed-specific inherited ocular diseases will help detect carrier and affected animals.

CLIENT EDUCATION

- Retinal degeneration alone does not cause ocular pain.
- Animals often adjust well to blindness.

AUTHOR & EDITOR: CHERYL L. CULLEN

Restrictive/Unclassified Cardiomyopathy, Feline

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Restrictive cardiomyopathy (RCM): relatively uncommon primary disorder of the myocardium; characterized by severe left or biatrial enlargement with normal to slightly thickened ventricular myocardium, normal to slightly reduced ventricular volume, and normal to slightly reduced systolic function. On a two-dimensional echocardiogram, the presence of right and left ventricles of normal dimensions together with moderate to marked biatrial enlargement in the absence of any valvular, shunting, or stenotic lesions are hallmarks of RCM.
- Restrictive physiology (secondary RCM): common physiologic consequence of changes to the myocardium (usually fibrosis); results in a restrictive filling pattern. Commonly develops secondary to cardiac diseases such as DCM, chronic valvular insufficiencies or end-stage hypertropic cardiomyopathy (HCM).
- Unclassified cardiomyopathy (UCM): relatively common disorder of the myocardium; characterized by severe left or biatrial enlargement with mixed ventricular myocardial changes, including areas of thickening mixed with areas of thinning, mild to severe ventricular dilation, and mild to severe systolic dysfunction (decreased ventricular contractility), which could be global or regional.

SYNONYMS

- Intermediate-form cardiomyopathy: ICM (UCM)
- Restrictive filling or physiology: ventricular filling is similar to restrictive cardiomyopathy (RCM) but echocardiographic findings reveal abnormal ventricular myocardium

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Feline, middle-aged to older; no apparent sex predilection, although a female predominance has been reported.
- Accurate prevalence is difficult to determine owing to overlapping diagnostic criteria in the past. However, RCM/UCM appears to be the second most common myocardial disease in the cat after hypertrophic cardiomyopathy.

GENETICS & BREED PREDISPOSITION: No definitive breed predilection but may be seen more commonly in certain breeds (Persian, Birman, Balinese, Siamese, Burmese)

ASSOCIATED CONDITIONS & DISORDERS

- Congestive heart failure (CHF) is commonly seen: left-sided (pulmonary edema) or biventricular (pulmonary edema, pleural effusion, ascites).
- Cardiogenic embolism (systemic arterial thromboembolism) may be more commonly associated with this form of myocardial disease compared to hypertrophic cardiomyopathy.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Primary RCM: idiopathic disorder involving ventricular stiffness and in which ventricular dimensions are normal.
- Secondary RCM: myocardial disorders involving ventricular stiffness and in which ventricular dimensions are abnormal (see pp. 565 and 309). The information presented below will focus on primary RCM.
- Clinical presentation is variable but similar with both types of cardiomyopathy (RCM/UCM).

HISTORY, CHIEF COMPLAINT

- Dyspnea and tachypnea (from pulmonary edema) are most common. Some cats will have ascites and dyspnea from pleural effusion.
- Some cats will present for cardiogenic embolism, with or without concomitant CHF. Some cats will have a history of episodic lameness not associated with trauma.

PHYSICAL EXAM FINDINGS: Can be quite variable but could include:

- Soft systolic murmur (seemingly less common than in hypertrophic cardiomyopathy, presumably because left ventricular outflow tract obstruction and systolic anterior motion of the mitral valve occur less frequently with RCM/UCM).
- Gallop heart sound is often noted, especially if CHF is present.
- Muffled heart/lung sounds when pleural effusion is present
- Pulmonary crackles possible with pulmonary edema
- Ascites as a manifestation of biventricular CHF
- Absent femoral arterial pulses, cyanosis of nailbeds, cool paws, and firm, painful gastrocnemius muscles if aortic thromboembolism is present
- Pulse deficits from arrhythmias may be noted.

ETIOLOGY AND PATHOPHYSIOLOGY

- Primary RCM: idiopathic
- Secondary, noninfiltrative restrictive physiology:
  - Dilated cardiomyopathy
  - Hypertrophic cardiomyopathy
  - Diffuse myocardial fibrosis
- Secondary, infiltrative restrictive physiology:
  - Myocarditis
- Secondary RCM endomyocardial form:
  - Endomyocardial fibrosis (idiopathic)
- UCM:
  - Regional or diffuse areas of fibrosis
  - Regional or diffuse intramural myocardial ischemia (unproven)
- RCM/UCM: similar pathophysiologic effects resulting from excessive ventricular stiffness and, therefore, limitation in ventricular diastolic filling
  - Severely impaired (restricted) filling of ventricles induces diastolic dysfunction/failure, which results in elevated atrial pressures, pulmonary or systemic venous pressures, and congestion (pulmonary edema and/or ascites, respectively).
  - Systolic function is variable depending upon the underlying cause of the myocardial disease.
  - Dilated atria can allow blood stasis as well as having areas of endocardial fibrosis; both factors can result in mural thrombus formation.
- Emboli originating from a cardiac thrombus can infarct the terminal aorta, thoracic limbs, kidneys, bowel, or brain.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Restrictive cardiomyopathy and UCM commonly result in acute onset of dyspnea with or without cardiogenic embolism (saddle thrombi), often in cats with no known history of heart disease. While thoracic radiographs can confirm congestive heart failure, echocardiography is required to make a definitive diagnosis of the underlying cardiac disease.

DIFFERENTIAL DIAGNOSIS

- Physical:
  - Tachypnea/dyspnea:
    - Pulmonary disease
    - Pleural disease
    - CHF from other causes
  - Muffled heart/lung sounds:
    - Pleural disease
    - Obesity
    - Pneumothorax
  - Pulmonary crackles:
    - Pulmonary disease
    - Ascites:
      - Abdominal disease (generally more common than CHF as a cause of ascites in cats)
      - Effusive disease (e.g., feline infectious peritonitis, neoplasia, others)
      - CHF from other causes
    - Heart murmur:
      - Other cardiac disease
      - Physiologic murmur (i.e., anemia, hyperthyroidism)

        - Caudal paresis/paralysis:
            - Neurologic disease
            - Trauma
    - Electrocardiogram (ECG):
        - Arrhythmias:
            - Other cardiac disease
            - Systemic disease
            - Trauma
    - Thoracic radiographs:
        - Cardiomegaly
        - Other cardiac disease
        - Pericardial disease
    - Pulmonary infiltrates:
        - Pulmonary disease
        - Noncardiogenic pulmonary edema
    - Pleural effusion:
        - Pleural disease
        - Neoplastic disease
        - Effusive disease

INITIAL DATABASE

- ECG:
    - Arrhythmias are commonly seen.
        - Atrial premature complexes (APCs), ventricular premature complexes (VPCs), atrial fibrillation
    - Evidence of left ventricular and/or atrial enlargement may be seen.
- Thoracic radiographs:
    - Cardiomegaly:
        - Variable: usually left ± right atrial enlargement
        - Possible left ventricular enlargement
    - Pulmonary venous congestion/edema:
        - Often present
    - Pleural effusion:
        - Can be seen
- Echocardiogram:
    - Severe left atrial or biatrial dilation
    - Relatively normal-appearing ventricles (primary idiopathic RCM or secondary infiltrative restrictive physiology)
    - Hypertrophic segments interspersed with thin segments of the ventricular myocardium, with variable systolic function and ventricular dilation (secondary, noninfiltrative restrictive physiology, and UCM)
    - Left atrial thrombi may be seen.
    - Pericardial effusion may be present.
    - By definition, regurgitant valvular lesions, cardiac shunts, and stenotic lesions are absent or insignificant with primary RCM but can be seen with secondary RCM (restrictive physiology).

ADVANCED OR CONFIRMATORY TESTING

- Spectral Doppler echocardiogram (ventricular inflow):
    - Increased E wave amplitude
    - Shortened E wave deceleration time
    - Reduced A wave amplitude
    - Increased E/A wave ratio
    - Preserved respiratory variability on transtricuspid inflow profile
- Tissue Doppler imaging:
    - Reduced Ea and Aa velocities

TREATMENT

TREATMENT OVERVIEW

The vast majority of cats with RCM/UCM present in CHF and/or for cardiogenic embolism. Most of these cats will require acute treatment for these complications and then require lifelong chronic therapy to delay recurrence of CHF or cardiogenic embolism.

ACUTE GENERAL TREATMENT

- See Heart Failure, Acute/Decompensated, p. 468.
- See Aortic Thromboembolism, p. 88.
- There is no known treatment for slowing the progression or reversing idiopathic RCM or UCM.

CHRONIC TREATMENT

- Prevent recurrent fluid retention (lifelong treatment):
  - Furosemide: 1-2 mg/kg PO q 12-24 h (use lowest dose possible to maintain congestive-free state)
  - ACE inhibitors (either one is acceptable):
    - Enalapril: 0.25-0.5 mg/kg PO q 12-24 h
    - Benazepril: 0.25-0.5 mg/kg PO q 12-24 h
- Improve cardiac function:
  - Digoxin (if systolic dysfunction [decreased left ventricular contractility] is present): 0.03125 mg PO q 24-48 h
  - Pimobendan (if systolic dysfunction [decreased left ventricular contractility] is present): 0.625-1.25 mg PO q 12 h (not clinically studied or approved at this time). Monitor for anxiety/hyperesthesia, tachycardia as possible adverse effects.
  - β-Blockers (especially if ventricular arrhythmias are present):
    - Atenolol: 6.25-12.5 mg PO q 12-24 h
- Prevent cardiogenic embolism (arterial thromboembolism); lifelong treatments. Options can include any one of the following:
  - Antiplatelet agents:
    - Clopidogrel: 18.75 mg PO q 24 h (usually well tolerated, but if vomiting is seen, give with food); *or*
    - Aspirin: 25 mg/kg PO q 48-72 h (usually well tolerated but rarely can result in GI ulceration); *or*
    - Combination clopidogrel and aspirin (usually well tolerated but increased risk for bleeding)
  - Anticoagulants:
    - Low-molecular-weight heparins:
      - Dalteparin: 100 IU/kg SQ q 12-24 h; or
      - Enoxaparin: 1-1.5 mg/kg SQ q 12-24 h (has been shown to have an antithrombotic effect without measurable anti-Xa levels)
    - Synthetic Xa-inhibitors:
      - Fondaparinux: 0.06 mg/kg SQ q 12 h
  - Combination therapy:
    - Clopidogrel + dalteparin *or* enoxaparin *or* fondaparinux

BEHAVIOR/EXERCISE

Cats receiving antithrombotics have an increased risk for bleeding. Avoiding moderate or greater trauma should be avoided, so uncontrolled access to the outdoors should be avoided.

DRUG INTERACTIONS

- Aggressive diuretic administration together with ACE inhibitor therapy can result in acute, reversible renal failure.
- Combined antithrombotics theoretically can confer an increased risk of bleeding, although this has not been seen clinically.

POSSIBLE COMPLICATIONS

- Recurrent, intractable congestive heart failure is most common cause of death.
- Cardiogenic embolism can result in acute decompensation, reduced quality of life, or sudden death.

RECOMMENDED MONITORING

- Owners should watch for onset of dyspnea and possible embolic events.
- Repeated evaluation of thoracic radiographs and echocardiogram to evaluate for progression and alterations to medical therapy.

PROGNOSIS AND OUTCOME

- Guarded to good for treatment of acute CHF
- Guarded for treatment of acute cardiogenic embolism
- Poor to guarded for long-term survival (months to 1 year)

PEARLS & CONSIDERATIONS

COMMENTS

- RCM and UCM are irreversible diseases, and the cat is likely to have recurrent CHF episodes even with effective therapy.
- While cardiogenic embolism is a negative prognostic indicator and likely to occur again, many of these cats can do quite well with appropriate therapy and time; owners should at least consider treating such cats.

TECHNICIAN TIPS

- Intravascular volume overload can happen quickly, so excessive flushing of IV catheters with heparinized saline should be avoided.
- Development of reperfusion injury/hyperkalemia can happen very quickly in cats with cardiogenic embolism; monitor heart rate, serum electrolyte, and acid-base status closely.

CLIENT EDUCATION

Owners should watch for onset of dyspnea and possible signs of embolie events.

Renomegaly

BASIC INFORMATION

DEFINITION

Unilateral or bilateral enlargement of the kidneys. See table for normal anatomic parameters.

SYNONYMS

Kidney enlargement, nephromegaly

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dependent on underlying cause

GENETICS & BREED PREDISPOSITION: Persians and other longhaired cats are more commonly affected by polycystic kidney disease, which is inherited in an autosomal-dominant fashion in Persian cats.

Modified from Christie BA: Anatomy of the urinary system. In Slatter D, editor: Textbook of small animal surgery, ed 3, Philadelphia, 2003, Saunders, p 1562.

Characteristic Features of the Kidneys

Feature	Dog	Cat
Type	Unipyramidal (fused pyramids)	Unipyramidal (single pyramids)
Kidney mass as a percentage of body weight	0.6	0.6-1.0
Total nephrons per kidney	415,000	190,000
Kidney length in proportion to length of lumbar vertebra (L2)	2.9	2.7
Kidney width in proportion to length of lumbar vertebra (L2)	1.6	1.7
Ventral displacement in proportion to length of lumbar vertebra (L2)	L: 0.7	L: 0.7
	R: 0.3	R: 0.7
Diffusely hyperechoic renal cortex on ultrasound exam	Pathologic	Normal or pathologic

RISK FACTORS: Presence of certain infectious diseases (i.e., feline leukemia virus [FeLV], feline infectious peritonitis [FIP], leptospirosis) or disorders that may lead to urinary obstruction (i.e., urolithiasis, neoplasia)

CONTAGION & ZOONOSIS: Cat-to-cat transmission of FeLV and FIP can occur. Leptospirosis can be transmitted to other animals as well as to humans.

ASSOCIATED CONDITIONS & DISORDERS: Acute renal failure or chronic kidney disease (CKD)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Unilateral or bilateral renal enlargement
- May be an incidental finding

HISTORY, CHIEF COMPLAINT

- Lethargy, depression

- Anorexia
- Polyuria and polydipsia (PU/PD)
- Vomiting

PHYSICAL EXAM FINDINGS

- Depression
- Fever
- Palpably enlarged kidneys (unilateral or bilateral)
- Renal or abdominal pain
- Abdominal enlargement
- Pale mucous membranes
- Oral ulcers or erosions
- Halitosis

ETIOLOGY AND PATHOPHYSIOLOGY

- Neoplasia:
  - Several primary renal and metastatic tumors can cause unilateral or bilateral renomegaly.
  - Examples include lymphoma (historically most common in cats and may be related to FeLV; renomegaly is usually bilateral), renal carcinoma (most common in dogs), nephroblastoma, and cystadenocarcinoma (can occur in German shepherds and is associated with dermatofibrosis).
- Inflammation/swelling:
  - Infectious causes include FIP (granulomatous inflammation), leptospirosis, and renal abscesses (abscesses usually unilateral).
  - Ethylene glycol intoxication can cause acute bilateral renal swelling and pain.
- Hydronephrosis:
  - Unilateral or bilateral ureteral obstruction due to strictures, uroliths, or neoplasia (ureteral or in the bladder trigone)
  - Ectopic ureters
- Other:
  - Polycystic kidney disease: most common in Persian and domestic longhaired cats
  - Compensatory hypertrophy: unilateral enlargement of remaining kidney following removal of or severe damage to the other
  - Hematoma: usually unilateral enlargement and following trauma (rare)
  - Portosystemic shunt (increased glomerular filtration rate is often concurrent; both can be reversible with shunt ligation).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Renomegaly is apparent on physical exam; whether one or both kidneys is/are enlarged is an important feature that helps narrow the differential diagnosis. Typically, abdominal ultrasound is used for characterizing the enlargement and making a definitive diagnosis in some cases. Basic laboratory tests help identify the impact on renal function and further pinpoint the specific disorder as needed.

DIFFERENTIAL DIAGNOSIS

- Other causes of abdominal masses or enlargement
- Specific causes (e.g., neoplasia, hydronephrosis, polycystic kidney disease, etc.)

INITIAL DATABASE

- CBC: inflammatory leukogram and/or nonregenerative anemia may accompany infectious or neoplastic diseases. Thrombocytopenia may be present with leptospirosis. Polycythemia and/or extreme leukocytosis can occur (although rarely) with some renal neoplasms.
- Serum biochemical profile: abnormalities are consistent with acute renal failure (ARF) or CKD: azotemia, hyperphosphatemia, hyperkalemia, or hypokalemia; urine specific gravity <1.030 (dogs) or 1.035 (cats). Hyperglobulinemia is present in some chronic inflammatory disorders (e.g., FIP).
- Urinalysis: proteinuria and hematuria with some neoplastic and inflammatory disorders. Calcium oxalate monohydrate and dihydrate crystals may be observed with ethylene glycol toxicity.
- Abdominal ultrasound (see table): very effective at differentiating major causes and detecting presence of uroliths
- Abdominal radiographs (see table): effective at ruling out other causes of abdominal enlargement/masses and identifying

radiopaque uroliths

ADVANCED OR CONFIRMATORY TESTING

- Urine culture and sensitivity (C&S)
- Serologic evaluation or other diagnostic tests for infectious disease (leptospirosis, FeLV, FIP)
- Thoracic radiographs to rule out metastatic disease
- Serum or urine ethylene glycol assay
- Aspirate cytologic examination of renal masses
- Excretory urography/intravenous pyelography.
- Renal biopsy (although contraindicated if a bleeding disorder, hydronephrosis, abscess, cyst or if only one kidney is present)
- Exploratory laparotomy

TREATMENT

TREATMENT OVERVIEW

- Resolve underlying cause of renomegaly if possible.
- Treat associated disorders (e.g., ARF or CKD).

ACUTE GENERAL TREATMENT

Treat ARF if present, and address any related toxicity (i.e., ethylene glycol) or infection (i.e., leptospirosis).

CHRONIC TREATMENT

- Neoplasia: may involve nephrectomy if disease is unilateral with no sign of metastatic disease, or chemotherapy if tumor is potentially responsive to drug therapy (e.g., lymphoma).
- Hydronephrosis: correct cause of obstruction or ectopic ureter.

PROGNOSIS AND OUTCOME

Depends on the underlying cause and concurrent disorders (e.g., renal failure)

Renal Tubular Acidosis

BASIC INFORMATION

DEFINITION

Renal tubular acidosis (RTA) is an uncommon group of renal tubular disorders that result in hyperchloremic metabolic acidosis with a normal glomerular filtration rate.

- The tubular defect may result in decreased tubular resorption of $Hco3^-$ (proximal RTA) or defective acid secretion (distal RTA).
- Proximal RTA may be recognized along with proximal tubular resorption defects of glucose, phosphate, sodium, potassium, uric acid, and amino acids as part of Fanconi syndrome (see p. 377).

SYNONYMS

- Classic or type I: distal RTA
- Type II: proximal RTA
- Type IV: hypoaldosteronism or aldosterone resistance causing distal RTA (see p. 573); hyperkalemic RTA

EPIDEMIOLOGY

SPECIES, AGE, SEX: RTA is rare in both dogs and cats. Age of onset is dependent upon etiology (inherited, 3 to 4 years of age; acquired, any age).

GENETICS & BREED PREDISPOSITION: Dogs: basenjis, border terriers, Norwegian elkhounds (Fanconi syndrome)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Some or all may be present:

- Polyuria/polydipsia +/−
- Anorexia +/−
- Lethargy +/−
- Weakness +/−
- Signs consistent with urolithiasis (distal RTA) +/−
- Animals with proximal RTA often lack any signs of illness.

PHYSICAL EXAM FINDINGS

- Renomegaly +/−
- Dehydration +/−
- Poor haircoat +/−
- Muscular weakness +/−
- Weight loss +/−
- Nephrolithiasis/urolithiasis (distal RTA) +/−
- Bone demineralization (distal RTA) +/−

ETIOLOGY AND PATHOPHYSIOLOGY

Etiology:

- Inherited: dogs, Fanconi syndrome (see p. 377)
- Acquired:
  - Any substance that can cause renal tubular toxicosis; toxins (e.g., heavy metals, ethylene glycol, 4-pentenoate, maleic acid), drugs (gentamicin, cephalosporins, outdated tetracycline, cisplatin, salicylate, streptozotocin). Tubular toxicosis reported after feeding jerky treats.
  - Copper storage disease (dogs):
  - Neoplasia (multiple myeloma)

- Hypoparathyroidism with concurrent hypovitaminosis D
- *Escherichia coli* pyelonephritis (cats)
- Ischemia-induced renal failure
- Hypoaldosteronism or aldosterone resistance (e.g., spironolactone)

Pathophysiology:

- Proximal RTA:
  - Dysfunction of the proximal tubule, leading to decreased bicarbonate resorption
  - Distal tubular bicarbonate resorption mechanisms are intact.
  - Acidosis is less severe than in distal RTA, since the distal tubule is able to partially compensate.
- Distal RTA:
  - Impaired hydrogen ion secretion in the collecting ducts
  - Urinary acid secretion is decreased, little change in bicarbonate resorption.
  - Nephrocalcinosis, urolithiasis (typically calcium phosphate), bone demineralization, and potassium wasting are possible features.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

RTA should be considered in animals with hyperchloremic metabolic acidosis if recognized on serum chemistry profile and confirmed by blood gas analysis. Specific findings on diagnostics tests differ depending on the form of RTA (distal, proximal, hyperkalemic).

DIFFERENTIAL DIAGNOSIS

- Hyperchloremic metabolic acidosis: diarrhea, Fanconi syndrome, posthypocapnic metabolic acidosis, dilutional acidosis, hypoadrenocorticism, medications (carbonic anhydrase inhibitors, spironolactone, ammonium chloride)
- Alkaline urine: urinary tract infection with urease-producing bacteria (e.g., *Proteus, Staphylococcus, Klebsiella* spp.), postprandial, dietary

INITIAL DATABASE

- CBC: typically unremarkable
- Serum biochemistry profile: hypokalemia, hyperchloremia, normal anion gap, decreased Tco2
  - Hyperkalemia and hyponatremia may be seen with aldosterone deficiency or resistance (type IV RTA).
- Blood gas analysis: hyperchloremic metabolic acidosis is expected.
- Urinalysis: proximal RTA = pH < 6, distal RTA = pH > 6. Glucosuria common in proximal RTA only.
- Urine culture: urinary tract infection with urease-producing bacteria must be ruled out.
- Abdominal radiographs or ultrasound: rule out nephrolithiasis or urolithiasis (distal RTA only).

ADVANCED OR CONFIRMATORY TESTING

- Glomerular filtration rate: normal, but measurement not routinely required.
- Differentiation of proximal and distal RTA (important for therapeutic management):
  - Urinary fractional excretion of $Hco3^{-}$:
    - Urine fractional excretion of $Hco3^{-}$ is measured after normalization of plasma $Hco3^{-}$ with alkali administration.
      - Normal (<5%) with distal RTA
      - Markedly increased (>15%) with proximal RTA
  - Ammonium chloride tolerance test:
    - Administer 110 mg/kg ammonium chloride PO. Monitor urine pH before and q 1 h for 6 hours after administration:
      - In healthy dogs and cats, urine pH should decrease to a minimum of 5.0 and 5.5, respectively, after ammonium chloride administration.
      - Failure to acidify urine is consistent with distal RTA.

TREATMENT

TREATMENT OVERVIEW

Treatment goals are resolution of acidemia (Tco2 or $Hco3^-$ > 12 mEq/L) and correction of hypokalemia (if present).

ACUTE AND CHRONIC TREATMENT

- Administration of a mixture of potassium and sodium citrate (1 mEq/kg to >10 mEq/kg q 24 h):
  - The dose and ratio of potassium to sodium citrate should be titrated to maintain plasma potassium and bicarbonate within the respective reference ranges.
  - Generally, proximal RTA requires higher alkali dosages than distal RTA.
- Bicarbonate can be used as an alternative alkali (1-10 mEq/kg/d PO, titrated to effect). An 8-oz (227-gram) box of baking soda can be added to 3 qts (2.88 L) of distilled water to create a 1-mEq/mL solution of bicarbonate which can be kept refrigerated up to 2 months.
- Sodium bicarbonate can aggravate potassium wasting, necessitating potassium supplementation. Potassium gluconate should be used instead of potassium chloride.
- Type IV: therapy for hypoaldosteronism or discontinuation of aldosterone inhibitors.

NUTRITION/DIET

Although RTA is usually associated with a normal glomerular filtration rate, animals with progressive tubular disease and associated azotemia should receive a protein- and phosphorus-restricted renal diet.

POSSIBLE COMPLICATIONS

- Inadequate or overzealous administration of alkali or electrolytes can result in metabolic disturbances.
- Urolithiasis and osteomalacia are potential complications of distal RTA.

RECOMMENDED MONITORING

Blood gas analysis, urine pH, and serum potassium concentrations should be monitored regularly, with frequency of monitoring tailored according to severity of metabolic disturbance.

PROGNOSIS AND OUTCOME

- Prognosis is variable and dependent upon inciting cause and response to therapy.
- Animals with acquired RTA (especially toxin induced) may have spontaneous resolution. Others may develop progressive chronic kidney disease within a few months of diagnosis.
- Animals with complex tubular disorders (i.e., Fanconi syndrome) that have progressed to the point of showing overt clinical signs generally have a poorer prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- Renal tubular acidosis is a rare condition in small animals (with the exception of basenji dogs).
- Prior to diagnosis of RTA, other more common causes of metabolic acidosis should be definitively ruled out.

Renal Secondary Hyperparathyroidism

BASIC INFORMATION

DEFINITION

Renal secondary hyperparathyroidism (RSHP) results from the effects of excessive production of parathyroid hormone (PTH) in animals with chronic kidney disease (CKD)/renal failure.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Any animal with CKD

RISK FACTORS: CKD: IRIS (International Renal Interest Society) stages 3 and 4 most commonly, with some in stage 2; rare for those in stage 1

ASSOCIATED CONDITIONS & DISORDERS: Hyperphosphatemia, hypocalcemia, and CKD

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: History of CKD; chief complaint is usually associated with exacerbation of signs of CKD (see pp. 205 and 207).

PHYSICAL EXAM FINDINGS: Variable combinations of signs of CKD (see History, Chief Complaint and relevant cross-references [above]). Skull and jaw lesions ("rubber jaw") occasionally occur in growing dogs with RSHP.

ETIOLOGY AND PATHOPHYSIOLOGY

- Declining kidney function increases phosphorus retention, which leads to increased PTH:
  - Increased circulating phosphorus inhibits renal synthesis of calcitriol, the active form of vitamin D, removing calcitriol-mediated inhibition of PTH synthesis.
- Increased secretion of PTH stimulates calcitriol synthesis; however, maintenance of normal calcitriol concentrations will be at the cost of continued elevation of PTH.
- Progressive decline in calcitriol synthetic capacity and circulating concentrations reduces calcium (Ca) entry into the circulation from bone and intestine, decreasing serum ionized calcium (Ca^i) concentrations. Excessive PTH rarely results in hypercalcemia (tertiary hyperparathyroidism).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis should be suspected in patients with CKD.

DIFFERENTIAL DIAGNOSIS

- Primary and tertiary hyperparathyroidism
- Hypovitaminosis D; nutritional secondary hyperparathyroidism

INITIAL DATABASE

- Laboratory assessment of CKD
- Total serum Ca: usually normal to low, occasionally slightly high; serum Ca^i is more reliable and often does not parallel serum total Ca.

ADVANCED OR CONFIRMATORY TESTING

- Measure serum PTH concentration using a two-site method for intact PTH; contact a veterinary laboratory for sample collection, preparation, and submission instructions (can degrade during transport if not chilled). Increased PTH can occur

within reference range (usually upper half) in early phases of CKD.
- Measure Cai with PTH to determine appropriateness of the response.
- Measure 25-hydroxy-vitamin D; many patients with renal secondary hyperparathyroidism also have a component of nutritional secondary hyperparathyroidism.
- Radiography may reveal diffuse bone demineralization. Pathologic fractures are rare. The earliest lesion in facial bones of young growing animals is lamina dura dentes demineralization, seen using high-definition dental technique (see p. 1246).
- High-frequency ultrasonography of the neck will reveal parathyroid gland enlargement of multiple glands.

TREATMENT

TREATMENT OVERVIEW

The goals of treatment are to decrease PTH levels and reduce the rate of CKD progression by reducing dietary phosphorus intake, increasing endogenous synthesis of calcitriol and, as indicated, by further reducing intestinal phosphate absorption (binders) and providing exogenous calcitriol.

ACUTE GENERAL TREATMENT

Reduce the animal's phosphorus intake by providing a phosphorus-restricted diet, which ranges in content from 0.4-1.6 mg P/kcal.

CHRONIC TREATMENT

- If restriction of phosphorus intake is inadequate or if phosphorus-restricted diets are refused, provide intestinal phosphorus binders with food, starting at the lowest dose and increasing the dose as necessary to control serum phosphorus to a target of approximately 4 mg/dL (lower half of reference range). Intestinal phosphorus-binding effects are greatest when the binder is given with food (increases fecal phosphorus excretion). Options include:
  - Aluminum hydroxide (30-90 mg/kg per day in food)
  - Calcium carbonate (90-150 mg/kg per day in food)
  - Calcium acetate (60-90 mg/kg per day in food)
  - Chitosan (1 g/10 lb twice daily with food)
  - Lanthanum carbonate (35-50 mg/kg per day in food)
- Aluminum- and calcium-containing binders can be used in combination to reduce the dose of each, which minimizes the risk of hypercalcemia and aluminium accumulation.
- Prescribe calcitriol (2.5-3.5 ng/kg PO q 24 h) after serum P < 6 mg/dL.
- Recommend therapy for animals with CKD as appropriate (see p. 207).

DRUG INTERACTIONS

Calcitriol can accentuate soft-tissue mineralization in animals with increased serum Cai or phosphorus.

POSSIBLE COMPLICATIONS

- Ionized hypercalcemia (>6 mg/dL in dogs; 5.5 mg/dL in cats): increased total serum Ca occurs in 10%-20% of dogs and cats with CKD before treatment; Cai may be increased, normal, or low. Hypercalcemia is dangerous only when Cai is increased. When Ca is increased:
  - Change calcitriol supplementation from once daily administration to giving twice the dose every other day, or decrease the daily dose by 50% to decrease Ca absorption from the intestine.
  - If serum phosphorus is too low with phosphate restricted diets, increase the animal's dietary phosphorus intake.
  - Change to a class of non-calcium containing intestinal phosphate binder if hypercalcemia develops while the animal is receiving calcium salt phosphate binders, or decrease the daily dose by 50%.

RECOMMENDED MONITORING

- Measure PTH and Cai (from the same sample) after 1, 3, and 6 months of therapy to determine initial and subsequent adequacy of RSHP control and twice yearly thereafter for stable animals.
- Modify extent of dietary phosphorus restriction, dosage, and types of intestinal phosphorus binders and changes in calcitriol dose on PTH and Cai results.
- Measure serum phosphorus to ensure control of hyperphosphatemia.
- Refer animals with persistently increased Cai for evaluation of primary or tertiary hyperparathyroidism.
- Monitor the animal's CKD as needed.

PROGNOSIS AND OUTCOME

- Days to weeks of survival if CKD is severe and renal secondary hyperparathyroidism cannot be controlled
- Months to years of survival is possible but guarded to poor for animals with CKD and uncontrolled RSHP. Long-term survival in cats with treatment of CKD is far more common than in dogs.
- Worse for animals with uncontrollable hyperphosphatemia
- Survival increases with appropriate PTH-lowering therapy.

PEARLS & CONSIDERATIONS

COMMENTS

- Nearly impossible to lower PTH if serum P > 6 mg/dL
- Reference ranges for serum phosphorus levels often include results from growing animals, which are much higher than for adult animals.
- The goal for serum phosphorus during CKD is 4 mg/dL (midrange to lower half of reference range) versus the upper limit of many reference ranges for adults (<6 mg/dL).

PREVENTION

- Appropriate phosphorus restriction can control or prevent development of RSHP in early CKD.
- Calcitriol can prevent development of parathyroid gland hyperplasia in RSHP.
- Calcitriol treatment is necessary to control RSHP in more advanced CKD.

CLIENT EDUCATION

Medical progress visits will be necessary to monitor CKD and determine adequacy of RSHP control.

Renal Neoplasia

BASIC INFORMATION

DEFINITION

Neoplasms arising in the kidney parenchyma of epithelial (carcinoma), mesothelial (sarcoma), or mixed embryonal (nephroblastoma) origin

SYNONYMS

Wilms' tumor (nephroblastoma), kidney tumors

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs: older adults. Nephroblastomas reported in young dogs. Cats: Older adults, but young cats may develop feline leukemia virus (FeLV)-related lymphoma.

GENETICS & BREED PREDISPOSITION: Nodular dermatofibrosis genetically associated with multiple, bilateral renal cystadenocarcinomas in German shepherds

RISK FACTORS: Dogs: no sex predominance, except possibly sarcomas in females. Cats: FeLV infection associated with renal lymphoma.

CONTAGION & ZOONOSIS: Cats: FeLV-related lymphoma (cat-to-cat)

ASSOCIATED CONDITIONS & DISORDERS: Paraneoplastic polycythemia; nodular dermatofibrosis with renal cystadenocarcinoma

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Primary renal tumors are associated with minimal clinical signs until advanced stage
- Renal lymphoma in cats may disseminate to the central nervous system (CNS)

HISTORY, CHIEF COMPLAINT

- Hematuria
- Lethargy
- Inappetence
- Abdominal mass
- Weight loss
- Vomiting
- Polyuria/polydipsia (PU/PD)
- Flank pain
- Behavior changes
- Acute collapse

PHYSICAL EXAM FINDINGS

- Renomegaly
- Abdominal mass
- Pale mucous membranes
- Abdominal distension +/– fluid wave
- Shock (if actively bleeding)

ETIOLOGY AND PATHOPHYSIOLOGY

- Lymphoma: may occur spontaneously (dogs and cats) or associated with FeLV (cats)
- Carcinoma: renal cell carcinoma, transitional cell carcinoma, or adenocarcinoma with tubular or papillary differentiation:

    - Mass in renal parenchyma leads to hematuria and proteinuria.
    - Pyuria common; may be secondary to inflammation from tumor or bacterial infection
    - Anemia secondary to blood loss (with hypoalbuminemia) or diminished renal erythropoietin production
    - Polycythemia (rare) due to erythropoietin or erythropoietin-like secretion
    - Metastasis common (16%-48% at diagnosis, 61% at death)
    - Unilateral or (rarely) bilateral
- Sarcoma: hemangiosarcoma, renal sarcoma, leiomyosarcoma, fibrosarcoma, malignant fibrous histiocytoma, and spindle-cell sarcomas reported
    - May be metastatic from other site
    - Hematuria common
    - Hypoalbuminemia less common
    - Polycythemia (rare)
    - Flank pain more common than in carcinomas
    - Metastasis common
- Nephroblastoma:
    - Anemia
    - Associated with young, but reported in older dogs
    - Metastasis common
- Benign tumors:
    - Hemangioma most common (dogs)
    - Renal adenomas and leiomyomas most common (cats)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A renal tumor should be suspected in cases of persistent hematuria, flank pain, polycythemia, or retroperitoneal mass. Confirmation of the diagnosis requires imaging including radiography, ultrasonography, or advanced planar imaging.

DIFFERENTIAL DIAGNOSIS

- Physical exam:
    - Abdominal mass +/− pain +/− ascites:
        - Urinary tract infection, urolithiasis, bladder tumor
        - Mass in spleen, mesenteric lymph node, or retroperitoneal space
        - Ruptured splenic or hepatic mass with hemoperitoneum
        - Abdominal trauma or coagulopathy with peritoneal or retroperitoneal bleeding
        - Renal cysts
        - Hydronephrosis
    - Abdominal pain without mass:
        - Pyelonephritis
        - Ethylene glycol ingestion
- Radiographic:
    - Mass in spleen, mesenteric lymph node, or retroperitoneal space
    - Ruptured splenic or hepatic mass with hemoperitoneum
    - Retroperitoneal fluid: blood or urine
    - Renal cyst or hydronephrosis
- Ultrasonographic:
    - Renal abscess or granuloma
    - Metastatic neoplasia
- Urinalysis:
    - Urinary tract infection
    - Urolithiasis
    - Ureter or bladder tumor
    - Idiopathic renal hematuria

INITIAL DATABASE

- CBC, chemistry profile, urinalysis: anemia or polycythemia possible, thrombocytopenia occasionally, azotemia (prerenal and renal), hypoalbuminemia, proteinuria, and hematuria
- Abdominal radiographs: mass, possibly peritoneal or retroperitoneal fluid
- Thoracic radiographs: metastasis (16%-48% at diagnosis)
- Abdominal ultrasound: renal mass and possibly metastasis to any abdominal organ, including adrenal gland and vena cava

- Prothrombin time and partial thromboplastin time if suspect disseminated intravascular coagulation

ADVANCED OR CONFIRMATORY TESTING

- Cytology or biopsy necessary for diagnosis
- Renal scintigraphy or excretory urogram to assess functional renal mass prior to nephrectomy
- Veterinary bladder tumor antigen test (V-BTA [Alidex Inc, Redmond, Wash.]) may detect renal pelvic transitional cell carcinoma.
- Echocardiogram if hemangiosarcoma, to rule out cardiac mass
- Cerebrospinal fluid (CSF) tap and bone marrow aspirate cytologic analysis if lymphoma (to stage disease)

TREATMENT

TREATMENT OVERVIEW

The goal of treatment is to remove the source of bleeding, pain, or polycythemia. Surgery is the primary treatment modality with demonstrated benefit for tumors other than lymphoma. Complete resection is ideal.

ACUTE GENERAL TREATMENT

- Stabilize with crystalloids, colloids, and oxygen-carrying capacity.
- Address renal insufficiency with fluid diuresis.
- Surgically remove bleeding mass.
- Begin chemotherapy with caution in lymphoma:
  - L-Asparaginase, 10,000 U/m^2 IM once on day 1
  - Cytosine arabinoside, 50 mg/m^2 subcutaneously q 12 h × 3 days for first week starting day 1
  - Vincristine, 0.5 mg/m^2 IV q 7 days starting day 1
  - Cyclophosphamide, 50 mg/m^2 PO once daily for 4 days each week starting day 1 if no evidence of cystitis
- Alleviate pain with opioids.

CHRONIC TREATMENT

- Lymphoma: if remission achieved with COAP protocol (see pp. 669 and 675), after 6 weeks administer doxorubicin IV at 30 mg/m^2 for dogs >30 kg or 1 mg/kg for dogs <30 kg and cats, q 3 weeks.
- Others:
  - No prospective clinical trials exist
  - Most literature reports based on doxorubicin or actinomycin-D
  - Anecdotal reports of response to carboplatin for carcinomas
  - Carcinomas may express cyclooxygenase 2 (COX-2), so 0.3 mg/kg piroxicam PO once daily recommended if azotemia absent.

BEHAVIOR/EXERCISE

Postoperative physical restriction as usual for a laparotomy

DRUG INTERACTIONS

Avoid combining drugs with similar toxicity profiles, such as cisplatin and piroxicam.

POSSIBLE COMPLICATIONS

Neutropenia, thrombocytopenia, sepsis, and renal injury secondary to chemotherapy

RECOMMENDED MONITORING

- Monitor CBC prior to every chemotherapy treatment and 7-10 days later.
- Monitor BUN, creatinine, and urine specific gravity for renal function.

PROGNOSIS AND OUTCOME

- Benign: good
- Lymphoma: guarded to poor
  - 60% remission rate; median duration 4 months (cats)
  - For solid tumors, survival is dependent on therapy.
  - 16-month median with surgery
  - < 1-month median without surgery
  - Chemotherapy not demonstrated to make a difference
- Carcinomas: guarded to poor
  - Rare survivals >1 year
- Sarcomas: guarded to poor
  - Reportedly more aggressive than carcinomas
- Nephroblastomas: guarded to poor
  - Rare reports of long survivals
- Metastatic potential of all tumors is high.
  - Lymphoma metastasis to CNS is lower with cytosine arabinoside in chemotherapy protocol.
  - Chemotherapy effect on metastasis of carcinomas, sarcomas, nephroblastomas unevaluated

PEARLS & CONSIDERATIONS

COMMENTS

- Hematuria in the absence of other clinical signs may suggest renal neoplasia.
- Early detection is critical for successful treatment.
- Definitive diagnosis is necessary for prognosis and therapeutic decisions.
- Complete resection offers best chances for long survival.
- Polycythemia usually resolves with nephrectomy.

TECHNICIAN TIPS

- Polycythemia (PCV > 55%-65%, depending on breed) may be a sign of renal tumor.
- Careful handling of all excreta from dogs receiving chemotherapy is important to prevent exposure to active metabolites.

CLIENT EDUCATION

Signs are subtle and nonspecific, so advanced diagnostic tests and imaging are most useful early. Nephrectomy may be palliative and maximize quality of remaining life.

UROLOGY: LEAH A. COHN

Renal Dysplasia

BASIC INFORMATION

DEFINITION

Disorganized renal development resulting from arrested or anomalous cellular processes; occurs uncommonly in dogs and rarely in cats.

SYNONYMS

Familial renal disease, progressive juvenile nephropathy

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs (rarely cats) of either gender; onset of signs ranges from weeks to years of age, with most animals developing signs prior to 2 years.

GENETICS & BREED PREDISPOSITION: Familial; reported in a number of common breeds (e.g., golden retriever, boxer, cocker spaniel, Lhasa apso, shih tzu) and less common breeds (e.g., Dutch kooiker, Finnish harrier, soft-coated wheaten terrier).

RISK FACTORS: In utero viral infection (e.g., canine herpesvirus, feline panleukopenia)

ASSOCIATED CONDITIONS & DISORDERS

- Chronic kidney disease (CKD; staged as I to IV; see p. 205)
- Stunted growth
- Renal (fibrous) osteodystrophy
- Systemic hypertension

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Familial
- Nonfamilial

HISTORY, CHIEF COMPLAINT: Clinical signs may be absent. When present, abnormalities may include:

- Anestrus +/−
- Anorexia/wasting (if stage III to IV CKD present)
- Bone pain (if osteodystrophy present)
- Depression/lethargy (if stage III to IV CKD present)
- Hematuria +/−
- Polyuria and polydipsia (PU/PD) common
- Poor wound healing (if stage III to IV CKD present)
- Stunted growth +/−
- Vomiting/diarrhea (if stage III to IV CKD present)

PHYSICAL EXAM FINDINGS: Physical examination may be unremarkable, but abnormalities can include:

- Calcinosis circumscripta uncommon
- Dehydration (if stage III to IV CKD present)
- Enlarged mandible/maxillae (if osteodystrophy present)
- Muscular twitching (if osteodystrophy present)
- Oral ulceration/halitosis (if uremia present)
- Pallor (if stage III to IV CKD present)
- Pathologic fracture (if osteodystrophy present)
- Pliable mandible (“rubber jaw”) (if osteodystrophy present)
- Poor haircoat +/−

- Small kidneys on abdominal palpation common but inconsistent finding
- Small stature/poor body condition common but inconsistent finding

ETIOLOGY AND PATHOPHYSIOLOGY

- The microscopic appearance of kidneys should be mature by 70 days of age (some development and histologic change normally continues during the first 2 months of life). Disorganized parenchymal development with immature or anomalous structures characterizes renal dysplasia with histologic features inappropriate for the animal's age.
- Poorly developed kidneys result in renal failure and eventual death.
- Diminished renal conversion of vitamin D to the active form, calcitriol, contributes to secondary hyperparathyroidism and subsequent renal osteodystrophy. This complication is more pronounced in juvenile renal disease.

DIAGNOSIS 

DIFFERENTIAL DIAGNOSIS

Azotemia:

- Prerenal (e.g., dehydration, gastrointestinal bleeding)
- Renal (e.g., acute renal failure or CKD of any cause)
- Postrenal (e.g., urinary obstruction, urinary tract rupture)

INITIAL DATABASE

- Blood pressure (BP; see pp. 1068 and 1209):
  - CBC: nonregenerative anemia
- Serum biochemical profile: abnormalities become more likely and more severe as stage of CKD progresses. Common findings include:
  - Azotemia
  - Hyperphosphatemia
  - Hypokalemia
  - Hypercalcemia/hypocalcemia
  - Metabolic acidosis
  - Hypercholesterolemia
  - Hypoalbuminemia
- Urinalysis: isosthenuric or minimally concentrated urine characteristic, variable hematuria, proteinuria, glucosuria
- Urine culture and sensitivity (C&S) to rule out secondary infection
- Abdominal radiography:
  - Small kidneys
  - Poor abdominal detail (young age, poor body condition)
  - Soft-tissue mineralization
- Ultrasonography:
  - Small, irregularly shaped kidneys
  - Thin renal cortex
  - Hyperechoic renal parenchyma
  - Poor corticomedullary distinction
  - Soft-tissue mineralization

ADVANCED OR CONFIRMATORY TESTING

- Serum parathyroid hormone (PTH) concentration: initially normal, then rises. Intention is to delay/prevent this rise using calcitriol therapy.
- Serum ionized calcium: to confirm biologically significant hypercalcemia; may be normal initially and then may increase as PTH concentration rises.
- Assessment of glomerular filtration rate: may have a role in evaluating nonazotemic animals suspected of having renal dysplasia.
- Renal histopathologic examination: required to confirm diagnosis:
  - Asynchronous nephron development
  - Immature glomeruli and/or tubules
  - Persistent fetal mesenchyme
  - Persistent metanephric ducts
  - Atypical tubular epithelium

- Dysontogenetic metaplasia

TREATMENT

TREATMENT OVERVIEW

Renal dysplasia cannot be reversed or cured; the goal of therapy is to delay progression of kidney disease, maintain hydration, address signs of uremia, and address complications of overt CKD such as anemia and acid-base and electrolyte disorders.

ACUTE GENERAL TREATMENT

Acute treatment will address uremia, dehydration, electrolyte, and acid-base disorders (see pp. 207 and 205).

CHRONIC TREATMENT

- See Chronic Kidney Disease, Occult ("Asymptomatic"), p. 205; Chronic Kidney Disease, Overt ("Symptomatic"), ; Protein-Losing Nephropathy, ; Renal Secondary Hyperparathyroidism, p. 976. Besides those described below, other treatments to consider address hyperphosphatemia, systemic hypertension, GI ulceration, anorexia, anemia, hypokalemia, and acidosis.
- Vomiting: address promptly, as dehydration may lead to rapid deterioration of renal function. Commonly used antiemetics include maropitant (dogs 2 mg/kg PO q 24 h for 5 days), metoclopramide (0.2-0.5 mg/kg SQ or IM q 8 h), or ondansetron (0.1-0.2 mg/kg IV q 12 h). Provide crystalloid fluid therapy as needed to replace losses.
- Bone pain (renal osteodystrophy): opioids (e.g., full mu agonists [e.g., oxymorphone, 0.03-0.2 mg/kg SQ, IM, or IV; fentanyl patch] or buprenorphine, 0.01-0.02 mg/kg SQ, IM, or IV q 6-8 h). Avoid administering nonsteroidal antiinflammatory drugs (NSAIDs), which have potentially negative renal effects.
- Early calcitriol therapy may delay or prevent bone changes and should be considered before hyperphosphatemia occurs:
  - Initial dose 1.65-3.63 ng/kg (= 0.00165-0.00363 mcg/kg) PO q 24 h (dogs and cats); dose is adjusted based primarily on serum calcium and phosphorus concentrations (± PTH concentrations).
  - Maintain Ca (mg/dL) × P (mg/dl) product of <70; avoid hypercalcemia; if total calcium elevated, confirm with ionized calcium.
  - Ideally, PTH should be within reference range during treatment. If low, dose is decreased; if high, dose is increased.
  - Calcitriol loses efficacy when phosphorus >8 mg/dL. Typically, calcitriol is used in conjunction with a phosphorus-reducing diet and noncalcium-containing phosphate binders.

NUTRITION/DIET

Renal diets with optimal protein and phosphorus content are indicated (see p. 207).

DRUG INTERACTIONS

- Vascular calcium channel blockers (amlodipine) and angiotensin-converting enzyme (ACE) inhibitors used concurrently may produce hypotension.
- Phosphate binders can interfere with absorption of orally administered medications.
- Concurrent use of calcitriol and calcium-containing phosphate binders, thiazide diuretics, corticosteroids, and barbiturates should be avoided.
- Nephrotoxic drugs (e.g., aminoglycosides) or drug combinations (e.g., NSAIDs plus ACE inhibitors) should be avoided whenever possible.
- Drugs which undergo renal elimination may need adjustment in dose strength or frequency in animals with CKD.

POSSIBLE COMPLICATIONS

- Hypotension may result from use of a calcium channel blocker and/or ACE inhibitors.
- Calcitriol may lead to hypercalcemia and/or ectopic mineralization of tissues.
- Complications of CKD include uremia, systemic hypertension, GI ulceration, anemia, electrolyte disorders, acidosis renal osteodystrophy.

RECOMMENDED MONITORING

- Monitor calcium and phosphorus levels 2 weeks after beginning calcitriol therapy and at least monthly thereafter for adjusting dosages. Ideally, measure PTH levels prior to and 1-2 months after therapy has started.
- The clinician is advised to monitor the animal as he/she would other animals with CKD (see p. 207); monitoring includes complete physical examination; measurement of BP; serum biochemistry profiles and blood gas determinations to assess azotemia, electrolyte, and acid-base status; and monitoring for clinical signs suggesting urinary tract infection.

PROGNOSIS AND OUTCOME

- Depends on degree of dysplasia, age at onset of signs, severity of dysfunction at diagnosis, and subsequent treatment.
- It is an irreversible condition; long-term prognosis is generally poor.

PEARLS & CONSIDERATIONS

COMMENTS

- Renal dysplasia can occur in any breed of dog or cat.
- There is no specific therapy, but animals are managed as for CKD and its complications.

PREVENTION

- Do not breed affected animals.
- Inform owners of appropriate vaccination of cats against panleukopenia.

CLIENT EDUCATION

Owners should research breed-associated diseases prior to considering adoption or purchase.

Regurgitation

BASIC INFORMATION

DEFINITION

The passive, retrograde expulsion of food and/or fluid from the esophagus or pharynx into the oral and/or nasal cavities

EPIDEMIOLOGY

SPECIES, AGE, SEX: Congenital causes may produce clinical signs as early as weaning; acquired forms usually in young to middle-aged animals. Idiopathic megaesophagus occurs spontaneously in adult dogs between 7 and 15 years of age, without sex or breed predisposition.

GENETICS & BREED PREDISPOSITION

- Dogs:
  - Wire-haired fox terriers and miniature Schnauzers: hereditary megaesophagus
  - German shepherd, Newfoundland, Great Dane, Irish setter, and sharper familial megaesophagus
  - German shepherd and Irish setter: vascular ring anomalies
  - German shepherd: gastroesophageal intussusception
  - German shepherd, Jack Russell terrier, springer spaniel, Labrador retriever, and Scottish terrier: myasthenia gravis
  - Shar-pei: hiatal hernia
  - Medium- to large-breed dogs: hypothyroidism; link to megaesophagus remains anecdotal.
  - Great Dane, rottweiler, standard poodle, and West Highland white terrier (hypoadrenocorticism)
- Cats: Siamese (familial megaesophagus); longhaired breeds (hairballs)

ASSOCIATED CONDITIONS & DISORDERS: Aspiration pneumonia (most common and serious complication of megaesophagus), rhinitis, esophageal strictures

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Esophageal
- Pharyngeal

HISTORY, CHIEF COMPLAINT

- “Vomiting” is commonly reported by owners of animals that are regurgitating; accordingly, clinicians should question owners about what the animal does when food is ejected from the mouth (more details in Differential Diagnosis below).
- Coughing
- Dyspnea
- Weakness
- Weight loss

PHYSICAL EXAM FINDINGS: Findings are variable:

- Emaciation
- Weakness
- Esophageal bulge (pressure on abdomen, close nostrils)
- Fever
- Respiratory signs
- Abnormal neurologic examination

ETIOLOGY AND PATHOPHYSIOLOGY

- Regurgitation indicates esophageal or pharyngeal dysfunction due to mechanical obstructive disease or functional (motility) abnormalities such as megaesophagus.

- Esophageal disease:
  - Megaesophagus: primary (idiopathic) or secondary
  - Esophagitis
  - Esophageal obstruction/foreign body
  - Esophageal mass (e.g., *Spirocerca lupi)*
  - Esophageal diverticulum
  - Esophageal stricture/stenosis
  - Vascular ring anomaly
  - Other motility disorder
  - Thoracic neoplasia (e.g., thymoma)
- Pharyngeal disease:
  - Pharyngeal obstruction
- Other alimentary tract disease:
  - Gastroesophageal intussusception
  - Pyloric outflow obstruction
  - Hiatal hernia
- Neuromuscular disease:
  - Myasthenia gravis
  - Botulism
  - Tetanus
  - Anticholinesterase activity (e.g., organophosphate toxicity)
  - Dysautonomia
  - Polyradiculoneuritis
- Immune-mediated:
  - Systemic lupus erythematosus
  - Polymyositis
- Intoxications:
  - Lead
  - Thallium
  - Organophosphate
- Endocrine:
  - Hypothyroidism (speculative)
  - Hypoadrenocorticism

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The essential first step is to clarify whether regurgitation, dysphagia, or vomiting is present. Some patients may exhibit more than one, or the owner may not be sure, but in most cases it is possible to identify regurgitation specifically from the history. The next step consists of obtaining thoracic radiographs for confirmation and to assess the lung parenchyma for evidence of aspiration. An extensive diagnostic workup is generally involved with megaesophagus, because many primary disorders may cause it.

DIFFERENTIAL DIAGNOSIS

- It is essential to distinguish regurgitation from vomition and dysphagia, since the underlying causes, treatment approaches, and outcomes are generally very different.
- Regurgitation: passive (usually); undigested food (covered by mucus or saliva); sausage shaped; neutral pH; immediately postprandial or delayed (hours). Forceful abdominal compressions leading to ejection of food from the mouth suggest vomiting rather than regurgitation (see pp. 1173 and 1175).

INITIAL DATABASE

- Usually normal
- CBC: Aspiration pneumonia may occasionally cause leukocytosis.
- Serum chemistry: some metabolic diseases can result in esophageal dysfunction (e.g., electrolyte imbalance with hypoadrenocorticism).
- Thoracic, pharyngeal, and cervical radiographs: megaesophagus, vascular ring anomaly, foreign bodies, and other such findings
- Contrast radiography/esophagram

ADVANCED OR CONFIRMATORY TESTING

- Fluoroscopy (see p. 1205)
- Esophagoscopy
- Esophageal manometry
- Radiographic scintigraphy to measure transit time
- Thyroid-stimulating hormone (TSH) and free T4 tests: hypothyroidism
- ACTH stimulation test: hypoadrenocorticism
- Antinuclear antibody test: immune-mediated causes
- Acetylcholine (ACh) receptor antibody test: myasthenia gravis
- Bioassay techniques: botulism and tetanus
- Toxin analysis: lead, thallium, and organophosphates

TREATMENT

TREATMENT OVERVIEW

Successful treatment requires elimination of the underlying cause whenever possible; temporary or lifelong supportive care helps minimize the risk of complications.

ACUTE GENERAL TREATMENT

- Aspiration pneumonia: appropriate antibiotic therapy and supportive care
- For esophageal disease other than idiopathic megaesophagus: treat and correct disease (e.g., surgery for removal of foreign bodies or vascular anomalies).
- For systemic causes of regurgitation: treat underlying disease.

CHRONIC TREATMENT

- Megaesophagus (see p. 1408)
- Bypass the esophagus with a gastrostomy tube (see pp. 1270, 1273) if necessary.
- Motility-modifying drugs are controversial in treating megaesophagus, because their efficacy is unproven; increasing lower esophageal tone could hinder the transit of food from esophagus to stomach:
    - Metoclopramide (0.2-0.5 mg/kg PO q 8 h or q 12 h) increases the lower-esophageal sphincter pressure and gastric emptying and reduces gastroesophageal reflux.
    - Cisapride (0.5 mg/kg q 8 h or q 12 h) increases lower esophageal peristalsis and sphincter pressure (cats > dogs) and accelerates gastric emptying. This drug can be difficult to obtain.

POSSIBLE COMPLICATIONS

- Aspiration pneumonia
- Esophageal rupture due to foreign bodies
- Esophageal stricture formation
- Esophageal reflux

RECOMMENDED MONITORING

- Check for resolution of clinical signs for animals whose causes were systemic.
- Regularly check thoracic radiographs for signs of aspiration pneumonia.

PROGNOSIS AND OUTCOME

Depend greatly on the cause of the regurgitation and presence or absence of complications

PEARLS & CONSIDERATIONS

COMMENTS

- Clinicians should make sure the animal is regurgitating and not vomiting.
- Aspiration pneumonia often does not increase the white blood cell (WBC) count, even if extensive.

CLIENT EDUCATION

The owner should be aware of the clinical signs of aspiration pneumonia and seek immediate veterinary attention if they occur.

Reflex Dyssynergia

BASIC INFORMATION

DEFINITION

Upper motor neuron (UMN) dysfunction preventing coordinated urinary bladder contraction and urethral sphincter relaxation during micturition. Sacral spinal cord lesions, diseases associated with the urethra, and an idiopathic condition can each mimic reflex dyssynergia.

SYNONYMS

Detrusor-sphincter dyssynergia, detrusor-sphincter incoordination, functional urethral obstruction, UMN bladder

EPIDEMIOLOGY

SPECIES, AGE, SEX: Affects dogs and cats of any age, depending on causation. More often observed in male dogs; an idiopathic dyssynergia-like condition affects predominantly large-breed male dogs.

RISK FACTORS

- Thoracolumbar spinal cord injury/disease
- Dyssynergia-like condition:
  - Following relief of urethral obstruction
  - Sacral spinal cord injury/disease

ASSOCIATED CONDITIONS & DISORDERS

- Bladder atony/hypotonia
- Urinary tract infection

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- True reflex dyssynergia: neurogenic suprasacral lesions
- Dyssynergia-like conditions: neurogenic and non-neurogenic disorders

HISTORY, CHIEF COMPLAINT

- Frequent attempts at voiding with inability to empty bladder completely are characteristic.
- Normal initiation of voiding with interruption of urine stream; short spurts of urine followed by cessation of urine flow.
- Animal may strain with no urine produced.

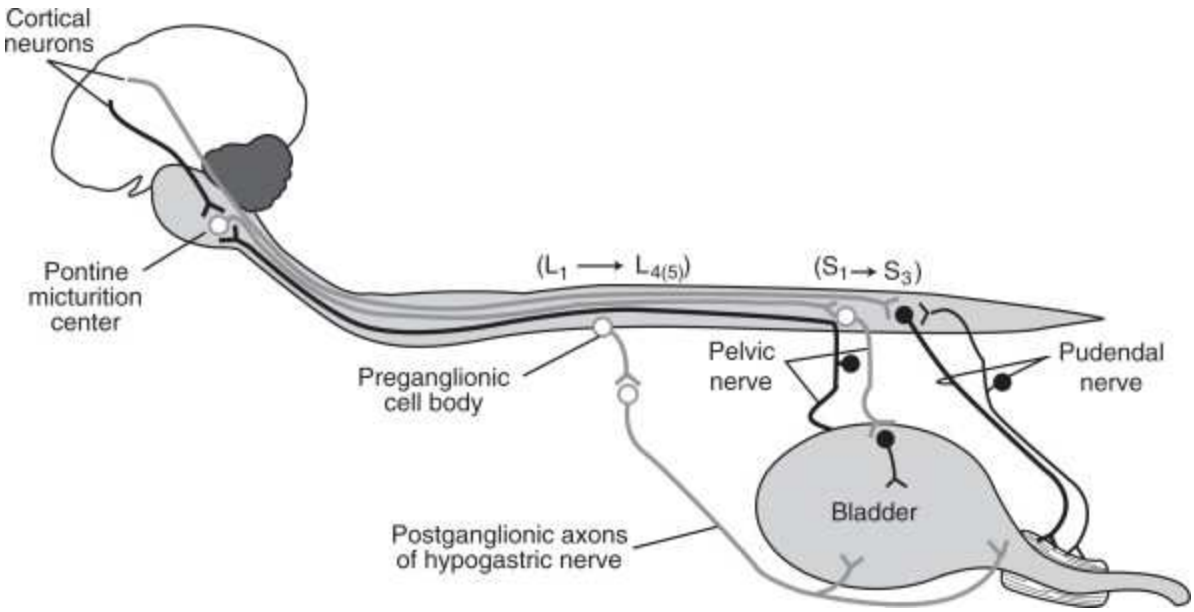
PHYSICAL EXAM FINDINGS

- Manual bladder expression difficult
- Clinicians should palpate the bladder before and after voiding: turgid, incomplete emptying of bladder, increased residual urine volume are expected.
- Perineal reflex is present or exaggerated.
- Neurologic dysfunction unrelated to urination may be present.
- Rectal and vaginal examinations are indicated to assess structural causes (e.g., sacral vertebral lesion) versus other causes of dysuria (e.g., urethral lith or mass). Anal tone is normal/good.
- Observation of urination: thin, interrupted urine stream

ETIOLOGY AND PATHOPHYSIOLOGY

- Disordered urinary retention resulting from central nervous system (CNS) lesion located between the pontine micturition center and the sacral spinal cord (suprasacral spinal cord: L7 to brainstem)

- UMN lesion causes a loss of inhibitory pathways:
  - To sympathetic innervation of the internal urethral sphincter (smooth muscle)
  - To somatic innervation (pudendal nerve) of the external urethral sphincter (striated muscle)
- Additional factors include increased sensory input (sacral nerves), increased sympathetic output, and bladder neck hypertrophy.
- Neurogenic dyssynergia-like conditions occur when pelvic nerve damage results in weakened detrusor contraction that cannot override urethral sphincter tone.
- In animals with non-neurogenic dyssynergia-like conditions, there is a similar failure of simultaneous relaxation of the internal or external urethral sphincter with detrusor contraction. This may be idiopathic or may follow irritation/disease of the urethra.



REFLEX DYSSYNERGIA Neurologic pathways to and from the urinary bladder.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A diagnosis of primary reflex dyssynergia is made by exclusion of other conditions that mimic signs. The diagnostic plan should include eliminating conditions that cause mechanical (anatomic) obstruction of the urethra. The physical and neurologic examinations can define an anatomic or neurologic differential.

DIFFERENTIAL DIAGNOSIS

- Anatomic urethral obstruction:
  - Intraluminal (e.g., urethral plug/lith, transitional cell carcinoma, urethritis)
  - Extraluminal (e.g., prostatomegaly, pelvic granuloma)
- Functional urethral obstruction (dyssynergia-like conditions):
  - Neurogenic:
    - Sacral spinal cord disease
    - Pelvic plexus injury
    - Cauda equina disease
  - Non-neurogenic:
    - Idiopathic
    - Following relief of urethral obstruction
    - Secondary urinary tract infection
    - Bladder neck obstruction
    - a-Adrenergic agonist administration (e.g., phenylpropanolamine, pseudoephedrine)
    - Myopathic disease
- Bladder wall atony (see p. 104)

INITIAL DATABASE

- Urethral catheterization: unobstructed. Residual urine volume increased (normal, 0.2-0.4 mL/kg in dogs; or <10 mL in dogs and <2 mL in cats).
- Rectal examination: good anal tone, no pelvic/urethral mass
- Neurologic examination (see p. 1311), including perineal and bulbocavernosus reflexes:
  - Neuroanatomic lesion localization: spinal cord, usually T3-L3
- Clinical pathologic examination:
  - CBC and serum biochemistry: unremarkable
  - Urinalysis and urine culture: secondary urinary tract infection common
- Caudal abdominal and pelvic radiographs, abdominal ultrasound: no urethral obstruction or mass, possible vertebral injury/disease

ADVANCED OR CONFIRMATORY TESTING

- Contrast urethrography: rule out urethral obstruction if necessary.
- Cystoscopy and urethroscopy: identify masses, obtain biopsies, remove small calculi.
- Neurodiagnostic procedures: confirm lesion localization, extent of lesion, and suspected cause:
  - Myelography to evaluate for intramedullary or extramedullary compressive disease
  - Electromyography of the anal sphincter muscle to assess pudendal nerve
  - Somatosensory-evoked response testing to evaluate ascending sensory pathways
  - Advanced imaging:
    - MRI
    - CT
- Urodynamic procedures:
  - Cystometry to assess bladder function
  - Urethral pressure profile to assess urethral tone, which is the only means to confirm idiopathic dyssynergia-like condition
  - Leak point pressure measurement to assess urethral resistance

TREATMENT

TREATMENT OVERVIEW

It is important to treat the underlying cause. Supportive therapies include bladder emptying and pharmacologic management. Bladder emptying prevents secondary bladder atony (see p. 104) and urine retention that predispose to urinary tract infection. Pharmacologic therapy is often empirical; starting at lower end of the dosage range, response to therapy is noted and dose adjusted.

ACUTE GENERAL TREATMENT

- Urinary bladder catheterization:
  - Indwelling urinary catheter (closed-collection system)
  - Intermittent catheterization has a lower risk of inducing UTI
- Urethral sphincter relaxation (see p. 104):
  - Smooth muscle relaxation (a-antagonists):
    - Phenoxybenzamine: dogs, 0.25 mg/kg PO q 8-12 h; cats, 1.25-5 mg/cat PO q 12 h. Onset of action is delayed up to 4 days. Possible side effects: hypotension, tachycardia, and increased intraocular pressure. Contraindications: cardiovascular disease, glaucoma, and renal failure. (Commercially prepared product, Dibenzyline 10-mg capsules [Wellspring Pharmaceutical Corp.], has become cost-prohibitive; USP-grade powder for compounding is more cost-effective.)
    - Prazosin: dogs, 1 mg/15 kg PO q 8-12 h; cats, 0.25-0.5 mg/cat PO q 12-24 h. Possible side effects are hypotension and mild sedation; contraindications same as phenoxybenzamine, above.
  - Striated muscle relaxation (skeletal muscle relaxants):
    - Diazepam: dogs, 2-10 mg/dog PO q 8 h; cats, 2-5 mg/cat PO q 8 h, or 0.2-0.5 mg/kg IV as needed. A centrally acting muscle relaxant. Possible side effects: sedation, excitation, and idiosyncratic acute hepatocellular necrosis in cats.
    - Methocarbamol: dogs, 15-20 mg/kg PO q 8 h; cats, initial dose 33 mg/kg PO q 8 h, then 20 mg/kg PO q 8 h. A centrally acting muscle relaxant. Possible side effects: weakness, sedation, lethargy and vomiting.
- May add drugs to stimulate detrusor muscle contraction (see p. 104):
  - Bethanechol (parasympathomimetic): dogs, 5-25 mg PO q 8 h; cats, 1.25-5 mg PO q 8 h. Possible side effects: ptyalism, vomiting, diarrhea, and bronchoconstriction; contraindications are urinary or gastrointestinal (GI) obstruction.
  - Cisapride (prokinetic; enhances acetylcholine release): dogs, 0.5 mg/kg PO q 8 h; cats, 1.25-5 mg/cat PO q 8-12 h. Possible side effects: diarrhea and abdominal pain.

CHRONIC TREATMENT

- Resolution of underlying disorder
- Intermittent bladder catheterization or manual bladder expression
    - Complete emptying with manual expression may take several attempts; allow the animal to relax between attempts.
- Long-term drug therapy
- Address secondary urinary tract infection (see p. 276).

DRUG INTERACTIONS

Start treatment with an α-antagonist (e.g., prazosin) prior to bethanechol. Bethanechol may enhance urethral sphincter tone (has nonspecific cholinergic effects on the caudal mesenteric ganglia, causing further stimulation to the hypogastric nerve).

RECOMMENDED MONITORING

- Observe voiding activity daily.
- Monitor residual urine volume.
- Perform a periodic urine culture/urinalysis after removal of indwelling catheter and at least every 3 months until condition has resolved.

PROGNOSIS AND OUTCOME

- Good prognosis with resolution of underlying disease but may require weeks to resolve
- Good prognosis for resolution of dyssynergia-like conditions when underlying cause eliminated (e.g., urethral inflammation)
- Fair prognosis for medical control of idiopathic dyssynergia-like condition

PEARLS & CONSIDERATIONS

COMMENTS

- Reflex dyssynergia is a common sequela of severe spinal cord injury.
- If prolonged recovery from the spinal cord injury is expected, initiate an α-antagonist early (3-5 days from initial onset of action).

PREVENTION

Successful management depends on identification and treatment of underlying disorder.

TECHNICIAN TIPS

- Aseptic protocols (cleanse external catheter and genital areas; change collection bag) to reduce risks for urinary tract infection should be instituted in patients requiring urinary catheterization.
- Secondary urine overflow also will increase risks for urine scald and decubitus ulceration. The patient should be kept clean and dry on a padded surface with frequent (q 4 h) rotation if recumbent.

CLIENT EDUCATION

- Manual bladder expression or intermittent catheterization may be required.
- Watch for signs of urinary tract infection (e.g., change in color or odor).

AUTHOR: JOAN R. COATES

EDITOR: LEAH A. COHN

Refeeding Syndrome

BASIC INFORMATION

DEFINITION

Potentially fatal shifts in fluid and electrolytes associated with either enteral or parenteral feeding of previously malnourished animals or those with little or no food intake for 10 or more days. True incidence is unknown in veterinary medicine, but given the fact that this is a preventable idiogenic problem, clinicians should be familiar with this syndrome.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Can occur in any malnourished animal; aged and critically ill animals may be at increased risk.

RISK FACTORS: Malnutrition, prolonged starvation, emaciated, animals receiving supplemental nutritional support, overly aggressive nutritional support of malnourished animals, animals that have neurologic problems and dysphagias, reportedly diabetic ketoacidosis (dogs), and hepatic lipidosis (cats)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: This is a secondary syndrome. Variable combinations of fluid retention, hypokalemia, hypophosphatemia, and hypomagnesemia may occur within the first 4 days of refeeding by any route. However, these abnormalities maybe noted in as little as 24 hours after the start of refeeding. Overt clinical signs tend to become apparent when serum phosphorus < 1.5 mg/dL (0.5 mmol/L). Thiamin (vitamin B1) deficiency has been reported in humans but not in animals with refeeding syndrome.

HISTORY, CHIEF COMPLAINT

- Animals generally are malnourished or have had prolonged starvation and/or are undergoing treatment for an illness that requires nutritional support. Therefore, signs of the primary illness may initially overshadow the chief complaint of refeeding syndrome.
- Chief complaint depends on the exact pattern of abnormalities secondary to the fluid shifts and serum electrolytes in each animal.

PHYSICAL EXAM FINDINGS

- Weakness, weight loss, reduced muscle mass, and signs resulting from primary disease process are all possible physical exam findings. Signs of individual abnormalities vary with severity and presence of concurrent illness. Many animals do not show clinical signs until the abnormality is severe; these tend to be primarily related to fluid and electrolyte abnormalities.
- Fluid shifts resulting in fluid overload or retention: rapid weight gain ± serous nasal discharge, chemosis, restlessness, shivering, tachycardia, tachypnea, dyspnea, pulmonary crackles, vomiting, and diarrhea. These clinical signs may occur even when on recommended or conservative fluid rates.
    - Hypokalemia: (serum K^+ < 3.5 mEq/L), severe muscle weakness, arrhythmia, ileus, and decreased urinary concentrating ability
    - Hypophosphatemia: (serum $PO4^{2-}$ < 1.5 mg/dL or 0.5 mmol/L), hemolytic anemia, muscle weakness, rhabdomyolysis, renal tubular defects, cardiac dysfunction, fluid intolerance and arrhythmias
    - Hypomagnesemia: (serum Mg^{2+} < 1 mEq/L), cardiac arrhythmia, tremors, weakness, tetany, and secondary hypokalemia and hypocalcemia

ETIOLOGY AND PATHOPHYSIOLOGY

- Disease and malnutrition result in decreased serum levels of glucose. Catecholamines, glucagon, and glucocorticoid hormones increase to maintain serum glucose levels via gluconeogenesis by utilizing triacylglycerides and protein as precursors.
- The body has adapted to the decreased caloric intake (starvation metabolism) or increased caloric utilization (stress metabolism if concurrent disease process is present) with resulting depletion of lean body mass and intracellular electrolytes. These alterations may occur early in the clinical course.
- Refeeding allows use of carbohydrates (glucose) as the primary fuel source once more.
- Carbohydrate intake results in increased insulin secretion. This stimulates cellular uptake of phosphorus for manufacture of

adenosine triphosphate (ATP) and protein synthesis, which can lead to profound hypophosphatemia and subsequent hemolysis.
- Feeding can also drive other molecules and electrolytes into the cells, resulting in acute extracellular deficiencies (hypoglycemia, hypomagnesemia, and hypokalemia) and fluid balance abnormalities.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

This syndrome should be suspected in any animal with a significant alteration (a change of 20% or greater) in the serum concentrations of potassium, phosphorous, or magnesium after the onset of any type of nutritional support. These electrolyte abnormalities may occur in as brief a time period as 24 hours and up to 5 days after the onset of nutritional support.

DIFFERENTIAL DIAGNOSIS

- Any disease with prolonged anorexia or malnutrition
- Exacerbation of the primary disease

INITIAL DATABASE

- Body weight
- Serum glucose, albumin
- Venous blood gas and serum biochemical profile, including electrolyte determinations: hypokalemia, hypophosphatemia, hypomagnesemia are common.
- CBC: generally unremarkable
- Urinalysis

TREATMENT

TREATMENT OVERVIEW

Therapy consists of normalization of serum electrolytes via intravenous supplementation and close monitoring, maintaining fluid balances, and a gradual reintroduction of calories to the patient. The amount of time it takes to achieve resting energy expenditure (REE) calories depends upon the severity of the underlying cause and the length of time the patient was without adequate caloric intake. A general rule of thumb is to go slow and take between 4 and 7 days to achieve REE. Frequently these patients require 24-hour monitoring, central sampling lines, blood transfusions, multiple constant rate infusions, point-of-cage laboratory testing, and intensive nursing care.

ACUTE GENERAL TREATMENT

- When the signs of refeeding syndrome first become apparent: reduce the rate of feeding by 50%–75%.
- Red blood cell transfusions if severe anemia.
- Address electrolyte deficits according to the following table: *Caution with use in renal failure patients. *Do not exceed 0.5 mEq/kg/h. †Do not exceed 60 mEq/L concentration being infused through a peripheral vein. ‡Administered as a CRI, never as a bolus.*To convert to mg/dL, multiply the mmol/L value by 3.1.†Both the CRI and bolus methods should be used with caution in renal failure. Renal failure patients, decrease dose by 30%-50%.

Recommendations for Intravenous Electrolyte Supplementation in Refeeding Syndrome

Phosphate (Potassium Phosphate = 4.4 mEq K^+ and 3 mmol $PO4^{2-}$)				
Serum Concentrations mmol/L*	**Dose†**	**Monitor Serum Levels**		
0.7-1	0.03 mmol/kg/h	Every 8-12 hours		
0.5-0.7	0.03-0.09 mmol/kg/h	Every 6-8 hours		
<0.5	0.09-0.12 mmol/kg/h	Every 4-6 hours		
Magnesium (Magnesium Sulfate or Chloride)				
	Dose (mEq/kg/d)	**Dose (mEq/kg/h)**	**Dose (mg/kg/d)**	**Dose (mg/kg/h)**
Continuous rate infusion (CRI)	0.75-1 mEq/kg/d	0.02-0.04 mEq/kg/d	125 mg/kg/d	3.7-5.2 mg/kg/h
Bolus	0.16-0.24 mEq/kg		20-30 mg/kg	
Potassium Chloride (2 mEq/mL)				
Serum Concentrations (mEq/L)	**mEq/L KCl to Add to 1 L Fluid**	**Maximal Fluid Infusion Rate (mL/kg/h)**		
3.6-5.0	20	25		
3.1-3.5	28	18		
2.6-3.0	40	12		
2.1-2.5	60	8		
<2.0	80	6		

- The trends of change are more important than the absolute lab values.
- Continue to provide some caloric input as electrolyte abnormalities are being addressed, and closely monitor fluid ins and outs.

CHRONIC TREATMENT

- Slow increase in the caloric amounts until normal intake returns
- The more severe the abnormalities, the slower the increase in caloric support should be.
- The length of time from introduction of calories to REE may be 4-7 days' time.

NUTRITION/DIET

No specific diet can prevent this syndrome. The amount and rate of caloric input result in electrolyte and fluid shifts in susceptible patients.

POSSIBLE COMPLICATIONS

- Repair of hypokalemia and hypocalcemia in hypomagnesemic animals may depend on magnesium replacement.
- Phosphorus supplementation must be gradual (i.e., slow CRI over hours to days) to reduce the risk of renal failure and hypocalcemia.
- Must closely monitor changes in serum electrolyte concentrations and cardiovascular system (ECG and blood pressure) during therapy

RECOMMENDED MONITORING

- Body weight taken daily
- Glucose and electrolyte concentrations q 4-6 h until normalized, then daily during enteral or parenteral feeding
- Hematocrit if hypophosphatemia is present
- Venous blood gases every 6-12 hours until cardiovascular stability is achieved
- Renal parameters and urine output
- ECG and blood pressure until electrolyte concentrations have normalized

PROGNOSIS AND OUTCOME

Guarded to good depending on underlying problem, familiarity with the syndrome, level of patient care, and severity of refeeding syndrome.

PEARLS & CONSIDERATIONS

COMMENTS

Although not common in veterinary animals, a high index of suspicion for the syndrome should be maintained in any depleted animal during the initial period (24 hours to 5 days) of refeeding. This is a potentially fatal syndrome which is exacerbated by our therapeutic intervention of providing nutritional support.

PREVENTION

- Correctly identify fluid and electrolyte abnormalities, and start to correct prior to instituting nutritional support.
- Identify at-risk patients.
- Use caution in return to feeding (e.g., start with 25%-50% of basal energy requirements or 5–10 Kcal/kg/d).
- Monitor electrolytes, blood gas, and renal parameters daily.
- Recognize that some replacement-fluid recommendations assume normal food intake; ill and hospitalized animals often are anorexic and may require less fluid supplementation.

TECHNICIAN TIPS

- Daily physical examinations by the technical staff
- Encouragement to the veterinarians in the use of central lines and frequent monitoring
- Discouragement of the use of forced syringe feedings
- General excellent nursing care such as grooming and ensuring patient comfort

AUTHOR: ELIZABETH O'TOOLE

EDITOR: KATHRYN E. MICHEL

Red Eye

BASIC INFORMATION

DEFINITION

- Conjunctival, episcleral/scleral, or palpebrai hyperemia
- The term *red eye* does not traditionally apply to redness within the anterior chamber (i.e., hyphema).

SYNONYMS

Conjunctival hyperemia, conjunctival injection, episcleral/scleral hyperemia or injection

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats, no age or gender predisposition

RISK FACTORS

- Trauma
- Systemic infectious or inflammatory diseases
- Coagulopathy
- Current therapy with potentially irritating topical ophthalmic medications (e.g., pilocarpine, neomycin, prostaglandin analogs, aminoglycosides)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Variable but may include any or all of the following:

- “Red” eye, by definition (layperson's description: ”bloodshot” eye)
- Blepharospasm
- Ocular discharge
- Cloudiness of eye
- Loss of vision

PHYSICAL EXAM FINDINGS

- Conjunctival vessel hyperemia: diffuse conjunctival redness:
  - Usually indicates ocular surface (i.e., superficial) disease, including:
    - Conjunctivitis
    - Superficial keratitis (see and 825)
  - Vessels appear to originate in conjunctival fornix and branch as they approach limbus.
- Episcleral/scleral hyperemia: discrete engorgement and tortuosity of episcleral vessels:
  - Usually indicates intraocular disease (see pp. 1151 and 448), deep corneal disease (see p. 250), or episcleritis/scleritis (see p. 356)
  - Vessels originate near limbus and follow a deep, straight course toward the conjunctival fornix.
- Both conjunctival and episcleral/scleral vessel injection can occur in the same eye. Ocular discharge and blepharospasm are nonspecific signs; other signs depend on the underlying cause of red eye:
  - Blepharitis; hyperemic, swollen eyelids:
    - ± Mucopurulent ocular discharge
    - Normal intraocular examination
  - Conjunctivitis (see pp. 237 and); hyperemic conjunctiva:
    - Chemosis (conjunctival swelling)
    - Ocular discharge
    - Normal intraocular examination
  - Keratitis (see and 825):
    - Corneal opacities (see p. 245)
    - Corneal vascularization (see p. 254)
    - Corneal vessels that cross the limbus and branch suggest superficial corneal disease.

        - Vessels that start at the limbus and form a dense, straight pattern on cornea suggest deep corneal disease and/or intraocular disease.
        - ± Fluorescein dye retention
    - Uveitis (see p. 1151); any or all of the following:
        - Aqueous cells or flare
        - Constricted pupil
        - Abnormal appearance to iris (see p. 624)
        - Hyphema (see p. 571)
        - Fibrin clot in anterior chamber
        - Hypopyon (see p. 583)
        - Low intraocular pressure.
    - Glaucoma (see p. 448):
        - Dilated pupil
        - Diffuse corneal edema
        - ± Buphthalmos (see p. 778)
        - Fundic exam: optic disk cupping
        - Lens luxation (see p. 644): consistent with primary or secondary glaucoma

ETIOLOGY AND PATHOPHYSIOLOGY

Dilation of conjunctival and/or episcleral/scleral vessels:

- Typically inflammatory response to superficial and/or deep ocular disease
- May be caused by passive congestion (e.g., large, space-occupying orbital lesion; see p. 790)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Initial suspicion comes from history and/or physical examination. Diagnosis of the cause of red eye is achieved with a comprehensive ophthalmic examination.

DIFFERENTIAL DIAGNOSIS

- See Etiology, above.
- A "red" eye may also involve more than one ocular disease (e.g., corneal ulceration with secondary uveitis).

INITIAL DATABASE

Complete ophthalmic examination (see p. 1313), including:

- Schirmer tear test; a low result (<5-10 mm/min) indicates keratocon-junctivitis sicca (KCS).
- Fluorescein stain application; a positive result (stain retention) indicates corneal ulceration.
- Intraocular pressure measurement; elevated level (>30 mm Hg) is diagnostic of glaucoma; level is typically low (<10-15 mm Hg) with uveitis.

ADVANCED OR CONFIRMATORY TESTING

- Variable depending on results of initial examination and testing (i.e., suspected cause)
- Corneal or conjunctival swabs for cytologic examination, ± culture and sensitivity (C&S), for conjunctivitis, corneal ulcers, keratitis, or blepharitis
- CBC, serum chemistry panel, titers for infectious disease, radiography, ultrasonography for certain causes of uveitis (see p. 1151)
- Biopsy of lesion and histopathologic exam for refractory or complex blepharitis or episcleritis/scleritis

TREATMENT

TREATMENT OVERVIEW

Treatment goals are to control/resolve underlying cause, decrease inflammation, eliminate infection if present, achieve appropriate

intraocular pressure if abnormal, eliminate ocular pain, and maintain vision.

ACUTE AND CHRONIC TREATMENT

- Loss of vision is an emergency that requires immediate determination and treatment of underlying cause (see p. 141). Glaucoma, severe uveitis, and severe keratitis should be considered in acute or progressive vision loss concurrent with red eye(s).
- Blepharitis:
  - Determine underlying cause.
  - Patient often needs systemic antibiotic and/or antiinflammatory therapy.
  - See Demodicosis, p. 289; Juvenile Cellulitis, ; Pemphigus Complex, p. 850.
- See Keratoconjunctivitis Sicca, .
- See Conjunctivitis, Cats, p. 237; Conjunctivitis, Dogs, .
- See Corneal Ulceration, p. 250.
- See Uveitis, .
- See Glaucoma, p. 448.
- See Episcleritis/Scleritis, .
- See Orbital Disease, p. 790.

POSSIBLE COMPLICATIONS

Variable depending on underlying condition and cause; may include:

- Loss of eye
- Loss of vision
- Worsening of systemic disease

PROGNOSIS AND OUTCOME

- Variable depending on underlying cause
- Lack of vision at presentation is often a poor prognostic indicator (return of vision uncommon).

PEARLS & CONSIDERATIONS

COMMENTS

Avoid:

- Topical corticosteroids in any eye with positive fluorescein dye retention (or unknown fluorescein status).
- Systemic corticosteroids until preliminary diagnostic tests are performed or a diagnosis is reached, because these drugs are generally contraindicated for treating infectious systemic disease.

CLIENT EDUCATION

Seek veterinary attention promptly at first sign of red eye, because many causes of red eye are globe and/or vision threatening.

Recurrent Flank Alopecia, Canine

BASIC INFORMATION

DEFINITION

Skin disorder of unknown etiology characterized by episodes of truncal hair loss with spontaneous regrowth that often occurs on a recurrent basis

SYNONYMS

Canine recurrent flank alopecia (CRFA), canine idiopathic cyclic flank alopecia, cyclic follicular dysplasia, seasonal flank alopecia

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs of either sex and any reproductive status can be affected.
- Mean age at onset of first episode is 4 years (range 8 months to 11 years).
- Most dogs have an onset of alopecia between November and March (Northern Hemisphere).

GENETICS & BREED PREDISPOSITION: Boxers may account for approximately half of all cases, but other breeds at high risk include English bulldog, Airedale terrier, and schnauzer (miniature, standard, and giant). Although CRFA seems to affect virtually any breed, this condition appears to be rare to absent in the plush-coat Nordic breeds, German shepherds, and cocker spaniels.

RECURRENT FLANK ALOPECIA, CANINE Recurrent flank alopecia in a boxer. Note characteristic distribution of alopecia and hyperpigmentation.

(Copyright Dr. Manon Paradis.)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Fairly abrupt onset of bilateral alopecia affecting the thoracolumbar region

PHYSICAL EXAM FINDINGS

- Nonscarring alopecia, usually bilaterally symmetrical, with well-demarcated borders
- Marked hyperpigmentation of the alopecic skin is common.
- The alopecia is usually confined to the thoracolumbar region, but on rare occasions, this condition is seen in association with

alopecia on the dorsum of the nose, base of the ears, base of tail, and perineum.
- Spontaneous regrowth of a normal coat occurs in 3-8 months (range: 1-14 months) in most dogs.
- Most dogs develop recurrent alopecic episodes every year; however, some dogs have an occasional year when the alopecia does not recur.
- The degree of alopecia is variable, with some dogs developing a virtually identical hair loss (size and duration) year after year, and other dogs developing larger areas and/or longer episodes of hair loss as years go by.
- In a few cases, hair regrowth may become less complete after several episodes; it may even progress to an end-stage permanent flank alopecia and marked hyperpigmentation.
- Occasionally a dog may have only one isolated episode of alopecia during its lifetime.

ETIOLOGY AND PATHOPHYSIOLOGY

- The high incidence in some breeds and the familial character of CRFA suggest a genetic influence.
- The seasonal nature and annual recurrence suggest that photoperiod may be involved. The higher incidence of CRFA at higher latitude (around or north of the 45th parallel in the Northern Hemisphere) supports the implication of light exposure in this disorder.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on history, clinical findings, and ruling out other differentials (e.g., exclusion of hypothyroidism in dogs >2 years of age). The rapid onset of well-demarcated truncal alopecia with spontaneous hair regrowth in predisposed breeds and the absence of inflammation and pruritus make it quite distinctive.

DIFFERENTIAL DIAGNOSIS

- Endocrinopathies (hypothyroidism, hyperadrenocorticism, hyperestrogenism)
- Other follicular dysplasias
- Telogen defluxion

INITIAL DATABASE

- Thyroid testing for adult dogs
- Other endocrine testing if indicated by history and physical exam findings

ADVANCED OR CONFIRMATORY TESTING

Skin biopsies for dermatohistopathologic examination:

- Nonspecific changes suggestive of endocrinopathies may be observed. In addition, truncated, keratin-filled atrophic primary and secondary hair follicles (“witch's feet”) are suggestive of, but not pathognomonic for, CRFA.
- Biopsies may further support the diagnosis but are sometimes not performed by dermatologists who are confident in the diagnosis based on characteristic lesions and seasonal recurrence.

TREATMENT

TREATMENT OVERVIEW

The goal is to reduce or prevent hair loss.

ACUTE AND CHRONIC TREATMENT

- Oral melatonin, administered at the rate of 3-6 mg/dog PO q 8-12 h for 1-2 months, may be beneficial in up to 50%-75% of cases (whether initiated before or shortly after the onset of alopecia).
- To prevent hair loss, administer melatonin 1-2 months prior to the expected episode of alopecia.
- To shorten the duration of an existing alopecic episode, start melatonin administration as soon as possible after the onset of alopecia.

PROGNOSIS AND OUTCOME

Dogs affected with CRFA are healthy otherwise, and benign neglect is a valuable therapeutic approach.

PEARLS & CONSIDERATIONS

COMMENTS

The unpredictable course of CRFA and the spontaneous regrowth of hair render the evaluation of any therapeutic agent difficult, whether used for preventing the condition or to shorten an existing episode of alopecia.

Rectoanal Stricture

BASIC INFORMATION

DEFINITION

Uncommon disorder involving narrowing of anal or rectal lumen diameter

SYNONYM

Anorectal stricture

EPIDEMIOLOGY

SPECIES, AGE, SEX: While atresia ani is a congenital failure to form a normal anal opening and is seen in young puppies and kittens, stricture formation is generally a sequela to disease processes that occur in middle-aged to older animals. RISK FACTORS: Anal trauma or surgery

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Tenesmus, diarrhea, hematochezia, and ribbon-like stools
- Animals with advanced or metastatic malignancy may present with weight loss, anorexia, and lethargy.

PHYSICAL EXAM FINDINGS: Stricture is usually palpable on digital rectal examination.

ETIOLOGY AND PATHOPHYSIOLOGY

- Stricture may be related to a primary infiltrative process such as inflammatory, infectious, or neoplastic disease.
- Stricture formation may also be seen secondary to surgery, penetrating trauma, radiation, or enema administration.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is suspected based on presenting history and physical/rectal examination findings. Confirmation of the cause of the stricture may require endoscopy and biopsy.

DIFFERENTIAL DIAGNOSIS

Possible causes of rectoanal stricture:

- Neoplasia:
  - The most common malignant tumor of the rectum is adenocarcinoma (see p. 37).
  - Other tumor types include lymphoma, leiomyosarcoma, and hemangiosarcoma.
  - Benign neoplasia may include adenoma, fibroma, or leiomyoma.
- Inflammatory disease such as colitis
- Infectious disease: histoplasmosis has been reported to cause rectal stricture in one dog.
- Trauma: direct or from bone ingestion
- Scar formation secondary to surgery (e.g., anal sacculectomy, perianal fistula repair, mass excision), enema, or radiation therapy

INITIAL DATABASE

- Gentle digital rectal palpation
- Assessment of location (identifying possible organ of origin), symmetry (circumferential versus focal), pain, and evidence of metastasis (palpation of sublumbar lymph nodes)

- CBC, serum chemistry analysis, and urinalysis: usually within normal limits
- Abdominal radiographs:
  - Potential for visualizing area of stenosis as well as megacolon cranial to stricture
  - Evidence of underlying cause of stricture, metastatic disease (± thoracic radiographs)

ADVANCED OR CONFIRMATORY TESTING

- Contrast radiography may help localize stricture (see p. 1204).
- Abdominal ultrasound can help assess for diffuse metastatic disease.
- Colonoscopy should be used for visualizing extent of stricture formation and to acquire biopsy samples.

TREATMENT

TREATMENT OVERVIEW

Treatment is aimed at increasing luminal size through the strictured area and preventing recurrence by treating the underlying cause.

ACUTE GENERAL TREATMENT

- With the animal under general anesthesia, mild strictures can be dilated using gentle digital or balloon bougienage.
- Treatment with balloon dilation and local triamcinolone injections has been reported to improve clinical signs in dogs with non-neoplastic strictures.
- Surgical intervention, if possible, is indicated to resect stricture or cause of stricture and obtain a definitive biopsy sample:
  - Use a rectal pull-through or dorsal rectal approach.
  - Colostomy has been reported in dogs as an option for rectal obstruction or perforation.

POSSIBLE COMPLICATIONS

Surgical complications include incontinence, dehiscence, infection, and recurrence of stricture or neoplasia.

PROGNOSIS AND OUTCOME

- Prognosis is related to histopathologic findings. Approximately 50% of rectal neoplasms are malignant. Reported outcome for adenocarcinoma is poor.
- Regardless of the underlying etiology, there is a high likelihood for stricture reformation. Multiple balloon or surgical procedures may be required to correct the problem, and this likelihood should be discussed with the owner prior to initiating treatment.

PEARLS & CONSIDERATIONS

COMMENTS

- It is common to cause iatrogenic tears of the rectum or anus during stricture treatment, so care is warranted when performing digital or balloon bougienage.
- If resection of stricture is performed, avoid enema administration for 24 hours prior to surgery to reduce intraoperative fecal contamination (fecal spillage from the anus during surgery).

TECHNICIAN TIPS

- Close observation of the patient's ability to defecate will be required in postoperative/posttreatment period. Adjustments in diet (type and consistency) plus the addition of stool softeners (Metamucil) may be necessary.
- Temporary postoperative/posttreatment fecal incontinence will necessitate good perineal hygiene.

AUTHOR: JANET KOVAK MCCLARAN

EDITOR: RICHARD WALSHAW

Rectal Prolapse

BASIC INFORMATION

DEFINITION

Rectal prolapse is eversion of the anal mucosa or full-thickness rectal wall through the anal opening.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Can occur at any age, but young dogs and cats are most frequently affected.

GENETICS & BREED PREDISPOSITION: Manx cats may be predisposed. RISK FACTORS: Recent perineal surgery ASSOCIATED CONDITIONS & DISORDERS: Any condition that causes tenesmus may be associated with rectal prolapse: gastrointestinal (GI) parasitism; neoplasia of the colon, rectum, or anus; rectal foreign bodies; colitis; perineal hernia; prostatic disease; urinary disease; dystocia.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Partial prolapse (mucosa only)
- Complete prolapse (all layers of the rectal wall)

HISTORY, CHIEF COMPLAINT

- Visualization of red tissue protruding from anus
- Straining to defecate or urinate (tenesmus)
- Diarrhea

RECTAL PROLAPSE Clinical image of rectal prolapse in a dog.

(Courtesy Dr. Richard Walshaw.)

PHYSICAL EXAM FINDINGS

- Partial prolapse: a few millimeters of red, swollen mucosa protruding through anus
- Complete prolapse: cylindrical mass protruding from anus; tissue may be red, ulcerated, or necrotic.
- Other findings consistent with underlying cause for straining (i.e., enlarged prostate, palpable neoplastic mass, etc.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Animal affected by underlying disease that causes straining
- Repetitively increased intraabdominal pressure from straining causes weakness of perirectal and perianal connective tissue or muscles, resulting in prolapse.
- Inflammation or edema of mucosa may result in more straining and can exacerbate prolapse.
- Prolapsed tissue may become traumatized or desiccate, resulting in ulceration and necrosis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is made by visual inspection and rectal palpation.

DIFFERENTIAL DIAGNOSIS

- Prolapsed intussusception. Therapeutic importance of differentiating from rectal prolapse: prolapsed intussusception generally requires laparotomy, whereas rectal prolapse does not.
- Neoplastic mass protruding from anus

INITIAL DATABASE

- Rectal examination: insert a blunt probe between prolapsed tissue and rectal wall. The probe cannot be passed cranially with rectal prolapse but will pass at least a few centimeters into a fornix created by everted colon in cases of prolapsed intussusception.
- CBC, serum chemistry profile, urinalysis, and urine culture may identify underlying cause of straining and indicate an animal's metabolic status.
- Abdominal radiographs may demonstrate conditions associated with rectal prolapse (i.e., neoplastic masses, prostatomegaly, urinary calculi).
- Fecal analysis for intestinal parasitism

RECTAL PROLAPSE Clinical image of colonic intussusception, an important differential diagnosis for rectal prolapse. In this condition, a digit may be passed into the rectum, as shown in this anesthetized animal. With rectal prolapse, bowel is everted at the anus, not within the colon, and rectal palpation is not possible.

(Courtesy Dr. Richard Walshaw.)

ADVANCED OR CONFIRMATORY TESTING

- Abdominal ultrasonography to identify associated conditions
- Proctoscopy and biopsy to rule out potential underlying causes (colitis, neoplasia); may be indicated in older animals, but is rarely needed in young animals.

TREATMENT

TREATMENT OVERVIEW

Treatment consists of correction of the prolapse by manual reduction (if viable) or surgical resection (if necrotic), and prevention of recurrence by treating the underlying cause of the problem.

ACUTE GENERAL TREATMENT

- Acute treatment with patient under general anesthesia to prevent tenesmus during prolapse reduction.
- Lavage prolapsed tissue with saline and inspect viability.
- Apply lubricant and manually reduce (gentle digital pressure) if tissue is viable.
    - Apply dextrose (50%) to tissue to decrease edema and aid in reduction.
- Place purse-string suture around rectum at mucocutaneous junction to maintain reduction. The purse-string suture should be tight enough to prevent prolapse but should still allow for passage of soft stools. Tightening the suture over a syringe case (3 mL in most small animals is adequate) may prevent overtightening.
- Resection and anastomosis of diseased tissue if tissue is not viable

CHRONIC TREATMENT

- Maintain purse-string suture for 3-5 days, and begin treatment of underlying cause of straining.
- If the patient undergoes resection and anastomosis, he/she should receive a low-residue diet and stool softeners to reduce postoperative straining.
- Perform a colopexy if prolapse repeatedly recurs after appropriate acute treatment.

POSSIBLE COMPLICATIONS

- Continued tenesmus
- Dyschezia, hematochezia
- Recurrent prolapse
- Leakage, dehiscence, and stricture if resection performed

PROGNOSIS AND OUTCOME

Good prognosis if surgically treated and underlying cause reversible

PEARLS & CONSIDERATIONS

COMMENTS

- Place a lubricated finger or small syringe case in rectum while tightening purse-string suture to prevent overtightening.
- Apply a local anesthetic to the rectal tissue after removal of the purse-string suture, which may help prevent recurrence.
- Empirically treat all young animals with rectal prolapse for intestinal parasitism, even if fecal flotation result is negative.

TECHNICIAN TIPS

Important points regarding postreduction/postoperative care:

- Maintain appropriate level of analgesia/sedation:
    - Pain control
    - Prevention of tenesmus (to prevent recurrence)
- Perianal/perineal hygiene:
    - Especially after defecation
    - Warm-pack the area to decrease swelling and ease discomfort.
- Diet:
    - Prevent tenesmus, constipation, and diarrhea.
    - GI diet (e.g., Iams Low Residue) to promote formed but soft stool
    - Stool softener (Metamucil R) to promote pain-free defecation and no tenesmus

AUTHOR: JANET KOVAK MCCLARAN

EDITOR: RICHARD WALSHAW

Radiation Therapy: Adverse Reactions

BASIC INFORMATION

DEFINITION

Radiation reactions are considered acute (or early) if they occur during or shortly after radiation and subside after radiation completion. Reactions with clinical signs that persist over a longer period of time or occur months to years after treatment are considered chronic (or late).

SYNONYM

Radiation complications

EPIDEMIOLOGY

SPECIES, AGE, SEX: Any patient treated with radiation will be at risk for development of radiation reactions.

RISK FACTORS

- Radiation dose, fraction size, radiation energy, overall treatment time, field size, previous surgery, concurrent administration of chemotherapy, and necrotic or unhealthy tissues may influence a patient's risk for the development of adverse radiation reactions. Cats are less likely to have radiation side effects than dogs.
- Site-specific risk factors include:
  - Skin: presence of skin folds, tangential radiation fields, poor nutrition, individual differences, use of bolus, use of electron therapy, coincident infection
  - Head/neck: periodontal disease, coincident infection, concurrent xerostomia
  - Heart: doxorubicin treatment

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute effects: depend on total dose, dose per fraction, and overall treatment time
- Chronic effects: depend highly on dose per fraction

HISTORY, CHIEF COMPLAINT: Owners are most likely to report history or complaints in form of physical exam findings listed below.

PHYSICAL EXAM FINDINGS: All physical exam findings are directly related to tissues present within radiation therapy field and usually confined to limits of the radiation treatment field.

- Skin effects:
  - Acute: hyperemia, dry desquamation, moist desquamation, ulceration, necrosis, hair loss, lymphedema, pain
  - Chronic: telangiectasia, fibrosis, necrosis, lymphedema, hyperpigmentation or hypopigmentation, leukotrichia, loss of pliability/flexibility/range of motion, pain, dry desquamation, chronic wound
- Head/neck effects:
  - Acute: stomatitis, mucositis, pharyngitis, esophagitis (erythema, edema, confluent or patchy white/yellow membrane formation), xerostomia, dry/cracked lips, ulceration, pain, difficulty swallowing, secondary infection with bacteria or fungi (soft, curdlike white patches), swelling of parotid/submandibular salivary glands, keratitis, keratoconjunctivitis sicca, blepharospasm, periocular crusting, corneal edema
  - Chronic: osteonecrosis (bone pain, swelling, evidence of infection, exposed bone, nonhealing gingival ulcers), xerostomia, regurgitation, dental caries, keratoconjunctivitis sicca, cataract formation, retinitis, blindness
- Bone effects (chronic): clinical/radiographic evidence of fracture, necrosis, infection, or secondary tumor
- Heart effects (acute/chronic): signs relative to pericarditis, chronic constrictive pericarditis, or restrictive cardiomyopathy due to myocardial fibrosis, such as fever, tachycardia, presence of pericardial effusion, cardiac tamponade, pleural effusion, dyspnea, conduction abnormalities, exercise intolerance, subclinical valvular defects
- Bladder effects (acute/chronic): pain on palpation, clinicopathologic evidence of cystitis (pollakiuria, nocturia, dysuria, hematuria)
- Lung effects (acute/chronic): clinical and radiograph signs compatible with acute pneumonitis and chronic fibrosis (fever, dyspnea, cough, production of sputum, signs of right heart failure if pulmonary hypertension exists). Fibrosis usually, not

always, preceded by pneumonitis.
- Colon/rectal effects (acute/chronic): diarrhea secondary to acute enteritis, hematochezia, sense of urgency, chronic diarrhea, proctitis, stricture, fistula formation secondary to chronic colorectal/anorectal injury
- Central nervous system effects (acute/chronic): signs compatible with location of irradiation field (neurologic deficits, seizures, ataxia, blindness, dementia, somnolence, endocrinopathies)

ETIOLOGY AND PATHOPHYSIOLOGY

- Radiation lesions induced in normal tissues are attributed primarily to loss of specific target cells or clonogenic cells. Hence, acute effects develop in rapidly renewing tissues such as skin, gastrointestinal (GI) tract, or bone marrow.
- This target cell theory also applies to vascular damage as the predominant lesion in chronic effects, as endothelial cells are slowly lost to mitotic death.
- In addition, cytokines induced immediately after irradiation have been shown to contribute to the progression of chronic effects.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Few differentials exist for radiation therapy site-specific side effects short of progression or recurrence of tumor.

INITIAL DATABASE

- Minimum database to rule out metabolic contribution to complications
- Diagnostic imaging (radiographs, CT, MRI) where applicable to determine extent/nature of disease
- Biopsies where necessary to differentiate tumor recurrence from radiation reaction
- Clinician-based assessment: Veterinary Radiation Therapy Oncology Group (VRTOG) Acute/Chronic Radiation Scoring Scheme (see reference)

ADVANCED OR CONFIRMATORY TESTING

Generally not necessary. In people:

- Chronic skin fibrosis measured by tissue compliance meter, ultrasound measurement, or BTC-2000 suction device in humans
- Xerostomia measured by functional radioisotope imaging, salivary flow output, and patient assessment in humans
- Pulmonary function tests for confirmation of decreased lung capacity

TREATMENT

TREATMENT OVERVIEW

- Improving patient quality of life by minimizing pain, establishing return to function, and ruling out tumor recurrence
- Amelioration of acute side effects may decrease risk of chronic side effects for some tissue types.

ACUTE TREATMENT

- Skin effects:
  - Protect irradiated skin from heat, cold, sunlight, friction, and other sources of irritation.
  - Avoid use of tape.
  - Avoid swimming.
  - Clean moist desquamation with aluminum subacetate (Domeboro) soaks, 1/3 strength hydrogen peroxide (1%), or diluted chlorhexidine solution.
  - Use of skin care products anecdotal but include: Aquaphor, Collasate, vitamin A/E ointment, aloe vera gel, Theracare, 1% hydrocortisone ointment, silver sulfadiazine, Miaderm, Biafine, Radioplex.
  - Keep site free of crusts to encourage reepithelialization.
  - Use of ointments preferable to creams or lotions
  - Bandages promote moist environment and are not advised when possible. If necessary, use moisture vapor–permeable dressings (Tegaderm, Mepilex).
  - Antibiotic therapy to control infection, and antiinflammatory therapy to decrease inflammation
  - Pain management and breaks in radiation therapy where necessary

- Head/neck effects:
  - Stomatitis/mucositis/esophagitis:
    - Maintain good oral hygiene.
    - Use of soft, bland diet with decreased amount, increased frequency, and room temperature. Avoidance of salty, acidic foods.
    - Mouthwashes to cleanse and lubricate the oral cavity (saline, sodium bicarbonate solutions, dilute tea, dilute hydrogen peroxide, “magic mouthwash”; avoid alcohol preparations).
    - Topical anesthetics and coating agents such as viscous lidocaine (Xylocaine), sucralfate suspensions, Acemannan-containing gel all proven to ameliorate mucositis. NOTE: viscous lidocaine may burn initially prior to taking effect.
    - Omega-3 fatty acid, arginine, glutamine, and oral zinc supplementation all proven in humans to ameliorate pathologic or clinical evidence of mucositis
    - Antibiotics (aerobic gram-negative bacteria most likely) and/or antifungals topically (chlorhexidine rinse with topical suspension of nystatin) or systemically for secondary infections
    - Narcotic analgesics and nutritional support for severe effects
  - Xerostomia (dry mouth):
    - Increase fluid intake.
    - Maintain good oral hygiene.
    - Use of salivary substitutes (short-lived) or pilocarpine (Salagen) (may have unacceptable side effects), acupuncture, olive oil rinse, subcutaneous amifostine, and autotransplantation of salivary gland tissue to site outside radiation field all reported to ameliorate signs in humans.
  - Acute ocular effects: topical antibiotics and steroids if no corneal ulceration present; topical antibiotics and anesthetics if corneal ulceration present; supplementary eye lubrication
- Acute heart effects: pericarditis managed primarily by prevention. Rest, nonsteroidal antiinflammatory drugs, and mild diuretics often all that is needed during self-limiting, subclinical resolution. Subtotal parietal pericardiectomy if clinical signs do not resolve. Coenzyme Q10 used for prevention in humans.
- Acute bladder effects: maintain patient hydration; increase fluid intake to dilute urine (less irritating). Treat underlying urinary infections, treat bladder spasms (phenazopyridine hydrochloride, Urimax, flavoxate hydrochloride agents, oxybutynin used in human oncology), rule out recurrent tumor.
- Acute lung effects: glucocorticosteroids provide much clinical utility despite lack of published evidence. Rest, oxygen therapy, antibiotics as needed. Supportive care with expectorants and bronchodilators.
- Acute bowel effects: see chronic bowel effects below.
- Acute central nervous system side effects: edema and temporary demyelination usually responsive to antiinflammatory doses of steroids. Anticonvulsants as necessary.

CHRONIC TREATMENT

- Skin effects:
  - Fibrosis: physical therapy, impedance-controlled microcurrent treatment, hyperbaric oxygen, pain management, glucocorticosteroids in the initial setting (limited usefulness for established fibrosis), pentoxifylline ± vitamin E, and superoxide dismutase all are methods to delay or reduce fibrosis in human oncology. Investigational treatments include decorin (inhibitor of transforming growth factor beta [TGF-b]), angiotensin-converting enzyme (ACE) inhibitors, and interferons.
  - Lymphedema: Manual Lymphatic Drainage (specialized massage with specific stroke duration, orientation, pressure, sequence) combined with compression bandages, exercise, skin care, pressure gradient sleeves, and/or pneumatic pumps method to ameliorate lymphedema in human oncology. Diuretics to cause acute reduction in the initial setting (limited usefulness for long-term owing to removal of lymph fluid but not proteinaceous debris from interstitial space). Benzopyrones (coumarin), autologous lymphocyte injection, and selenium proven methods to improve resolution in humans. Of interest but less usefulness, glucocorticosteroids, weight management, hyperbaric oxygen, antibiotic therapy, flavonoids, surgical intervention.
- Chronic head/neck effects:
  - Osteonecrosis (a.k.a., osteoradionecrosis): antibiotics, surgical débridement
  - Esophageal stricture (see p. 365): dilatations and semisolid diet, feeding tubes, hydrocortisone injection at the stricture site
  - Xerostomia: see Acute Treatment above.
  - Cataract formation can be treated with surgical removal.
- Chronic bone effects: surgical intervention, antibiotics. Secondary tumor management as needed.
- Chronic heart effects: antipyretics for fever, centesis for tamponade, pericardiectomy if severe. Medical management by veterinary cardiologist.
- Chronic bladder cystitis/fibrosis: see Acute Treatment above. Surgical intervention for fistula formation.
- Pulmonary fibrosis ameliorated by captopril in human oncology. Oxygen and glucocorticosteroids as needed.
- Chronic bowel effects: initial management with increased dietary fiber and diphenoxylate (Lomotil) or loperamide. Addition of opioid analgesics titrated to effect. Topical viscous lidocaine for anorectal irritation. Glucocorticosteroid-containing suppositories (ProctoFoam, Canasa) for acute inflammation. Sucralfate or short-chain fatty acid (butyrate) enemas for bleeding. Topical formalin, topical amifostine, coagulation with electrocautery, laser therapy, argon plasma beam coagulation,

and hyperbaric oxygen for refractory bleeding in human oncology.
- Late central nervous system side effects: glucocorticosteroids (dexamethasone) ideal in early onset radiation necrosis. May consider surgical resection if area of necrosis is localized.

DRUG INTERACTIONS

- Concurrent use of some chemotherapeutics may exacerbate radiation side effects.
- Concurrent use of antioxidants may interfere with radiation cell kill.

POSSIBLE COMPLICATIONS

- Skin effects: progression of moist desquamation to full-thickness necrosis and secondary infection, necessitating surgical débridement. Unrelenting fibrosis or lymphedema, necessitating surgical intervention.
- Oral cavity effects: *Candida albicans* yeast infection can increase severity of stomatitis/mucositis. Rare reports of trismus (contractions of muscles of mastication) with reduced capacity to open mouth.

RECOMMENDED MONITORING

Advise recheck of patient at 1, 2, 3, 5, 7, 9, and 12 months and every 3-6 months post radiation therapy completion.

PROGNOSIS AND OUTCOME

Prognosis for most acute radiation reactions is excellent if managed efficiently and in a timely manner. Prognosis for most late radiation reactions is guarded to poor for complete recovery. Prevention of late radiation reactions is of great concern during radiation therapy planning.

PEARLS & CONSIDERATIONS

COMMENTS

- Use VRTOG Toxicity Criteria Scale to document reactions.
- This review is not all inclusive. Consult with veterinary radiation oncologist as need arises.

PREVENTION

- Use of intensity-modulated radiation therapy/image-guided radiation therapy/conformal radiation therapy techniques, to allow increased dose to tumor while also increasing normal tissue sparing
- Acute skin effects: reduce skin folds, remove bolus where necessary, avoid topical agents immediately prior to radiation therapy, use higher-energy radiation, and ensure surgical wounds have healed prior to initiation of radiation therapy.
- Chronic skin effects: early detection and treatment
- Head/neck effects: preradiation therapy dental prophylaxis and removal of unhealthy teeth to decrease severity of mucositis and risk of osteonecrosis. Amifostine as a radiation protector routinely used to prevent development of xerostomia (dry mouth) in humans. Ocular: tape eyelids open for anterior megavoltage beam fields to the eye to decrease dose to cornea and conjunctiva (otherwise, the eyelids will serve as a site of radiation dose buildup, increasing the radiation dose delivered to the cornea).

CLIENT EDUCATION

- Teach family members when to expect and how to manage acute effects. Promote role of radiation therapist in client education and side-effect management.
- Prepare notebook with photographs of radiation side effects as a tool for client education. Use serial photographs to display effects as they heal with time.
- Use handouts describing potential effects and management to encourage client information recall.

AUTHOR: TRACY A. LADUE

EDITOR: KENNETH M. RASSNICK

Rabies

BASIC INFORMATION

DEFINITION

Fatal polioencephalitis of warm-blooded animals and humans caused by a *Lyssavirus* sp. and generally transmitted by the bite of an infected mammal

SYNONYMS

Hydrophobia, rage

EPIDEMIOLOGY

SPECIES, AGE, SEX: Warm-blooded animals of all ages are susceptible:

- Foxes, coyotes, wolves, and some rodents are highly susceptible.
- Moderately susceptible species include dogs, cats, horses, sheep, goats, and humans.
- In the United States, cats are the domestic species most frequently reported rabid, with −200−300 cases/year.
- Birds and opossums have a low susceptibility.
- Rabies has been reported in ferrets, rabbits, and one guinea pig.
- Often endemic in wild animals, with periodic outbreaks (epizootics)
- In the United States, the most important species-adapted strains are in the fox, raccoon, skunk, and bat.
- Salivary gland infections occur in vampire bats without producing clinical signs in the bats, resulting in prolonged viremia. Insectivorous bats may also be infected.

RISK FACTORS

- Contact with wildlife, especially raccoons, skunks, bats, and foxes
- Lack of vaccination against rabies
- Exposure to aerosols in bat caves
- Modified live-virus rabies vaccines used in immunocompromised animals

CONTAGION & ZOONOSIS

- Highly zoonotic disease
- Transmission is most commonly by bite.
    - The risk of human infection is far greater through a rabid animal's bite (5%-80%) than a scratch (0.1%-1%).

GEOGRAPHY AND SEASONALITY

- Worldwide
- Rabies-free regions include New Zealand, some Caribbean islands, the British Isles, parts of Scandinavia, Japan, and Hawaii.
- Rabies is a disease of wildlife in the United States:
    - Raccoons: mainly eastern part of the United States but now spreading west
    - Skunks: mainly in California and the north central and south central states
    - Bats: 48 contiguous United States and responsible for most human cases in the last 20 years
    - Foxes: Arctic fox in Alaska, red and gray fox in southeast United States
- The dog is the primary species involved in transmission of rabies in the Southern Hemisphere.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Clinical signs can be variable but predominantly arise from central nervous system (CNS) dysfunction.

- Prodromal form:
    - Characterized by a change in behavior, which may include anxiety, solitude, and apprehension

    - Fever may be present.
    - Pruritus may be present at the site of exposure.
    - Lasts 2-3 days
- Paralytic (dumb) form (majority of canine cases, minority of feline cases): o Characterized by lethargy, difficulty swallowing, ptyalism, voice or bark change, dropped jaw, and lower motor neuron paralysis, often first in the wounded limb
    - Lasts 1-7 days, from onset of overt signs to death
- Furious form (majority of feline cases, minority of canine cases):
    - Characterized by aggression, biting, altered voice, paralysis, seizures, and ataxia
    - Hyperesthesia and hyperresponsiveness to auditory and visual stimuli are possible
    - Lasts 2-4 days, from onset of overt signs to death

HISTORY, CHIEF COMPLAINT

- History of wound may or may not be present:
    - Given the pathophysiology of rabies, neurologic clinical signs beginning within 1 week of the occurrence of a wound are extremely unlikely to be related to rabies infection via the wound.
- Behavioral changes are very common and can be varied:
    - Aggression, viciousness, irritability, excitability, nervousness, apprehension, and anxiety
    - Abnormal or erratic behaviors, such as licking, biting, wandering, disorientation, ataxia, seizures, or paralysis
- Ptyalism and change in bark
- No clinical signs; exposure is suspected but not confirmed.

PHYSICAL EXAM FINDINGS: Onset of clinical signs is variable in timing: signs occur 2 weeks to several months after exposure. Signs include fever, dropped jaw, ptyalism, inability to swallow, and mandibular and laryngeal paralysis. Lower motor neuron limb signs, ataxia, and cranial nerve deficits may be present.

ETIOLOGY AND PATHOPHYSIOLOGY

- Single-stranded RNA virus of the genus *Lyssavirus,* family Rhabdoviridae
- Transmission:
    - Virus within saliva is transmitted via a wound or mucous membranes.
    - Inhalation of aerosolized virus may occur with exposure to bats.
    - Ingestion of infected tissues is also possible but rare.
    - Transmission has also occurred in humans through organ transplantation.
- Virus replicates in local tissues, where it enters neuromuscular junctions and neurotendinous spindles.
    - Virus is vulnerable to immune-mediated destruction (e.g., vaccine-induced) in local tissues but becomes protected once it reaches peripheral nerves or the CNS.
- Spreads by intraaxonal flow through peripheral nerves to the spinal cord and brain. Replicates within the CNS and then moves outward through peripheral, sensory, motor, and cranial nerves.
- Large amount of virus present in salivary glands, where it is shed. Salivary virus excretion begins up to 2 weeks before the onset of neurologic signs.
- The incubation period varies and depends on the innervation at the bite site, distance of the bite site to the CNS, and virus variant and amount of virus in the exposure; can range from 2 weeks to as long as 6 months or more.
- Once clinical signs are apparent, death ensues within 10 days.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is suspected in any animal with an unknown or incomplete rabies vaccination history that develops acute neurologic signs. Confirmation requires direct IFA of brain or nervous tissue.

DIFFERENTIAL DIAGNOSIS

- Encephalitis: viral (canine distemper, feline leukemia virus, feline immunodeficiency virus, feline infectious peritonitis); immune-mediated (e.g., granulomatous meningoencephalitis); rarely, protozoal, rickettsial, bacterial, fungal
- Pseudorabies
- Toxicity (e.g., lead)
- Cerebral cysticercosis caused by larval *Taenia solium* mimics rabies in dogs.
- Portosystemic shunt
- Hypoglycemia
- Neoplasia

- Trauma
- Causes of ptyalism (see p. 930)

INITIAL DATABASE

- The clinical suspicion of rabies is based on history and physical examination.
- CBC, serum chemistry panel, and urinalysis are unhelpful.

ADVANCED OR CONFIRMATORY TESTING

- Cerebrospinal fluid (CSF) analysis may show nonspecific increases in protein and leukocytes.
- Direct IFA test of nervous tissue is the confirmatory test of choice:
  - Chill—do not freeze—the body or brain of any dead/euthanized rabies suspect.
  - Immediately submit the brain to a state-approved laboratory for rabies IFA testing.
  - Use extreme caution in obtaining samples and shipping specimens; zoonosis can occur if rabies virus is aerosolized (e.g., when an electric saw is used for opening the skull and proper protection is not used) or is inadvertently inoculated.
- A new reverse transcriptase PCR is useful with small samples such as saliva and spinal fluid and has been shown to be as rapid as the IFA test.
- Direct IFA testing of dermis: skin biopsy of sensory vibrissae of the maxillary area should not be used (false-negative results).

TREATMENT

TREATMENT OVERVIEW

- Invariably fatal; recovery is extraordinarily rare.
- Suspects must be confined and quarantined.
- The first reported survival of a human who did not receive rabies pre- or postexposure prophylaxis was recently described. The case has prompted further exploration of the treatment she received, termed the “Wisconsin Protocol.” Rifampin, amantadine, and the induction of a ketamine/mid-azolam coma were the mainstays of treatment.

RECOMMENDED MONITORING

- Management of rabies suspects varies with immunization status and local laws. The attending veterinarian should contact the local state veterinarian.
- Most public health laws require a 10-day confined observation period after human exposure from a suspected dog or cat:
  - Virus shedding in saliva before the onset of neurologic signs in infected animals is usually 1-5 days but may be up to 13 days.
- All rabies suspects must be securely confined and monitored for behavioral changes and/or neurologic signs suggestive of rabies.
- A healthy dog or cat that bites or scratches an individual should be confined and monitored for 10 days:
  - If clinical signs do not develop within 10 days of bite/scratch, there has been no exposure to rabies virus.
  - If clinical signs consistent with rabies develop during the 10-day quarantine period, the animal must be euthanized and its brain submitted immediately for examination. If infection is confirmed within 24-48 hours, there is adequate time to begin human postexposure prophylaxis.
- Unvaccinated dogs or cats that are exposed to a known rabid animal or to any bat or wild, carnivorous mammal:
  - Typically the animals are placed in quarantine for up to 6 months.
  - The animals must be monitored for the onset of clinical signs (with vaccination 1 month prior to release) or euthanized immediately at presentation or at the time of onset of clinical signs consistent with rabies.
- Vaccinated dogs or cats that are exposed to a known rabid animal or to any bat or wild, carnivorous mammal:
  - Immediate revaccination for rabies is indicated.
  - A period of monitoring must follow, typically for 45 days. When a dog or cat with an expired rabies vaccination status is exposed to a rabid animal, individual factors will determine the recommended course. Clinicians should contact the state veterinarian.

PROGNOSIS AND OUTCOME

- Fatal
- Cats and dogs will typically succumb within 7-10 days after onset of clinical signs.
- Rare cases of recovery in dogs, cats, and humans

- Experimental treatment with nanoviri-cides has shown a 30% survival rate compared to standard treatment (0% survival); currently being investigated by the Centers for Disease Control and Prevention.

PEARLS & CONSIDERATIONS 

COMMENTS

- If clients are concerned regarding possible or known human exposure to rabies, they must see their physician immediately.
- Clinicians should notify the local public health official.
- Signs take weeks to months to develop after exposure, but once signs are present, death ensues quickly (<2 weeks).
- Travel to rabies-free areas has been facilitated by a vaccinate-microchip-and-blood test protocol that shows adequate neutralizing antibody levels (e.g., >0.5 IU/mL) and no clinical signs of rabies typically over a 6-month period prior to departure. This reduces the burden of travel on the pet (previously a 6-month quarantine in the destination country/state). The specific jurisdiction can provide detailed requirements (e.g., for the United Kingdom: http://www.defra.gov.uk/wildlife-pets/pets/travel/pets/index.htm).
- A new Rabies Rapid Screen Saliva test is being marketed by Dyne Immune but has not undergone sensitivity and specificity testing at this time and cannot be recommended until more data are published.

PREVENTION

- All dogs and cats should be vaccinated for rabies after 12 weeks of age, again at 12 months of age, and then every 3 years or yearly depending on state regulations.
- An immediate booster vaccination in immunized dogs and cats exposed to rabies is advised.
- Cats should only receive inactivated vaccines; do not use modified live virus (MLV) vaccines in cats.
- Disinfect contaminated cages, food dishes, and instruments with a diluted solution of 1 part bleach to 32 parts tap water.

TECHNICIAN TIPS

- Gloves should be worn during examination of all unknown or unvaccinated animals and during examination of bite wounds of unknown origin as a protection against rabies.
- The classic vicious, “foaming at the mouth” image is only true in some 10% of rabid dogs. A majority of dogs with rabies are lethargic and poorly responsive but highly infectious. Therefore, strict precautions to avoid being bitten are wananted around animals with these signs.

CLIENT EDUCATION

- Keep pets from roaming (“leash laws”).
- Inform clients of state and local policies.
- Advise the client to bring animal to a veterinarian immediately if exposure is suspected. With human exposure, individuals should immediately contact a physician.

1ST EDITION AUTHOR: LISA TIEBER NIELSON

Systemic Lupus Erythematosus

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A multisystemic autoimmune disease affecting at least two different organ systems

EPIDEMIOLOGY

SPECIES, AGE, SEX: More commonly reported in dogs than cats; young to middle-aged animals are predisposed.

GENETICS & BREED PREDISPOSITION

- Systemic lupus erythematosus (SLE) is clearly heritable in dogs.
- German shepherds may be overrepresented.

GEOGRAPHY AND SEASONALITY: Exposure to UV light may trigger cutaneous lesions.

ASSOCIATED CONDITIONS & DISORDERS: When additional clinical signs occur, it is often difficult to determine if a concurrent disease is present or instead represents an additional manifestation or complication of SLE or its treatment.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: The diagnosis of SLE is made when any three of the following occur concurrently or over any period of time:

- Cutaneous lesions, especially skin exposed to sunlight and/or at mucocutaneous junctions
- Oral mucosal ulcers
- Nonseptic, nonerosive polyarthritis
- Glomerulonephritis
- Hemolytic anemia and/or thrombocytopenia
- Leukopenia
- Polymyositis or myocarditis
- Serositis (nonseptic inflammatory effusion in the abdominal, pleural, or pericardial cavity)
- Neurologic disorder (seizures, psychosis, or polyneuritis)
- Significant serum antinuclear antibody (ANA) titer

HISTORY, CHIEF COMPLAINT

- Lameness is the most common primary complaint in dogs.
- Nonspecific lethargy and poor appetite
- Skin lesions
- Signs may wax and wane, confusing response to treatment.

PHYSICAL EXAM FINDINGS

- Lameness with swollen, painful joints. The carpi, tarsi, elbows, and stifles are most frequently involved.
- Fever
- Lymphadenopathy and/or splenomegaly
- Cutaneous lesions: erythema, scaling, crusting, depigmentation, and alopecia. Lesions may develop on the skin, mucocutaneous junctions, and oral cavity.

ETIOLOGY AND PATHOPHYSIOLOGY

- SLE occurs when a stimulus triggers the appropriate susceptibility genes in a patient.
- Triggering factors may include vaccination, drug administration, stress, infection, or exposure to UV radiation.
- SLE patients produce antibodies directed against a broad range of nuclear, cytoplasmic, and cell-membrane molecules. Antibodies against the patient's own DNA are measured with the ANA test.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of SLE is not based on a single test but on the constellation of clinical signs (see Disease Forms/Subtypes, above) and exclusion of other possible etiologies.

DIFFERENTIAL DIAGNOSIS

- Tickborne disease
- Neoplasia and paraneoplastic syndromes
- Bacterial, fungal, or viral infection
- Other immune-mediated diseases

INITIAL DATABASE

- CBC, including manual differential: may show anemia, leukocytosis, or leukopenia
- Platelet count: may be normal or low
- Serum biochemical profile: abnormalities reflect the site of inflammation (e.g., azotemia and hypoalbuminemia with glomerular involvement)
- Urinalysis: proteinuria is possible
- Urine protein/creatinine ratio
- Urine culture and sensitivity (C&S)
- Skin biopsies: may reveal inflammatory infiltrates at the dermoepidermal junction and vacuolar change in the basal columnar cells
- Radiographs of affected joints: may reveal nonerosive joint swelling
- Arthrocentesis of multiple joints: may reveal sterile neutrophilic inflammation
- Serum ANA titer:
    - Serum ANA commonly stated as a requirement for the diagnosis of SLE, but sensitivity and specificity of this test are not known in the dog and cat.
    - Normal ranges are determined by individual laboratories.
    - False-positive results can occur with various medications (nonsteroidal antiinflammatory drugs [NSAIDs], antibiotics, others).
    - False-positive or false-negative results can occur as a result of variable laboratory standardization, variable quality control, and other factors.
- Lupus erythematosus (LE) cell test: rarely useful
- Thoracic radiographs: may reveal pleural or pericardial effusion (usually subtle)
- Abdominal ultrasonography: usually normal
- Tickborne disease titers to rule out diseases that can mimic SLE (glomerulonephritis, polyarthritis, hematologic changes, etc.)
- Cats: feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) serologic tests

ADVANCED OR CONFIRMATORY TESTING

- see Disease Forms/Subtypes, above
- Coombs' test: usually negative
- Platelet autoantibodies: rarely useful
- Rheumatoid factor: usually negative
- Immunohistologic evaluation of skin biopsies (immunoperoxidase and immunofluorescent staining): may demonstrate immunoglobulin and complement deposits at the epidermal basement membrane, which are specific for immune-mediated dermatopathies.

TREATMENT

TREATMENT OVERVIEW

At least three aspects of treatment should be considered:

- Resolve clinical signs.
- Prevent renal failure.
- Realize that because of the natural waxing and waning of the disease, aggressive therapy may not be indicated for all cases.

ACUTE GENERAL TREATMENT

- Prednisone/prednisolone, 1 mg/kg PO q 12-24 h initially
- With severe disease, the addition of azathioprine, 2.2 mg/kg PO q 24 h, should be considered.
- Proteinuria may be lessened with enalapril, 0.5 mg/kg PO q 12 h, along with dietary protein optimization/restriction; omega-3 fatty acid supplementation and low-dose aspirin, 0.5 mg/kg q 12 h, may also be added.
- Closely monitor for gastrointestinal (GI) ulcers if NSAIDs and corticosteroids must be used together.

CHRONIC TREATMENT

- Treat the patient until all clinical and laboratory abnormalities have resolved, then attempt to taper drugs.
- In general, decrease doses by half every 2-4 weeks while monitoring clinical and laboratory abnormalities.
- The minimum duration of immunosuppressive therapy should be 4-6 months.
- If signs recur during drug taper, increase level to the previous dose, and attempt to taper more slowly.

BEHAVIOR/EXERCISE

Avoid outdoor activity and/or use topical sunscreen for patients showing cutaneous or mucocutaneous lesions.

DRUG INTERACTIONS

- Concurrent NSAIDs and corticosteroid administration should be avoided owing to the potential for GI ulceration.
- Prolonged administration of azathioprine may cause bone marrow suppression. To reduce the risk, administration q 48 h is recommended once clinical signs and laboratory abnormalities have resolved.

POSSIBLE COMPLICATIONS

- Progressive renal insufficiency
- Infections (such as urinary tract infection) from long-term immunosuppression

RECOMMENDED MONITORING

- If prednisone is administered, monitor body weight closely and avoid obesity.
- If azathioprine is administered, monitor CBC every 2 weeks while azathioprine is being administered daily. Bone marrow suppression is unusual when azathioprine is tapered to 2.2 mg/kg q 48 h; in this case, monitor CBC every 2-3 months.
- If immunosuppressive medications are needed chronically, a urine culture is indicated every 3 months even in the absence of clinical signs of infection.
- Monitor CBC, serum biochemistry profile, and urinalysis every 3 months once in remission.
- Serum ANA may be useful to detect relapse.

PROGNOSIS AND OUTCOME

- Not well-known; many cases wax and wane
- Good for most cases
- Progressive renal disease indicates guarded prognosis

PEARLS & CONSIDERATIONS

COMMENTS

- The diagnosis of SLE is not based on a single test but on the constellation of clinical signs and exclusion of other possible etiologies.
- Treatment with doxycycline is useful to exclude infectious causes of polyarthropathy.
- Arthrocentesis: perform arthrocentesis on at least three joints, even if not swollen or painful.
- Biopsy of skin lesions must include intact epithelium. Ulcerated lesions are inherently nondiagnostic. Erythematous areas adjacent to ulcers yield the most conclusive results.
- Many animals are euthanized not from progressive disease but due to adverse effects of corticosteroids. Avoid obesity, and routinely monitor for infection of the skin and urinary tract.
- Combination immunosuppressive therapy with azathioprine is often more effective and has fewer adverse effects than prednisone/prednisolone alone.

TECHNICIAN TIPS

Many of the effects of SLE, notably polyarthritis, may be painful. Patients showing clinical signs that are known or suspected to be caused by SLE should be handled and walked as gently as possible, with an awareness that pain may cause them to be uncooperative or aggressive even with handling that would be normal for a healthy animal.

PREVENTION

- Although a link has not been proven, future vaccinations should be limited to those considered absolutely essential.
- Stressful circumstances should be avoided if possible to minimize risk of recurrence.

CLIENT EDUCATION

- Routine monitoring should be scheduled to detect relapse of disease and adverse effects of immunosuppressive medications.
- Many dogs live normal lives after the diagnosis.

AUTHOR: MICHAEL STONE

EDITOR: SUSAN M. COTTER

Systemic Inflammatory Response Syndrome

BASIC INFORMATION

DEFINITION

- A systemic dysregulated inflammatory process which leads to disorders of microcirculation, organ perfusion, and finally to organ dysfunction. Untreated, systemic inflammatory response syndrome (SIRS) leads to multiple organ dysfunction syndrome (MODS; see 732) and death.
- SIRS is defined clinically as the presence of two or more of the following conditions in dogs and cats:
  - Dogs: body temperature > 40°C or < 38°C; heart rate > 120 bpm in a calm, resting dog; hyperventilation or PaCO2 < 30 mm Hg; and white blood cell (WBC) count > 18,000/mm^3 or < 5000/mm^3 or > 5% immature (band) forms.
  - Cats: body temperature > 40°C or < 38°C; heart rate > 140 bpm in a calm, resting cat; respiratory rate >20 breaths per minute or PaCO2 < 28 mm Hg; and WBC count > 18,000/mm^3 or < 5000/mm^3 or > 5% immature (band) forms.
  - SIRS may or may not be associated with infection.

EPIDEMIOLOGY

SPECIES, AGE, SEX: There are no species, age, or sex predilections.

HISTORY, CHIEF COMPLAINT: May include vague complaints such as lethargy, anorexia, vomiting, or diarrhea or may include a specific event (i.e., trauma, burn injury, heat stroke).

PHYSICAL EXAM FINDINGS

- Often varied and may include generalized depression, fever, tachycardia, or tachypnea.
- By definition, findings associated with an underlying inflammatory condition (i.e., pancreatitis, severe polytrauma) and two or more of the four criteria already listed are expected in animals with SIRS.
- Specific physical exam findings depend on the underlying cause of the SIRS.

ETIOLOGY AND PATHOPHYSIOLOGY

- SIRS can arise from a number of causes which commonly include sepsis, pancreatitis, burns, massive trauma (e.g., hit by car, fall from high elevation, attack by other animal), hypovolemic shock, immune reactions (autoimmune disease), heat stroke, and tissue ischemia of various causes.
- Inflammation is a response to infection, antigen challenge, or tissue injury that is designed to eradicate microbes or irritants and potentiate tissue repair; however, excessive inflammation may lead, via SIRS, to physiologic decompensation, organ dysfunction, and death.
- A balance normally exists among proinflammatory cytokines and antiinflammatory cytokines; however, for cases in which the proinflammatory response predominates, severe systemic inflammation may ensue as typified by SIRS.
- In addition to high circulating cytokine levels, systemic inflammation is also associated with activation of the clotting cascade and release of vasoactive mediators such as nitric oxide (NO).
  - High systemic cytokine levels may result in myocardial dysfunction, altered intracellular oxygen utilization, and direct inflammatory injury.
  - Activation of the clotting cascade can cause microvascular thrombosis and tissue hypoperfusion.
  - Increased production of NO and metabolites can lead to peripheral vasodilation, decreased peripheral vascular resistance, and hypotension.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of SIRS is based upon having two or more of the following criteria: the presence of tachycardia (or bradycardia in cats), fever or hypothermia, tachypnea, and a leukocytosis/leukopenia with or without a left shift in a patient who has a condition known to incite the systemic release of inflammatory mediators.

DIFFERENTIAL DIAGNOSIS

SIRS is a catch-all phrase for systemic inflammation, multiple causes are possible.

INITIAL DATABASE

Main goal is to determine the source of the systemic inflammatory response:

- CBC: by definition, will show either a WBC count >18,000 or <5000/mcL or will show the presence of >5% band forms (immature neutrophils). Thrombocytopenia and evidence of hemoconcentration may be present.
- Serum biochemistry panel: commonly shows electrolyte abnormalities, hypoalbuminemia, hyperglycemia or hypoglycemia, hyperbilirubinemia, elevated blood urea nitrogen (BUN)/creatinine (azotemia), and/or elevated liver enzymes, depending on the source of the inciting problem and extent of inflammatory response's effects on visceral organs (progression towards MODS).
- Urinalysis: isosthenuria (normal free water excretion versus renal compromise if azotemia is present simultaneously), concentrated urine (if dehydration/hypovolemia and normal renal function), glucosuria (stress, diabetes mellitus), proteinuria (systemic inflammation, urinary tract inflammation, glomerulopathy), and cellular casts (tubular damage) may be seen.
- Urine culture and sensitivity (C&S) is indicated in animals with SIRS, even in the absence of an active urine sediment.
- Blood cultures should be considered.

ADVANCED OR CONFIRMATORY TESTING

Not specific, depends on disease/injury

TREATMENT

TREATMENT OVERVIEW

- In managing an animal with SIRS, there are three essential treatment principles:
  - Hemodynamic stability and support of acute life-threatening organ dysfunction
  - Prolonged support of vital organ function using interventions that minimize iatrogenic injury
  - Modulation of the host-based inflammatory response with interventions that target its specific mediators
- The specific therapeutic goals for treating the systemic inflammatory response syndrome depend on the underlying cause.

ACUTE GENERAL TREATMENT

- IV fluids (crystalloids and colloids) are used for treating hypovolemia and electrolyte abnormalities. During treatment, monitor and maintain electrolytes, BP, and central venous pressure (i.e., mean arterial pressure should be maintained above 60 mm Hg, and central venous pressure should be maintained above 5 mm Hg). Dextrose-containing solutions may need to be added to the treatment regimen if the patient is hypoglycemic; however, hyperglycemia should probably be avoided because an increase in mortality has been associated with hyperglycemia in humans with critical illness. Blood products (plasma, whole blood, and/or packed red blood cells [RBCs]) may need to be used if continued blood loss is documented (see 1347).
- Crystalloid fluids: initial shock dose of 90 mL/kg (dog), 70 mL/kg (cat). Administer this dose IV as a bolus of one-third of the total amount. Then reassess the patient (i.e., measure BP, heart rate), and administer the remainder of the shock dose if the measured parameters have not normalized or substantially improved.
- Colloid fluids: colloids are useful when hypoperfusion and/or hypotension persist and when the shock dose of fluids has already been given as crystalloids. Administer Hetastarch (or other colloid) IV either as a bolus or as a constant rate infusion. A dose for initial bolus is 10-20 mL/kg in dogs and 10-15 mL/kg in cats (should be given over 10-15 minutes in a cat, because it has been associated with nausea). Administer a constant rate infusion of 20 mL/kg per day after the initial bolus if the patient's disease process and cardiovascular status require continued colloid therapy. In humans, coagulopathies have been associated with the use of hetastarch. Therefore, colloids should be used with caution in patients with known coagulopathies.
- Fresh frozen plasma transfusion: 10 mL/kg
- Whole blood transfusion: 20 mL/kg should be given over 4 hours and can be given faster if the patient requires it because of active bleeding; monitor for transfusion reactions (fever, tachypnea, vomiting; see pp. 1347 and 1111).
- Packed RBC transfusion: dose of 10 mL/kg, at a rate of over 3-4 hours; can be given faster if patient requires the transfusion because of active bleeding or hemolysis; monitor for transfusion reactions (fever, tachypnea, vomiting; see pp. 1347 and 1111).
- Antimicrobial therapy may be necessary if bacterial translocation or subsequent infections are suspected as possible complications (e.g., transition towards sepsis). Type and dosage of antibiotic depends on suspected source of infection. For example, bacterial translocation from the gastrointestinal (GI) tract, as can occur after prolonged hypotension or a primary GI insult (e.g., parvoviral enteritis), should be treated with a combination of ampicillin, 22 mg/kg IV q 8 h, and either enrofloxacin, 5 mg diluted 1:1 in sterile water and given slowly IV q 12-24 h (q 24 h maximum in cats, owing to retinal toxicity risk; with caution in patients < 6 months old); or gentamicin, 5-6 mg/kg IV q 24 h (only if renal function is adequate and patient is fully hydrated).

- Corticosteroids are generally contraindicated for patients with SIRS unless relative adrenal insufficiency is suspected.

PROGNOSIS AND OUTCOME

The prognosis and outcome for SIRS depend on the underlying cause and its severity.

PEARLS & CONSIDERATIONS

COMMENTS

SIRS caused by a noninfectious etiology may nevertheless progress to sepsis due to development of a nosocomial infection.

Systemic Hypertension

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A sustained elevation in the arterial blood pressure (BP). In dogs and cats, systemic hypertension is suspected if sustained systolic BP > 160 mm Hg, diastolic BP > 95 mm Hg, or both.

SYNONYM

Arterial hypertension

EPIDEMIOLOGY

SPECIES, AGE, SEX: Systemic hypertension occurs in both dogs and cats, and there is no significant age or sex predisposition in either species. However, some systemic diseases commonly associated with systemic hypertension (e.g., chronic kidney disease, hyperthyroidism) are more common in older animals.

GENETICS & BREED PREDISPOSITION: There is no breed predisposition in cats. Sighthounds (e.g., deerhounds, Irish wolfhounds) have higher normal BP ranges than other breeds. Although essential hypertension has been diagnosed in one family of dogs, systemic hypertension usually occurs secondary to other diseases and as such is not inherited.

ASSOCIATED CONDITIONS & DISORDERS

- Although essential (cause unknown) hypertension is diagnosed in veterinary patients, most cases of systemic hypertension occur as a complication of another systemic disease. In cats, the most common diseases associated with systemic hypertension are chronic kidney disease and hyperthyroidism. Many cats with hyperthyroidism have subclinical kidney disease; in these animals, it is unclear whether kidney disease, hyperthyroidism, or both are responsible for the hypertension. The prevalence of hypertension in cats with diabetes mellitus is still unclear.
- In dogs, the diseases most commonly associated with systemic hypertension are chronic kidney disease (especially proteinuric renal disease), hyperadrenocorticism, diabetes mellitus, and pheochromocytoma. Less typical causes of systemic hypertension in either species include hyperaldosteronism, acromegaly, and use of hypertensive medications (e.g., phenylpropanolamine, excessive thyroxine supplementation).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Systemic hypertension can be diagnosed based on clinical signs (clinical systemic hypertension) or as part of a diagnostic evaluation of a systemic disease, with the animal showing no overt clinical signs (subclinical systemic hypertension).

HISTORY, CHIEF COMPLAINT

- Signs associated with the underlying disease
- Lethargy, changes in activity or appetite, or mentation changes:
  - Owner may interpret the signs as “signs of aging.”
- Acute blindness, intraocular hemorrhage
- Intracranial neurologic signs:
  - Generalized seizures
  - Focal facial seizures

PHYSICAL EXAM FINDINGS

- Signs of underlying systemic disease (e.g., signs of kidney disease or hyperthyroidism)
- Ocular: vitreal or retinal hemorrhage, retinal detachment, hyphema, vascular tortuosity
- Nervous system: signs of intracranial disease, changes in mentation (usually decreased but may include heightened anxiety), seizures (generalized or focal facial)
- Cardiovascular system: new murmur (typically a murmur of mitral insufficiency), arrhythmia, gallop sound, left ventricular hypertrophy on echocardiographic examination
- Other: epistaxis, photophobia

ETIOLOGY AND PATHOPHYSIOLOGY

- Likely to be multifactorial; individual mechanisms may predominate in some diseases:
  - Abnormalities in renal sodium handling
  - Inappropriate activation of the reninangiotensin-aldosterone system
  - Inappropriate activation of the sympathetic nervous system
  - Hypersensitivity to the effects of cortisol
  - Blood volume expansion secondary to underlying disease states
- Better understanding of mechanisms in individual diseases is likely to lead to more effective tailoring of therapy.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in one of two clinical contexts: either a patient is evaluated for clinical signs consistent with hypertensive decompensation (e.g., acute vision loss), or systemic hypertension is identified in a compensated patient (e.g., as part of evaluating a patient that has chronic kidney disease). BP measurement is a simple confirmatory test, but technical confounders, notably patient anxiety (the white coat effect) and incorrect cuff size or placement, must be avoided to achieve an accurate reading.

DIFFERENTIAL DIAGNOSIS

- Ocular signs: coagulopathies; uveitis; inflammatory, infectious, or neoplastic diseases; trauma
- Neurologic signs: intracranial lesions
- Cardiovascular signs: primary cardiac disease, other secondary cardiac diseases
- Epistaxis: coagulopathies, trauma, neoplasia, fungal rhinitis

INITIAL DATABASE

- Initial diagnostic testing as guided by underlying disease if known
- BP measurement (see p. 1209)
- If systemic hypertension is diagnosed in a patient without known predisposing disease:
  - Dogs: CBC, serum chemistry profile, urinalysis with urine protein analysis if proteinuria is present, complete funduscopic examination
  - Cats: CBC, serum chemistry profile, urinalysis, serum thyroxine if patient is ≥10 years old, complete funduscopic examination
  - Both species: consider thoracic radiographs or abdominal ultrasound.

ADVANCED OR CONFIRMATORY TESTING

Repeated BP measurements over the course of several hours may be needed if animal is excited or very anxious during the first measurement period.

TREATMENT

TREATMENT OVERVIEW

- Systemic hypertension with clinical signs present:
  - First priority: prompt reduction of systolic BP to <160-180 mm Hg
  - Second priority: initiating clinical evaluation for causative disease
- Systemic hypertension found in conjunction with causative underlying disease but no clinical signs of hypertension are present:
  - Institute optimal therapy of causative condition.
  - Confirm elevated BP values on more than 1 occasion to lessen the chance of anxiety- or excitement-related elevations of BP.
  - If systolic BP > 180 mm Hg on more than one measurement occasion, begin antihypertensive therapy.
  - Systolic BP is 160-180 mm Hg on more than one measurement occasion:
    - If underlying disease can be controlled (e.g., hyperthyroidism or hyperadrenocorticism) or cured (e.g., hyperthyroidism if surgery/ radioiodine therapy is available), monitor BP during therapy of underlying disease, and treat if systolic BP continues to exceed 160 mm Hg after optimal therapy of underlying disease.
    - If underlying disease is unknown or unlikely to be cured (e.g., chronic kidney disease), begin antihypertensive

therapy.

ACUTE GENERAL TREATMENT

- Discontinue any hypertensive medications.
- Emergency antihypertensive therapy for animals with acute ocular or neurologic signs:
  - Dogs, either oral or IV therapy (start at low end of dose and titrate to effect):
    - Nitroprusside: 0.5-5 mcg/kg/min as continuous rate infusion IV; *or*
    - Hydralazine (oral): 0.5-2 mg/kg PO q 12 h
  - Cats:
    - Amlodipine: 0.625 mg PO q 24 h if cat =5 kg; 1.25 mg PO q 24 h if cat >5 kg; *or*
    - Hydralazine: 0.5-2 mg/kg PO q 12 h

CHRONIC TREATMENT

Dogs: medications from different groups may be added if original medication is not adequate to control hypertension:

- Angiotensin-converting enzyme inhibitors:
  - Enalapril: 0.5 mg/kg PO q 12-24 h; *or*
  - Benazepril: 0.25-0.5 mg/kg PO q 24 h
- Calcium (Ca) channel blockers:
  - Amlodipine: 0.01-0.2 mg/kg PO q 12-24 h

Cats:

- Ca channel blockers (preferred first line therapy):
  - Amlodipine: 0.625 mg PO q 24 h if cat ≤5 kg; 1.25 mg PO q 24 h if cat >5kg
- Angiotensin-converting enzyme inhibitors:
  - Usually inadequate as monotherapy but may have additive effects when given with other medications
  - Enalapril: 0.5 mg/kg PO q 12-24 h
  - Benazepril: 0.25-0.5 mg/kg PO q 12-24 h
- Beta-antagonists (beta-blockers):
  - May be useful to control heart rate if hyperthyroidism is present
  - Atenolol: 6.25 mg PO q 24 h if cat ≤5 kg; 12.5 mg PO q 24 h if cat >5kg

DRUG INTERACTIONS

- BP-lowering sedatives (e.g., acepromazine) should be used with caution in animals receiving any antihypertensive medication.
- Two medications from the same drug group should not be used together (e.g., benazepril and enalapril).

POSSIBLE COMPLICATIONS

- Hypotension:
  - Resuscitate as needed.
  - Reduce dose of BP medication.
  - Reevaluate need for antihypertensive medication.
- Uncontrolled hypertension despite drug therapy:
  - Review medications and administration information with caregiver.
  - Add medications from other classes if needed.
  - Consult a specialist for further additions/modifications if hypertension is not controlled with two antihypertensive medications at upper end of dosing ranges.
- Previously controlled hypertension now out of desired target range:
  - Dogs: hypertension may worsen over time, or underlying disease may be inadequately controlled:
    - Ensure optimal therapy of underlying disease.
    - Screen for hypertensive medications and check postpill serum thyroxine concentration in animals receiving thyroid supplementation.
    - Add additional antihypertensive medications or increase doses of present medications to high end of dosage range if tolerated.
  - Cats: hypertension control is usually stable once achieved. If BP continues to increase over time, treat as recommended in dogs, above.

RECOMMENDED MONITORING

- Once the condition is controlled, check BP in hypertensive patients every 3 months.
- If doses/medications change, recheck BP in 3-5 days after change to ensure efficacy.

PROGNOSIS AND OUTCOME

- If retinal detachment (see p. 985) has occurred, the retina may reattach with good control of blood pressure, but prognosis for return of vision is variable.
- Prognosis for resolution of other clinical signs of hypertension (e.g., focal facial seizures, changes in mentation, hyphema) is favorable if BP can be controlled with medication and underlying diseases can be controlled as well.
- Prognosis of systemic hypertension may be affected by prognosis of causative disease.

PEARLS & CONSIDERATIONS

COMMENTS

- Owners may interpret clinical signs of hypertension as “signs of aging,” and vigilance regarding monitoring of BP in animals at risk will detect subclinical cases.
- Any dog or cat with a systemic disease known to cause hypertension should have its BP monitored periodically regardless of clinical signs.
- High BP detected in young animals with no risk factors is often spurious.

CLIENT EDUCATION

For optimal patient management, inform clients that:

- Hypertension is usually a complication of another disease rather than primary disease in itself.
- Control of hypertension is necessary to avoid catastrophic ocular or neurologic damage and to minimize ongoing damage to susceptible organs (e.g., kidneys).
- If the underlying disease is not curable, therapy for systemic hypertension is likely to be lifelong.
- Many patients will require more than 1 medication to adequately control hypertension, and the need for medication may increase over time.

EDITOR: ETIENNE CÔTÉ

Synovial Cell Sarcoma

BASIC INFORMATION

DEFINITION

A malignant tumor in the tissue lining the capsule of a joint

SYNONYM(S)

SCS, synovial sarcoma

EPIDEMIOLOGY

SPECIES, AGE, SEX: The median reported age is 8.5 years. Rare in cats.

GENETICS & BREED PREDISPOSITION: Golden retrievers and flat-coated retrievers seem to be overrepresented.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Histopathologically, there are two cell types: epithelioid (synovioblastic) and spindle (fibrosarcomatous) cell types.

HISTORY, CHIEF COMPLAINT: Most animals present with a slow-growing mass over a joint and concurrent lameness.

PHYSICAL EXAM FINDINGS: The clinical signs are directly related to the site of involvement and local invasiveness. Physical examination abnormalities include lameness and the presence of a mass near the affected joint. Other lameness-related findings could include stiffness of gait, reduced range of motion, crepitus, joint swelling, and pain. Depending on the duration of disease, joint instability may be present (ligament tear, subluxation). Other nonspecific clinical signs include lethargy, anorexia, and hemiparesis.

ETIOLOGY AND PATHOPHYSIOLOGY

- Synovial cell sarcoma (SCS) is a locally invasive tumor, and underlying bone destruction is common.
- Metastasis to regional lymph nodes, lungs, and other sites occurs in up to 25% of cases.
- In dogs, SCS most frequently involves the stifle and elbow, although other sites have been reported.
- No known etiologic factors

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A diagnosis of SCS is suspected based on the clinical presentation of chronic progressive lameness if the neoplasm is involving an appendicular joint, typically in an older dog.

DIFFERENTIAL DIAGNOSIS

- Degenerative joint disease, immune-mediated, or infectious arthritis
- Histiocytic sarcomas also occur in the periarticular tissue of large appendicular joints (see 535). This is the main tumor to distinguish SCS from, since the biological behavior and therapy is distinct.
- Other joint tumors reported in dogs include fibrosarcoma, rhabdomyosarcoma, osteosarcoma, malignant fibrous histiocytoma, liposarcoma, hemangiosarcoma, myxoma, malignant giant cell tumor of soft tissue, lymphoma, hemangioma, and undifferentiated sarcoma.
- Histologically, it may be challenging to differentiate SCS from histiocytic sarcoma, other mesenchymal tumors, and epithelial malignancies. Special immunohistochemical stains are almost always necessary to confirm a diagnosis of SCS.

INITIAL DATABASE

- Regional radiographs of the affected joint are recommended to help rule out other causes of musculoskeletal lameness.

  - Regional radiographic abnormalities include soft-tissue swelling; in advanced cases, cortical destruction and periosteal reaction are evident.
  - Radiographic evidence of lysis involving the proximal and distal bones of a joint is suggestive of SCS; however, other soft-tissue sarcomas can cross the joint space and should be ruled out.
- Fine-needle aspirate (FNA) and cytologic examination of the mass or the affected joint are useful in identifying and differentiating other causes of lameness.
- After a diagnosis of malignancy has been confirmed, the minimum database should include laboratory evaluation of CBC, serum biochemical analysis, urinalysis, three-view thoracic radiographs, cytologic or histologic examination of the draining lymph node, and abdominal ultrasound to rule out any abdominal visceral metastasis.

ADVANCED OR CONFIRMATORY TESTING

- If necessary, a CT scan or an MRI can be performed to evaluate the local extension of the causative lesions.
- An immunohistochemistry test is necessary to confirm a histologic diagnosis and differentiate SCS from histiocytic sarcoma and other malignancies; however, reliability of current immunohistochemistry stains may be equivocal, owing to marked variation in proportions and differentiation of the cellular elements involved with the mesenchymal tissue adjacent to the synovial membrane.
- In cases of SCS, positive histochemical staining for cytokeratin (epithelial marker) and histologic grade may predict outcome and prognosis.

TREATMENT

TREATMENT OVERVIEW

Limb amputation is the mainstay of the treatment. If an en bloc excision or limb amputation is not an option, external beam radiation therapy can be considered with a curative or palliative intent.

ACUTE GENERAL TREATMENT

- Analgesic and nonsteroidal antiinflammatory drugs (NSAIDs) are often indicated for pain palliation.
- Limb amputation
- Local resection followed by radiotherapy to the tumor bed can be attempted if the animal is not a candidate for limb amputation. Efficacy of radiotherapy is not known.

CHRONIC TREATMENT

Efficacy of chemotherapy has not been determined for canine SCS. For dogs with high-grade tumors or dogs that present with overt metastasis, adjuvant chemotherapy with drugs such as doxorubicin, platinum agents, and ifosfamide may prove beneficial. Consultation with a medical oncologist is recommended.

RECOMMENDED MONITORING

Periodic evaluation for distant metastasis and local recurrence

PROGNOSIS AND OUTCOME

- Clinical outcome is excellent after limb amputation in cases with no gross detectable metastatic disease. A median survival of 28-36 months has been reported in dogs treated by means of limb amputation alone, with or without adjuvant chemotherapy.
- It may be possible to better determine the prognosis of dogs with SCS based on certain prognostic factors. Prognostic factors for survival of dogs with SCS treated with amputation include clinical stage (no metastases: >48 months; metastases: 3 months), histologic grade (grade I or II: 36 months; grade III: 7 months), and cytokeratin staining (negative: >48 months; positive: 4 months).

PEARLS & CONSIDERATIONS

COMMENTS

- Histopathologically, the majority of cases exhibit a biphasic pattern resembling both mesenchymal and epithelioid origins. Because of these features, pathologists may have to differentiate between a poorly differentiated carcinoma, histiocytic

sarcoma, and SCS.
- SCS is rarely diagnosed in cats. Among the nine reported cases of feline SCS, there have been six reports of malignant SCS and three reports of benign synovioma.

EDITOR: KENNETH M. RASSNICK

Syndrome of Inappropriate Antidiuretic Hormone Secretion

BASIC INFORMATION

DEFINITION

Disorder caused by release of antidiuretic hormone (ADH) in the absence of normal osmotic or nonosmotic stimuli

SYNONYMS

Secretion of inappropriate antidiuretic hormone; SIADH. Antidiuretic hormone: vasopressin

EPIDEMIOLOGY

SPECIES, AGE, SEX: Rare disease of the dog; no gender or age predilection

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Lethargy
- Inappetence
- Neurologic signs

PHYSICAL EXAM FINDINGS

- Weakness
- Tremors
- Seizures
- No evidence of peripheral edema or ascites

ETIOLOGY AND PATHOPHYSIOLOGY

- In this syndrome, ADH release occurs independent of normal stimuli secondary to central nervous system (CNS) disease or as an idiopathic occurrence.
- In dogs, the syndrome of inappropriate antidiuretic hormone secretion (SIADH) has been reported as an idiopathic phenomenon in two cases, secondary to a CNS disease in two cases (hypothalamic tumor, amebic meningoencephalitis), in a dog with heartworm disease, and in a dog with an undifferentiated carcinoma.
- In people, SIADH has been associated with pulmonary disease, cranial disease, malignant neoplasms, and drugs.
- Inappropriate ADH release results in increased water resorption at the renal collecting ducts, which leads to volume expansion and hyponatremia.
- Volume expansion leads to reduced proximal tubular sodium resorption and enhanced natriuresis.
- Neurologic signs secondary to cerebral edema occur as a consequence of volume expansion and hyponatremia.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

SIADH is rarely diagnosed but should be considered in patients with hyponatremia for which other differentials have been excluded via complete database (CBC/biochemistry profile/urinalysis), ACTH stimulation testing, thyroid testing, and clinical signs. Paired urine and plasma osmolality and urine and plasma sodium measurements are required for confirmation of diagnosis.

DIFFERENTIAL DIAGNOSIS

- Hyponatremia (see 1402):
  - Hypoadrenocorticism
  - Diabetes mellitus
  - Gastrointestinal (GI) sodium loss (vomiting, diarrhea)
  - Chronic congestive heart failure

- Psychogenic polydipsia
- Artifact (hyperlipidemia)
- Acute renal failure
- Severe liver disease
- Nephrotic syndrome
- Severe hypothyroidism with myxedema

INITIAL DATABASE

- CBC, serum biochemical profile, urinalysis: hyponatremia, normal renal parameters
- Thoracic radiographs: possible underlying pulmonary disease, such as primary or metastatic neoplasia
- Adrenocorticotropic hormone (ACTH) stimulation test: normal response
- Total thyroxine level (T4): normal or low. Further testing to exclude primary hypothyroidism may be required (see 1403).

ADVANCED OR CONFIRMATORY TESTING

- Plasma osmolality: decreased (<280-310 mOsm/kg)
- Urine osmolality: inappropriately increased (>100 mOsm/kg) in the face of plasma hypoosmolality and hyponatremia
- Urine sodium concentration: increased despite hyponatremia

TREATMENT

TREATMENT OVERVIEW

Therapy for SIADH centers on correction of hyponatremia and therapy of the underlying disease if identified.

ACUTE GENERAL TREATMENT

- Severe hyponatremia (<120 mEq/L; see 1402) should be corrected with IV fluid therapy using conventional crystalloid solutions (0.9% saline, lactated Ringer's solution) to raise serum sodium levels at a rate of less than 8-12 mEq/L/day.
- Hypertonic saline (3%-5%) should be used with caution, as it may raise the serum sodium concentrations too rapidly in cases of chronic hyponatremia.
- Administration of furosemide in conjunction with fluid therapy reduces the risk of extracellular fluid (ECF) volume expansion in already overhydrated patients.
- Once serum sodium concentrations have been corrected to >125 mEq/L, water intake may be restricted to a volume less than urine output to promote free water loss and restore normal body fluid volume.

CHRONIC TREATMENT

- Chronic management of SIADH is directed at treating the underlying cause.
- A selective ADH receptor antagonist, OPC-31260 (Otsuka Pharmaceutical, Tokyo), has been reported to palliate signs in a dog with SIADH over a 3-year treatment period (3 mg/kg PO q 12 h).
- Other antidiuretic hormone receptor antagonists (e.g., tolvaptan, conivaptan) are available for human patients, but their use in dogs with clinical hyponatremia remains poorly described (novel treatment).

POSSIBLE COMPLICATIONS

- Rapid correction of chronic hyponatremia can result in osmotic demyelination syndrome due to brain dehydration as free water moves out of the brain and into the relatively hypertonic serum (see 1402).
- Clinical signs of osmotic demyelination syndrome occur 3-4 days after rapid correction of hyponatremia, are neurologic in nature (lethargy, ataxia, hypermetria, paresis), and may be fatal.

RECOMMENDED MONITORING

Serial (q 4 h) monitoring of serum sodium concentration during acute correction phase and periodic monitoring during chronic management

PROGNOSIS AND OUTCOME

Prognosis is dependent on the underlying cause of SIADH.

PEARLS & CONSIDERATIONS

COMMENTS

- ADH release may be stimulated by various drugs used during anesthesia (barbiturates, narcotics) and can result in impaired free water excretion and hyponatremia in the postoperative period, similar to what is seen in animals with SIADH. Restriction of water intake is generally sufficient to restore normal water balance in these animals.
- During treatment, never increase serum sodium concentration by more than 0.5 mEq/L/h (risk of osmotic demyelination syndrome and life-threatening cerebral complications).

AUTHOR: SARAH L. NAIDOO

EDITOR: SHERRI IHLE

Syncope

BASIC INFORMATION

DEFINITION

A sudden and transient loss of consciousness resulting in collapse, followed by spontaneous recovery. The cause is a transient cerebral deficiency of oxygen.

SYNONYMS

Faint, collapse

Neurocardiogenic syncope: vasovagal syncope

Tussive syncope: “cough-drop” phenomenon

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dependent on underlying cause: cardiac versus noncardiac causes. Acquired heart disease: middle-aged to older animals; congenital heart disease: young animals.

GENETICS & BREED PREDISPOSITION

- Tussive syncope (older small-breed dogs with pulmonary disease)
- Neurocardiogenic syncope (boxer, golden retrievers, brachycephalic breeds?)
- According to underlying heart disease (many breed predilections)

RISK FACTORS

- Autonomic dysfunction (neurocardiogenic syncope)
- Drugs: -blockers, diuretics, vasodilators (hypotensive syncope)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Acute collapse, with altered or loss of consciousness
- Either no clinical signs or staggering or ataxia prior to the event
- Exercise, excitement, or coughing may precipitate the event.
- ± Clonic movements
- ± Involuntary urination or defecation
- No postictal phase
- Duration: seconds (and virtually always < 1 minute; otherwise, likely to be fatal)
- Recovery: complete and rapid

PHYSICAL EXAM FINDINGS: Dependent on underlying disorder(s):

- Cardiac:
  - ± Murmur
  - ± Arrhythmia
  - ± Altered arterial pulse quality
  - ± Pulse deficits
  - ± Cyanotic mucous membranes
  - ± Pulmonary rales or crackles
- Neurologic exam (see p. 1311):
  - ± Cranial nerve abnormalities
  - ± Altered reflexes
  - ± Proprioceptive deficits
  - ± Altered mentation
- Upper airway exam:

- ± Brachycephalic syndrome (i.e., stenotic nares, hypoplastic trachea, everted laryngeal saccules, elongated soft palate)

ETIOLOGY AND PATHOPHYSIOLOGY

- Cardiac:
  - *Bradyarrhythmias:* syncope can result when there is a >6-8 second pause in electrical activity (i.e., failure of subsidiary pacemaker in third-degree atrioventricular [AV] block, sinus arrest associated with sick sinus syndrome [SSS]).
  - *Tachyarrhythmias:* rates > 300 bpm for >6 seconds (i.e., supraventricular tachycardia [SVT] or ventricular tachycardia) in dogs; cats uncommonly experience syncope with tachyanhythmias but more so with bradycardias. Heart rate and time necessary for syncope may vary depending on underlying cardiac structure (i.e., a slower heart rate for a shorter duration may cause syncope in an animal with underlying myocardial or valvular heart disease). Various outcomes: nonsustained tachyarrhythmia results in a return to sinus rhythm; overdrive suppression leads to sinus arrest or possibly ventricular fibrillation.
  - *Outflow obstruction* (i.e., pulmonic stenosis, subaortic stenosis, cor pulmonale due to heartworm disease with secondary pulmonary hypertension):
    - Classic theory: exercise results in vasodilation of systemic arterioles. Fixed obstruction to flow results in inadequate increase in cardiac output, leading to hypotension and syncope.
    - Alternate theory: contractility, cardiac output, and flow increase through stenosis during exercise. Increased left ventricular systolic pressure causes overstimulation of left ventricular mechanoreceptors. Reflex activation of cardiac afferent vagal fibers results in increased parasympathetic tone to heart and systemic blood vessels, resulting in bradycardia, vasodilation, and subsequent syncope.
  - *Cyanotic heart disease:* (i.e., right-to-left patent ductus arteriosus, tetralogy of Fallot): syncope is due to hypoxemia and/or hyperviscosity of blood from polycythemia, or else is from arrhythmias.
  - *Masses obstructing inflow or outflow of blood (rare):* intracardiac mass lesions reduce cardiac output by restricting blood flow through atrioventricular valves or obstructing a ventricular outflow tract. Pericardial disease compromises cardiac output by interfering with systemic venous return (i.e., cardiac tamponade).
  - *Congestive heart failure:* syncope mechanism presumed to be similar to autonomic dysfunction (see below).
- Noncardiac:
  - *Neurologic syncope:* increased intracranial pressure with resultant decrease in cerebral perfusion (i.e., cerebral edema, brain tumors, meningitis, encephalitis, cerebral vascular obstructions, acute bleed). Syncope occurs very rarely, in contrast to seizures, with these diseases.
  - *Metabolic syncope:* abrupt decrease in oxygen or nutrient delivery (i.e., glucose) to the brain (oxygen concentration is affected by blood flow, hemoglobin concentration, and oxygen tension). Seizures > syncope.
  - *Tussive syncope:* proposed mechanisms:
    - Increased intrathoracic pressure transiently increases intracranial pressure and diminishes cardiac venous return and resultant cardiac output; cerebral blood flow is decreased during paroxysms of coughing.
    - Coughing stimulates vagal afferent transmission to the vasomotor center in the medulla, with subsequent stimulation of vagal efferente to the heart and blood vessels (bradycardia, hypotension).
  - *Autonomic dysfunction:* excessive baroreflex resulting in cardiac inhibition and/or peripheral vasodilation (i.e., neurocardiogenic syncope, carotid sinus sensitivity, carotid body tumor).
  - *Peripheral vasomotor dysfunction:* abnormality of peripheral vasoconstriction, muscle tone, heart rate, and/or respiration, resulting in syncope (postural hypotension).
  - *Undetermined:* ~40% of human syncope cases despite extensive testing; likely similar percentage in veterinary medicine

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

Diagnosis is largely based on patient signalment; historical events prior to, during, and after the episode; and complete cardiovascular and neurologic exams. Since the episode often is not witnessed directly by the veterinarian (to confirm or refute syncope), a simple test is video recording by the owner when an event occurs at home. Confirmatory testing may involve ambulatory electrocardiogram (ECG) monitoring and/or central nervous system (CNS) imaging depending on the suspected cause. Consider consultation with and/or referral to a veterinary cardiologist +/− veterinary neurologist.

DIFFERENTIAL DIAGNOSIS

- Primary cardiac disease (see above)
- Hypotension (inadequate cardiac output, poor vascular tone)
- Hypoxemia (pulmonary thromboembolism, pulmonary disease, right-to-left shunt)

- Abnormal blood or metabolic constituents (hypoglycemia, hypokalemia, anemia)
- Neoplasia (splenic hemangiosarcoma)
- Neurologic and neuromuscular disorders (epilepsy, structural central nervous system disorders, narcolepsy, myasthenia gravis)

INITIAL DATABASE

- CBC: ± anemia, thrombocytopenia
- Serum biochemistry panel: ± electrolyte abnormalities, ± metabolic derangements
- Urinalysis: ± proteinuria with AT III loss and subsequent hypercoagulable state (thromboembolism)
- Blood pressure: normal result does not rule out transient hypotension
- ± Heartworm antigen test
- ± Heartworm microfilaria test
- Thoracic radiographs: ± evidence of structural heart disease, ± pulmonary parenchymal abnormalities (i.e., pulmonary artery abnormalities with heartworm disease, cardiogenic pulmonary edema)
- Echocardiogram: ± congenital or acquired heart disease
- Resting ECG: ± rhythm abnormalities
- Neurologic exam (see p. 1311): ± neurologic deficits

ADVANCED OR CONFIRMATORY TESTING

- Videotaping: episodes that are not convincingly syncopal based on history alone (a common problem) and do not occur in the veterinary facility may be evaluated objectively by having the owner videotape them at home.
- Holter monitor (see p. 1287): 24-hour ECG; helpful in establishing a diagnosis 42% of the time
- Cardiac event recorder: digital loop recorder that is patient or owner activated, programmed to capture the heart rate and rhythm prior to and after the syncopal episode(s); diagnostic yield 85%
- Abdominal ultrasound: may be helpful in identification of mass(es)
- CT/MRI/cerebrospinal fluid tap: neurologic disease. see pp. 1233, 1302, and 1228.

TREATMENT

TREATMENT OVERVIEW

Treatment involves addressing the primary etiology in order to alleviate syncopal episodes and prevent sudden death.

ACUTE GENERAL TREATMENT

Acute treatment is aimed at the underlying cause or at stabilization procedures:

- Blood loss: fluids, blood products, etc.
- Pericardial effusion with cardiac tamponade: pericardiocentesis
- Continuous ECG
- *Bradyarrhythmias*
  - SSS, third-degree AV block: medical management may be effective if arrhythmia is due to excessive vagal tone and atropine responsive (i.e., anticholinergics [propantheline] and -agonists [terbutaline]; see individual diseases for specific treatment recommendations). Temporary pacemaker if bradyarrhythmia is refractory to medical management and animal is showing persistent clinical signs.
- *Tachyarrhythmias:*
  - Ventricular tachycardia: oral or intravenous medical management depending on malignancy of the arrhythmia (i.e., oral options: mexiletine, sotalol, amiodarone, atenolol; intravenous options: lidocaine, procainamide, esmolol); see p. 1165. Cautious use of or avoid -blockers in cases with systolic dysfunction/dilated cardiomyopathy.

CHRONIC TREATMENT

- Treatment of underlying cause if systemic disorder
- Bradyarrhythmias:
  - Medically refractory SSS, high-grade second-degree AV block, third-degree AV block: permanent pacemaker
- Tachyarrhythmias: see p. 1165
- Severe outflow obstructions:
  - Limit exertion in all cases.
  - Subaortic stenosis (SAS; see p. 1057): -blockers if severe
  - Pulmonic stenosis (see p. 941): -blockers if severe

    - Hypertrophic obstructive cardiomyopathy (see p. 565): β-blocker, calcium channel blocker
    - Heartworm disease with secondary pulmonary hypertension (see pp. 474 and)
- Cyanotic heart disease-induced polycythemia: phlebotomy, or hydroxyurea 50 mg/kg PO q 48-72 h, adjusted based on response
- Congestive heart failure (see p. 470)
- Neurologic syncope: treatment of underlying cause
- Metabolic syncope: treatment of underlying cause
- Tussive syncope: cough suppressant (e.g., butorphanol, 0.1-0.5 mg/kg PO q 8-12 h), bronchodilator (aminophylline, 10 mg/kg PO q 8 h), treatment with diuretics (e.g., furosemide, 2 mg/ kg IV, SQ) if pulmonary edema is present
- Autonomic dysfunction: anticholinergics (e.g., propantheline bromide, 0.5-1 mg/kg PO q 8 h if bradycardia related), -blocker (e.g., atenolol, 0.25-1 mg/kg PO q 12 h if tachycardia related). Treatment modalities are aimed at maintaining heart rate and/or preventing sympathetic surge. Medical management fails to address hypotensive component of reflex arc, and animals may continue to faint, potentially requiring a pacemaker.

BEHAVIOR/EXERCISE

- Limit exertion/excitement in severe outflow obstructions, cyanotic heart disease, impending/decompensated left congestive heart failure, ventricular arrhythmias, and neurocardiogenic syncope.

DRUG INTERACTIONS

β-Blockers, diuretics, and vasodilators can exacerbate hypotension.

POSSIBLE COMPLICATIONS

Sudden death

RECOMMENDED MONITORING

Serial evaluations as needed to acquire initial database and confirmatory testing

PROGNOSIS AND OUTCOME

- Highly dependent on underlying etiology
- Excellent for bradyarrhythmias treated with pacemaker implantation
- Fair to good with supraventricular tachycardia responsive to medical therapy
- Guarded with ventricular tachycardia treated medically; poor if systolic dysfunction/dilated cardiomyopathy present
- Variable prognosis with outflow obstructions (i.e., severe SAS has a poor long-term prognosis).
- Good with tussive syncope treated medically if cough responds well to therapy
- Good prognosis with autonomic dysfunction. Treatment is usually unrewarding. Fortunately, sudden death is not common.
- Poor prognosis: neoplasia

PEARLS & CONSIDERATIONS

COMMENTS

- Syncopal episodes may be difficult to differentiate from seizures. Video-recording and ECG event monitoring (see p. 1287) are simple, noninvasive tests that greatly help differentiate between the two.
- Syncope, while uncommon in cats, occasionally occurs with hypertrophic obstructive cardiomyopathy and with bradyarrhythmias (e.g., third-degree AV block).
- In SSS, bradyarrhythmias (e.g., sinus arrest) typically cause syncopal episodes warranting pacemaker therapy prior to addressing tachyarrhythmias (e.g., SVT; see p. 111).
- In 40% of human cases, an etiology is never identified; similar percentages are suspected in veterinary medicine.

PREVENTION

- Tussive syncope: cough suppressant, bronchodilator, treatment with diuretics if pulmonary edema is present
- Autonomic dysfunction: anticholinergics, β-blocker

TECHNICIAN TIPS

- In-house ECG telemetry is useful for identifying bradyarrhythmias and tachyarrhythmias.
- “Seizure bells” can be placed on hospitalized patients presenting for syncope to help alert the staff when an animal has an episode.

CLIENT EDUCATION

- Treatment and prognosis are dependent on the underlying etiology.
- Sudden death is possible but is dependent on the underlying etiology.

Supraspinatus/Infraspinatus Tendon Disorders

BASIC INFORMATION

DEFINITION

Disorders of the extraarticular tendons in the shoulder area of dogs, often representing degenerative changes bilaterally

SYNONYMS

- Supraspinatus mineralization: calcification of supraspinatus tendon
- Supraspinatus tendinosis: nonmineralized tendinopathy, chronic tendinopathy, chronic tendon injury, chronic tendinitis, biceps tendon impingement, tendon enlargement

EPIDEMIOLOGY

SPECIES, AGE, SEX: Medium to large-breed adult dogs of both genders

GENETICS & BREED PREDISPOSITION: Supraspinatus tendon disorders have been associated with Labrador retrievers and rottweilers. Infraspinatus contracture is classically seen in hunting or working dogs. Ossification of infraspinatus tendon-bursa has only been described in Labrador retrievers.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Supraspinatus mineralization and tendinosis represent degenerative disorders and are likely related. Infraspinatus muscle contracture may be of traumatic origin. Ossification of the infraspinatus tendon-bursa is a recently described disorder of unknown origin.

HISTORY, CHIEF COMPLAINT: Supraspinatus mineralization and tendinosis, and infraspinatus tendon-bursa ossification lead to intermittent or waxing-waning weight-bearing unilateral front limb lameness with gradual onset. Infraspinatus contracture is associated with acute onset of lameness, resolving initially but leading to a subsequent chronic lameness, with characteristic stance and gait abnormalities.

PHYSICAL EXAM FINDINGS

- All disorders may be associated with disuse atrophy of spinatus muscles.
- Dogs with supraspinatus mineralization or tendinosis tend to show signs of pain on shoulder flexion. They may or may not show signs of pain on digital palpation of the supraspinatus tendon. Signs of pain are elicited by palpation of the bicipital tendon in some cases.
- Dogs with infraspinatus contracture, in the acute stage, may show tenderness/pain during muscle palpation. In the chronic stage, this disorder leads to a stance with the elbow adducted and the foot abducted. During the stride, the distal limb circumducts in a lateral arc. There is atrophy of the infraspinatus muscle, and the limb is permanently supinated. In lateral recumbency with the affected side up, the dog may be unable to rest the distal limb on the floor/table. Pain is usually not evident in the chronic stage.
- Infraspinatus tendon-bursa ossification is associated with pain on direct digital pressure over the tendon insertion in half of affected individuals.

ETIOLOGY AND PATHOPHYSIOLOGY

- Supraspinatus mineralization and tendinosis are probably overuse syndromes and are localized in the avascular zone of the tendon, an area predisposed to poor healing. These two conditions have very similar histopathologic features and may both represent chronic tendon injury.
- Supraspinatus disorders lead to swelling and increased mass of the tendon insertion, which may cause pressure and impingement/displacement of the underlying bicipital tendon.
- Infraspinatus contracture may be a result of traumatic incomplete rupture of the muscle, which becomes replaced with fibrotic tissue.
- Ossification of the infraspinatus tendon of insertion may coincide with ossification (osteochondromatosis) of the bursa, or each condition can occur alone. A degenerative cause is suspected.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

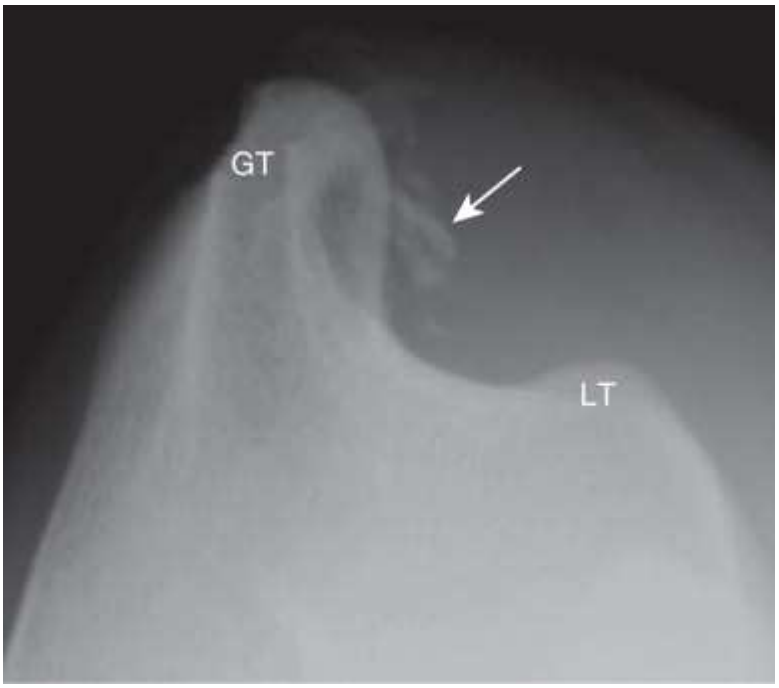
Infraspinatus contracture in the chronic stage may be diagnosed with physical examination. Supraspinatus mineralization and ossification of infraspinatus tendon-bursa require radiographic examination. Supraspinatus tendinosis is not evident on radiographic examination and requires advanced imaging. Supraspinatus mineralization and ossification of the infraspinatus tendon-bursa may be coincidental, and other reasons for lameness must be ruled out before pursuing treatment.

DIFFERENTIAL DIAGNOSIS

- Bicipital tenosynovitis, with or without tendon mineralization
- Osteoarthritis of the glenohumeral joint
- Shoulder instability/luxation
- Elbow dysplasia
- Osteosarcoma of the proximal humerus
- Nerve sheath tumor (especially prior to onset of neurologic dysfunction)

INITIAL DATABASE

- Orthopedic and neurologic evaluations
- Radiography of the scapulohumeral joint; lateral, craniocaudal, and cranioproximal-craniodistal views—the latter for supraspinatus/biceps tendon imaging. Supraspinatus mineralization is located craniomedial to the greater tubercle but not centered within the intertubercular groove.
- CBC, serum biochemistry panel, urinalysis: in older dogs



SUPRASPINATUS/INFRASPINATUS TENDON DISORDERS Radiographic skyline view. Supraspinatus mineralization is evident medial to the greater tubercle *(arrow). GT,* Greater tubercle; *LT,* lesser tubercle.

ADVANCED OR CONFIRMATORY TESTING

- Localization of pain involves applying digital pressure to the insertion of the supraspinatus tendon (craniomedial greater tubercle of humerus), the bicipital tendon (intertubercular groove), and infraspinatus tendon of insertion (lateral and distal to greater tubercle). Note that these disorders inconsistently result in pain on direct palpation of the structures.
- MRI of the shoulder joint is an excellent imaging modality in these disorders and many of their differential diagnoses.
- Ultrasonographic examination of the cranial shoulder area may identify the increased tendon mass of supraspinatus, tendinosis, mineralization/ossification of supra- or infraspinatus tendons, and may identify differential or coinciding diagnoses such as bicipital tenosynovitis.
- Arthroscopic examination of the shoulder joint further identifies differential or coinciding disorders.

TREATMENT

TREATMENT OVERVIEW

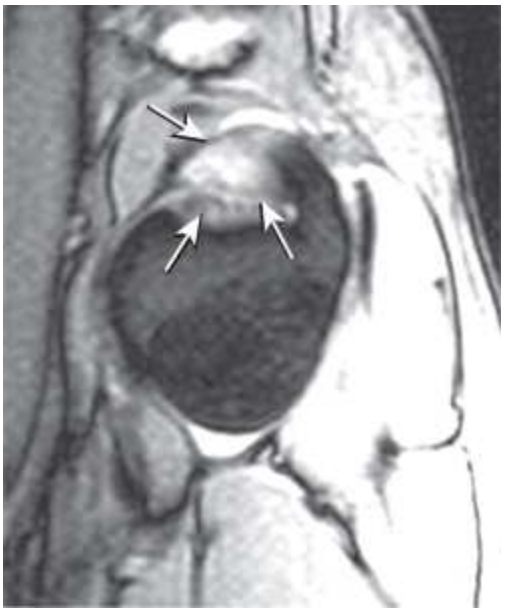
Surgical treatment is usually indicated if lameness is refractory to rest and antiinflammatory medication. With infraspinatus contracture, the goal is return to full function of the affected limb.

ACUTE GENERAL TREATMENT

- Supraspinatus tendinopathies usually do not respond to nonsteroidal antiinflammatory drug (NSAID) treatment, and corticosteroid injections are likely contraindicated.
- Extracorporeal shockwave therapy has led to improvement in a few dogs with supraspinatus mineralization.
- If acute infraspinatus trauma is suspected, early fasciotomy may be indicated to decompress the muscle and avoid compartment syndrome. However, the acute phase is often not identified, owing to the spontaneous recovery of the initial lameness.
- Seven of 13 dogs with ossification of the infraspinatus tendon-bursa improved after injection of long-acting corticosteroid (methylprednisolone acetate, 20 mg/mL, 1-2 mL IA once or twice, 3 weeks apart) into the glenohumeral joint, or NSAID treatment. One case improved after 4 months of restricted activity only. Medical management should be attempted prior to considering surgery.

CHRONIC TREATMENT

- Surgery for supraspinatus mineralization entails longitudinal tendon incisions to evacuate the mineralized deposits. Surgery for supraspinatus tendinosis has only been reported in a few cases, but good to excellent results have been achieved by resection of the mass in the tendon insertion and thus decompression of the bicipital tendon. Arthroscopic examination of the shoulder joint in the same session is usually indicated to rule out other intraarticular coinciding or differential disorders.
- Degenerative tendon disorders in people may be treated with rest alone for 6 months or more, and some human studies show similar outcomes of long-term rest as in surgically treated cases.
- Infraspinatus contracture treatment consists of tenotomy and excision of the tendon insertion. Immediate ability to pronate the limb is achieved. Leash walks are performed immediately postoperatively, and normal activity is resumed 10-14 days after infraspinatus tenotomy.
- Ossification of infraspinatus tendon-bursa in cases refractory to medical management have been treated by excision of ossified masses, leading to improvement in 4/6 cases.



SUPRASPINATUS/INFRASPINATUS TENDON DISORDERS Transverse magnetic resonance mage (MRI) through proximal humerus in a dog with supraspinatus tendinosis. An increased mass of high signal intensity is located within the insertion of the supraspinatus tendon, craniomedially on the greater tubercle *(arrowheads).* Biceps tendon is visible medially in intertubercular groove *(arrow).*

NUTRITION/DIET

Dietary management to prevent or treat obesity is likely beneficial for long-term management.

BEHAVIOR/EXERCISE

- Exercise is restricted for 2-4 weeks after supraspinatus surgery. Physical therapy with passive range-of-motion exercises and walking are recommended as soon as possible after surgery. However, swimming may not be indicated, as it has been suggested to put increased strain on the supraspinatus tendon. Swimming or other vigorous exercise should be avoided until 8-12 weeks after supraspinatus surgery.
- Supraspinatus disorders may be caused by overuse. Excessive high-impact activities may have to be discontinued. Jumping and digging have been proposed to result in increased supraspinatus strain.
- After supraspinatus healing is complete, consistent daily low-impact physical activity (walking, swimming, running on soft surfaces) is recommended.
- Surgical treatment for infraspinatus contracture usually returns the dog to full function.

POSSIBLE COMPLICATIONS

- Seroma
- Infection
- Unresolving lameness, reflecting a degenerative process such as mineralization, may be an incidental finding.

PROGNOSIS AND OUTCOME

- Dogs with supraspinatus mineralization have shown good to excellent outcome (mild intermittent lameness to normal function) in 80%–90% of operated cases and in all of 3 cases treated conservatively (rest and NSAIDs). Extracorporeal Shockwave therapy resolved lameness in 2 dogs reexamined at 20 and 49 days, respectively.
- Surgical treatment of supraspinatus tendinosis has shown good to excellent outcome in 7/8 cases.
- Surgical treatment of infraspinatus contracture usually leads to en excellent outcome.
- Though 12/13 dogs with ossification of infraspinatus tendon-bursa improved with medical and/or surgical treatment, the majority continued to show a mild lameness.

PEARLS & CONSIDERATIONS

COMMENTS

- Supraspinatus mineralization and tendinosis may lead to increased pressure on the bicipital tendon and have been associated with bicipital tenosynovitis.
- Deeply positioned supraspinatus mineralizations may be more prone to cause clinical signs than superficial ones because of increased interference with the biceps tendon.
- None of the tendon disorders have an inflammatory background, and antiinflammatory treatment with corticosteroids is dubious and potentially harmful. However, clinical response has been noted with glenohumeral joint injection of corticosteroids in ossification of infraspinatus tendon-bursa.
- Never inject corticosteroids into a joint if the synovial fluid is discolored, cloudy, or has decreased viscosity. Do not inject corticosteroids into a tendon, because it severely impairs tendon healing.
- Long-term rest alone (>6 months) and other physical therapy modalities such as eccentric loading may be effective treatments for degenerative tendinopathy but have not been evaluated in veterinary medicine.

EDITOR: JOSEPH HARARI

Superficial Necrolytic Dermatitis

BASIC INFORMATION

DEFINITION

A progressively debilitating skin disease associated with a severe internal disease process

SYNONYMS

Hepatocutaneous syndrome, glucagonoma syndrome, metabolic epidermal necrosis, necrolytic migratory erythema, diabetic dermatopathy

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Uncommon in dogs, rare in cats
- Middle-aged to geriatric patients; no sex predilection

GENETICS & BREED PREDISPOSITION: Cocker spaniel, Shetland sheepdog, West Highland white terrier, and Scottish temer

RISK FACTORS: Administration of phenobarbital. Ingestion of mycotoxin.

ASSOCIATED CONDITIONS & DISORDERS: Most cases have been associated with hepatopathy, which explains the former name, *hepatocutaneous syndrome.* A few cases have been associated with a functional pancreatic α-cell glucagon secreting tumor (also known as glucagonoma syndrome). Other associated conditions in dogs include cirrhosing or fibrosing hepatopathy (see p. 212), idiopathic vacuolar hepatopathy (see p. 1153), diabetes mellitus (see p. 1547), extrapancreatic glucagonoma (liver, spleen, adrenal glands and mesenteric lymph nodes), copper storage disease, hyperglucagonemia. Associated diseases in cats include pancreatic carcinoma, hepatopathies, and thymic amyloidosis.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Owners usually observe footpad lesions first, as dermatologie changes may precede onset of clinical signs of internal disease. Lethargy, anorexia, weight loss, lameness, reluctance to walk/signs of pedal pain, and pruritus are frequently reported. Other chief complaints may include polyuria and polydipsia. Dermatitis may wax and wane.

PHYSICAL EXAM FINDINGS: Dermatologie lesions are characterized by thickening, Assuring, and crusting of footpads, and interdigital erythema. Crusts, erosions, and ulcers can affect pinnae, mucocutaneous junctions (oral cavity, eyes, anus and genitalia), elbows and other pressure points, ventral abdominal and inguinal regions. Regional lymphadenopathy and hyperthermia are possible.

ETIOLOGY AND PATHOPHYSIOLOGY

A proposed mechanism: glucagonemia-induced glycogenesis from amino acids or increased hepatic catabolism of amino acids results in low plasma amino acid concentration and epidermal cellular starvation (i.e., keratinocyte degeneration, necrosis, and epidermal edema). Deficiencies of essential fatty acids, zinc, and biotin and hypoalbuminemia may also be involved.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of SND is initially suspected on physical exam of the skin (especially footpads), hepatic ultrasonographic findings, or a combination of both. No single test result is pathognomonic for SND; a conclusive clinical diagnosis is reached with histopathologic analysis of skin biopsies and hepatic ultrasonographic findings, and is further solidified if a commonly associated disorder (see above) is present. If serum levels of liver enzymes/bile acids are normal, and the liver does not show the typical ultrasonographic pattern but typical dermatohistopathologic findings are present, consider glucagonoma as the primary cause.

DIFFERENTIAL DIAGNOSIS

- Autoimmune/immune mediated causes: pemphigus foliaceus, drug-induced pemphigus, systemic lupus erythematosus, paraneoplastic pemphigus, cutaneous vasculitis, erythema multiforme, toxic epidermal necrolysis
- Infectious causes: bacterial (pyoderma), fungal (dermatophytosis, *Malassezia* dermatitis), protozoal (leishmaniasis)
- Parasitic causes: demodicosis
- Nutritional causes: zinc-responsive dermatosis
- Neoplastic causes: epitheliotropic lymphoma
- Idiopathic: nasodigital hyperkeratosis

INITIAL DATABASE

- The minimal dermatologic database includes deep skin scrapings (typically negative, although secondary demodicosis may occur), cytologic evaluation of the skin (patients often have a bacterial or *Malassezia* overgrowth) +/− dermatophyte culture (typically negative).
- The minimal clinicopathologic database includes a CBC (nonregenerative anemia, leukocytosis are possible), serum biochemistry profile (elevated alkaline phosphatase, alanine aminotransferase, serum glucose and fructosamine levels; hypoalbuminemia; decreased blood urea nitrogen) and urinalysis (glucosuria).

ADVANCED OR CONFIRMATORY TESTING

- Abdominal ultrasonography:
  - Ultrasonographic hepatic findings are characterized by hypoechoic nodules with a hyperechoic trabecular network throughout the liver, resulting in a “honeycomb” or “Swiss cheese” pattern of the hepatic parenchyma. Occasionally hepatic metastases are detected. Ultrasonographic detection of pancreatic and extrapancreatic glucagonomas can be difficult.
- Histopathology and immunohistochemistry:
  - Skin biopsy: epidermis has a “French or Dutch flag” (i.e., red-white-blue layers) appearance:
    - Upper layer (stratum corneum): parakeratotic hyperkeratosis staining red (eosinophilic); crusts
    - Middle layer (stratum spinosum): intracellular edema, vacuolation, and necrosis of the keratinocytes staining white (pallor)
    - Deep layer (stratum basale): hyperplasia staining blue (basophilic)
- Ultrasound-guided hepatic biopsy (first perform platelet count, arterial blood pressure, and coagulation panel to assess bleeding risk). Hepatic neoplasia or idiopathic vacuolar hepatopathy (characterized by nodular hyperplasia and hepatocyte vacuolar degeneration adjacent to areas of parenchymal collapse). Immunohistochemistry can demonstrate antiglucagon antibody-positive neoplastic cells on samples obtained from pancreas, liver, spleen, adrenal glands, and mesenteric lymph nodes by ultrasound-guided biopsy, exploratory laparotomy, or postmortem.
- Other assays:
  - Fasting and postprandial bile acid values are frequently elevated (nonspecific).
  - Complete plasma amino acids (hypoaminoacidemia supportive of diagnosis of SND) testing is available at Amino Acid Analysis Laboratory Service (University of California, Davis). Contact laboratory for sample handling and cost (www.vetmed.ucdavis.edu/vmb/aal/aal.html).
  - Because of their lack of specificity, usefulness of plasma glucagon (hyperglucagonemia) and serum insulin (hyperinsulinemia) testing is limited.

TREATMENT

TREATMENT OVERVIEW

Treatment consists of a threefold approach: supportive therapy for the dermatologic manifestations, management of internal disease process (which may require hospitalization), and surgical removal of neoplasm whenever possible.

ACUTE GENERAL TREATMENT

- Pain management
- Treat secondary bacterial and fungal infections with appropriate therapy (avoid systemic azole antifungal therapy because of potential hepatotoxicosis).
- Gentle shampoo therapy

CHRONIC TREATMENT

- Slow intravenous amino acid infusions: 25 mL/kg over 6-8 hours. Repeat every 7-14 days based on response. Some dermatologists recommend 3 treatments the first week, followed by once or twice weekly thereafter. Most patients will demonstrate clinical improvement within 5-10 days.

    - 10% crystalline amino acid crystalline solution (Aminosyn [Abbott Laboratories]) is product of choice. Because of the high osmolality of this solution, a central (jugular) venous catheter is recommended to reduce risk of thrombophlebitis.
    - 3% amino-acid and electrolyte solution (ProcalAmine [B. Braun]) is an alternative product. Lower cost and lesser hypertonicity (can therefore be injected in peripheral veins).
- Insulin therapy if indicated
- Somatostatin analog, octreotide (inhibits glucagon release), 2 mcg/kg SQ q 12 h, can improve skin lesions and systemic signs in patients with nonresectable or relapsing glucagonoma-associated disease. Anorexia is a likely side effect.

NUTRITION/DIET

- High-quality, high-protein diet. Adding 3-6 entire hard-boiled eggs or egg whites per day to the diet may be beneficial.
- Vitamin E supplementation, 400 IU q 12 h PO
- Oral essential fatty acid and zinc methionine supplementation (Zinpro), 1.5 mg/kg q 24 h PO
- Oral nutraceutical *S*-adenosylmethionine, 18-22 mg/kg PO q 24 h (SAMe, Denosyl SD-4, Zentonil, S-Adenosyl) can attenuate liver damage.

DRUG INTERACTIONS

Using antiinflammatory doses of oral glucocorticosteroids is controversial. It may give temporary relief, but diabetes and deterioration of the liver are possible complications.

POSSIBLE COMPLICATIONS

- Discomfort experienced while walking may become sufficiently severe to constitute a reason for euthanasia.
- Monitor for signs of encephalopathy (slow down infusion rate if indicated) when using intravenous amino acid infusions.
- Postsurgical pancreatitis and biliary obstruction may occur.

PROGNOSIS AND OUTCOME

- SND in dogs: guarded to poor, even in dogs with a history of phenobarbital administration, and despite drug discontinuation.
- Glucagonoma syndrome in dogs: good. Surgical excision of pancreatic tumor may result in remission.
- SND in cats: poor

PEARLS & CONSIDERATIONS

TECHNICIAN TIP

The pododermatitis associated with SND may be extremely painful. Use care and a gentle approach when walking dogs suspected or confirmed of having SND (may be reluctant to walk owing to intense foot pain; do not misinterpret this as “stubbornness”).

Subinvolution of Placental Sites

Additional Images Available on Website

BASIC INFORMATION

DEFINITION

Delay of the normal uterine involution process in the bitch beyond 12 weeks after whelping, manifesting as persistent bloody vaginal/vulvar discharge in a dog that is otherwise well

SYNONYMS

SIPS, metrorrhagia (uterine bleeding) postpartum, placentitis postpartum

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Not often observed clinically; however, histopathologic prevalence is 8%–21%.
- Young bitches < 3 years old; no effect of litter size

RISK FACTORS: Low parity (especially in first pregnancy/litter)

ASSOCIATED CONDITIONS & DISORDERS: Anemia, postpartum metritis, and uterine rupture could occur as a result of subinvolution of placental sites but are very rare sequelae.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of recent whelping
- Likely primiparous bitch (first litter)
- Hemorrhagic vaginal/vulvar discharge persistent even after pups are weaned
- Persistent postparturient serosanguineous vaginal/vulvar discharge
- Bitch is otherwise in good health.

PHYSICAL EXAM FINDINGS

- Discharge is red rather than normal brown lochia.
- Slight pallor of mucous membranes if discharge is copious
- Abdominal palpation: discrete uterine swellings of various sizes often felt on palpation
- Physical exam generally reveals an otherwise healthy animal.

ETIOLOGY AND PATHOPHYSIOLOGY

- Normally, expulsion of the fetal membranes and lochia takes place in the immediate postpartum period, and a mild serosanguineous discharge may last 3-5 weeks after parturition.
- With SIPS, the endometrium and myometrium are invaded by placental cells (trophoblasts).
- Failure of these cells to regress prevents normal involution, which then results in chronic hemorrhagic vaginal/vulvar discharge in a bitch that usually has no other clinical signs. Severe metrorrhagia is rare in absence of coagulopathy or uterine laceration.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is often presumptive (history and physical exam). Typically primiparous younger bitches with a range of hemorrhagic vaginal discharge: from a few drops of blood passing from the vulva for several weeks postpartum that usually subside without therapy, to acute life-threatening metrorrhagia requiring transfusion.

DIFFERENTIAL DIAGNOSIS

- Proestrus
- Metritis
- Cystic endometrial hyperplasia/pyometra
- Vaginitis
- Vulvar, vaginal, or uterine tumor
- Urinary tract hemorrhage (e.g., bacterial cystitis, calculi)
- Coagulopathy
- Brucellosis
- Trauma

INITIAL DATABASE

- CBC: unremarkable. Note: mild normocytic, normochromic anemia is normal in postpartum bitches.
- Serum biochemistry profile: unremarkable
- Vaginal cytologic examination showing trophoblasts

ADVANCED OR CONFIRMATORY TESTING

- Definitive diagnosis: histologic examination based on biopsy specimen of placental sites (rarely done)
- Vaginoscopy (see p. 1361): to distinguish vaginal bleeding from blood derived from the uterus
- Abdominal ultrasound: focal thickenings of the uterine wall and a fluid-distended lumen; color Doppler velocity measurements of blood flow differentiates SIPS from normally involuting uteruses.
- Abdominal radiographs: focal areas of uterine irregularity

SUBINVOLUTION OF PLACENTAL SITES Vaginoscopic view of the cranial vagina from a bitch with subinvolution of placental sites (SIPS), showing bloody discharge originating from the uterus.

(Courtesy Auke C. Schaefers-Okkens.)

TREATMENT

TREATMENT OVERVIEW

Often, spontaneous remission occurs without the need for medical or surgical intervention. Ovariohysterectomy (OHE) is required in

acute cases with severe metrorrhagia.

ACUTE GENERAL TREATMENT

- Observation (benign neglect):
  - Erosion through the uterine wall resulting in peritonitis is possible but rare.
  - In most cases, SIPS resolves spontaneously.
- OHE indicated if:
  - Bitch is not intended for future breeding.
  - Hemorrhage is severe.
- Acute life-threatening uterine bleeding may require blood transfusion (see p. 1347)
- Systemic and intrauterine antibiotics may be indicated when metritis or peritonitis is present.
- Megestrol acetate (not earlier than 6 weeks after parturition): first week of treatment, 0.1 mg/kg once daily PO; second week of treatment, 0.05 mg/kg once daily PO

POSSIBLE COMPLICATIONS

- Infection: bloody vaginal discharge in bitches > 6 weeks after parturition with no signs of endometritis (this is a period in which endometritis is normally not seen):
  - By not treating the discharge, can continue until next proestrus/estrus
- Endocrine adverse effects of megestrol acetate

RECOMMENDED MONITORING

Recheck animals showing any signs of systemic illness.

PROGNOSIS AND OUTCOME

- With spontaneous remission, future reproductive success is not compromised.
- Affected bitches are not predisposed to SIPS in subsequent pregnancies.

PEARLS & CONSIDERATIONS

COMMENTS

SIPS is the most common cause for persistent postparturient serosanguineous vaginal/vulvar discharge in an otherwise healthy bitch.

PREVENTION

Ovariohysterectomy or not breeding an intact female dog will prevent this problem from occurring.

CLIENT EDUCATION

Careful monitoring for complications such as vaginitis (foul smelling) that may lead to metritis and systemic illness.

SUGGESTED READING

Dickie MB, et al: Diagnosis and therapy of the subinvolution of placental sites in the bitch. J Reprod Fertil Suppl 47:471, 1993.

EDITOR: MICHELLE KUTZLER

Subcutaneous Emphysema

BASIC INFORMATION

DEFINITION

Accumulation of air in subcutaneous tissues

EPIDEMIOLOGY

SPECIES, AGE, SEX: More often seen in cats than in dogs (cats have a thin dorsal tracheal membrane compared to dogs).

RISK FACTORS

- Endotracheal intubation, especially in cats
- Jugular venipuncture
- Trauma to airways
- Bite wounds (anaerobic infection of subcutis; disruption of the pulmonary system by penetrating wounds)
- Surgery of the airways, especially upper airway surgery

ASSOCIATED CONDITIONS & DISORDERS

- Pneumomediastinum
- Pneumoretroperitoneum
- Pneumopericardium
- Pneumothorax

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of recent anesthesia with intubation, trauma, or surgery
- History of recent jugular venipuncture, transtracheal aspiration, or other penetrating medical procedure of the neck
- Dyspnea, discomfort
- Rapid onset of swelling of the body, initially around the neck but may progress to total body

PHYSICAL EXAM FINDINGS: Animal may manifest respiratory discomfort. Characteristic crackling sensation (crepitus) on palpation of the skin overlying the trapped air is pathognomonic.

- Initially focal (especially around the neck) and progressing rapidly to affect the whole body: suggests airway perforation/rupture as source; dyspnea, discomfort may or may not be present.
- Focal in an animal showing signs of severe illness; may suggest infection-related subcutaneous emphysema. A meticulous search for penetrating wounds is indicated.

ETIOLOGY AND PATHOPHYSIOLOGY

- A break in the integrity of the airway at any point between the pharynx and terminal bronchioles
- An independent source of gas formation (bacteria) in the subcutis
- With any of the following three mechanisms, air may remain trapped in the subcutaneous tissues by unidirectional valve action of the airway trauma:
    - Rupture of dorsal tracheal membrane (cats > dogs)
    - Rupture of dorsolateral or ventrolateral tracheal annular ligament
    - Penetrating wound in cervical area

Specific etiologies:

- Related to anesthetic administration of intubation:
    - Overinflation of endotracheal cuff
    - Use of a stiff stylet to guide the endotracheal tube through the larynx causes punctures in trachea

- Manipulation of the head without disconnecting the endotracheal tube
- Surgical
- Traumatic:
  - Bite wounds
  - Lacerations or penetrating foreign objects, including jugular venipuncture and transtracheal aspirates
- Infectious:
  - Inoculation of gas-forming bacteria (e.g., anaerobes) during penetrating injuries such as bite wounds anywhere on the body can produce infection of the subcutis.
- Idiopathic

SUBCUTANEOUS EMPHYSEMA External appearance of a domestic long-haired cat with marked subcutaneous emphysema. Note severe distention of the subcutaneous space, manifesting as a diffusely bloated appearance over the torso but not the head.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A history of recent intubation or tracheal trauma with or without acute onset of increased body size is suggestive. The characteristic "bubble wrap"–like feeling on palpation and/or the presence of subcutaneous air on radiographs confirms the diagnosis.

DIFFERENTIAL DIAGNOSIS

Tracheal avulsion/rupture; radiographs reveal physical separation of the trachea; surgery is required.

INITIAL DATABASE

- CBC and serum biochemical profile: generally unremarkable for cases of airway trauma; may show evidence of infection (neutrophilia, left shift, toxic changes) if subcutaneous emphysema is due to anaerobic infection of the subcutis.
- Radiographs of neck and thorax show presence of air trapped under the skin.

ADVANCED OR CONFIRMATORY TESTING

Tracheoscopy:

- Lesions may be difficult to visualize.
- Negative finding does not rule out tracheal trauma as cause for subcutaneous emphysema.
- CT scan of trachea may be required to detect presence and/or extent of tracheal rupture.
- Surgical exploration if severe

TREATMENT

TREATMENT OVERVIEW

Most patients will heal spontaneously in 1-2 weeks. More severe trauma requires surgical repair.

SUBCUTANEOUS EMPHYSEMA Radiograph showing severe subcutaneous emphysema, apparent as gas lucencies throughout the subcutis.

ACUTE GENERAL TREATMENT

- In animals without respiratory discomfort:
  - Supportive care while awaiting spontaneous absorption of the air
  - Cage rest
- In animals with mild discomfort:
  - Consider light sedation
  - Removal of air via an 18-G or 16-G needle. Air may be gently massaged toward the needle for evacuation. Needle suction alone may not able to remove the trapped air. Air removal via skin stab incisions is not advised.
  - Repeat this procedure to keep the animal comfortable as needed.
  - Penrose drains can be placed into the subcutis (similar to treating a subcutaneous abscess) to allow for continuous drainage of air. Generally less labor intensive and more effective than repeated centesis.
  - Analgesia (e.g., with butorphanol, 0.1-0.3 mg/kg IV q 4-6 h)
- In animals with recurrent/refractory subcutaneous emphysema and progressive respiratory distress:
  - If dyspnea is due to compression of the airways by trapped air in the subcutis or mediastinum, trapped air should be allowed to drain, leading to improved respiratory effort.
  - Surgical repair of the trachea if conservative measures are inadequate or if radiography suggests tracheal avulsion/rupture
  - Analgesia (e.g., with butorphanol, 0.1-0.3 mg/kg IV q 6-8 h)

DRUG INTERACTIONS

Avoid subcutaneous drug administration until normalized.

POSSIBLE COMPLICATIONS

Depending on the etiology of the subcutaneous emphysema: tracheal rupture, pneumothorax, and pneumoretroperitoneum are possible, as is sepsis (if bacterial infection of the subcutis).

RECOMMENDED MONITORING

Evaluate rate and depth of respiration as an indicator for the level of comfort in the animal and consider the need for surgical

treatment.

PROGNOSIS AND OUTCOME

In animals that do not develop respiratory distress, the prognosis is good, and spontaneous recovery will occur between 3 and 15 days.

PEARLS & CONSIDERATIONS

COMMENTS

- Most animals will recover with supportive care and will not require surgery.
- Sloughing of the skin is not a recognized complication of subcutaneous emphysema.
- Some animals show discomfort and pain during the presence of subcutaneous emphysema. Analgesic treatment should be initiated.
- Avoid subcutaneous drug administration in patients with subcutaneous emphysema (variable absorption).

TECHNICIAN TIPS

- Prevent overinflation of endotracheal cuffs.
- Perform cautious, appropriate jugular venipuncture, especially in cats.
- Disconnect endotracheal tubes prior to repositioning of the animal's head.

AUTHOR: HANS GELENS

EDITOR: ELIZABETH ROZANSKI

Subaortic Stenosis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Common congenital malformation of the canine heart; uncommon in kittens.
- Hallmark: a narrowing of the outflow tract of the left ventricle (LVOT)
- May be fixed (fibrous nodule, band, annulus, fibromuscular tunnel) or dynamic (systolic anterior motion of the mitral valve or SAM, asymmetric septal hypertrophy)

SYNONYMS

Subvalvular aortic stenosis, SAS

EPIDEMIOLOGY

SPECIES, AGE, SEX

- First noted in puppies < 12 months old (usually after 6 to 8 weeks of age)
- The lesion has never been documented during fetal life in any species.
- The severity of narrowing often is progressive during a puppy's growth, and the true severity of narrowing cannot be determined until the dog is fully grown (at least 1 year old).
- Depending on the study, subaortic stenosis (SAS) is either the most common congenital heart defect of dogs or is second to patent ductus arteriosus.
- In cats, hypertrophic cardiomyopathy (see p. 565) affecting the interventricular septum or associated with SAM may produce the same effect of left ventricular outflow obstruction as SAS.

GENETICS & BREED PREDISPOSITION

- Large-breed dogs (Newfoundland, golden retriever, rottweiler, boxer, German shepherd, Bouvier des Flandres, Bernese mountain dogs and Dogues de Bordeaux)
- Hereditary transmission (autosomal dominant with a polygenic pattern) has been demonstrated in the Newfoundland dog and is suspected in the golden retriever (autosomal recessive)
- Cannot be attributed specifically to sire or dam in any breed (no apparent sex linkage)
- Recognized risk of mildly affected dogs to produce more severely affected offspring

ASSOCIATED CONDITIONS & DISORDERS

- Mild/moderate aortic valvular regurgitation/insufficiency: very commonly observed echocardiographically in dogs with SAS; often inaudible on auscultation.
- Mitral dysplasia, patent ductus arteriosus, and a variety of aortic arch abnormalities have also been associated with some SAS cases.
- Dogs with SAS are predisposed to bacterial endocarditis of the aortic valve.
- A decreased aortoseptal angle is often seen with SAS and possibly represents a predisposing anatomic factor.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Many distinct malformations are grouped under the heading of SAS.

- Fixed obstruction:
  - Grade 1: small raised nodules of thickened endocardium
  - Grade 2: narrow ridge of thickened endocardium that partially encircles the left ventricular outflow tract
  - Grade 3: fibrous band, ridge, or collar completely encircles the left ventricular outflow tract.
  - This grading system is only for gross pathologic findings. It is unrelated to murmur intensity or clinical signs.
- Dynamic obstruction:
  - Systolic anterior motion of the mitral valve:
    - Narrowing of the left ventricular outflow tract and papillary muscle distortion caused by left ventricular hypertrophy slightly distort the mitral valve such that a small amount of mitral regurgitation occurs.

- Septal hypertrophy or malalignment:
  - The left ventricular hypertrophy induced by SAS may itself further contribute to left ventricular outflow obstruction because of hypertrophy of the interventricular septum.
  - The aortic arch may be congenitally malaligned in its attachment to the left ventricular outflow tract, resulting in SAS due to protrusion of the interventricular septum into the subvalvular area.

HISTORY, CHIEF COMPLAINT: In most cases, the condition causes a heart murmur in a dog not showing any overt clinical signs. However, severe cases may show:

- Exertional fatigue or syncope
- Congestive heart failure (CHF) (rare)
- Sudden death
- Some moderate cases show exaggerated or long-lasting panting after exercise as their only clinical sign

PHYSICAL EXAM FINDINGS: Often unremarkable except for a systolic, ejection-type (crescendo-decrescendo) heart murmur, heard loudest in the left cranial thorax (between the third and fifth intercostal spaces) or at the thoracic inlet (immediately lateral to the trachea). Intensity of the heart murmur grossly correlates with severity of disease:

Grades 1 to 3/6 = mildly to moderately affected dogs

Grades 4 to *6/6* = severely affected dogs

- Murmur may radiate cranially through the carotid arteries to the neck and head or to the right hemithorax
- Weak and slow rising femoral pulse (*pulsus parvus et tardus*) in severe cases
- A diastolic heart murmur is sometimes heard with aortic valve insufficiency
- Premature beats and pulse deficits (due to ventricular arrhythmias) may be detected, in severe cases

ETIOLOGY AND PATHOPHYSIOLOGY

- The etiology is multifactorial and may be caused by the combination of persistence of embryonal endocardial tissue that retains potential capacity for chondrocytes proliferation and predisposing anatomic characteristics of the LVOT such as increased mitral-aortic separation, decreased aortoseptal angle and a small aortic annulus which increase the shear stress and stimulate cellular proliferation
- The consequence of SAS, regardless of its subtype is an elevated left ventricular pressure overload that results in:
  - An increase in left ventricular systolic pressure and a pressure gradient across the subaortic lesion.
  - An increased blood flow velocity through the left ventricular outflow tract.
  - Compensatory left ventricular concentric hypertrophy (diffuse, symmetrical thickening of the left ventricle).
- This process may lead to left-sided CHF in some cases.
- With worsening SAS over time, left ventricular thickening may exceed intra-myocardial (coronary) blood supply, which does not grow along with the hypertrophied myocardial cells:
- The result is relative underperfusion of left ventricular tissue and ventricular arrhythmias or, less commonly, myocardial infarction.
- Either process may be responsible for sudden death (common in severe SAS).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is first suspected on auscultation of a systolic heart murmur loudest at the left or right heart base or cranial sternal region. Electrocardiography, thoracic radiographs, and blood tests may help raise or lower the likelihood of SAS, but a definitive diagnosis requires Doppler echocardiography.

DIFFERENTIAL DIAGNOSIS

- Other systolic heart murmur heard between the left second and fourth intercostal spaces:
  - Pulmonic stenosis
  - Tetralogy of Fallot
  - Atrial septal defect
  - Incompletely ausculted patent ductus arteriosus
- High output states:
  - Hyperthyroidism
  - Anemia
  - Fever

- Exercise (rare); note that physical activity increases the heart rate, which may make apparent a murmur of SAS that was not audible at rest. The distinction between this phenomenon and a benign, exercise-induced heart murmur requires echocardiography.

- Juvenile "innocent" heart murmur:
  - Puppies and kittens < 6 months old
  - Soft heart murmur, grades 1 to 3/6, short (early to midsystolic)
  - Often disappears with a change in body position or exercise/increase in heart rate
  - Electrocardiogram (ECG), thoracic radiographs, and echocardiogram are normal

INITIAL DATABASE

- ECG:
  - May be normal in mild to moderate cases
  - Left ventricular hypertrophy pattern often present (R wave > 3 mV in lead II) but not striking even in some moderate to severe cases; unreliable as a screening tool
  - ST segment may be slurred, depressed, or elevated in severe cases (myocardial hypoxia)
  - Ventricular arrhythmias in severe or long-standing cases
- Thoracic radiographs:
  - Often normal; unreliable as a screening tool for SAS
  - Helpful mostly to rule out congestive heart failure
  - Variable left-sided cardiomegaly (left ventricular and atrial enlargement), usually only with moderate to severe cases
  - Poststenotic dilatation of the aortic root may be visible in severe cases
- Echocardiogram: (definitive diagnosis):
  - Two-dimensional (2-D):
    - Often normal in mildly affected dogs
    - Subvalvular obstruction lesion or narrowed left ventricular outflow tract
    - Left ventricular concentric hypertrophy (diffuse, symmetrical left ventricular thickening)
    - Variable dilatation of the left atrium
    - Dilated ascending aorta
  - M-Mode:
    - Normal to increased left ventricular fractional shortening (poorly sensitive)
    - SAM sometimes observed
  - Doppler study:
    - Turbulent, high-velocity systolic signal in the left ventricular outflow tract and aortic root. Normal range (controversial) = up to 2 m/s; "gray zone" = 2-2.3 m/s; >2.3 m/s = highly suggestive of SAS when corresponding murmur and breed are also present; exception in the boxer breed and possibly others, where such elevated velocities may be normal (requiring two-dimensional aortic measurements for further evaluation)
    - Determination of the peak pressure gradient in combination with the indexed effective orifice area (IEOA) estimates the severity of disease; peak pressure gradient = 4 × (Doppler-derived LVOT velocity in m/s)^2
      - 16-40 mmHg = mild SAS
      - 40-100 mmHg = moderate SAS
      - >100 mmHg = severe SAS
      - IEOA < 0.6 cm^2/m^2 = severe SAS
    - Diastolic signal of aortic regurgitation is present in most cases of SAS

ADVANCED OR CONFIRMATORY TESTING

Cardiac catheterization and angiography: virtually never used for diagnosis. The procedure is invasive, requires general anesthesia, and provides little additional information over echocardiography.

TREATMENT

TREATMENT OVERVIEW

- No definitive treatment exists for curing SAS
- Only severe cases need therapy. True moderate and mild cases are asymptomatic and do not need therapy. Rarely, some moderate cases will have ventricular arrhythmias which will be addressed through medical treatment.
- Excision of the stenotic tissue via open-heart surgery or dilatation of the stenosis via non-invasive balloon valvuloplasty have not yet been shown to provide an outcome that is superior to conservative, medical management.
- Recurrence of the stenotic lesion is often observed after balloon dilation or surgery possibly as a result of anatomic characteristics of the LVOT that were left unaltered after surgery (e.g., abnormal aortoseptal angle).

ACUTE GENERAL TREATMENT

see Ventricular Arrhythmias, p. 1165; Heart Failure, Acute/Decompensated, p. 468.

CHRONIC TREATMENT

- Mild SAS: no treatment
- Moderate SAS: mild exercise restriction (only avoid vigorous activity) and ß-adrenergic blocking agent to prevent or control ventricular arrhythmias when present:
  - Atenolol, 0.25-1 mg/kg PO q 12-24 h; begin at low dose and increase titration over 2-4 weeks until upper end of dose range or signs of intolerance (lethargy, inappetence) warranting dosage reduction; *or*
  - Sotalol, 0.5-2 mg/kg PO q 12 h, up titration as per atenolol. Sotalol might be more effective in certain breeds (e.g., boxers).
- Severe SAS:
  - Open resection of the obstructing lesion is possible.
  - Balloon dilation of the stenosis; survival not longer than with medical management
  - β-Adrenergic blocking agent to prevent or control ventricular arrhythmias:
    - Atenolol or sotalol (see above); exercise restriction
- SAS with CHF: see p. 468

DRUG INTERACTIONS

- Concurrent use of antacids can alter the bioavailability of atenolol.
- Calcium channel blockers may cause hypotension and bradycardia when administered together with atenolol.
- Effects of theophylline can be blocked by β-adrenergic blocking agents like propranolol.

POSSIBLE COMPLICATIONS

- Ventricular arrhythmias/ventricular tachycardia
- Exertional syncope or sudden death
- Left-sided heart failure
- Aortic valve endocarditis

RECOMMENDED MONITORING

- Control ventricular arrhythmias when present (ambulatory ECG recordings [see] recommended if syncope is noted and for monitoring efficacy of antiarrhythmic treatment if possible).
- SAS is a progressive disease when a dog is growing; therefore, the final cardiac evaluation should be done at 12 months of age or older to stage the severity of disease.

PROGNOSIS AND OUTCOME

- Favorable: mild to moderate SAS
  - Normal quality of life and longevity, especially when follow-up visit shows no progression of SAS
- Poor: severe SAS
  - Median survival time is 19 months when untreated.
  - Most dogs die suddenly, usually within the first 3 years of life.
  - Medical management might increase median survival to 4.5 years.

PEARLS & CONSIDERATIONS

COMMENTS

- The combination of a =grade 4/6 ejection heart murmur that radiates cranially to the thoracic inlet and over the carotid arteries along with a weak femoral pulse in a puppy is highly suggestive of severe SAS.
- The severity of ventricular arrhythmias detected by extended (24-hour) ambulatory ECG recordings correlates with the severity of disease.
- Dogs with peak pressure gradients > 125 mm Hg are very likely to develop serious complications or sudden death.
- Because of the progressive nature of SAS during growth, the lesion/heart murmur may be clinically silent in very young puppies but becomes increasingly prominent at >2-3 months of age.

- Overtly healthy boxer dogs may have systolic murmurs without obvious SAS. This phenomenon is potentially caused by a relatively smaller outflow tract in that breed, predisposing them to increased ejection velocity and development of murmurs.
  - Grades I-III/VI murmur
  - No SAS lesion on echocardiography
  - Differentiation between SAS and the normal state in these dogs is challenging and requires echocardiography (left ventricular thickening, left atrial enlargement, and aortic insufficiency suggest SAS), ECG (ventricular arrhythmia of left ventricular origin suggests SAS), and follow-up exams (progression of these abnormalities and of Doppler-derived pressure gradient suggest SAS).
- Identification of the most mildly affected animals (clinically silent "carrier") such as dogs with a soft systolic murmur only apparent at higher heart rates, and a structurally normal heart on two-dimensional echocardiography, remains extremely challenging. Diagnosis in these cases involves a combination of physical examination, Doppler echocardiography, and tightly controlled follow-up exams (both the animal in question and its siblings and/or offspring).

PREVENTION

- Vigilance regarding the possible need for antibiotics is important in all SAS cases during periods of anticipated bacteremia (dental procedures, surgery, severe skin disease, other concurrent bacterial disease); avoiding overuse of antibacterials is also important.
- Use breeding dogs that have been screened for SAS.

CLIENT EDUCATION

- In cases of severe SAS, avoid prolonged, vigorous exercise.
- Contact breeders to notify them of SAS cases.

Pyle RL, Abbott JA: Subaortic stenosis. In Bonagura JD, Twedt DC, editors: Kirk's current veterinary therapy XIV. St Louis, 2008, Saunders Elsevier, pp 757–761.

AUTHOR: MARIE C. BÉLANGER

EDITOR: ETIENNE CÔTÉ

Stunted Growth

BASIC INFORMATION

DEFINITION

Slowed or retarded growth rate; failure to attain expected body size/stature; uncommon disorder

SYNONYMS

Cretinism (congenital hypothyroidism [rare]); delayed growth, dwarf, runt, poor-doer, unthrifty; pituitary dwarfism (growth hormone deficiency, hyposomatotropism [rare])

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats, age and sex vary with cause
- Failure to grow is usually recognized by 1 year of age (most noted prior to 2 years).
- First 3 months: growth hormone deficiency, congenital hypothyroidism, cleft palate, congenital megaesophagus, persistent right aortic arch (PRAA), other vascular ring anomaly, parasitism, juvenile hyperparathyroidism
- Under 1 year: juvenile diabetes, portosystemic shunt, exocrine pancreatic insufficiency, cardiac abnormalities, renal disease, osteochondrodystrophies, ciliary dyskinesia
- Under 2 years: most noted prior to 2 years. Nutritional deficiencies in giant breed dogs might manifest later. Renal diseases, hepatopathies.

GENETICS & BREED PREDISPOSITION

- Pituitary dwarfism: German shepherd, Karelian bear dog, spitz, toy pinscher
- Congenital hypothyroidism: fox terrier, boxer, giant schnauzer, Abyssinian cat
- Osteochondrodysplasia: various, including Labrador retriever, Irish setter
- Cleft palate: shih tzu, English bulldogs, pointers, Swiss sheepdog, Brittany spaniel
- Congenital megaesophagus: Irish setter, German shepherd, Labrador retriever, miniature schnauzer
- Vascular ring anomaly: German shepherd, Irish setter
- Pancreatic acinar atrophy: German shepherd
- Portosystemic shunt: Havanese, Yorkshire terrier, Maltese, Dandy Dinmont terrier, pug, miniature schnauzer
- Polycystic kidney disease: Cairn terrier, West Highland white terrier, Persian, Himalayan
- Hereditary nephritis: English cocker spaniel, Samoyed
- Renal dysplasia: Malamute, chow chow

RISK FACTORS

- Varies with disease
- Most risk factors are not identified except genetic diseases.
- Malnutrition: poor-quality feed
- Hypothyroidism: maternal exposure to iodine-131 (^{131}I)

CONTAGION & ZOONOSIS: Some intestinal parasites present risks of visceral larval migrans to humans.

ASSOCIATED CONDITIONS & DISORDERS

- Juvenile diabetes mellitus: pancreatic acinar atrophy and exocrine pancreatic insufficiency
- Pituitary dwarfism: hypoadrenocorticism
- Portosystemic shunt: urate urolithiasis, microvascular dysplasia
- Megaesophagus: myasthenia gravis, vascular ring anomaly
- Cleft palate: middle ear abnormalities

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Nutritional:
  - Poor feed or insufficient supply
  - Mechanical problems: cleft palate, megaesophagus, PRAA
  - Maldigestion/malabsorption: parasites, intestinal infections (salmonella, histoplasmosis), pancreatic acinar atrophy
- Endocrine:
  - Congenital hyposomatotropism, congenital hypothyroidism, juvenile hyperparathyroidism, diabetes mellitus
- Cardiac diseases:
  - Patent ductus arteriosus, others
- Metabolic:
  - Portosystemic shunt, microvascular dysplasia
  - Renal dysplasia, other nephritis
- Chondrodysplastic

HISTORY, CHIEF COMPLAINT

- May be unnoticed by owner
- Pet lags behind littermates in growth.
- Diet history, deworming history, onset and progression of signs are important.
- Medication exposure
- Signs of mental dullness
- Polyuria/polydipsia

PHYSICAL EXAM FINDINGS

- Varies with disease. Important distinctions are good versus poor body condition and proportionate versus disproportionate dwarfism:
  - Hyposomatotropism and chondrodysplastic animals are in good body condition, whereas other disorders lead to poor body condition.
  - Congenitally hypothyroid patients and chondrodysplastic patients are disproportionate dwarfs (limbs are exceptionally short). This is in contrast to proportional dwarfism (e.g., toy poodle) in which the limbs, trunk, and head are of appropriate relative sizes.
- Examine patient for:
  - Mental dullness or disorientation
  - Dwarfism
  - Cleft palate
  - Cough, respiratory distress
  - Heart murmur
  - Bloated abdomen
  - Signs of diarrhea staining coat

ETIOLOGY AND PATHOPHYSIOLOGY

Specific pathophysiologic mechanism varies with disease:

- Inability to ingest, absorb, or utilize nutrients
- Inability to properly execute growth

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Stunted growth may be obvious on the physical exam or subtle. Evaluation for inciting factors begins with history (errors in management or basic care) and physical examination (signs of concurrent or contributory disorders) and proceeds to basic laboratory tests and diagnostic imaging as needed. Unusual endocrinopathies may be considered diagnoses of exclusion.

DIFFERENTIAL DIAGNOSIS

see Disease Forms/Subtypes, above.

INITIAL DATABASE

- Fecal flotation
- CBC:
  - Microcytic anemia: portosystemic shunt, polycythemia
  - Eosinophilia: hypoadrenocorticism, parasitism
  - Lymphocytosis/neutropenia: hypoadrenocorticism
- Serum biochemistry panel:
  - Low albumin: exocrine pancreatic insufficiency, portosystemic shunt, infiltrative bowel disease
  - Hyperglycemia: diabetes mellitus
  - Hypoglycemia: hypoadrenocorticism
  - High calcium with normal or low phosphorus: hypoparathyroidism
  - High blood urea nitrogen: renal disease versus prerenal azotemia
- Urinalysis:
  - Urine specific gravity < 1.035: kidney disease, hypothyroidism; may be normal in nonazotemic patient (elimination of free water)
  - Glucose: diabetes mellitus
  - Protein: nephritis, glomerulopathies
  - Casts, infection: nephritis
  - Urate uroliths: portosystemic shunt, microvascular dysplasia
- T4: congenital hypothyroidism

ADVANCED OR CONFIRMATORY TESTING

- Trypsinlike immunoreactivity: pancreatic acinar atrophy/exocrine pancreatic insufficiency
- Urine bacterial culture and sensitivity
- ACTH stimulation test: hypoadrenocorticism
- Abdominal ultrasound: kidney disease, portosystemic shunt
- Scintigraphy: portosystemic shunt, ciliary dyskinesia
- Xylazine stimulation, serum level of insulin-like growth factor: hyposomatotropism

TREATMENT

TREATMENT OVERVIEW

Correct diseases that are reversible.

ACUTE GENERAL TREATMENT

Generally not acute presentations

CHRONIC TREATMENT

- Varies with disease
- Examples, depending on disorder: close portosystemic shunt, treat parasitism, improve diet, provide thyroxine, insulin, pancreatic enzyme replacement.

POSSIBLE COMPLICATIONS

- Death: patent ductus arteriosus, portosystemic shunt, extreme malnutrition
- Diabetic ketoacidosis: congenital diabetes mellitus
- Aspiration pneumonia: megaesophagus, PRAA

RECOMMENDED MONITORING

Frequent physical exams

PROGNOSIS AND OUTCOME

- Guarded; most of the diseases are serious and irreversible.
- With surgical reversal, improved longevity of portosystemic shunt patients and patent ductus arteriosus patients may be achieved as long as underlying microvascular dysplasia and irreversible cardiac changes, respectively, are not present.

- Osteochondrodysplastic dogs can fare well, but the disorder is irreversible.

PEARLS & CONSIDERATIONS

COMMENTS

- Key to diagnosis is distinction between good and poor thrift and proportionate and disproportionate dwarfism.
- Adequate nutrition and effective deworming should be assured prior to more expensive diagnostics.

PREVENTION

Careful attention to genetic lines in purebred dogs

CLIENT EDUCATION

The prognosis varies with the disease.

SUGGESTED READING

Ihle SL: Failure to grow. In Ettinger SJ, Feldman EC, editors: Textbook of veterinary internal medicine, ed 6, Philadelphia, 2005, WB Saunders, pp 80–83.

AUTHOR: DENNIS SPANN

EDITOR: ETIENNE CÔTÉ

Strychnine Toxicosis

BASIC INFORMATION

DEFINITION

A rapid-onset (30 minutes to 2 hours after ingestion), potentially fatal toxicosis characterized by neurologic dysfunction. Now rare, mainly of historical interest.

SYNONYM

Strychnine: *Nux vomica*

EPIDEMIOLOGY

SPECIES, AGE, SEX

- All animals are susceptible; dogs are more commonly involved than cats.
- Male dogs are more commonly involved.

GENETICS & BREED PREDISPOSITION: Younger dogs and large-breed dogs, such as German shepherds, are overrepresented.

GEOGRAPHY AND SEASONALITY

- Year-round
- Rural and urban dogs equally affected
- Most cases are reported in the western part of the United States and in the Midwest.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Availability or presence of strychnine-containing bait in pet's environment; evidence of exposure
- Rapid onset of apprehension (30 minutes to 2 hours), nervousness, chewing movements, muscular rigidity, tonic-clonic convulsions

PHYSICAL EXAM FINDINGS

- Hyperesthesia, apprehension, nervousness initially
- Severe muscle stiffness, rigidity
- Hyperthermia (>104°F[>40°C]), caused by muscle activity and not febrile in origin
- Sawhorse stance
- Eventually, tetanic seizures (marked by violent, stiff limb movements):
  - Occur spontaneously or may be initiated by external stimuli (touch, sound, sudden bright light)
- Opisthotonos, mydriasis, exophthalmos, and cyanosis may be present before death.
- Vomiting and hypersalivation (uncommon)

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

- Strychnine is a bitter indole alkaloid from the seeds of the vinelike Southeast Asian or Australian trees, *Strychnos nux-vomica* and *Strychnos ignatii*.
- Since 1978 in the United States, strychnine has been a restricted-use pesticide and rodenticide (licensed exterminators only) or has been forbidden in certain U.S. states. Over-the-counter preparations contain <0.5% strychnine; preparations used by licensed exterminators may contain up to 5% strychnine.
- Malicious or accidental strychnine toxicosis occurs when nontarget animals ingest strychnine-containing baits.

Mechanism of Toxicosis:

- Strychnine competitively and reversibly inhibits the inhibitory neurotransmitter glycine at postsynaptic neuronal sites in the spinal cord and medulla. This results in unchecked reflex stimulation of motor neurons affecting all the striated muscles, resulting in generalized rigidity and tonic-clonic seizures caused by these direct central nervous system (CNS) effects.
- Death usually results from respiratory arrest and exhaustion from prolonged seizuring.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Strychnine toxicosis should be suspected based on history of exposure if available and rapid onset of neurologic signs (muscular rigidity, seizures). Diagnosis can be confirmed by identifying strychnine alkaloid in vomitus or urine, but submission and turnaround time makes this confirmation clinically impractical. Given the rapid course of progression of this disorder, treatment is initiated when strychnine intoxication is confirmed (e.g., container with label is available) or reasonably suspected.

DIFFERENTIAL DIAGNOSIS

- Other intoxications causing seizures: metaldehyde, tremorgenic mycotoxins/garbage toxicosis, organochlorine, organophosphorus or carbamate pesticides, zinc phosphide, nicotine
- Tetanus
- Hypocalcemic tetany
- Hepatic encephalopathy

INITIAL DATABASE

Because of the rapid onset of clinical signs, no specific changes are expected on CBC, serum biochemistry profile, or urinalysis at presentation, other than elevated creatine kinase (CK); metabolic acidosis and myoglobinuria possible.

ADVANCED OR CONFIRMATORY TESTING

- On postmortem examination, no characteristic lesions are seen. In cases that have prolonged convulsions before death, agonal hemorrhages of the heart and lungs and cyanotic congestion due to anoxia may be seen.
- Occasionally, poisoned animals may have undigested red or green strychnine-laced grain seeds (wheat, milo, barley) in their stomach.
- Presence of strychnine alkaloid in the vomitus, stomach contents, liver, kidney, or urine is considered diagnostic. In living animals, submit stomach contents (vomitus or stomach washings) or urine early (within the first several hours of exposure). Urine may not contain detectable amounts of strychnine if samples are collected late (1-2 days after the exposure). Seal samples (stomach contents, liver, or kidney) in a plastic bag, freeze them, and then submit them to a veterinary diagnostic laboratory for strychnine analysis.

TREATMENT

TREATMENT OVERVIEW

Because of rapid progression, strychnine toxicosis is a medical emergency. Patients presented early (prior to onset of clinical signs) should be decontaminated via induction of vomiting and administration of activated charcoal. In patients already showing clinical signs, treatment is targeted to reducing or abolishing those signs (controlling seizures, maintaining respirations, and general supportive care). Because CNS effects cause seizures and respiratory depression, many patients will require anesthesia for 24-48 hours.

ACUTE GENERAL TREATMENT

- Control seizures and prevent asphyxia. Do not attempt to decontaminate patients that are already showing neurologic effects. Control seizures and stabilize the patient first.
    - Anticonvulsants:
        - Diazepam, 0.5-2 mg/kg IV, has been used with variable success.
        - If unsuccessful, pentobarbital sodium, 3-15 mg/kg IV to effect; repeated as needed
        - Short-lasting alternative requiring constant rate infusion (easier to titrate, more costly) is propofol, 3-6 mg/kg IV to effect, then 0.2-0.6 mg/kg/min infusion to effect (maintain anesthesia).
        - Isoflurane gas anesthesia: used if seizures are not controlled with the preceding treatment measures
    - Muscle relaxants:
        - Methocarbamol, 100-200 mg/kg IV; repeat as needed; maximum dose of 330 mg/kg per day; *or*

        - Glyceryl guaiacolate (5% solution, 50 mg/mL), 110 mg/kg IV to effect
    - Intubate and provide positive pressure ventilation for severely affected animals (see p. 1362).
- Decontamination of patient:
    - Induction of vomiting (see p. 1364): useful within 30 minutes and only in patients showing no clinical signs
    - Gastric lavage (see p. 1281): used if emesis cannot be induced or when suspected lethal doses have been ingested; intubate the patient with a cuffed endotracheal tube to reduce aspiration risk if the patient is unconscious.
    - Enterogastric lavage: also called *through-and-through lavage*; induce general anesthesia (unless patient is already unconscious). Begin with gastric lavage followed by an enema/colonic irrigation under low pressure and at body temperature. Continue until fluids exit via the gastric tube; used if known ingestion of potentially lethal dose. Premedication: atropine, 0.04 mg/kg IV (to decrease enteric muscle tone, helping fluid flow).
    - Activated charcoal, 2-4 g/kg, with a cathartic such as sorbitol (5-10 mL/kg, 3% solution) PO or via stomach tube
- Supportive care:
    - IV fluid diuresis (24-48 hours or longer)
    - Treat hyperthermia if present (see p. 1281).
    - Confine the patient in a dark, quiet room.
    - Acidification of urine: ammonium chloride, 100 mg/kg PO q 12 h, may help increase urinary excretion of strychnine.

POSSIBLE COMPLICATIONS

- Myoglobinuria and associated renal failure
- Disseminated intravascular coagulation from hyperthermia

RECOMMENDED MONITORING

- Body temperature
- Respiratory rate and character
- Acid-base status

PROGNOSIS AND OUTCOME

- Poor prognosis if status epilepticus uncontrolled by medications listed above; consider euthanasia.
- Good prognosis if seizures are controlled early

PEARLS & CONSIDERATIONS

COMMENTS

- Sporadic strychnine poisoning of animals still occurs.
- Strychnine is ionized in an acidic pH; therefore, it is mainly absorbed from the small intestine, emphasizing the importance of rapid intervention before the onset of signs. Strychnine and its metabolites are mainly excreted in the urine. A toxic dose is eliminated within 24-48 hours following exposure.
- Oral lethal dose in dogs is 0.75 mg/kg; for cats, the dose is 2 mg/kg.
- Ingestion of 1.7 g (1/4 tsp) of 0.5% strychnine bait in a 25-lb (11.3-kg) dog can be lethal.

PREVENTION

Do not use strychnine-containing baits in any pet's environment.

Stridor and Stertor, Respiratory

BASIC INFORMATION

DEFINITION

Stridor: a harsh, high-pitched sound occurring during inspiration as a result of partial upper airway obstruction Stertor: inspiratory noise occurring specifically during sleeping, e.g., snoring

EPIDEMIOLOGY

SPECIES, AGE, SEX: No predilection, given the broad spectrum of possible underlying diseases

GENETICS & BREED PREDISPOSITION: Brachycephalic breeds are predisposed to partial upper airway obstruction and stridor.

RISK FACTORS

- Nasal/nasopharyngeal disorders, either through primary obstruction (mass, foreign body, mucosal edema) or secondarily due to obstruction by discharge
- Pharyngeal, laryngeal, and tracheal disorders

ASSOCIATED CONDITIONS & DISORDERS: Powerful, sustained inspirations against an obstructed upper airway are associated with the development of noncardiogenic pulmonary edema.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Owners may report stridor individually as a chief complaint or concurrently with other signs suggesting respiratory disease (coughing, nasal discharge, sneezing, dyspnea, epistaxis), pharyngeal disease (gagging, dysphagia), or intermittent complete respiratory obstruction (decreased exercise tolerance, syncope). Clinical signs often may be exacerbated by excitement. Many animals show no clinical signs at rest. Owner may report voice change with laryngeal involvement.

PHYSICAL EXAM FINDINGS

- Stridor of nasal cavity origin: nasal discharge, occlusion of air flow from one or both nostrils, stenotic nares in brachycephalic breeds, stridor disappears with open-mouth breathing, periodontal disease with evidence of tooth root abscessation or tooth loss
- Stridor of pharyngeal, laryngeal, or tracheal origin: coughing, gagging, dyspnea, hyperthermia, open-mouth gasping, unilateral discharge from the ear (sometimes seen in cats with nasopharyngeal polyps)

ETIOLOGY AND PATHOPHYSIOLOGY

- During inspiration, air pressure in the upper airway is low, allowing air to flow in through the nares or mouth and fill the lungs.
- Obstruction narrows airway diameter, causing turbulence proximal to the obstruction during inspiration. The turbulence is audible as stridor.
- Any obstructions of the upper airway can be drawn into the lumen during inspiration (dynamic obstruction), exacerbating the obstruction and causing further airflow turbulence and stridor.
- Stridor may be absent on expiration if the pressure of exhaled air opens the airway (e.g., laryngeal paralysis, other dynamic obstructions).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Physical examination and radiographs of the trachea and lungs help localize the lesion causing respiratory stridor. Rhinoscopy, laryngoscopy, tracheoscopy, and/or CT scans are often necessary to determine the exact etiology of the airway obstruction.

DIFFERENTIAL DIAGNOSIS

- Stridor of nasal cavity origin:
  - Brachycephalic syndrome (stenotic nares)
  - Foreign body (nasal)
  - Neoplasia (nasal)
  - Nasopharyngeal polyp
  - Rhinitis (fungal, bacterial, viral, parasitic, tooth root abscess, chronic vomiting or regurgitation)
  - Trauma
  - Coagulopathy
- Stridor of pharyngeal, laryngeal, or tracheal origin:
  - Brachycephalic syndrome (elongated soft palate; everted laryngeal saccules; hypoplastic trachea)
  - Laryngeal paralysis
  - Foreign body (pharyngeal, laryngeal, or tracheal)
  - Neoplasia (pharyngeal, laryngeal, or tracheal)
  - Nasopharyngeal polyp
  - Trauma
  - Coagulopathy
  - Laryngeal or tracheal collapse
  - Tracheal stenosis
  - Extraluminal compression of the trachea (neoplasia, granuloma, cervical lymphadenopathy)

INITIAL DATABASE

- CBC, serum biochemistry profile, and urinalysis to rule out underlying systemic diseases
- Nasal cavity stridor:
  - Assessing airflow through both nostrils, using a wisp of cotton ball or a cold glass slide (warm, moist, expired air fogging the glass if the nasal passage is patent)
- Pharyngeal, laryngeal, and tracheal stridor:
  - Cervical radiographs to rule out laryngeal and tracheal masses and foreign bodies:
    - The normal larynx (especially if mineralized and/or radiographed obliquely) should not be misinterpreted as a foreign body.
  - Thoracic radiographs:
    - Intrathoracic trachea
    - Lungs (noncardiogenic pulmonary edema; underlying abnormalities, e.g., infection, pulmonary hemorrhage [coagulopathy])

ADVANCED OR CONFIRMATORY TESTING

- Coagulation profile to rule out coagulopathies
- Nasal cavity stridor:
  - Rhinoscopy (see p. 1335) with biopsies, cytologic examination, and bacterial culture and sensitivity (aerobic) if discharge is present
  - CT (see p. 1233) scan of nasal cavity and pharynx
  - Dental radiographs (see p. 1246; tooth root abscesses)
- Pharyngeal, laryngeal, and tracheal stridor:
  - Laryngoscopy (see p. 1295) under light general anesthesia to evaluate laryngeal and oral anatomy and rule out laryngeal paralysis
  - If severe open-mouth inspiratory dyspnea: may be possible to visualize caudal pharynx and larynx with patient awake (laryngeal paralysis, pharyngeal foreign body, laryngeal/pharyngeal mass), using only a bright light source
  - Pharyngoscopy and tracheoscopy with biopsies, cytologic examination, and bronchoalveolar lavage

TREATMENT

TREATMENT OVERVIEW

Remove or decrease obstruction of the upper airway. In moderate cases, oxygen supplementation and sedation may be required. In severe cases, tracheotomy may be necessary to restore air flow to the lungs.

ACUTE GENERAL TREATMENT

- Nasal stridor: rarely associated with dyspneic crisis, as dogs and cats will open-mouth breathe to circumvent nasal obstruction.
- Pharyngeal, laryngeal, and tracheal stridor: if associated with severe obstruction, may cause (in increasing order of severity)

severe upper airway dyspnea, cyanosis, collapse, and respiratory arrest

- Patients with marked respiratory stridor associated with exaggerated, severe inspiratory efforts require immediate attention.
  - Calm environment
  - Oxygen supplementation if tolerated (see p. 1318)
  - Sedation should be considered, especially if the degree of inspiratory dyspnea is severe and the patient is known to otherwise be healthy (e.g., butorphanol, 0.05-0.3 mg/kg IV).
- In cases of pharyngeal, laryngeal, or tracheal stridor with deterioration or failure to improve despite the measures described above:
  - If the obstruction is cranial to the midcervical trachea and stridor and dyspnea are severe, either anesthesia and endotracheal intubation (see p. 1292) or a tracheotomy if intubation is not possible (see p. 1344) should be considered.
  - If the obstruction is caudal to the midcervical trachea and stridor and dyspnea are severe despite the treatments mentioned above, immediate preparations should be made for tracheoscopy and/or surgical intervention.
  - If the site of obstruction is unknown, the patient must undergo radiography or direct visualization of the pharynx and larynx to determine the best intervention.

CHRONIC TREATMENT

Correction of underlying causes (as applicable):

- Brachycephalic airway surgery (nasal wedge resection, soft palate resection [staphylectomy], everted laryngeal saccule resection [laryngeal sacculectomy])
- Arytenoid lateralization (laryngeal tie-back surgery) for laryngeal paralysis
- Surgical excision of masses or polyps
- Endoscopic or surgical retrieval of foreign bodies
- Antimicrobial therapy for infectious disease

RECOMMENDED MONITORING

- Respiratory effort improvement/deterioration
- Mucous membrane color (pallor/cyanosis)
- Pulse oximetry and arterial blood gas analysis if debilitated or severely affected patient

PROGNOSIS AND OUTCOME

Dependent on the underlying disease

PEARLS & CONSIDERATIONS

COMMENTS

- Cats are much more reluctant than dogs to breathe with their mouths open. As a result, significant nasal cavity obstruction can cause marked respiratory distress in a cat, whereas a dog would simply pant more to bypass the obstruction.
- Stridor is often exacerbated by excitement and exercise.

TECHNICIAN TIPS

- Keep the environment around an acutely dyspneic animal as calm as possible. Do not force an oxygen mask on the animal if it is resisting. Sedation may help calm the animal and reduce dyspnea.
- Animals with stridor on a hot day often become hyperthermic. Be sure to check body temperature and actively cool animals with temperatures greater than 40°C or 102°F.

Storage Diseases

BASIC INFORMATION

DEFINITION

Inherited disorders that result in intracellular accumulation of specific storage product(s) owing to a deficiency in an enzyme or cofactor necessary for further metabolism of the substance. The accumulated storage products cause subsequent cellular dysfunction. This discussion will be limited to the lysosomal storage disorders, in which the substance that fails to be processed accumulates in the lysosomes. see also online Section lll table: Storage Diseases for a summary of clinical information on these disorders.

SYNONYM

Lysosomal storage disorders

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats
- Age of onset varies; typically normal at birth and develop clinical signs within first several weeks to months of life.
- Signs may not become apparent until much later in life.
- No known sex predilection

GENETICS & BREED PREDISPOSITION

- Generally have an inherited basis (mostly autosomal recessive)
- Can occur as spontaneous mutation

RISK FACTORS: Affected relatives or breeds that are at risk. Please refer to the online Section lll table: Storage Diseases, and to the suggested reading list below, for a complete list of breeds susceptible to specific disorders.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Sphingolipidoses:
  - Globoid cell leukodystrophy (Krabbe disease):
    - Deficiency: β-d-galactocerebrosidase
    - Clinical signs: multifocal; predominantly ataxia, pelvic limb paresis/paralysis. Cerebellar dysfunction may be the predominant early sign.
  - Gangliosidosis GM1 (Norman-Landing disease):
    - Deficiency: β-galactosidase
    - Clinical signs: multifocal; predominantly cerebellar dysfunction; may progress to tetraplegia
  - Gangliosidosis GM2 (Derry disease):
    - Deficiency: β-galactosidase
    - Clinical signs: multifocal; predominantly cerebellar dysfunction; may progress to tetraplegia
  - Glucocerebrosidase deficiency (Gaucher disease):
    - Deficiency: β-D-galactocerebrosidase
    - Clinical signs: multifocal; predominantly cerebellar ataxia, tremors, hyperactivity
  - Sphingomyelinase deficiency (Niemann-Pick disease):
    - Deficiency:
      - Type A: sphingomyelinase
      - Type B: cholesterol esterification deficiency
      - Type C: NPC1 mutation
    - Clinical signs: ataxia, head tremors, paraparesis, weight loss, depression
- Glycoproteinoses:
  - Fucosidosis:

        - Deficiency: α-l-fucosidase
        - Clinical signs: initially forebrain dysfunction predominates and progresses over 2-3 years to include ataxia, dysphagia, vision and hearing loss, nystagmus, and dysphonia.
            - Relatively late onset of clinical signs; neurologic dysfunction begins between 12 and 18 months of age.
            - Palpable enlargement of the ulnar nerves secondary to edema and infiltration with lipid-filled phagocytes and Schwann cells
    - Mannosidosis:
        - Deficiency: α-d-mannosidase
        - Clinical signs include skeletal abnormalities, ataxia, head tremor; possibly gingival hyperplasia.
    - Neuronal glycoproteinosis (Lafora disease):
        - Deficiency: unknown
        - Clinical signs: forebrain dysfunction predominates within the first year of life.
    - Galactosialidosis:
        - Deficiency: protective protein/cathepsin A
        - Clinical signs: predominantly ataxia
- Mucopolysaccharidoses:
    - Mucopolysaccharidosis type I (Hurler syndrome):
        - Deficiency: α-l-iduronidase
        - Clinical signs: predominantly pelvic limb gait disorder without overt neurologic deficits; patients may have hyperextensible joints and plantigrade stance; skeletal and craniofacial abnormalities may be present.
    - Mucopolysaccharidosis type II (Hunter disease):
        - Deficiency: iduronate-2-sulfatase
    - Mucopolysaccharidosis type III (Sanfilippo syndrome):
        - Type IIIA: heparan sulfate sulfamidase deficiency
        - Type IIIB: *N*-acetyl-a-D-glucosaminidase deficiency
        - Clinical signs: not well described; predominantly tremors and ataxia
    - Mucopolysaccharidosis type VI (Maroteaux-Lamy syndrome):
        - Deficiency: arylsulfatase B
        - Clinical signs: predominantly skeletal malformations (kyphosis, facial deformities); upper motor neuron paraparesis
    - Mucolipidosis II (I-cell disease):
        - Deficiency: *N*-acetylglucosamine-1-phosphotransferase
        - Clinical signs: not well described
    - Mucopolysaccharidosis type VII (Sly disease):
        - Deficiency: β-D-glucuronidase
        - Clinical signs: not well described; skeletal deformities, ataxia, corneal cloudiness
- Proteinoses:
    - Ceroid lipofuscinosis (Batten Disease):
        - Deficiency:
            - Cathepsin D[d]
            - CLN5[d]
            - CLN2 (TTP1)[d]
            - CLN8[d]
        - Clinical signs: behavioral changes and visual deficits seen initially. Progresses over several years to include seizures, ataxia, tremors, hypermetria.
            - Encephalopathic signs usually first seen at 1-2 years of age (range of disease onset 6 months-10 years)
            - A form of ceroid lipofuscinosis selectively involving the cerebellum and thalamus has been described in dogs.
            - Cats typically demonstrate rapid neurologic decline.
- Oligosaccharidoses:
    - Glycogenosis type 1a:
        - Deficiency: glucose-6-phosphatase
    - Glycogenosis type II (Pompe disease):
        - Deficiency: α-glucosidase
    - Glycogenosis type IIIa:
        - Deficiency: glycogen debranching enzyme (AGL gene)
    - Glycogenosis type IV (Andersen disease):
        - Deficiency: glycogen debranching enzyme

HISTORY, CHIEF COMPLAINT

- Normal at birth
- Clinical signs typically become apparent within the first 6 months of life and slowly progress over 1 to 2 years.

- Intention tremors are common chief complaints.
- Specific presenting complaints depend on the specific storage disease.
- May have history of affected relatives

PHYSICAL EXAM FINDINGS

- General physical examination is typically unremarkable.
- Neurologic exam findings depend on the specific storage disease; findings may include:
  - Mentation changes (behavioral changes, aggression, loss of learned behavior)
  - Menace deficits, central blindness
  - Gait abnormalities (ataxia, paresis)
  - Proprioceptive deficits
  - Intention tremors
  - Exercise intolerance
- Hepatomegaly (gangliosidosis, glycogenosis types I and III, mannosidosis, mucopolysaccharidoses types I and VII, and sphingomyelinosis) or splenomegaly (mucopolysaccharidosis type I, sphingomyelinosis) have been noted as a result of accumulation of storage products in the cells of these organs.
- May exhibit skeletal or connective tissue abnormalities (mannosidosis, mucopolysaccharidoses types I and VI, mucolipidosis type II)
- Retinal degeneration with ceroid lipofuscinosis and in cats with mucolipidosis II
- Dwarfism with gangliosidosis in English springer spaniels
- Peripheral nerve involvement associated with fucosidosis, globoid cell leukodystrophy, glycogenoses, sphingomyelinosis

ETIOLOGY AND PATHOPHYSIOLOGY

- Normally, substances undergo sequential metabolic degradation via specific lysosomal enzymes. Interruptions in these specific pathways can occur if one enzyme (or more) is deficient or dysfunctional, leading to accumulation of the substance prior to that enzymatic step.
- Accumulated byproduct(s) will lead to cellular dysfunction, presumably by cell swelling, toxic effects of accumulated material(s), or both.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

These unusual disorders are suspected in young patients with relentlessly progressive neurologic deficits with or without associated general physical abnormalities. Confirmatory clinical tests exist for some disorders; definitive diagnosis for any of them is obtained from histologic analysis of tissue, typically at postmortem when unthrifty animals die or are euthanized.

DIFFERENTIAL DIAGNOSIS

Any slowly progressive multifocal or diffuse encephalopathy, cerebellar dysfunction, or neuromuscular dysfunction should be considered as a differential diagnosis.

- Degenerative:
  - Leukodystrophy/spongy degeneration
  - Neuronal degeneration or cerebellar abiotrophy
  - Neuraxonal dystrophy
  - Cognitive dysfunction
- Anomalous:
  - Congenital hydrocephalus
  - Caudal occipital malformation syndrome
  - Intracranial arachnoid cyst
  - Dandy-Walker syndrome
  - Miscellaneous malformations
- Infectious:
  - Fungal (*Cryptococcus neoformans*, *Coccidioides immitis*, *Histoplasma capsulatum*, *Blastomyces dermatitidis*), viral (canine distemper virus, feline immunodeficiency virus [FIV] infection, feline leukemia virus [FeLV] infection), protozoal (*Neospora caninum*, *Toxoplasma gondii*, *Hepatozoon americanum*), verminous, rickettsial, and bacterial meningoencephalitis
- Inflammatory:
  - Necrotizing meningoencephalitis of small-breed dogs

- Granulomatous meningoencephalomyelitis (GME)
- Eosinophilic meningoencephalitis

- Metabolic:
  - Organic acidurias (e.g., L-2-hydroxyglutaric aciduria in the Staffordshire bull terrier, malonic aciduria in the Maltese)
  - Mitochondrial encephalopathies (e.g., pyruvate dehydrogenase deficiency in Sussex spaniels)
  - Hepatic, renal, hypoglycemic, and electrolyte-associated encephalopathies
- Neoplastic: primary or metastatic
- Nutritional: thiamine deficiency
- Toxic: lead
- Vascular: global ischemia, thromboembolic disease

INITIAL DATABASE

- CBC, serum biochemical profile, urinalysis:
  - May reveal leukocytes containing vacuoles or storage product
  - Some disorders show evidence of multiple affected organs.
  - Performed to rule out other metabolic disorders
- Serologic titers: performed to rule out infectious diseases

ADVANCED OR CONFIRMATORY TESTING

- Supportive diagnostic tests:
  - Cerebrospinal fluid (CSF) analysis:
    - Typically normal
    - Protein level may be elevated, but nucleated cell count should remain normal.
  - CT or MRI:
    - Brain atrophy with secondary ventriculomegaly
    - Diffuse changes in tissue intensity (due to accumulation of storage products)
- Confirmatory diagnostic tests (only available for certain storage disorders) can identify specific storage products, deficient enzyme activity, and/or presence of the defective gene responsible for the disease.
- Urine assays:
  - Oligosaccharides and glycopeptides can be profiled in urine samples using thin-layer chromatography to determine the particular compound that is accumulating and being excreted.
- Enzymatic assays:
  - Measures lysosomal enzyme activity for a panel of known lysosomal enzymes
  - Performed using whole blood leukocytes, kidney or liver biopsy samples, or cultured skin fibroblasts
  - Available for some enzymes (i.e., some storage diseases) and the level of activity of an affected animal can be compared to an age-matched control.
  - Since these diseases are commonly autosomal recessive, an affected animal would have significantly decreased enzyme activity, and a heterozygous carrier would have 50% of the enzyme activity of a homozygous animal.
- Molecular genetic testing for affected gene (DNA testing):
  - The specific genetic mutation responsible for a disease may vary among different species and breeds, so molecular testing is very specific concerning breed and species for any given disease.
- Histopathologic evaluation:
  - Peripheral nerve, muscle, liver, or lymph node biopsy may be diagnostic in some cases.
  - Brain biopsy guided by CT scan
  - Postmortem/necropsy:
    - Requires use of special staining techniques to characterize the specific storage product

TREATMENT

TREATMENT OVERVIEW

- Goal is to reduce the accumulation of cellular storage products.
- Mostly limited to supportive care and maintenance of quality of life for as long as possible
- Future therapeutic options may involve gene therapy or transferring normal copies of the dysfunctional gene to the patient's cells using a viral vector. Once the functional copy of the gene becomes incorporated into the cell, it begins to produce the deficit enzyme. Has been shown effective in treatment of feline α-mannosidosis.

RECOMMENDED MONITORING

- Progressive neurologic impairment is expected.

- Monitoring for quality of life

PROGNOSIS AND OUTCOME

- Poor
- For most disorders, progressively worsening neurologic signs lead to euthanasia within the first year of life.
- For those disorders with a slower progression, progressive neurologic dysfunction leads to euthanasia or death within 1-2 years of diagnosis.

PEARLS & CONSIDERATIONS

COMMENTS

- The field of medical genetics is rapidly advancing, and genetic tests and therapies such as gene transfer therapy may provide a more favorable prognosis in the future.
- Consultation with a veterinary neurologist is recommended to obtain the most up-to-date diagnostic and treatment information available.

PREVENTION

- Maintain responsible breeding practices.
- Genetic testing is available for a limited number of these storage diseases and may be used for identifying carriers.

CLIENT EDUCATION

- Caution owners about the possibility of personality changes or aggressive behavior associated with these disorders, especially where children may be involved.
- Counsel owners concerning the progressive nature of storage disorders and likelihood of eventual euthanasia.
- Counsel breeders about the inheritance of the condition and availability of DNA testing.

Stomatitis

BASIC INFORMATION

DEFINITION

Inflammation of the mucous lining of any of the structures in the mouth (storna); in clinical use, the term should be reserved to describe 'widespread oral inflammation (beyond gingivitis and periodontitis) that may also extend into submucosal tissues.

SYNONYMS

Lymphocytic-plasmacytic stomatitis, gingivostomatitis (cats); ulcerative stomatitis (dogs); alveolar, labial/buccal, sublingual and caudal stomatitis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Adult cats and dogs

GENETICS & BREED PREDISPOSITION

- Cats: sometimes is seen in group-housed families (may be pathogen-associated; no known genetic predispositions)
- Dogs: ulcerative stomatitis appears to be a familial disorder in Maltese dogs.

RISK FACTORS: Cats: prior exposure to viral diseases such as feline calicivirus (FCV), feline herpesvirus (FHV), or feline immunodeficiency virus (FIV)

CONTAGION & ZOONOSIS: Cats: *Bartonella henselae,* FCV, and FHV

ASSOCIATED CONDITIONS & DISORDERS

- Juvenile hyperplastic gingivitis <1 year old, presenting with severe inflammation and swelling of the gingiva of incisors, canines, and premolare; unknown if juvenile hyperplastic gingivitis can progress to adult stomatitis
- Cats with stomatitis often show resorption of multiple teeth (see p. 1104).

STOMATITIS Cat with inflammation of gingiva, alveolar mucosa, labial and buccal mucosa, and mucosa lateral to the palatoglossal folds. Note that the mucosa of the hard palate usually is not inflamed in cats with stomatitis.

(Copyright Alexander M. Reiter.)

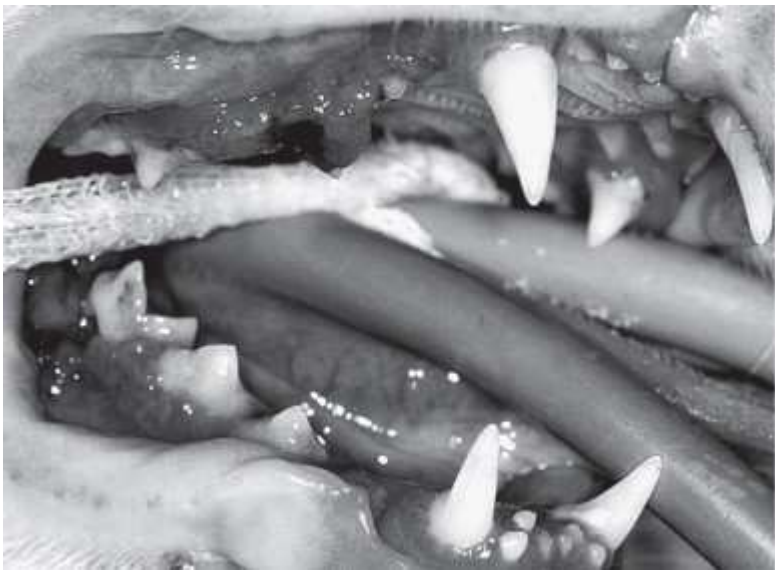
CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Dogs: ulcers most commonly found on the buccal mucosa of the lip and cheek facing plaque-laden tooth surfaces; in severely affected dogs, sometimes found on lateral margins of the tongue and on edges of the hard palate adjacent to teeth.

HISTORY, CHIEF COMPLAINT: Affected animals show signs of pain ‘when eating or when owner touches the mouth. Decreased grooming; drooling; sometimes weight loss.

PHYSICAL EXAM FINDINGS: Cats:

- Symmetric, bright red ulcerated lesions of the alveolar and buccal mucosa (rostral stomatitis) and/or the area lateral to the palatoglossal folds (caudal stomatitis)
- Lesions sometimes affect the lateral margins of the tongue extending caudally to include the palatoglossal folds.
- Commonly, poor body condition and hair coat if condition is chronic



STOMATITIS Young cat with inflammation of the gingiva, alveolar mucosa, and labial and buccal mucosa. Note proliferative changes of gingival tissue, entirely covering the crown of the right maxillary third premolar tooth.

(Copyright Alexander M. Reiter.)

Dogs:

- Oral ulcers: most commonly found on the buccal mucosa of the lip and cheek facing plaque-laden tooth surfaces
- In severely affected dogs, sometimes found on lateral margins of the tongue and on edges of the hard palate adjacent to teeth
- Halitosis, drooling, and reluctance to chew on hard treats or diets

ETIOLOGY AND PATHOPHYSIOLOGY

- Immune-mediated disease seemingly related to degree of dental plaque accumulation. Plaque bacteria play a role in the progression of the disease, and control of oral bacteria can be a critical contributor to successful management.
- The most reliable treatment in both species is extraction of teeth in affected areas of the mouth +/− extraction of all teeth, eliminating bacteria-laden dental plaque deposits.
- FCV and FHV infection may play a role in the immune system's aberrant response to plaque: 88% of stomatitis cats shed both viruses (versus 21% of cats without stomatitis). FCV-PCR is positive in 97% of cats with caudal stomatitis. Note: experimental FCV infection produces oral ulcerations but not chronic stomatitis.
- Evidence for a cause-effect relationship between *Bartonella* and feline stomatitis has not been provided.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on bilaterally symmetric inflammation that extends beyond the gingiva to include alveolar mucosa, labial and buccal mucosa, and/or mucosa lateral to the palatoglossal folds. Anesthetized examination at the time of initial diagnosis allows for coupling of confirmatory biopsy and initial dental care to reduce plaque and calculus and remove diseased teeth. Biopsy of any vesicles or mucocutaneous lesions is warranted to rule out autoimmune disease.

DIFFERENTIAL DIAGNOSIS

- Periodontal disease
- Squamous cell carcinoma or other less common neoplasia: more likely when disease is not bilaterally symmetric
- Eosinophilic granuloma: typically, isolated raised lesions on the tongue, lip, or palate
- In dogs, stomatitis may occasionally be a manifestation of autoimmune disease, including pemphigus vulgaris, bullous pemphigoid, systemic lupus erythematosus, and discoid lupus erythematosus. Look for other signs of autoimmune disease, including hematologic abnormalities, joint pain, fever, and pathologic proteinuria.
- Epitheliotropic lymphoma (mycosis fungoides)

INITIAL DATABASE

- Cats: FIV and FeLV tests; CBC, serum chemistry profile, and urinalysis are indicated for ruling out distant organ disease. Hypergammaglobulinemia due to a polyclonal gammopathy (via protein electrophoresis) is usually the most marked abnormality.
- Dogs: CBC, serum chemistry profile, urinalysis

ADVANCED OR CONFIRMATORY TESTING

- Biopsy of representative lesions; usually reported as caused by chronic inflammation, with a mixture of acute and chronic inflammatory cells (particularly lymphocytes and plasma cells). Since this pattern is expected when immune-responsive tissue is exposed to bacteria chronically, this biopsy is mainly helpful in ruling out neoplasia.
- In dogs, the characteristic location and appearance of the lesions rarely requires confirmatory biopsy except in cases where autoimmune disease or neoplasia is expected.

TREATMENT

TREATMENT OVERVIEW

Ideally, eliminate the condition by removing the plaque-retentive surfaces of the teeth and roots in their entirety; 93% of patients will be improved (80% will be clinically cured) by full-mouth or nearly full-mouth extractions. In cases where extraction is not an option, treat with strict plaque control, immunomodulators, +/− antimicrobials.

ACUTE GENERAL TREATMENT

Cats with severe generalized stomatitis:

- Antimicrobials (e.g., amoxicillin-clavulanate, 14 mg/kg PO q 12 h, and/or chlorhexidine gel or rinse 0.12% q 12 h), immunomodulators (typically a corticosteroid, such as prednisolone, 0.5-1 mg/kg PO q 24 h), and nursing care (nutritional support, grooming)
- Referral is indicated if uncertainty exists regarding the diagnosis, or if the attending practitioner is not equipped to provide necessary supportive and surgical care.
- Discuss extractions with the client and determine the client's willingness to perform full-mouth or nearly full-mouth (premolar and molars) extractions. If the client declines full-mouth extractions, schedule an appointment for anesthetized oral examination, including dental radiographs, biopsy, extraction of periodontally diseased teeth and teeth with resorption, and thorough scaling/polishing of remaining teeth. Follow with antibacterial treatment for 2 weeks, plus daily home oral hygiene (chlorhexidine gel or rinse, brushing the teeth daily, dental diet as the primary food) as soon as the cat will tolerate it.
- Reexamine the patient 2 weeks following dental treatment.
- If the cat is significantly improved, continue the home oral hygiene regimen, and reexamine the patient in 2-3 months.

Dogs with ulcerative stomatitis:

- Systemic antibacterial treatment (e.g., amoxicillin-clavulanate, 14 mg/kg PO q 12 h), chlorhexidine gel or rinse, and nursing care (soft food)
- 1-2 weeks later under general anesthesia: oral examination including dental radiographs, biopsy, extraction of periodontally diseased teeth, and thorough scaling/polishing of remaining teeth. Follow with daily home oral hygiene (daily toothbrushing, dental diet as the primary food) if the dog will tolerate it.
- If there is significant improvement, continue the chlorhexidine home care program, and reexamine the dog in 1-2 months. Excellent plaque control is the key to continued comfort of the dog. Some dogs may start to develop lesions (and oral pain) soon after initial treatment; in such cases, metronidazole may help at 20 mg/kg PO q 24 h for 1-2 weeks, then gradually reduce the dose (continuous treatment at 10 mg/kg PO q 48 h provides good control in some animals that relapse).

CHRONIC TREATMENT

Cats with severe, generalized stomatitis:

- If clinical signs and inflammation are still present, consider reinstituting oral prednisolone at 0.5-1 mg/kg PO q 12-24 h, and taper dose slowly over months to determine the lowest dose that controls clinical signs.
- If there is no improvement at all following dental treatment and prednisolone treatment, and there still are teeth in the diseased sections of the mouth, extract all remaining teeth.
- Clinical signs will persist in 20% of cats after extraction of all teeth. Refractory cases may be treated by a variety of modalities. Continuous or intermittent corticosteroids or nonsteroidal antiinflammatory drug (NSAID) treatment may provide relief, but try to avoid depot formulations owing to risk of diabetes mellitus and congestive heart failure. Cyclosporine (Neoral, 2.5 mg/kg PO q 12 h as a starting dose) shows promise in refractory cases, with up to 85% of cats showing improvement.
- CO2 laser treatment has provided apparent cures in select cases of severely proliferative disease, but therapy requires multiple anesthesias and placement of an esophagostomy tube (see p. 1267) after the first treatment to ensure caloric intake.
- Recombinant feline interferon (Virbagen Omega [Virbac]) has shown promise in treating refractory cases. In one of the most commonly used protocols, 5 MU is injected submucosally, diluted and divided as necessary to inject all inflamed areas. The remaining 5 MU are injected into a 100-mL bag of sodium chloride and frozen in ten 10-mL aliquots. The client gives 1 mL PO q 24 h for 100 days. The 10-mL fraction in use is refrigerated, and the other aliquots are kept frozen until needed.
- Azithromycin (5-10 mg/kg q 24 h for 5-21 days) has been advocated for treatment of *Bartonella*-seropositive cats. Long-term daily use of azithromycin should be approached cautiously because of its long half-life (35 hours) in cats.

Dogs with ulcerative stomatitis:

- If there is no improvement with initial treatment, extract all remaining teeth, and if necessary, start prednisone treatment (0.5-1 mg/kg PO q 12-24 h, titrating down to the lowest dose/frequency that controls clinical signs).

NUTRITION/DIET

- Soft food during healing
- Esophagostomy if severe oral discomfort precluding prehension and chewing of food (iatrogenic)

DRUG INTERACTIONS

Immunosuppressive drugs may have potentially severe side effects; adjust dose/frequency judiciously, and consult drug handbook for detailed information.

POSSIBLE COMPLICATIONS

- Failure to obtain clinical improvement: explaining this to the client at initial presentation and explaining the need for frequent treatment adjustments are important contributors to success.
- Exacerbation of preexisting infections (toxoplasmosis, FIV): due to immunosuppressive drug use

RECOMMENDED MONITORING

- Corticosteroids: monitor for evidence of diabetes mellitus.
- Cyclosporine: assess blood levels after 4-6 weeks and every 6-12 months thereafter. Target levels on a 12-hour-post blood sample are 400-600 ng/mL, but if patients are doing clinically well with a lower blood level, there is no need to increase the dose.

PROGNOSIS AND OUTCOME

Variable; response to full-mouth or near full-mouth extraction has been documented to be: 60% truly cured, 20% clinically cured

(some inflammation, no need for further therapy except home care), 13% slightly improved but needing further therapy, and 7% unimproved.

PEARLS & CONSIDERATIONS

COMMENTS

- There is no magic bullet, but extraction of teeth provides the most reliable results without long-term side effects. Extraction of teeth should be considered as an early option, not a last resort.
- In emaciated cats, rule out other causes before attributing weight loss/decreased appetite entirely to stomatitis.

PREVENTION

Good home oral hygiene from an early age may prevent development of disease in at-risk animals. However, lesions (in both dogs and cats) are often very painful, which makes animal compliance difficult.

TECHNICIAN TIPS

- Home oral hygiene is challenging in cats and dogs with painful, inflamed mouths. When teaching clients how to brush teeth, wait to start brushing until inflammation and pain are decreased with medical therapy and a professional dental cleaning.
- Performing full-mouth extractions requires a long duration of general anesthesia. To minimize anesthesia time, practice “four-handed dentistry.” Have all dental instruments available, and anticipate the surgeon's needs by having the next instrument ready and waiting.

CLIENT EDUCATION

Clients should understand that stomatitis may sometimes be controlled rather than cured. Initially, the concept of full-mouth extractions seems shocking to clients. Since full-mouth or nearly full-mouth extractions provides a “clinical cure” in 80% of cases, extraction represents the best chance of long-term relief of inflammation.

Stifle Joint Luxation

BASIC INFORMATION

DEFINITION

Complete derangement of the stifle joint in which ligaments, joint capsule, and menisci have been damaged

SYNONYMS

Multiple ligament injury of the stifle, stifle joint luxation

EPIDEMIOLOGY

RISK FACTORS: Trauma from falls, fights, or motor vehicle accidents

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Fall, fighting, or injury caused by a motor vehicle or firearm

PHYSICAL EXAM FINDINGS

- Non-weight-bearing extremity
- Extreme stifle joint pain
- Thickened or distorted stifle
- Severe joint instability

ETIOLOGY AND PATHOPHYSIOLOGY

- Uncommon condition of the stifle joint; 12% of all cases involving ligament injuries in dogs
- Extreme unnatural stress applied to joint, causing multiple ligamentous failures
- Both cruciate ligaments, at least one collateral ligament, joint capsule, and one or both menisci are torn or avulsed.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is confirmed by clinical history, physical examination, and radiography.

DIFFERENTIAL DIAGNOSIS

Femoral or tibial fractures involving the stifle joint

INITIAL DATABASE

- Orthopedic examination to confirm stifle joint instability; palpation performed with adequate pain management
- CBC and serum biochemistry panel based on American Society of Anesthesiologists (ASA) patient classification (see p. 1372)
- Thoracic and spinal radiographs when body trauma is suspected
- Craniocaudal and mediolateral radiographs of stifle

TREATMENT

TREATMENT OVERVIEW

The goal of therapy is restoration of stifle joint (congruency, motion) and limb functions.

ACUTE GENERAL TREATMENT

Surgical intervention:

- Inspect and remove damaged parts of menisci.
- Suture meniscal tibial ligaments if torn and menisci are intact.
- Débride remnants of cruciate ligaments, and use intracapsular or extra-capsular repairs.
- Primary repair of collateral ligaments or replacement with synthetic sutures
- Restoration of caudal cruciate ligament function is not necessary.
- Possible transarticular pinning of the stifle joint for immobilization during initial healing of soft tissues
- Temporary transarticular external skeletal fixation, with joint fixed at normal standing angle

CHRONIC TREATMENT

- External coaptation (soft padded bandage or half splint) for 3-4 weeks
- Transarticular pin or transarticular external skeletal fixation left in position for at least 3 weeks
- Initially, exercise restriction
- Following removal of external coaptation, physical therapy is initiated to restore joint function(s).
- Increased physical activity (rehabilitation) is allowed as stifle joint function is improving (see p. 1329).

STIFLE JOINT LUXATION Transarticular pin for temporary stabilization of stifle joint derangement in a cat.

POSSIBLE COMPLICATIONS

- Persistent stifle joint instability
- Osteoarthritis secondary to trauma and instability
- Reduced range of motion due to fibrosis

RECOMMENDED MONITORING

Monthly monitoring for stifle joint stability and range of motion

PROGNOSIS AND OUTCOME

- Good for restoration of adequate joint function
- Working or athletic dogs generally do not return to preinjury status.
- If treatment fails, arthrodesis or limb amputation can be considered.

PEARLS & CONSIDERATIONS

COMMENTS

Although prognosis appears grim during initial presentation, appropriate surgical techniques will often result in satisfactory restoration of function.

Steroid-Responsive Meningitis-Arteritis

BASIC INFORMATION

DEFINITION

Steroid-responsive meningitis-arteritis (SRMA) is a suspected autoimmune disorder characterized by inflammation of the meninges and meningeal arteries. The non-neurologic aspects of this disorder are discussed separately (see online chapter: Juvenile Polyarteritis).

SYNONYMS

SRMA, corticosteroid-responsive meningomyelitis, aseptic meningitis, beagle pain syndrome, canine juvenile polyarteritis syndrome, sterile suppurative meningitis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Young adult dogs (6-18 months old), but any age is possible.

GENETICS & BREED PREDISPOSITION

- Genetic factors are possible, but have not been proven.
- Most often diagnosed in boxers, Bernese mountain dogs, and beagles; however, any breed can be affected.

RISK FACTORS: Immune response may occur secondary to environmental or infectious causes.

CONTAGION & ZOONOSIS: Infectious cause has not been demonstrated.

ASSOCIATED CONDITIONS & DISORDERS: May occur concurrently in dogs with immune-mediated polyarthritis.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Classical (acute)
- Chronic

HISTORY, CHIEF COMPLAINT

- Classical (acute): cervical hyperesthesia and rigidity, fever, stiff gait, lethargy
- Chronic: as with acute disease, but with additional complaints suggestive of spinal cord dysfunction (proprioceptive deficits, paresis, ataxia)

PHYSICAL EXAM FINDINGS

- Typical of meningitis:
  - Cervical pain and rigidity; stiff, stilted gait; fever; lethargy
- In more protracted cases: gait abnormalities, proprioceptive deficits, back pain. Other neurologic signs are less commonly reported.

ETIOLOGY AND PATHOPHYSIOLOGY

- Idiopathic: possibly an autoimmune condition
- Classical (acute): histologic analysis demonstrates moderate to marked meningitis characterized by infiltration of neutrophils, macrophages, lymphocytes, and plasma cells, as well as degenerative changes and perivascular inflammation of the meningeal arteries. Lesions are most commonly found in the cervical spinal cord.
- Chronic: histologic analysis demonstrates moderate to marked fibrosis and patchy mineralization of the meninges.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected when a patient has signs of spinal pain or (less commonly) intracranial deficits. Advanced imaging helps rule out other differential diagnoses, and cerebrospinal fluid (CSF) analysis provides the most characteristic abnormalities.

DIFFERENTIAL DIAGNOSIS

- Infectious meningitis (bacterial, viral, protozoal, fungal)
- Diskospondylitis
- Inflammatory, noninfectious meningitis (e.g., granulomatous meningoencephalomyelitis [GME])
- Intervertebral disk disease
- Neoplasia (e.g., spinal meningioma, lymphoma, malignant histiocytosis)

INITIAL DATABASE

- CBC: leukocytosis, neutrophilia with left shift; may be normal in chronic cases
- Serum biochemistry profile: usually normal
- Urinalysis: usually normal
- Survey spinal radiographs: should be normal

ADVANCED OR CONFIRMATORY TESTING

- Immunoglobulin (Ig)A (serum or CSF) is often elevated and supports the diagnosis.
- CSF analysis (see p. 1228) often reveals an elevated protein level and white blood cell count with sterile neutrophilic pleocytosis in the acute stage of disease. Chronic cases may have normal CSF or mononuclear pleocytosis.
    - CSF culture and sensitivity should be negative.
- Infectious disease titers and/or advanced imaging (MRI (see p. 1302), CT (see p. 1233), myelography (see p. 1306)) may be required to rule out other diseases.

TREATMENT

TREATMENT OVERVIEW

The cornerstone of treatment is judicious immunosuppression adjusted to optimal response with fewest/no adverse effects.

ACUTE GENERAL TREATMENT

- Prednisolone: initially 2 mg/kg PO q 24 h for 1-2 days, then reduce to 1 mg/kg PO q 24 h for 2-4 weeks, then slowly taper by 25% every 3-4 weeks to lowest effective dose.
- Consider gastrointestinal (GI) protective agents (e.g., famotidine, 0.5 mg/kg PO or IV q 12-24 h, sucralfate 0.25-1 g PO q 8 h).
- Analgesics (e.g., tramadol, 2 mg/kg PO q 8-12 h; or amantadine, 2 mg/kg PO q 24 h for 4-6 weeks)

CHRONIC TREATMENT

Additional immunosuppressive medications may be required. Consider mycophenolate (CellCept, 5-10 mg/kg PO q 12 h), azathioprine (Imuran, 2 mg/kg PO q 24 h × 5 days, then q 48 h), or cyclosporine.

DRUG INTERACTIONS

- Drug interactions or altered metabolism of medications have been reported between corticosteroids and amphotericin B, furosemide, thiazide diuretics, digitalis glycosides, cyclosporine, phenytoin, phenobarbital, and mitotane.
- All immunosuppressive drugs carry the risk of excessive immune suppression, and some may have other (e.g., bone marrow suppressant) effects.
- Corticosteroids should not be given concurrently with nonsteroidal antiinflammatory drugs (NSAIDs) or other potentially ulcerogenic medications.

POSSIBLE COMPLICATIONS

Corticosteroid side effects: polyuria, polydipsia, polyphagia, weight gain, GI ulceration, iatrogenic hyperadrenocorticism, and others.

RECOMMENDED MONITORING

- Neurologic exam every 4-6 weeks
- Ideally, CSF analysis should be repeated every 4-6 weeks prior to reduction in medication dosage.

PROGNOSIS AND OUTCOME

- Classical (acute): generally good to excellent prognosis if treated early and aggressively
- Chronic: prognosis is fair to guarded owing to frequent relapses.
- Reports indicate 60% of dogs can be cured. Remaining patients require some level of corticosteroids long-term.

PEARLS & CONSIDERATIONS

COMMENTS

- SRMA has a good to excellent prognosis when patients are treated early in disease.
- CSF analysis should be performed early in the course of disease.

TECHNICIAN TIP

The hallmark physical sign of this disorder is neck pain. Handle with care and be aware of the possibility of pain-associated aggression.

CLIENT EDUCATION

Warn owners of corticosteroid side effects (e.g., polyuria, polydipsia, polyphagia, weight gain, GI ulceration, iatrogenic hyperadrenocorticism).

AUTHOR: MARK T. TROXEL

EDITOR: CURTIS W. DEWEY

Stab Wounds

BASIC INFORMATION

DEFINITION

- Low-energy impact, penetrating injuries inflicted by sharp instruments such as knives and screwdrivers and resulting in localized tissue trauma.
- This topic covers nonaccidental/malicious injuries causing incised wounds (cuts) and/or stab wounds.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Animals of any signalment
- Animals sustaining nonaccidental/malicious physical injuries are significantly more likely to be male than female; this gender difference may apply to stab wounds specifically.

GENETICS & BREED PREDISPOSITION

- Certain breeds (e.g., Staffordshire bull terrier) have been shown to be at markedly greater risk for nonaccidental/malicious physical injuries.
- Conversely, other breeds (e.g., Labrador retriever) are at markedly lower risk.
- Whether these breed predilections apply specifically to stab wounds remains to be proven.

RISK FACTORS

- Stabbing wounds are almost invariably the result of malicious intention, although impalement injuries from falls (e.g., onto pointed fence posts) have also been described.
- Working dogs with exposure to potentially dangerous encounters may be at greater risk.
- Outdoor cats

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Usually acute onset of signs
- Victim may be a working dog recently involved in a violent encounter.
- Unless an act of violence is evident or clear malicious intent is suspected, history may be vague.
- Repeated presentations for treatment of unexplained or poorly explained injuries should raise the suspicion of nonaccidental/malicious injury.
- Chief complaint (e.g., dyspnea, skin laceration, abdominal discomfort) may suggest localization of the wound.
- Animals with a minor, previously unattended wound may present for signs associated with infection.

PHYSICAL EXAM FINDINGS

- Obvious skin laceration
- Fever or hypothermia with infection
- Dyspnea or respiratory distress with lacerations to the chest or neck
- Abdominal distension or discomfort with abdominal wounds
- Tachycardia, tachypnea, and collapse with major hemorrhage

ETIOLOGY AND PATHOPHYSIOLOGY

- Injury reflects the shape and length of the weapon, location of injury, and direction of impact.
- In addition to the initial injury, further injury can result from injudicious removal of the weapon, which may involve twisting and dragging of the blade on its tract out of the wound.
- Penetrating wounds to the thorax or neck may cause cardiovascular collapse if major vascular structures or the heart are involved.

- Tension pneumothorax can result from injury to lung or major airway strictures.
- Penetrating wounds to the abdomen may cause injury to visceral organs, resulting in vascular injury, leakage of intestinal contents, leakage of bile, or leakage of urine.
- Laceration to the diaphragm can result in herniation of visceral organs and (potentially) bowel strangulation months to years later.
- Penetrating wounds to the head may cause hemorrhage or infection in the brain or eyes.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is based entirely on history (when known) and physical identification of compatible wounds. Diagnostic testing (e.g., radiographs) help elucidate the extent of internal injury suspected from the initial exam.

DIFFERENTIAL DIAGNOSIS

- Impaling from sticks
- Arrows
- Gunshot wounds
- Hemoabdomen
- Uroabdomen
- Spontaneous pneumothorax
- Sepsis

INITIAL DATABASE

- CBC, serum chemistry profile: unremarkable unless reflective of organ damage (e.g., uroabdomen) or preexisting condition
- Survey radiography, abdominal ultrasonography: identify internal injuries

ADVANCED OR CONFIRMATORY TESTING

As needed, based on extent and location of wound(s):

- CT scan (see p. 1233)
- MRI (see p. 1302)
- Selective angiography
- Fistulography (see online chapter: Fistulography)
- Wound culture
- Esophagoscopy (see p. 1284)

TREATMENT

TREATMENT OVERVIEW

Treatment goals are to control blood loss, maintain adequate oxygenation and ventilation, control infection, and manage the wound(s).

ACUTE GENERAL TREATMENT

- Control of airway and ventilation
- Cardiovascular resuscitation with IV fluid therapy or blood products
- Surgical exploration via celiotomy, thoracotomy, or other approach indicated by injuries
- Débride and close (with a drain) minor stab wounds to the soft tissue.
- Broad-spectrum antibiotics

CHRONIC TREATMENT

Short-term antibiotic therapy

POSSIBLE COMPLICATIONS

- Unidentified laceration to the diaphragm will often result in a diaphragmatic hernia days to years later.
- Wound sepsis

PROGNOSIS AND OUTCOME

- Depends on localization and severity of injury
- Depends on response to therapy

PEARLS & CONSIDERATIONS

COMMENTS

- Because a stabbing wound is externally small, it may go undetected in an animal with only vague signs. Therefore, close inspection of the skin (including clipping of hair when necessary) is recommended when a small cutaneous wound exists in an ill animal.
- History of a recent interaction involving a sharp instrument should prompt the clinician to perform a thorough search for suspicious injuries.
- Survey radiography or advanced imaging, including CT scan or MRI, may identify internal injuries such as hematoma, abscess, or subcutaneous emphysema.
- Because removal of an embedded blade may inflict additional tissue trauma, the injured animal should be kept quiet and as immobile as possible in the field; this is immediately followed by presentation of the patient to an emergency service for stabilization and cautious withdrawal of the instrument where radiographic, surgical, and supportive care (e.g., blood transfusion) facilities are available.

EDITOR: ELIZABETH ROZANSKI

1ST EDITION AUTHORS: THERESE E. O'TOOLE, ETIENNE CÔTÉ

Squamous Cell Carcinoma

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A malignant tumor arising from squamous epithelium

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Nasal planum (nonhaired, rostral, external part of nose):
  - Dog: rare site
  - Cat: squamous cell carcinoma (SCC) is the most common tumor in this site; older cats.
- Aural: generally occurs in older animals:
  - Dog: SCC is the second most common ear canal tumor (after ceruminous gland adenocarcinoma).
  - Cat: SCC may affect the pinna, often in cats with planum and periocular SCC; may also affect the ear canal, where it is the most common tumor type, equal in frequency to ceruminous gland adenocarcinoma.
- Digital:
  - Dog: SCC is the most common digital tumor, making up 35%-55% of such tumors; age between 7 and 11 years.
  - Cat: primary SCC of the digit is rare (about 10%). Digital carcinomas usually occur as metastasis from a bronchogenic carcinoma in older (mean of 13 years) cats.
- Oral:
  - SCC is one of the three most common malignant oral tumors, with nontonsillar SCC having a prevalence rate of approximately 7 per 100,000 dogs.
  - Dog: gingival area is most frequently affected, followed by lips, tongue, palate, and pharynx. Tonsillar SCC ranges in prevalence depending on the environment (urban dogs are more commonly affected). Middle-aged to older dogs are affected for most oral SCC, and there is no sex predilection. Gingival papillary SCC has been reported in very young (<1 year old) dogs.
  - Cat: SCC is the most common oral tumor in cats. SCC makes up about 75% of all feline oral tumors and occurs in the gingival and sublingual area in equal frequency. Older cats are affected; no sex predilection. Tonsillar SCC is very rare in cats.

GENETICS & BREED PREDISPOSITION

- Planum:
  - Dog: none
  - Cat: lightly pigmented animals; Siamese breed underrepresented
- Aural:
  - Dog: none
  - Cat: on pinna; found in lightly pigmented animals; Siamese breed underrepresented
- Digital:
  - Dog: approximately 75% are large-breed dogs, with around 70% having black coats. Breeds at increased risk include giant, standard, and miniature Schnauzers, Gordon setter, standard and miniature poodles, Scottish terrier, Labrador retriever, rottweiler, and dachshund. Digital SCC involving multiple digits has been reported in three related giant Schnauzers and has been reported in other large black dogs, including standard poodles, Labrador retrievers, and Gordon setters.
  - Cat: none
- Oral:
  - Dog: large dogs may be more likely to develop nontonsillar SCC than small dogs; white dogs may be predisposed to SCC of the tongue.
  - Cat: no predisposition

RISK FACTORS

- Solar exposure in white-coated cats is associated with increased risk of development of nasal planum, pinnal, and periocular SCC. Exposure to air pollution may be associated with development of tonsillar SCC in dogs. Gingival SCC has been reported to develop after oral radiation therapy in dogs. Oral SCC in cats may be associated with flea collar use, canned cat food or canned tuna consumption, and (possibly) environmental tobacco smoke. In one study, cats with SCC that were

exposed to environmental smoke were much more likely to over-express mutant p53 (a gene that when mutated can no longer function in its role as tumor suppressor) than cats with SCC living in nonsmoking environments.

GEOGRAPHY AND SEASONALITY: High altitude may increase the risk for solar exposure-induced SCC, as does living in countries with lower ozone coverage (e.g., New Zealand). Tonsillar SCC is about 10 times more likely to occur in dogs living in urban areas versus those living in rural areas.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Planum and pinna: clients may seek veterinary care because of the occurrence of crusted or ulcerated lesions or an actual mass. There may be bleeding or sneezing.
- Aural, external ear canal: there may be a visible mass, ear discharge, odor, pruritus, pain, facial nerve paralysis, head tilt, or circling. Compared to dogs, cats are more likely to present with neurologic signs.
- Digital:
  - Dog: lameness, swelling of digit, abnormal nail growth, fractured nail, licking/chewing at digit; oftentimes animals have a history of chronic nailbed infection treated with multiple different antibiotics with no improvement.
  - Cat: lameness; despite the fact that digital SCC in cats is usually metastatic from an underlying lung tumor, cats rarely have respiratory signs.
- Oral:
  - Dogs and cats may be presented for evaluation of difficulty eating, reluctance to eat, drooling, halitosis, bloody oral discharge, pawing at mouth, facial mass, oral mass, loose teeth, or weight loss. Dogs with tonsillar SCC may also be presented for evaluation of “lumps under jaw” due to large mandibular lymph node metastasis, with no other clinical signs.

PHYSICAL EXAM FINDINGS

- Planum and pinna: lesion may be proliferative or erosive; thus, mass or crusting and ulcerative lesion may be present. Regional lymph node may be enlarged.
- Aural, external ear canal: otic exam shows raised irregular mass, often ulcerated. Palpation of vertical ear canal may reveal large mass invading the area in late-stage cases.
- Digital:
  - Dog: painful swollen digit with an abnormal or absent toenail. Ulceration may be present. The regional lymph node may be enlarged.
  - Cat: swollen digit, ulcerated skin with purulent discharge; constant exsheathment, deviation, or loss of nail. About one third of animals present with multiple digits involved.
- Oral:
  - Gingival SCC: swelling or raised mass along gingival margin that may be irregular, ulcerated. Cats can have normal gingiva, with the tumor affecting the mandible/maxilla and causing a large swelling in the bone.
  - Tonsillar SCC: enlarged mandibular lymph nodes and enlarged irregular tonsils may be seen. Tonsillar enlargement is usually unilateral (see online chapter: Tonsillar Enlargement).
  - Sublingual SCC: irregular mass under tongue
- Multicentric squamous cell carcinoma in situ (MSCCIS, Bowen's disease, bowenoid in situ carcinoma [BISC]) is an uncommon disease reported mainly in cats. Lesions are multifocal and occur most commonly over the head, neck, dorsal thorax, abdomen, and proximal limbs. Lesions are found in haired and darkly pigmented skin and are not solar induced.

ETIOLOGY AND PATHOPHYSIOLOGY

- Planum and pinna: may begin as actinic keratosis and become locally invasive; low metastatic rate, possible association in some cases with papillomavirus
- Aural, external ear canal: locally invasive, more aggressive in cats than dogs; low metastatic rate (about 5%–15% in local lymph nodes)
- Digital:
  - Dog: locally invasive with digital (P3) bony destruction, low metastatic rate (5%–10% pulmonary; regional lymph node metastatic rate not well documented but uncommon; however, recent study reported 24% metastatic rate, site of metastasis not stated)
  - Cat: locally invasive with digital (P3) destruction. These are usually metastatic lesions from a pulmonary tumor. Lymph node involvement not documented.
- Oral:
  - Gingival and sublingual SCC: locally invasive with a low metastatic rate (5%–10% regional lymph nodes, 3% lung)
  - Tonsillar SCC: invasive and highly metastatic (98% regional lymph nodes, 63% lung)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of SCC is based upon signalment, physical examination findings, at times cytologic analysis, and most often via histopathologic evaluation from an incisional biopsy sample.

DIFFERENTIAL DIAGNOSIS

- Planum: fungal lesion (particularly *Cryptococcus* in cats), cutaneous lymphoma, mast cell tumor, fibrosarcoma, melanoma, eosinophilic granuloma, immune-mediated dermatopathy
- Aural:
  - Canal: severe hyperplasia in dogs with chronic otitis, ceruminous gland adenocarcinoma, adenoma, papilloma, polyp, plasmacytoma, basal cell tumor, melanoma, granuloma
  - Pinna: consider trauma, frostbite, insect bites; also see Planum, above.
- Digital:
  - Dog: melanoma, mast cell tumor, soft-tissue sarcoma, osteomyelitis, paronychia
  - Cat: usually metastatic lung tumor; bacterial paronychia; other primary tumors much less likely
- Oral:
  - Gingival mass in a dog: SCC, melanoma, fibrosarcoma, acanthomatous ameloblastoma (acanthomatous epulis). Less likely, osteosarcoma, plasma cell tumor, tooth root abscess, fungal disease, other primary tumors.
  - Gingival mass in a cat: SCC, fibrosarcoma, dental disease. Less likely, melanoma, other primary tumors.
  - Tonsillar mass in a dog: SCC, lymphoma. Less likely, bacterial or fungal infection.
  - Sublingual mass in a cat: SCC, foreign body, fungal infection, other neoplasia

INITIAL DATABASE

Dog, all sites:

- CBC, serum biochemistry profile, urinalysis; usually unremarkable
- Aspirate and cytologic examination from regional lymph nodes to assess for metastasis in all cases; unlikely to be positive but an easy test with prognostic value.
- Three-view thoracic radiographs to assess for metastasis; usually negative
- Fine-needle aspirate (FNA) and cytologic examination of the primary mass; it may be possible to obtain the samples on animal that is awake, but if sedation is needed, plan to biopsy as well.
  - Cytologic examination can provide a definitive diagnosis, but at times extreme inflammation of the tumor can make interpretation of the squamous cells difficult, necessitating a biopsy.

Cats:

- Planum and aural: see Dog, above. Hypercalcemia is rarely seen as paraneoplastic syndrome in ear canal SCC.
- Digital: three-view thoracic radiographs almost always reveal lung neoplasia; usually solitary mass but may be multiple. FNA and cytologic examination of the digital mass can provide a definitive diagnosis, but at times extreme inflammation of the tumor can make interpretation of the epithelial cells difficult. These cells, while usually pulmonary adenocarcinoma in origin, may have some squamous differentiation. FNA of the lung mass can confirm a lung tumor if the digit lesion is nondiagnostic.
- Oral: mandibular lymph node FNA and cytologic examination to assess for metastasis in all cases. Hypercalcemia may be seen as a paraneoplastic syndrome in some cats with oral SCC. Three-view thoracic radiographs to assess for metastasis.

ADVANCED OR CONFIRMATORY TESTING

- Incisional or excisional biopsy of the primary mass for histopathologic diagnosis
- Radiographs, CT scan, or MRI of lesion to assess for tumor extent, bone involvement, and to plan surgery or radiation therapy

TREATMENT

TREATMENT OVERVIEW

Excision of primary tumor with wide margins is often curative, as indicated by low metastatic rates in most primary locations except the tonsil. Owing to location and extent of lesion in many cases, however, wide excision may be difficult or impossible.

ACUTE GENERAL TREATMENT

Aggressive surgical resection; if margins are not complete on histologic evaluation, radiation is effective for microscopic disease.

- Planum:
  - Dog: excising the premaxilla along with the planum in cases with very large masses may provide better cosmesis.
  - Cat: excision is an excellent option if the tumor is not too extensive along the bridge of the nose or does not involve the lip or surrounding skin. Radiation, photodynamic therapy, cryotherapy, and intralesional chemotherapy (platinum drugs, 5-fluo-rocil [FU]) can be effective for small superficial lesions, with decreasing effectiveness for larger lesions. In one study, 6 out of 6 cats with large lesions had complete remission with intralesional carboplatin combined with radiation therapy (median follow-up time 9 months, with median time to recurrence or survival time not yet reached).
- Aural: total ear canal ablation with bulla osteotomy provides best survival times. In cats, the tumors can invade aggressively into the skull bones.
- Digital:
  - Dog: digital amputation; adjuvant therapy usually unnecessary
  - Cats: therapy unrewarding if metastatic lesion; if thoracic films are normal and only one digit is involved, amputation of the digit is recommended.
- Bowen's disease:
  - Systemic therapy has shown little benefit for this multifocal disease. Daily topical imiquimod has shown some efficacy in cats. This imidazoquinoline works via binding to surface toll-like receptors 7 and 8 on macrophages, which in turn leads to both innate and cell-mediated immune responses resulting in tissue-specific apoptosis. Survival times in a small series of cases (12 cats) exceeded 3 years.
- Oral:
  - Gingival: aggressive resection, including partial mandibulectomy or maxillectomy. Definitive radiation for residual microscopic disease if surgery does not provide tumor-free margins.
  - Tongue, dog: if rostral, surgical resection (40%-60% of the tongue can be removed with good function remaining, possibly more). Histologic grade predicts metastatic behavior; if high grade, consider chemotherapy.
  - Tonsillar: poor treatment options owing to invasiveness and metastatic behavior; multimodality therapy includes surgical debulking, if possible, of primary mass and involved lymph nodes, followed by chemotherapy and radiation; may extend survival times.
  - Sublingual and gingival, cat: very poor treatment options. Surgical excision usually not feasible. Radiation therapy and photodynamic therapy have been tried with limited success. Gemcitabine as a radiation sensitizer with palliative radiation has shown some short duration responses (50% complete and partial remission, with median duration 42.5 days) but may be associated with significant hematologic and normal tissue toxicity and thus cannot be recommended.
- Chemotherapy: piroxicam (0.3 mg/kg PO once daily; caution regarding gastric ulcerative effects) has some effect against gross SCC in dogs (18% complete and partial remission, 29% stable disease). Cisplatin combined with piroxicam also showed antitumor effect in dogs (55% complete and partial remission, 33% stable disease), but nephrotoxicosis is a significant concern when combining these drugs (about 40% renal toxicoses), so combining them is not recommended.

CHRONIC TREATMENT

- Cyclooxygenase (COX)-2 expression was shown in 40 out of 40 canine SCC cases, so therapy with piroxicam or other nonsteroidal antiinflammatory drugs (NSAIDs) may be of benefit.
- Only 9% of feline oral SCC cases and 0 out of 6 cutaneous SCC cases showed COX-2 expression, bringing into question the benefit of using NSAIDs for treatment of the feline disease.

PROGNOSIS AND OUTCOME

- Planum: excellent prognosis for cure if complete surgical resection. Median survival in cats with planum and/or pinna SCC: 673 days with surgery alone.
- Aural, canal: excellent prognosis for cure if treated early; unfortunately, tumors in cats have often progressed massively prior to identification, leading to a median survival time of only 3.8 months.
- Digital:
  - Dog: good prognosis with 95% 1-year and 75% 2-year survival rates. Median survival not reached in recent study (>1700 days).
  - Cat: for metastatic lesion, digital amputation median survival is only 1-2 months; for primary digital SCC, reported survival time with surgery is variable (3 weeks to 2 years).
- Oral:
  - Dogs with rostral SCC: wide surgical resection can be curative.
  - Dogs with mandibular or maxillary nonresectable SCC: radiation. Median survival time is 450 days. Control time for dogs with tumors greater than 4 cm diameter is generally shorter.
  - Dogs with tonsillar SCC: surgery and radiation. Median survival is 100 days. With surgery, radiation, and

chemotherapy (doxorubicin and cisplatin), median survival is 270 days.
- Dogs with lingual SCC: rostral masses can be cured with wide resection if low grade. Dogs with nonresectable lingual SCC can be treated with radiation therapy, but survival is generally short (i.e., median 4 months), with dogs being euthanized due to local proliferation or metastasis.
- Cats with mandibular SCC: radiation and mitoxantrone; without surgery, generally poor response; median survival is 180 days. Mandibulectomy and radiation: median survival is 14 months; euthanasia usually due to local recurrence.
- Cats sublingual: poor response to therapy; survival time <3 months.

PEARLS & CONSIDERATIONS

COMMENTS

- Planum: cosmesis and quality of life after a nosectomy are generally good to excellent, with high owner satisfaction. Early treatment when the lesion is small enough for a surgical cure is strongly recommended when possible.
- Aural:
  - Canal: complete ear ablation is needed; simple debulking is inadequate because the tumor will continue to invade inward, making a surgical cure impossible later.
  - Pinna: preneoplastic changes can extend along the entire edge of the pinna; complete pinnaectomy may be required for cure. If lesion is very small, simple removal of the affected tip of the ear can be considered, with a later decision made according to need for further excision based on histopathologic examination results.
- Digital:
  - Dog: tumors often go undiagnosed for extensive amounts of time due to treatment for a nailbed infection. Any questionable nonantibiotic-responsive digital swelling must be biopsied.
  - Cat: primary digit tumors are very rare; three-view thoracic radiographs are essential prior to surgery, because digital tumors are usually secondary.
- Oral:
  - Mandibular, maxillary, and lingual SCC in rostral locations in dogs can be cured with aggressive resection.
  - SCC in cats and in other locations in the mouth in dogs is difficult to address owing to invasiveness and/or metastasis.
  - Multimodality therapy may extend survival times, but quality of life can be an issue with the treatments:
    - Dogs with tonsillar SCC can have pronounced dysphagia and discomfort; surgical debulking may not alleviate clinical signs, and radiation therapy can contribute to local discomfort for several weeks.
    - Cats with mandibular or maxillary SCC can have temporary responses to chemotherapy and radiation, but side effects may necessitate placement of a feeding tube. The occasional cat with a small lesion may have a greatly extended survival time with surgery, radiation, and chemotherapy.
    - Case selection for multimodality treatment is important in both dogs and cats, and owners need to have realistic expectations for the success of the therapy.

PREVENTION

Planum and pinna: limit sun exposure in light-coated cats. Oral SCC in cats may be associated with flea collar use, canned cat food or canned tuna consumption, and (possibly) environmental tobacco smoke.

Sporotrichosis

BASIC INFORMATION

DEFINITION

A mycotic disease caused by *Sporothrix schenckii*. The disease is caused by a dimorphic fungus and clinically manifests with chronic granulomatous skin lesions.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Cats, dogs, humans, horses, pigs, cattle. Young to middle-aged cats and dogs predominate.
- “Rose-grower's disease” in humans

RISK FACTORS

- The disease is often associated with puncture wounds, so outdoor roaming dogs are overrepresented. In cats, fighting intact males predominate in contracting the disease.
- A higher concentration of organisms exists in soils rich in decaying organic matter, barberry and rose bush thorns, sphagnum moss, tree bark, and mine timbers.
- Immune suppression allows for dissemination.
- Punctures and other wounds allow for inoculation.

CONTAGION & ZOONOSIS

- Cat-to-cat or cat-to-human transmission is considered possible, especially to immunosuppressed people (via wounds or contaminated claws). Feline sporotrichosis may be a harbinger of sporotrichosis in dogs and humans in contact with these cases.
- Dog-to-dog or dog-to-human transmission is rare to unlikely owing to low numbers of organisms found in lesions.

GEOGRAPHY AND SEASONALITY: Worldwide distribution. Temperate to tropical climates.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Three clinical forms: cutaneous, cutaneolymphatic, and disseminated. Dogs: predominantly cutaneous, cutaneolymphatic. Cats: cutaneous, cutaneolymphatic, and disseminated.

HISTORY, CHIEF COMPLAINT

- Cutaneous lesions (nodular to ulcerated)
- Possible draining tracts
- Lethargy
- Anorexia

PHYSICAL EXAM FINDINGS

- Fever: suggests possible disseminated disease and immunocompromised state
- Depression
- Cats: ≈97% of affected cats have one or multiple skin lesions, commonly on the distal limbs, head, or tail base:
  - Draining puncture wounds, abscesses, or cellulitis
  - Ulcerations, purulent exudate, and large crusted lesions
  - ≈44% of affected cats have respiratory tract signs
- Dogs: multinodular truncal or head lesions; dermal or subcutaneous:
  - Ulcerations with purulent exudate and crust formation are possible.
  - Cutaneolymphatic form: nodules on distal limb, ascending via lymphatics and associated lymphadenopathy

ETIOLOGY AND PATHOPHYSIOLOGY

- Inoculation of mycelial form of *S. schenckii* into tissues leads to production of the yeast form
- Pyogranulomatous inflammation occurs, with organisms seen in macrophages and neutrophils.
- Lymphatic dissemination to spleen, liver, lung, eyes, bones, muscles, central nervous system [CNS])
    - Lung and liver are predominant sites for dissemination in cats.
- Dissemination is rare in dogs but may occur in up to 50% of cats, especially with immune-suppressive dosages of corticosteroids.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on geography, history, and physical exam findings, with positive cytologic results. Suspicion also is warranted if wounds are not responding to standard antibiotic therapy.

DIFFERENTIAL DIAGNOSIS

- Deep cutaneous bacterial infection, L-form bacterial infection
- Systemic mycosis
- Leishmaniasis (dogs)

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis: anemia, leukocytosis with neutrophilia, hypoalbuminemia, and hyperglobulinemia commonly observed
- Feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) serologic testing: positive in <1% and 8% of affected cats, respectively
- Cytologic examination from aspirates, exudates, or skin preps: diagnostic
    - Organism is small (slightly smaller than erythrocytes), round, oval, or cigar-shaped. Large numbers of organisms found in exudate in cats; small number found in dogs
- Positive bacterial cultures from secondary infection, often *Staphylococcus pseudintermedius*

ADVANCED OR CONFIRMATORY TESTING

- Histopathologic examination of nodules: diagnostic
- Fungal culture: notify laboratory of the possibility of *Sporothrix* organisms because of the infectious nature of sample to humans. Never culture suspected sporotrichosis lesions in-house (zoonosis risk).
- The Centers for Disease Control and Prevention, Atlanta, can perform fluorescent antibody testing on exudates or tissue.

TREATMENT

TREATMENT OVERVIEW

Removal of organisms, with treatment continuing for 30 days beyond apparent cure. Corticosteroids or other immunosuppressives are contraindicated.

ACUTE AND CHRONIC TREATMENT

Dogs; options include one of the following:

- Supersaturated solution of potassium iodide (SSKI) 40 mg/kg PO with food q 8 h for 30 days beyond apparent cure; *or*
- Ketoconazole 5-15 mg/kg PO with food q 8 h for 30 days beyond apparent cure; *or*
- Itraconazole 5-10 mg/kg PO with food q 12-24 h for 30 days beyond apparent cure

Cats:

- Itraconazole is the treatment of choice in cats; better absorption with suspension formula: 1.25-1.5 mg/kg (suspension) PO q 24 h for 30 days beyond apparent cure; or 5-10 mg/kg (capsules) PO q 12-24 h for 30 days beyond apparent cure.

POSSIBLE COMPLICATIONS

- SSKI can cause systemic iodination (ocular and nasal discharge, dry haircoat with scaling, vomiting, depression, collapse). If signs are mild, discontinue the medication for 1 week and reinitiate; if signs are severe, change treatment to alternative therapy.
- Ketoconazole can be hepatotoxic, especially in cats.
- Itraconazole has been found to be hepatotoxic in 10% of dogs treated with a dosage of 5 mg/kg q 12 h; better tolerated, fewer less side effects in cats.

RECOMMENDED MONITORING

With itraconazole or ketoconazole administration, monitor liver enzymes every 2-4 weeks for duration of therapy.

PROGNOSIS AND OUTCOME

- Response of cutaneous or cutaneolymphatic is fair to good. Of 266 cats treated in one study, 68 (26%) were cured, irrespective of extracutaneous signs or FIV status.
- Disseminated disease carries a guarded prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- Even after treatment is completed, use of immunosuppressive dosages of corticosteroids is contraindicated owing to reported recurrence of infection.
- Duration of therapy is often 3 months or more.
- Cats have been given iodide and ketoconazole, but because of high sensitivity, these are not recommended.

PREVENTION

- Limit outdoor roaming, especially in wooded areas.
- Castrate male cats to diminish fighting.

TECHNICIAN TIPS

- Wear gloves when handling infected animals.
- Wash hands and forearms with chlorhexidine or povidone-iodine scrub after wearing gloves.

CLIENT EDUCATION

- Sporotrichosis is a zoonotic disease, especially in cats.
- Separation of infected animals from immunosuppressed people is necessary.

Spongiform Encephalopathies

BASIC INFORMATION

DEFINITION

The spongiform encephalopathies are a heterogeneous group of diseases which have in common spongiform change within the brain, seen histopathologically. Lysosomal storage diseases may also be characterized by vacuolation of neurons, but in those cases the vacuoles are lysosomes distended with storage products. In the spongiform encephalopathies, vacuoles appear empty, and if intraneuronal, they are not membrane bound.

SYNONYMS

- Gray matter disease: transmissible spongiform encephalopathies (usually named for species, e.g., bovine spongiform encephalopathy [BSE]), prion disease
- White matter disease: use of the term *spongiform encephalopathy* to describe white matter disease is being dropped to avoid confusion with prion diseases. Better terms are *spongiform leukoencephalopathies* or *spongy degeneration of white matter*. Hereditary forms have specific names such as *Canavan's disease* or *maple syrup urine disease*.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Gray matter:
  - Transmissible: cats > 2 years of age
  - Hereditary: rottweiler dogs, signs begin at 6 weeks of age and progress over 6-7 months.
- White matter:
  - Acquired: dog or cat, any age or sex
  - Hereditary: dogs or cats
    - Signs begin at 3-5 weeks and progress rapidly in silkie terriers, Shetland sheepdogs, Samoyeds, and kittens
    - Signs begin at 4-6 months and progress over 6-8 months in Labrador retrievers and dalmatians.

GENETICS & BREED PREDISPOSITION

- Gray matter:
  - Transmissible: in sheep, mice, and humans, different polymorphisms in the prion protein gene can affect risk of infection. No such evidence in cats.
  - Hereditary: appears to be autosomal recessive in rottweilers
- White matter:
  - Acquired: no predisposition
  - Hereditary: appears to be autosomal recessive or maternal (mitochondrial) inheritance

CONTAGION & ZOONOSIS

- Gray matter:
  - Transmissible: ingestion of BSE-contaminated meat or byproducts can cause variant Creutzfeldt-Jacob disease in humans and feline spongiform encephalopathy in cats.

GEOGRAPHY AND SEASONALITY

- Gray matter:
  - Transmissible: only reported in European cats but could appear anywhere BSE appears
  - Hereditary: affected rottweilers have been reported in the United States and Europe.
- White matter: none

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Can be subdivided depending on whether vacuolation occurs within the myelin sheaths in the white matter or within neurons or their processes in the gray matter. Both can then be further subdivided into hereditary and acquired

forms. The acquired white matter diseases are toxic, whereas the acquired gray matter diseases are transmissible.

HISTORY, CHIEF COMPLAINT

- Gray matter:
  - Transmissible: behavior changes (timidity or aggression) progressing to ataxia, hypermetria, and hyperesthesia to touch and sound
  - Hereditary: ataxia, paresis, progressing to severe tetraparesis.
- White matter:
  - Acquired: at lower doses, bromethalin produces pelvic limb ataxia and paresis/paralysis. Higher doses produce severe muscle tremors and seizures.
  - Hereditary:
    - Labrador retrievers develop hypermetria and spastic paresis with episodes of decerebrate rigidity progressing to quadriplegia.
    - Shetland sheepdogs, Australian cattle dogs, and kittens have motor deficits, altered mentation, and seizures.

PHYSICAL EXAM FINDINGS

- Gray matter:
  - Transmissible: as described in History, Chief Complaint
  - Hereditary: ataxia and paresis with normal reflexes most prominent in the pelvic limbs and upper airway/inspiratory stridor (due to laryngeal paralysis). Progresses to severe tetraparesis and proprioception loss.
- White matter: as described in History, Chief Complaint

ETIOLOGY AND PATHOPHYSIOLOGY

- Gray matter:
  - Transmissible: caused by prions, enigmatic infectious proteins. Abnormally folded prion proteins build up within neurons as scrapie-associated fibrils and ultimately lead to cell death. Cats were infected at the height of the BSE outbreak in Europe.
  - Hereditary: gene has not been identified. Mutations in the prion protein gene can cause a spongiform encephalopathy in humans, but this was ruled out in rottweilers.
- White matter:
  - Acquired: toxins that uncouple oxidative phosphorylation, including bromethalin and hexachlorophene
  - Hereditary: a missense mutation in the mitochondrial gene for cytochrome B has been identified in Australian cattle dogs and Shetland sheepdogs. No mutation has been identified in other breeds of dogs or cats.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

The clinical diagnosis remains presumptive; confirmation is only possible at necropsy.

- Gray matter:
  - Should be suspected in progressive forebrain signs without other cause
  - Confirmed at necropsy
- White matter:
  - Suspected in cerebellar and long-tract signs
  - Imaging may show white matter edema.
  - Confirmed at necropsy

DIFFERENTIAL DIAGNOSIS

- Gray matter:
  - Transmissible: any cause of diffuse forebrain signs in adult cat:
    - Infectious: rabies, FIV, FIP, fungal, protozoal
    - Metabolic: hepatic, electrolytes, endocrine
    - Neoplasia: meningioma, astrocytoma, metastatic
    - Toxic: organophosphates, heavy metals
  - Hereditary:
    - Any cause of multifocal central nervous system (CNS) or peripheral nerve disease in a young dog
    - Other hereditary diseases of rottweilers: leukodystrophy, motor neuron disease, neuroaxonal dystrophy

        - Idiopathic laryngeal paralysis
        - Infectious: *Neospora*, distemper, tickborne, fungal
        - Toxic
- White matter:
    - Juvenile onset:
        - Any cause of diffuse white matter disease
        - Canine distemper
        - Lysosomal storage disease or other inborn error of metabolism
    - Neonatal onset:
        - Any cause of diffuse forebrain disease
        - Lysosomal storage disease or other inborn error of metabolism
        - Hepatic encephalopathy
        - Hypoglycemia

INITIAL DATABASE

- Neurologic exam (see p. 1311):
    - Localize lesion(s)
- CBC/serum biochemistry profile (including bile acids)/urinalysis:
    - Rule out metabolic disease and look for evidence of infection
- Brain imaging (CT or MRI; and):
    - Rule out structural disease
    - May see evidence of diffuse increase in water density of gray or white matter
- Cerebrospinal fluid (CSF) analysis:
    - Rule out encephalitis/meningitis

ADVANCED OR CONFIRMATORY TESTING

Ultimate diagnosis is only available postmortem: histopathologic lesions showing vacuolation in white matter or gray matter.

TREATMENT

TREATMENT OVERVIEW

Most are not amenable to treatment. Confirmation of gray matter spongiform encephalopathy is important for public health considerations. There are no specific treatments for any of the transmissible or hereditary spongiform encephalopathies. Treatment would be purely supportive and nonspecific, such as anticonvulsant drugs for seizures.

ACUTE GENERAL TREATMENT

Mannitol may improve the intramyelinic edema that can occur with bromethalin toxicity.

PROGNOSIS AND OUTCOME

- Prognosis for all spongiform encephalopathies is guarded to grave.
- Personality changes make animals with transmissible forms potentially dangerous.
- Hereditary forms have been inexorably progressive.
- Toxic spongiform leukoencephalopathies respond poorly to treatment but may recover if dose is low.

PEARLS & CONSIDERATIONS

COMMENTS

Transmissible spongiform encephalopathies will hopefully remain rare in dogs and cats. However, it is important to recognize them if they should occur because of their public health implications. A necropsy will be necessary to confirm a diagnosis of spongiform encephalopathy of gray matter, which should be reported to the appropriate agency.

PREVENTION

- Care with use of bromethalin rodenticides
- Do not feed bovine nervous system or byproducts to cats in BSE-endemic areas. Risk from deer with chronic wasting disease is unknown, but it would be wise to not feed deer nervous system or byproducts to cats.

CLIENT EDUCATION

Clients should be educated about transmissible spongiform encephalopathies so they can make intelligent choices regarding meat safety rather than being swayed by emotion or politics.

AUTHOR: DENNIS P. O'BRIEN

EDITOR: CURTIS DEWEY

Splenomegaly

BASIC INFORMATION

DEFINITION

Enlargement of the spleen—focal or generalized

EPIDEMIOLOGY

GENETICS & BREED PREDISPOSITION

- German shepherd, Great Dane (gastric dilatation volvulus [GDV] with splenic torsion)
- Boxer (mastocytosis)
- German shepherd, golden retriever, Labrador retriever (hemangiosarcoma)
- German shepherd (systemic mycoses, especially aspergillosis)
- Cocker spaniel (immune-mediated hemolytic anemia [IMHA])
- Bull mastiff and many others (lymphoma)
- Oriental-breed cats (feline infectious peritonitis [FIP])

RISK FACTORS: Living in endemic tickborne disease areas

GEOGRAPHY AND SEASONALITY: Tickborne diseases: more prevalent in tropical climates and during the summer

ASSOCIATED CONDITIONS & DISORDERS: Generalized lymphadenopathy (see p. 662)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Vague and nonspecific: anorexia, lethargy, weight loss
- Related to underlying disease rather than splenomegaly
- Chronic vomition if marked splenic enlargement
- Polyuria/polydipsia: paraneoplastic hypercalcemia

PHYSICAL EXAM FINDINGS

- Palpation of abdominal mass
- Abdominal distention if severe enlargement or hemoabdomen
- Lymph node enlargement: lymphoma, ehrlichiosis, mycoses, autoimmune disorders
- Collapse, pallor, tachycardia: splenic rupture, IMHA, acute babesiosis
- Petechiae: immune-mediated thrombocytopenia (ITP)

ETIOLOGY AND PATHOPHYSIOLOGY

- Generalized splenomegaly:
  - Infiltrative disorders:
    - Neoplastic: acute and chronic leukemia, systemic mastocytosis (more common in cats), lymphoma, multiple myeloma
    - Non-neoplastic: amyloidosis
  - Congestion:
    - Smooth muscle relaxants: barbiturates, halothane anesthesia
    - Splenic torsion (alone or in association with GDV)
    - Right-sided heart failure with portal hypertension
  - Inflammatory/infectious disorders (splenitis):
    - Suppurative: hematogenous dissemination of bacterial infection
    - Necrotizing: gas-forming anaerobes associated with splenic torsion
    - Eosinophilic: hypereosinophilic syndrome (cats)
    - Lymphoplasmacytic: ehrlichiosis, infectious canine hepatitis, babesiosis
    - Granulomatous: systemic mycoses

        - Pyogranulomatous: FIP
    - Lymphoreticular hyperplasia
        - Chronic bacteremic conditions: discospondylitis, brucellosis
        - Hemolytic disorders: IMHA, ITP
    - Extramedullary hematopoiesis
- Focal splenomegaly (splenic mass)
    - Neoplastic
        - Hemangiosarcoma, hemangioma, leiomyosarcoma, fibrosarcoma
    - Non-neoplastic
        - Hematoma, abscess, nodular hyperplasia, granuloma

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Splenomegaly warrants evaluation with a CBC and serum biochemistry profile in an attempt to find a possible etiology. Diagnostic imaging helps elucidate whether the enlargement is regional or diffuse, which narrows the differential diagnosis. Based on these results, specific tests (e.g., PCR if infection is suspected) or intervention (splenic aspirate, splenectomy) can be chosen to conclude the diagnosis.

DIFFERENTIAL DIAGNOSIS

- Other cranial abdominal organomegaly
- Other nonspecific abdominal masses

INITIAL DATABASE

- CBC:
    - Regenerative anemia: IMHA, splenic rupture, blood parasites
    - Nonregenerative anemia: ehrlichiosis, retroviral infections, neoplastic bone marrow infiltration
    - Pancytopenia: ehrlichiosis, bone marrow infiltration
    - Spherocytosis: IMHA
    - Hemoglobinemia, bilirubinemia: splenic torsion, hemolysis
    - Lymphoblastosis: lymphoma, infections (rarely)
    - Blood parasites: babesiosis, acute ehrlichiosis, feline hemoplasmas
    - Thrombocytopenia: ITP, babesiosis, ehrlichiosis and other rickettsial diseases
- Urinalysis:
    - Hemoglobinuria, bilirubinuria: hemolytic disease, splenic torsion
- Serum biochemistry profile:
    - Hyperglobulinemia: FIP, multiple myeloma, ehrlichiosis
    - Hypercalcemia: lymphoma, multiple myeloma, granulomatous disease
- Imaging:
    - Abdominal radiographs: confirm abdominal mass (if sufficiently large)
    - Thoracic radiographs: assess for metastases (take ventrodorsal, left-, and right-lateral views)
    - Abdominal ultrasonography: detect abdominal effusion, define splenic architecture, confirm splenic origin (mass), delineate metastatic abdominal masses, identify abdominal effusion far centesis
- Retroviral testing (cats)

ADVANCED OR CONFIRMATORY TESTING

- Fine-needle aspiration and cytologic examination to detect infectious agents or predominant inflammatory cell type:
    - Not recommended with mixed echogenicity masses (suspicion of hemangiosarcoma) because of risk (may hemorrhage) and poor diagnostic yield (heterogenous tumor)
- Histopathologic examination of tissue after splenectomy or of tissue samples taken at the periphery of large masses
- Bone marrow aspiration
- Exploratory laparotomy
- CT (abdominal)
- PCR: *Ehrlichia,* feline hemoplasmas
- Coagulation panel: disseminated intravascular coagulation

TREATMENT

TREATMENT OVERVIEW

Since splenomegaly is a sign attributable to many different types of disorders, treatment will depend on the underlying disease process.

ACUTE AND CHRONIC TREATMENT

Selected according to the etiology

POSSIBLE COMPLICATIONS

Susceptibility to infectious diseases after splenectomy

RECOMMENDED MONITORING

Monitor for ventricular arrhythmias for up to 3 days after splenectomy (splenic masses).

PROGNOSIS AND OUTCOME

- Good to excellent with uncomplicated infections (babesiosis, ehrlichiosis)
- Guarded to grave in the case of advanced-stage (metastatic) hemangiosarcoma
- With splenic masses, prognosis cannot be determined without complete histopathologic evaluation of tissue:
    - Hematoma/nodular hyperplasia (55% of splenic masses): 83% alive 2 months post splenectomy, 64% alive at 1 year. Most deaths/euthanasia due to unrelated causes.
    - Hemangiosarcoma (40% of splenic masses): 31% alive 2 months post splenectomy, 7% at 1 year. Most deaths/euthanasia due to hemangiosarcoma progression.

PEARLS & CONSIDERATIONS

COMMENTS

- Age does not discriminate between neoplastic and non-neoplastic splenic disease.
- Clinical signs are vague.
- A common clinical error is excessive suspicion of hemangiosarcoma on the basis of a splenic mass as the only abnormality.
- Differentiate splenomegaly from hepatomegaly by ability to move the spleen caudally during abdominal palpation. Raise patient's forelimbs to facilitate examination.
- Dogs with anemia, nucleated red blood cells, abnormal red cell morphology, or splenic rupture: greater chance of having splenic neoplasia
- The spleen is an accessible organ to obtain a diagnostic sample in evaluating systemic diseases (diffuse splenomegaly).
- For histopathologic examination of splenic masses after splenectomy, a submitted tissue sample should cross from normal tissue to abnormal/mass. Ideally, the whole spleen is submitted fresh on cold packs (not frozen).
- Gross appearance at laparotomy cannot discriminate between hematoma, nodular hyperplasia, hemangioma, and hemangiosarcoma; normal ectopic splenic tissue in abdomen may falsely appear to be metastases—be careful if considering euthanasia on the operating table.

PREVENTION

Regular tick control in endemic areas

AUTHOR: JOHAN P. SCHOEMAN

EDITOR: ETIENNE CÔTÉ

Splenic Torsion

BASIC INFORMATION

DEFINITION

Twisting of the pedicle of the spleen, resulting in occlusion and thrombosis of the splenic vasculature and splenic ischemia

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs: males more frequently affected

GENETICS & BREED PREDISPOSITION: Large-breed, deep-chested dogs (Great Danes, German shepherds)

RISK FACTORS: Gastric dilatation/volvulus (GDV)

ASSOCIATED CONDITIONS & DISORDERS

- GDV
- Splenic infarction

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Often vague, nonspecific signs for up to 3 weeks prior to diagnosis:
  - Intermittent vomiting, diarrhea
  - Weakness, depression
  - Anorexia
  - Abdominal distention
  - Weight loss
  - Discolored urine
- Acute collapse
- Previous episode of GDV

PHYSICAL EXAM FINDINGS

- Abdominal distention
- Abdominal mass/splenomegaly
- Any of the following may also be noted: abdominal pain, fever, dehydration, pale mucous membranes, icterus.
- If acute cardiovascular collapse: tachycardia, pale mucous membranes, prolonged capillary refill time, weak peripheral pulses

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology unknown:
  - Occurs in large-breed, deep-chested dogs
  - Associated with GDV:
    - Occurs in conjunction with GDV
    - GDV occurs after treatment of splenic torsion
- Proposed theory: repeated stretching of gastrosplenic and splenocolic ligaments, resulting in splenic hyper-motility

DIAGNOSIS

DIAGNOSTIC OVERVIEW

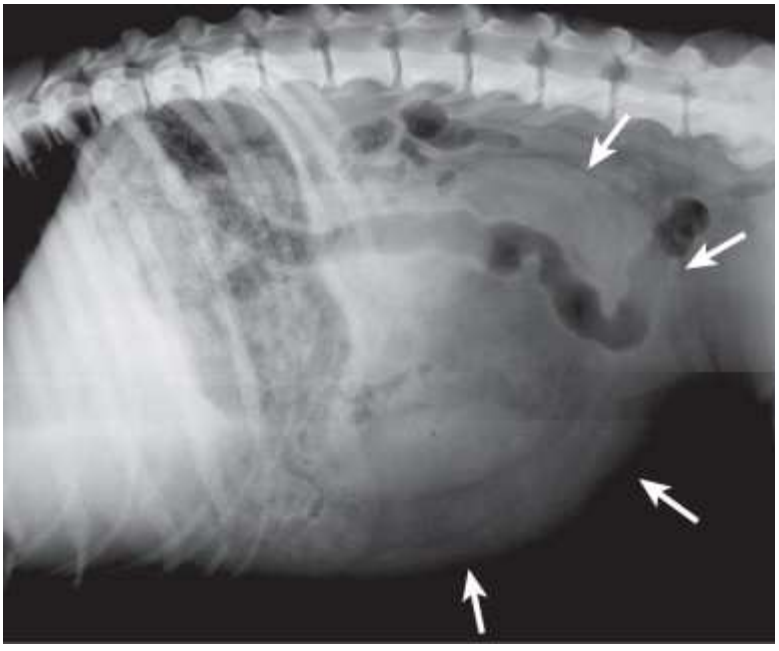
Diagnosis is suspected based on patient signalment, presenting history, and physical examination findings. Confirmation requires abdominal diagnostic imaging (radiographs, ultrasound) to demonstrate the uniformally enlarged, malpositioned spleen.

DIFFERENTIAL DIAGNOSIS

- Splenic neoplasia
- Other causes of splenomegaly (see p. 1428)
- Neoplasia of other abdominal organs (e.g., liver)
- GDV

INITIAL DATABASE

- CBC:
  - Anemia
  - Leukocytosis (neutrophilia, monocytosis: stress leukogram common)
- Serum biochemistry profile:
  - Elevated alkaline phosphatase (ALP), alanine aminotransferase (ALT), bilirubin concentrations
- Urinalysis:
  - Hemoglobinuria common
- Diagnostic imaging:
  - Survey abdominal radiographs:
    - Splenomegaly (diffuse):
      - May be the only abnormal radiographic finding
      - Often the enlarged spleen may have a "reversed C" shape.
      - Abnormal position of spleen in abdomen is common.
      - Gas bubbles may be seen within the spleen.
    - Peritoneal effusion is common and can obscure visceral detail to the point that the findings listed previously are not apparent, requiring abdominal ultrasonography.
    - Displacement of the small intestines
  - Abdominal ultrasound examination: indicated in all cases in which splenic torsion is suspected
    - Diffuse splenomegaly, appearing to curve around the hilus
    - Free abdominal fluid is generally present.
    - Diffusely hypoechoic spleen, "lacy" appearance of splenic parenchyma:
      - Linear echoes separating large hypoechoic areas. This appearance is a result of vascular congestion (hypoechoic) within the dilated sinusoids and vessels (the walls of which are the framework of the "lace").
      - Thrombi may be visible within the lumen of splenic vessels.
    - Doppler color flow:
      - Decreased blood flow through splenic veins
      - Lack of flow in regions associated with intravascular thrombi
- Electrocardiogram (ECG) if arrhythmia is noted on exam, if there is suspicion of syncope/collapse, or for postoperative monitoring



SPLENIC TORSION Lateral abdominal radiograph of a dog with splenic torsion. The characteristic "reversed C" shape of the torsed spleen is apparent *(arrowheads).*

(Courtesy Dr. Richard Walshaw.)

ADVANCED OR CONFIRMATORY TESTING

Coagulation profile: laboratory evidence of coagulopathy may exist, but a clinical bleeding problem is rarely detected.

TREATMENT

TREATMENT OVERVIEW

Splenectomy is the required treatment for this problem and should be performed as soon as the patient is stable. This time frame will depend on the clinical status of the patient at the time of presentation.

ACUTE GENERAL TREATMENT

- Preoperative patient stabilization:
  - Correction of fluid deficits and electrolyte imbalance
  - Blood products (see p. 1347):
    - Whole blood if hematocrit <20% or if acute large-volume blood loss
    - Fresh frozen plasma if coagulopathy is present
  - Treatment of cardiac arrhythmias if indicated (see p. 1165)
  - Perioperative antibiotic therapy:
    - Cefazolin, 22 mg/kg IV q 2 h
- Surgical intervention as soon as animal is stable:
  - Splenectomy without untwisting the pedicle
  - Gastropexy
- Postoperative supportive care:
  - Continuation of IV fluid and electrolyte therapy
  - Additional blood products if indicated
  - ECG monitoring:
    - Treatment of arrhythmias if indicated

POSSIBLE COMPLICATIONS

- Delay in diagnosis and treatment:
  - Splenic necrosis
  - Peritonitis/sepsis
  - Disseminated intravascular coagulation (DIC)
- Pancreatitis:
  - If distal portion of left limb of pancreas is involved in torsion of the splenic pedicle

PROGNOSIS AND OUTCOME

Good with early diagnosis and treatment; reported 100% postsurgical survival

PEARLS & CONSIDERATIONS

COMMENTS

- Splenic torsion can occur in association with GDV or as an isolated problem.
- The same type of dog that has the greatest risk of developing GDV also has an increased risk of developing isolated splenic torsion.
- Gastropexy after splenectomy for splenic torsion is indicated to prevent future GDV.

TECHNICIAN TIPS

Perioperative patient care and stabilization may involve:

- Fluid therapy and administration of blood products. Be familiar with calculations necessary for whole blood and plasma

transfusion requirements.
- ECG monitoring. Be able to recognize arrhythmias and seek appropriate veterinary assistance.
- Ensure that adequate analgesia is provided in the postoperative period.

CLIENT EDUCATION

Large-breed, deep-chested dogs that develop vague, nonspecific signs of abdominal problems (as already described in this entry) may have splenic torsion.

SUGGESTED READING

AUTHOR & EDITOR: RICHARD WALSHAW

Spirocercosis

BASIC INFORMATION

DEFINITION

A disease of dogs that is caused by the nematode *Spirocerca lupi* and is characterized by lesions that can affect the esophagus (with potential for esophageal malignancy), aorta, and vertebrae

EPIDEMIOLOGY

SPECIES, AGE, SEX: Primarily affects dogs. Young to middle-aged dogs overrepresented; dogs <1 year old unlikely to develop infection.

GENETICS & BREED PREDISPOSITION: Medium- and large-breed dogs predisposed

GEOGRAPHY AND SEASONALITY: This parasite is found in the southern United States and many tropical and subtropical regions. In some endemic areas, there is a disproportionately high prevalence in urban dogs compared to rural dogs, but this varies with geographic region.

CONTAGION & ZOONOSIS: Not a zoonotic disease

ASSOCIATED CONDITIONS & DISORDERS: Esophageal neoplasia (osteosarcoma, fibrosarcoma, undifferentiated sarcoma) may occur secondary to esophageal granuloma formation from the encysted worms. These dogs may also develop hypertrophic osteopathy. Thoracic aortic aneurysm may occur secondary to migration of *S. lupi* from the gastrointestinal (GI) tract into the aortic wall. Thoracic vertebral spondylitis has been reported to occur secondary to migration and granuloma formation. Salivary gland necrosis, esophageal perforation with associated mediastinitis, and pyothorax have also been reported.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Vomiting or regurgitation, odynophagia, ptyalism, weakness, respiratory difficulty, coughing, anorexia, melena, paraparesis

PHYSICAL EXAM FINDINGS: There are no pathognomonic physical examination findings. Physical examination findings are related to the area of the body affected by the parasite. In addition to the chief complaints listed above, the most common abnormalities include weight loss and fever.

ETIOLOGY AND PATHOPHYSIOLOGY

- Spirocercosis is caused by the migration of the nematode *S. lupi*. Carnivores are infected by ingestion of an intermediate host (coprophagous beetles) or other paratenic hosts (e.g., birds, hedgehogs, lizards, mice, rabbits) in which the parasite does not undergo further development during its passage.
- Adult *S. lupi* generally live within nodules in the esophagus and stomach. *Spirocerca* eggs pass with feces, where they are ingested by coprophagous beetles. The definitive host may acquire the infection by ingesting the beetle intermediate host or other paratenic host.
- The L3 larvae penetrate the stomach wall of the definitive host, and migration occurs within the walls of the gastric arteries to the thoracic aorta. From the aorta, they migrate to the esophagus. The prepatent period time from infection of the host to the first ability to detect the infection with diagnostic evaluation is approximately 5-6 months.
- Clinically significant lesions are related to the migration route and final destination site of the parasite. The most common scenario is esophageal granuloma formation.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Spirocercosis typically is suspected in a patient presented for evaluation of regurgitation and living in an area where the disease is prevalent. Thoracic radiographic findings are often supportive of the diagnosis, but direct visualization through endoscopy is required for confirmation prior to treatment.

DIFFERENTIAL DIAGNOSIS

- Regurgitation: other esophageal disorders such as megaesophagus, esophagitis, foreign bodies, esophageal stricture, gastroesophageal reflux disease
- Esophageal mass: esophageal neoplasia, granuloma of other origin
- Vomiting: both GI (inflammatory, infectious, parasitic, neoplastic, dietary) and extra-GI (metabolic, endocrine, pancreatitis) etiologies

INITIAL DATABASE

- CBC, serum biochemical profile, urinalysis; no characteristic abnormalities:
  - Anemia (53% of cases) typically normocytic, normochromic and nonregenerative
  - Leukocytosis
  - Elevation in serum creatine kinase: most common biochemical abnormality (54% of cases)
  - Increased alkaline phosphatase
  - Hyperproteinemia
- Fecal flotation:
  - Sugar flotation
  - Teleman's sedimentation:
    - May reveal characteristic small, elongated eggs
    - Variable yield; positive result in 29%-80% of cases
- Thoracic and abdominal radiographs indicated (dorsoventral and right lateral projections most accurate for thoracic films in canine spirocercosis); may reveal dorsoventral and right lateral projections most accurate for canine spirocercosis
  - Esophageal and stomach lesions (soft-tissue masses with/without calcification). A mass is typically noted in the caudal esophagus (53%-86% of cases of spirocercosis). Most affected dogs have more than one granuloma, but not all are seen radiographically.
  - Bony changes in the thoracic vertebrae
  - Evidence of metastasis when esophageal neoplasia is present
- Limb radiographs in patients with lameness or hard swelling of distal limbs, to assess for hypertrophic osteopathy

ADVANCED OR CONFIRMATORY TESTING

- Esophagoscopy and gastroscopy may allow for visualization of granulomas and for biopsy procedures. In most cases of spirocercosis, endoscopy is the confirmatory diagnostic procedure of choice.
- Thoracic CT may be useful for identifying esophageal masses and aortic aneurysm.
- Postmortem examination in patients with sudden death or who have been euthanized will also provide a definitive diagnosis.

TREATMENT

TREATMENT OVERVIEW

- Resolution of regurgitation or vomiting
- Prevent development of esophageal neoplasia or hypertrophic osteopathy.
- Prevention of sudden death due to rupture of aneurysm

ACUTE AND CHRONIC TREATMENT

- Doramectin (Dectomax [Pfizer]) 200 mcg/kg SQ q 14 days for 3 treatments
  - Treatment of choice
  - Permanent resolution/cure is expected in many or most dogs in 6 weeks' time or less.
  - Dogs with persistent lesions after 6 weeks have been treated safely and successfully using doramectin, 500 mcg/kg PO q 24 h × 6 weeks.
- Fenbendazole (50 mg/kg PO q 24 h × 5-7 days) or ivermectin (200-400 mcg/kg SQ q 14-28 days) have been used for treating spirocercosis.

POSSIBLE COMPLICATIONS

Do not use ivermectins in collies, Shetland sheepdogs, Australian shepherds, or other susceptible breeds or individuals (see pp. 625 and 706).

PROGNOSIS AND OUTCOME

Prognosis is variable:

- With appropriate treatment, cure is expected in many or most dogs in 6 weeks' time or less.
- However, presence of esophageal neoplasia, aortic aneurysm, or large masses obstructing flow of ingesta worsen the prognosis.
- Hypertrophic osteopathy worsens the prognosis (present in 39% of cases with esophageal malignancy, 0% of cases without esophageal malignancy)
- Radiographic evidence of spondylitis (68% vs. 38%) and bronchial displacement (52% vs. 17%) are significantly different between cases with esophageal malignancy versus those without malignancy, respectively.
- Sixty-three percent of dogs with spirocercosis may die or be euthanized within 1 month of admission.

PEARLS & CONSIDERATIONS

COMMENTS

- In North America and Europe, spirocercosis is a rare disease and is only considered when there is a high index of clinical suspicion.
- The characteristic lesion is a soft-tissue mass in the caudal esophagus; radiographically, foreign-body ingestion is an important differential diagnosis.
- A minority of dogs develop neoplastic transformation of esophageal granulomas (e.g., 13 out of 14 dogs with spirocercosis had esophageal masses, but only 1 out of 13 had esophageal neoplasia).

PREVENTION

Prevent dogs from eating beetles or paratenic hosts.

Spinal Cord Trauma

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Acute injury to the spinal cord caused by external trauma

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Common in dogs and cats
- Animals of any age, both sexes, and all breeds can be affected.

RISK FACTORS

- Unconfined
- Access to high places such as balconies

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Often documented trauma
- Abrupt-onset deficits, usually nonprogressive

PHYSICAL EXAM FINDINGS

- Focal spinal pain
- Neurologic deficits ranging from mild ataxia to paralysis
- Schiff-Sherrington posture (paraplegia with increased extensor tone in the pelvic limbs) possible with thoracic or lumbar injuries
- Presence or absence of deep pain caudal to the injury is the most important prognostic finding.
- Signs of other injuries may be present, including chest injury, abdominal injury, head injury, or orthopedic injury.

ETIOLOGY AND PATHOPHYSIOLOGY

- Causes include motor vehicle accidents, falls, bite wounds, and gunshot wounds.
- Primary injury is due to initial concussive injury to the cord and any persistent compressive injury due to displaced fracture/luxation, hematoma, or disk extrusion or unstable vertebral segments.
- Secondary injury is caused by metabolic changes, including release of free radicals that lead to progressive damage to cell membranes.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is usually suspected from a witnessed traumatic event and/or neurologic deficits indicating a spinal lesion. Plain radiography may indicate a vertebral lesion; if not, the diagnosis may remain presumptive (and treatment provided accordingly), or advanced imaging can be confirmatory.

DIFFERENTIAL DIAGNOSIS

- Acute intervertebral disk extrusion
- Pathologic fracture from neoplasia or infection
- Orthopedic injury, such as pelvic fracture

- Fibrocartilaginous embolism
- Ischemic neuromyopathy due to aortic embolus

INITIAL DATABASE

Spinal radiographs: initially perform lateral view only until vertebral instability is ruled out.

ADVANCED OR CONFIRMATORY TESTING

Myelography, CT, or MRI is indicated if plain radiographs are normal or do not correlate with clinical assessment, and to determine if there is persistent spinal cord compression if surgery is considered.

TREATMENT

TREATMENT OVERVIEW

- Treat any life-threatening injuries, such as shock.
- Prevent further spinal cord injury caused by unstable vertebral injuries.
- Minimize secondary injury.
- Decompress the spinal cord.

ACUTE GENERAL TREATMENT

- General trauma management (e.g., airway, oxygenation, IV fluids as indicated)
- Strap or tape the animal to a rigid board or gurney until an unstable vertebral injury is ruled out.
- Analgesics as needed for pain control
- Corticosteroids:
  - Methylprednisolone sodium succi-nate, 30 mg/kg IV within 8 hours of injury, 15 mg/kg IV at 2 and 6 hours later, then q 6 h for 24-48 hours
  - May slightly improve outcome with severe spinal cord injury
  - Starting treatment > 8 hours after injury is not effective and may be detrimental.
  - Other doses and other corticosteroid preparations are not indicated.
- Surgery:
  - Indicated for severe or progressive neurologic deficits and unstable vertebral injury or persistent compression of the spinal cord
  - Hemilaminectomy or dorsal laminectomy
  - Stabilization with pins or screws and bone cement, plates, or modified spinal instrumentation

CHRONIC TREATMENT

- Cage rest for 4-6 weeks on a clean, well-padded surface with good traction
- External splints are helpful for cervical and thoracolumbar injuries that do not require surgery.
- Manual bladder expression if urinary incontinence is present
- Physical rehabilitation (see p. 1329) such as passive range-of-motion and toe-pinch exercises; once spine is stable, assisted standing/walking, underwater treadmill, and swimming

DRUG INTERACTIONS

Avoid coadministration of corticosteroids and nonsteroidal antiinflammatory drugs (NSAIDs) (potentially severe gastrointestinal ulceration)

POSSIBLE COMPLICATIONS

- Decubital ulcers in nonambulatory animals
- Urinary retention in incontinent animals
- Infection in penetrating injuries, especially bite wounds
- Self-mutilation caudal to the site of injury due to paresthesia

RECOMMENDED MONITORING

- Initially evaluate neurologic status daily, including ability to urinate.
- Any deterioration indicates possible vertebral instability.

PROGNOSIS AND OUTCOME

- Voluntary movement: good prognosis
- Paralysis with intact deep pain perception: guarded prognosis
- Paralysis with loss of deep pain perception: very poor prognosis

PEARLS & CONSIDERATIONS

COMMENTS

- A common mistake is inaccurate assessment of deep pain. When there is no response to pinching with the fingers, use a hemostat to compress the digits or tail. Withdrawal of the limb indicates only an intact reflex arc (peripheral nerve and spinal segments) and does not mean the animal can feel pain. A behavioral response such as turning the head or vocalization indicates conscious perception of deep pain.
- Hemodynamic shock can affect testing of deep pain, so if initial test is negative, reassess the animal after resuscitation.

TECHNICIAN TIP

With loss of motor function, these patients may need assistance ranging in degree from simple to intensive (ambulating, urinating/defecating, eating, drinking). Providing this assistance can make the difference between a successful outcome and deterioration.

PREVENTION

Do not allow pets to roam freely or have unsupervised access to balconies and other dangerous areas.

SUGGESTED READING

Wheeler SJ, Sharp NJH: Trauma. In Wheeler SJ, Sharp NJH: Small animal spinal disorders: diagnosis and surgery, ed 2, London, 2005, Mosby-Wolfe, pp 171–191.

AUTHOR: WILLIAM B. THOMAS

EDITOR: CURTIS W. DEWEY

Spinal Cord Neoplasia

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Spinal tumors encompass a wide range of cancers.
- Spinal tumors can arise from vertebrae, meninges, or neuroparenchyma.
  - Vertebral neoplasia: osteosarcoma, fibrosarcoma, and hemangiosarcoma, plasma cell tumor/multiple myeloma, lymphoma, cartilaginous exostosis/osteochondroma
  - Meningeal: meningioma
  - Neuroparenchyma: peripheral nerve sheath tumors (PNST), glial tumors (oligodendroglioma, astrocytoma, oligoastrocytoma), ganglioma, nephroblastoma, ependymoma, metastatic choroid plexus carcinoma, cordoma
  - Mesenchymal tumors: myxoma/myxosarcoma, histiocytic sarcoma, infiltrative lipoma/liposarcoma
- Metastatic neoplasia: prostatic, mammary adenocarcinoma, osteosarcoma, transitional cell carcinoma, melanoma, thyroid carcinoma, pheochromocytoma

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Canine: middle-aged to older large-breed dogs:
  - Possible male predilection for meningioma (see p. 715)
  - Boxer and golden retriever predisposition for meningioma
- Feline: lymphoma; young (median age 2-3 years). Concurrent feline leukemia (FeLV) infection is common (see p. 671).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Canine: Chronic progressive paresis and/or proprioceptive ataxia (scuffing toes, knuckling, crossing limbs). Mean duration of signs = 6 weeks, range 1 day to 1 year. In one study, duration of clinical signs prior to diagnosis is longest for intradural/extramedullary, followed by extradural. Shortest duration for intramedullary tumors.
- Alternatively, acute paresis/plegia—absent voluntary motor function
- Feline lymphoma: acute onset (often 7 days or less)
  - Hyperesthesia
- Clinical signs relate to neuroanatomic lesion: lesions affecting the cervical spinal cord present with tetraparesis, whereas lesions affecting the thoracolumbar spinal cord present with para-paresis.

PHYSICAL EXAM FINDINGS

- Location-dependent
- Often asymmetric
- Focal pain on palpation of the vertebral column
- C1-C6 spinal cord: tetraparesis/plegia, postural reaction deficits, proprioceptive ataxia, normal to exaggerated myotatic reflexes, normal withdrawal reflexes, normal to increased muscular tone, lack of muscle atrophy in all four limbs
- C6-T2 spinal cord: tetraparesis/plegia, postural reaction deficits all four limbs, short, choppy gait (forelimbs), decreased withdrawal reflexes, decreased tone, muscle atrophy in thoracic limbs; proprioceptive ataxia, normal to exaggerated myotatic reflexes, normal withdrawal reflexes, normal to increased muscular tone, lack of muscle atrophy in pelvic limbs
- T3-L3 spinal cord: paraparesis/plegia, proprioceptive ataxia, normal to exaggerated myotatic reflexes, normal withdrawal reflexes, normal to increased muscular tone, lack of muscle atrophy in pelvic limbs; thoracic limbs normal
- L4-S3: hind limb paraparesis/plegia, short-strided, crouched pelvic limb gait, postural reaction deficits, decreased myotatic and withdrawal reflexes, decreased muscular tone, muscle atrophy in pelvic limbs; decreased perineal reflex, urinary incontinence and/or fecal incontinence, decreased tail function

ETIOLOGY AND PATHOPHYSIOLOGY

- Unknown
- Canine:

  - Meningioma commonly affects cervical spinal cord
  - Osteosarcoma: secondary to radiation therapy
  - Nephroblastoma (rare): dogs <2 years old, intradural/extramedullary, between T1O and L2 vertebrae
  - Multiple cartilaginous exostosis/osteochondroma can undergo malignant transformation to osteosarcoma or chondrosarcoma.
- Feline lymphoma: FeLV infection

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Paramount to establishing a presumptive diagnosis of spinal neoplasia is advanced imaging. MRI is the gold standard imaging technique that provides exceptional resolution of pertinent anatomy, allowing detailed characterization of lesions along the neural axis. Imaging characteristics such as lesion location (extravertebral, vertebral, extradural, intradural/extramedullary, or intramedullary), lesion intensity, lesion borders, and degree of contrast enhancement may suggest a specific tumor type. Ultimately, definitive diagnosis requires histologic evaluation. Advanced imaging should be performed by a board-certified veterinary specialist (often a neurologist or radiologist) trained specifically in MRI interpretation.

DIFFERENTIAL DIAGNOSIS

- Canine: intervertebral disk herniation, diskospondylitis, infectious meningomyelitis (canine distemper virus [CDV], rabies, fungal, *Neospora caninum/Toxoplasma gondii,* bacterial), granulomatous meningoencephalitis, trauma, orthopedic disease, caudal cervical spondylomyelopathy, fibrocartilaginous embolic myelopathy
- Feline: infectious meningomyelitis (feline infectious peritonitis virus, feline immunodeficiency virus [FIV], *T. gondii,* rabies, fungal, bacterial), trauma, aortic thromboembolism, intervertebral disk herniation (rare)

INITIAL DATABASE

- CBC, serum biochemical profile, urinalysis, thoracic and abdominal radiographs, survey (plain) radiographs of the vertebral column
- Feline: serologic testing for FeLV, FIV, *Cryptococcus neoformans, T. gondii*
- Canine: serologic testing for *C. neoformans, N. caninum, T. gondii,* paired titers (cerebrospinal fluid [CSF]/serum) for CDV

ADVANCED OR CONFIRMATORY TESTING

- Advanced imaging: MRI (see p. 1302) is the gold standard for spinal cord; CT (see p. 1233), combined CT/myelography, myelography.
  - MRI characterization of the lesion may provide a presumptive diagnosis: meningioma is often characterized as a broad-based, intradural/extramedullary lesion demonstrating uniformly strong contrast enhancement and dural tail.
  - CT more sensitive for bone abnormalities (lysis or proliferation) than radiographs or may be more sensitive than MRI
- CSF analysis (see p. 1228)
- Fluoroscopic guided needle aspiration/biopsy of vertebral lesion
- Spinal lymphoma: further staging required. FeLV/FIV testing, bone marrow evaluation. Renal, lymph node, and hepatosplenic involvement common
- Presumptive diagnosis based on anatomic location and imaging characteristics:
  - Vertebral: osteosarcoma, fibrosarcoma, hemangiosarcoma, plasma cell neoplasia, lymphoma, metastatic neoplasia
  - Extradural: lymphoma, metastatic neoplasia
  - Intradural/extramedullary: PNST, meningioma, nephroblastoma
  - Intramedullary: neuroparenchymal tumors (e.g., glial cell tumors [astrocytoma, oligodendroglioma]), metastatic neoplasia
- Definitive diagnosis: histopathologic examination

TREATMENT

TREATMENT OVERVIEW

The main therapeutic option for spinal tumors remains surgery. The exception to this involves hematopoietic neoplasms such as lymphoma and multiple myeloma, in which case chemotherapy +/− radiation therapy form the foundation of treatment. The goal of surgery is to provide decompression and to obtain a histologic diagnosis. Spinal surgery should only be performed by a board-certified neurologist or surgeon.

ACUTE GENERAL TREATMENT

- Based on tumor location. However, to date, primary treatment involves surgical debulking.
- Surgical decompression of affected site(s) via hemilaminectomy/dorsal laminectomy
- Spinal tumors: palliation with corticosteroids
- Vertebral tumors: palliation with radiation, bisphosphonate, corticosteroids

CHRONIC TREATMENT

- Variable depending on tumor type
- Incompletely excised meningioma, neuroparenchymal, and vertebral tumors should receive postoperative radiation therapy.
- Spinal lymphoma: systemic chemotherapy, radiation therapy
- Plasma cell tumor/multiple myeloma: systemic chemotherapy, radiation therapy

BEHAVIOR/EXERCISE

- Postoperatively, affected animals require strict exercise restriction for 4-6 weeks.
- Additionally, controlled physical rehabilitation (see p. 1329) under the guidance of trained personnel may be beneficial during recovery from surgery.

POSSIBLE COMPLICATIONS

Radiation myelopathy

RECOMMENDED MONITORING

- Periodic neurologic examination
- Repeat imaging studies
- Chemotherapy necessitates hematologic and biochemical monitoring dictated by protocol.

PROGNOSIS AND OUTCOME

- Variable based on tumor type, completeness of resection, and severity of neurologic deficits:
  - Patients lacking both motor function and nociception (pain perception) have a grave prognosis for return of function.
- Canine:
  - Surgical resection alone: in one study of dogs with spinal tumors of various histologic types, overall median survival was 240 days.
  - Surgical resection and postoperative radiation: in one report of 9 dogs (6 with spinal meningiomas), overall median survival was 510 days.
  - Specific tumors:
    - Meningioma—based on degree of resection:
      - Surgical resection alone: median survival 19 months; ranges from <30 days-1440 days
      - Surgery with postoperative radiation significantly increases the time to recurrence (neurologic deterioration) over surgery alone.
      - Vertebral tumors: osteosarcoma and fibrosarcoma: median survival 135 days (15-600 days)
      - PNST: median survival 203 days (120-300 days)
- Feline:
  - Lymphoma (COP protocol* [see pp. 673 and 674]): if complete remission achieved, median 14 weeks; if partial remission achieved, median 6 weeks. Longer remissions may be possible with doxorubicin-containing protocols.

PEARLS & CONSIDERATIONS

COMMENTS

- Based on imaging studies, the differential diagnosis may be narrowed substantially according to the anatomic location of the lesion.
- Definitive diagnosis requires histopathologic evaluation.
- Long-term remission can be possible regardless of completeness of excision.

TECHNICIAN TIPS

- Affected animals are often recumbent and unable to ambulate, requiring soft padded bedding and frequent changes in their recumbency to prevent development of decubital ulcers. Passive range of motion of paralyzed limbs and other physical therapy exercises may be performed to assist in recovery.
- Severely affected animals may not be able to urinate and therefore require manual bladder expression or maintenance of a urethral catheter and indwelling closed urinary collection system. Development of urinary tract infection is common.
- Affected animals are often painful pre-operatively and in the early postoperative time period, necessitating analgesic therapy.

Spider Envenomation

BASIC INFORMATION

DEFINITION

- Envenomating bites from widow spiders of the genus *Latrodectus.* resulting in mild to severe systemic signs including generalized muscle pain, weakness, paralysis, and death
- Envenomating bites from recluse spiders of the genus *Loxosceles,* resulting in acute onset of localized irritation and progressing to severe necrotizing wounds and occasionally systemic signs
- Bites from venomous spiders are well recognized but in general are a less common, geographic region-dependent phenomenon.

SYNONYMS

- Latrodectism: *Latrodectus* (widow spider) envenomation
- Loxoscelism, necrotic arachnidism: *Loxosceles* (brown recluse spider) envenomation

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Very young and aged animals may be more sensitive to the effects of spider venom.
- Cats are very sensitive to widow venom; mortality can exceed 90%.
- Dogs are highly susceptible to brown recluse envenomation.

RISK FACTORS: Patients with preexisting respiratory conditions (widow venom, respiratory muscles) or hematologic conditions (brown recluse, erythrocyte) may be at increased risk.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Witnessed or suspected spider on or near the animal (cats may vomit spiders)
- Specific signs are based on type of spider:
    - Widow: no to little local swelling and redness initially; reluctance to move begins <30-120 minutes after envenomation, with progressive signs of muscle pain and stiffness
    - Recluse: signs of local pain, pruritus, redness within 10-30 minutes; expanding necrotizing wound

PHYSICAL EXAM FINDINGS

- Widow: vomiting; muscle pain, rigidity, tremor, and cramping; tachypnea, atonic paralysis
- Recluse: “bull's eye” or “halo” cutaneous lesion (central vesicle; erythematous, ecchymotic periphery), progressively expanding; vesicle may be ruptured and shrunken, dark purple to black
    - Dermal lesion can range from 1-25 cm in size, depending on time line from bite.
    - Systemic signs may occur-24-72 hours, and can include hemolysis, hematuria, fever, arthralgia.

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

- Widow spiders:
    - Female *Latrodectus* spp. have an hourglass-shaped red or orange marking on the abdomen. Young spiders are red in color (and venomous), progressing to black with successive molts. Males are 1/20 female size, and fangs are too short for envenomation.
    - Important *Latrodectus* spp. in the United States:
        - *L. mactans* (black widow spider, southern black widow): throughout the United States, especially in the South
        - *L. hesperus* (western black widow spider): western United States

        - *L. variolus* (northern widow spider): northern part of the United States
        - *L. bishopi* (red widow spider; red-legged widow spider): Florida
        - *L. geometricus* (brown widow spider): Florida
- Recluse spider:
    - Brown recluse (or fiddle back/violin) spider (*Loxosceles reclusa)* (distinctive violin-shaped mark on dorsal cephalothorax, neck points to abdomen). These spiders are nocturnal, not aggressive, and can be active in a wide range of temperatures. Length 6-20 mm, long legs, three pairs of eyes.
    - *Loxosceles* are found through the south and south-central regions of the United States (Texas through Georgia) but can be found as far north as Iowa, Wisconsin, and Indiana.
    - Several *Loxosceles* species that live in the western United States (*L. rufscens, L. deserta, L. arizonica)* may produce mild necrotic lesions that are not as serious as the *L. reclusa* bite.

Mechanism of Toxicosis:

- Widow spider:
    - Alpha-latrotoxin is the main toxic component of widow venom; causes release and depletion of acetylcholine, norepinephrine (and others) at motor nerve endings and postganglionic sympathetic synapses, resulting in block of neurotransmission.
- Recluse spider:
    - Recluse venom contains several proteins, polypeptides, and necrotizing enzymes including hyaluronidase, esterase, alkaline phosphatase, and 5′-ribonucleotide phosphorylase and sphingomyelinase.
    - These proteins and enzymes work in different ways, causing inflammation, local ischemia, coagulation, occlusion of small capillaries, necrosis, depletion of clotting factors (VII, IX, XI, and XII), hemolysis, platelet activation, and thromboembolic disease.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Envenomation often is not witnessed. Diagnosis then depends on physical exam findings (compatible with envenomation) in a suitable geographic zone, and a window of time for possible envenomation (e.g., pet was unobserved for the preceding several hours). No definitive confirmatory test exists; therefore, many cases of suspected envenomation may in fact be caused by completely different etiologies, and a “spider bite” often is a working diagnosis that remains unproven.

DIFFERENTIAL DIAGNOSIS

- Widow spiders:
    - Toxicologic: bromethalin, macadamia nuts, or marijuana toxicosis
    - Spontaneous, nontoxicologic: meningoencephalitis, intervertebral disc disease, CNS neoplasia
- Recluse spiders:
    - Toxicologic: snakebite, insect sting, hemolytic toxins (zinc, *Allium),* corrosive burn
    - Spontaneous, nontoxicologic: cellulitis, decubital ulcer, pyoderma, hemolytic anemia (immune mediated), thrombocytopenia (immune-mediated)

INITIAL DATABASE

- Widow:
    - Vital signs (respiratory rate and depth, heart rate, temperature)
    - CBC: leukocytosis possible
    - Serum biochemistry profile: increased creatine phosphokinase, glucose, bilirubin possible
    - Urinalysis: normal to high specific gravity, ± albuminuria
    - Blood pressure: systemic hypertension possible
- Recluse:
    - CBC: acute intra vascular hemolysis, anemia
    - Coagulation profile: evidence of bleeding disorder possible
    - Serum biochemistry profile
    - Coombs’ test: negative
    - Urinalysis: hemoglobinuria

TREATMENT

TREATMENT OVERVIEW

- Widow: all patients should be hospitalized and treated intensively. If available, antivenin is indicated in severe cases. If muscular tremor or clonus is present, muscle relaxation helps avoid hyperthermia (muscle relaxants, diazepam). Pain control and treatment according to changes in vital signs and other parameters are important.
- Recluse: treatment will depend on which one of two possible syndromes the patient experiences: local cutaneous lesions only or possible systemic manifestations, which can begin 24-72 hours after envenomation. Therefore, patients should be hospitalized for observation and treatment. Dermal complications can be long standing, and systemic manifestations are potentially fatal if left untreated.

ACUTE GENERAL TREATMENT

- Widow spider:
  - Systemic analgesia is important:
    - Opioids for severe pain (e.g., hydromorphone, 0.1-0.2 mg/kg SQ, IM, or IV once or as needed up to q 2-4 h; or buprenorphine, 0.005-0.03 mg/kg IM, IV, or SQ q 6-12 h PRN)
    - Nonsteroidal antiinflammatory drugs (NSAIDs) for moderate pain (e.g., carprofen, 1 mg/kg PO q 12 h; or etodolac, 10-15 mg/kg PO q 24 h)
  - Muscle relaxants are important to reduce or eliminate muscle rigidity/tremor:
    - Diazepam, 0.2-0.6 mg/kg IV slow PRN, or 0.25-1 mg/kg PO q 8 h
    - Methocarbamol, 55-220 mg/kg IV slow, not to exceed 330 mg/kg/day, or 20-45 mg/kg PO q 8 h (oral route, 30 minute onset)
  - Widow spider antivenin (Lyovac, equine origin [Merck]): single vial can be effective in relieving muscle involvement up to 1-3 days after envenomation; relatively inexpensive and has a good shelf life, but anaphylaxis is possible (conduct skin test first: inject small volume SQ and monitor for acute inflammation).
  - Respiratory support for hypoventilating animals; supplemental oxygen as indicated
  - IV fluids: cautious use because of volume expansion, sodium administration; systemic hypertension is common following envenomation. Monitor blood pressure.
- Recluse spider:
  - Diphenhydramine, 2.2 mg/kg PO or IM q 8 h, to relive pruritus; corticosteroids at antiinflammatory levels (e.g., prednisone 1-2 mg/kg PO q 24 h) can also be used.
  - Broad-spectrum antibiotics for secondary infection (e.g., amoxicillin-clavulanate 10-20 mg/kg PO q 12 h)
  - Monitor and measure size (progression) of lesion daily.
  - Dapsone, a neutrophil migration inhibitor, may limit severity of lesions:
    - In dogs, 1 mg/kg PO q 24 h has been suggested; caution using in cats.
  - Surgical débridement not recommended
  - IV fluids to promote fluid diuresis if hemolysis occurs (protect renal tubules)
  - Packed red blood cells (RBCs) or whole blood for hemolytic anemia
  - Monitor and treat disseminated intravascular coagulation (DIC) if present.

CHRONIC TREATMENT

Manage necrotic lesions as open wounds (recluse spiders).

POSSIBLE COMPLICATIONS

Recluse spider bites can lead to scarring as they heal.

RECOMMENDED MONITORING

CBC, platelet count, and coagulation parameters

PROGNOSIS AND OUTCOME

Fatalities rare in dogs (widow and recluse); prognosis can be guarded in cats bitten by widows.

PEARLS & CONSIDERATIONS

COMMENTS

- Many spiders are capable of inflicting an envenomating bite. In the United States, however, with the exception of widow and

recluse spider bites, most bites will not cause more than a mild local reaction, although anaphylaxis remains possible.
- Check with a local human hospital pharmacy for availability of Lyovac widow antivenin.
- Hobo spider (*Tegenaria agrestis)* is an aggressive house spider found in the Pacific Northwest, where the recluse is not indigenous. Necrotizing skin lesions are similar but less severe than those inflicted by the brown recluse; treatment approach is similar to recluse spider bite.

1ST EDITION AUTHOR: ERIC DUNAYER

Sparganosis, Proliferative

BASIC INFORMATION

DEFINITION

Infection with the proliferating larval (metacestode) stages (spargana or plerocercoids) of pseudotapeworms (pseudophyllidean tapeworms), usually *Sparganum proliferum* or *Spirometra* spp.

SYNONYMS

Infection with these larval tapeworms may also be larval pseudophyllidiasis or larval cestodiasis. Infection with the adult stage of this parasite may be referred to as *spirometrosis*, *pseudophyllidiasis*, or *cestodiasis*.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Proliferative sparganosis may be found in dogs and cats of all ages and both sexes.

GENETICS & BREED PREDISPOSITION: Sporting/hunting breeds of dogs

RISK FACTORS

- Exposure to/contact with large stationary or slow-moving bodies of water inhabited by the first intermediate host, a copepod crustacean (*Cyclops* sp. water flea)
- Ingestion of infected transport host (rodent, reptile, amphibian, or bird)
- Direct inoculation of open wounds with flesh or meat containing plerocercoids (application of “medicinal” poultices; rare)

CONTAGION & ZOONOSIS: Sparganosis is zoonotic; thus precautions should be undertaken to prevent human infection (see Risk Factors, above).

GEOGRAPHY AND SEASONALITY: Proliferative sparganosis cases reported in dog, cat, and human in Florida, United States; dogs in Australia; and humans in Venezuela, Paraguay, Japan, Taiwan.

CLINICAL PRESENTATION

DISEASE FROMS/SUBTYPES

- There are two forms of sparganosis that occur with larval infections: nonproliferative and proliferative. Most infections are the nonproliferative form and are associated with the presence of a single, non-replicating larval stage (a sparganum) of *S. erinaceieuropaei* or *S. mansonoides* within the musculature or subcutaneous tissues of the intermediate or transport host, a common occurrence. If the nonproliferative form is ingested by a dog or cat, an adult tapeworm will develop in the small intestine of that host.
- The more rare form of the parasite, which produces proliferative sparganosis, is characterized by asexual replication of larvae (spargana) of *S. proliferum* within a variety of host tissues and the systemic migration of these larvae to other tissues, where they grow and repeat the process, ultimately resulting in the death of the host.

HISTORY, CHIEF COMPLAINT: History of free roaming; for typical complaints, see Physical Exam Findings, below.

PHYSICAL EXAM FINDINGS

- Axial musculature infection: signs of pain, diffuse swelling, progressive fore-limb lameness, and pitting subcutaneous edema
- Proliferating spargana in the thoracic cavity: dyspnea and fever
- Proliferating spargana in the peritoneal cavity: abdominal distention and/or signs of abdominal pain

ETIOLOGY AND PATHOPHYSIOLOGY

- In most instances, when infective spargana/plerocercoids within the second intermediate host (or the transport host) are ingested by the canine or feline definitive host, the plerocercoid develops to the adult pseudotapeworm within the small intestine of the dog or cat. Intestinal infection with the adult stage of this parasite, usually *Spirometra* spp. (*S.*

erinaceieuropaei or *S. mansonoides*), is a common finding in dogs and cats.

- In other instances when procercoids or spargana are ingested by the canine or feline definitive host, the plerocercoid will not undergo any further development but remains as the larval plerocercoid/spargana stage within the tissues of the canine or feline definitive host.
- The life cycle of the parasite involves both a first intermediate host, an aquatic crustacean (*Cyclops* sp.) and second intermediate host, a vertebrate host other than a fish (e.g., a frog). Paratenic or transport hosts may also be involved.
- Hermaphroditic adult tapeworm (*Spirometra* sp.) is found in the small intestine of canine or feline intermediate host. Tapeworm produces operculated ovum containing coracidium.
- Operculated egg makes contact with water.
- Coracidium emerges from the operculated egg and spins in water.
- Coracidium is ingested by aquatic crustacean (water flea). Within crustacean, coracidium develops into the first developmental stage, a procercoid.
- Crustacean containing procercoid is ingested by a second intermediate host, a vertebrate host other than a fish. Within the second intermediate host, the procercoid develops into the second developmental stage, a plerocercoid.
- The plerocercoid within the second intermediate host may be ingested by a transport or paratenic host (e.g., a small mammal such as a rodent). The plerocercoid does not undergo any further development within that host. Larval forms of *Spirometra* spp. can infect and survive in a series of transport hosts until finally consumed by a carnivore definitive host.
- In most instances, when the spargana are ingested by a canine or feline definitive host, the spargana will develop into adult pseudotapeworms within the small intestine of the host.
- In rare instances, when the spargana are ingested by a carnivore definitive host, the spargana will remain as spargana but migrate to various sites within the host tissues, where they undergo asexual replication, migrate to other tissues, and grow to repeat the process. These spargana do not mature to the adult stages when they are fed to a dog or cat.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

This very unusual disorder is diagnosed incidentally during evaluation of nonspecific abnormalities (e.g., muscle biopsy for myositis or cytologic analysis of fluid retrieved during abdominal/thoracic centesis).

DIFFERENTIAL DIAGNOSIS

- *Mesocestoides* spp. will produce a metacestode stage that undergoes a similar proliferative asexual replication in multiple tissue sites. Under the compound microscope, specimens of *Mesocestoides* will demonstrate some evidence of sucker development.
- Peritonitis
- Pleuritis
- Chronic panniculitis

INITIAL DATABASE

- CBC may reveal eosinophilia.
- Thoracic and/or abdominal radiographs: evidence of effusion
- Thoracocentesis (see p. 1338) or abdominocentesis (see p. 1193) may reveal replicating spargana:
    - Spargana may be grossly identified as being of cestode origin by the presence of calcareous corpuscles. They may be identified as being pseudophyllidean tapeworms by the absence of suckers on the developing scolex. These parasites may demonstrate the presence of two slitlike bothria instead of four suckers.

ADVANCED OR CONFIRMATORY TESTING

- Exploratory thoracotomy or laparotomy may reveal replicating spargana on histologic/cytologic analysis.
- A PCR-based assay for the detection of DNA from the spargana in host tissue is available from Oklahoma State University.

TREATMENT

TREATMENT OVERVIEW

It is extremely difficult to eliminate larval parasites (spargana or plerocercoids) from multiple tissue and organ sites, and the prognosis with systemic disease is guarded to poor.

ACUTE GENERAL TREATMENT

- If specimens are free within thoracic or abdominal cavities, these cavities may be lavaged with warm, sterile physiologic saline to physically remove as many spargana as possible.
- Mebendazole, 20 mg/kg PO q 24 h for 3 weeks, followed by praziquantel, 5 mg/kg PO q 24 h for a further 3 weeks, have not been used. These two drugs were alternated over a period of 3 months.

CHRONIC TREATMENT

- Secondary bacterial infection
- Cellulitis
- Culture and sensitivity of lesion, with appropriate antimicrobial therapy

POSSIBLE COMPLICATIONS

Since these spargana are capable of asexual replication, if one parasite is left remaining in situ, it is possible for proliferative sparganosis to return via exponential growth.

RECOMMENDED MONITORING

Thoracocentesis or abdominocentesis along with gross examination of collected specimens if effusions recur.

PROGNOSIS AND OUTCOME

The prognosis for dogs treated for proliferative sparganosis is guarded to poor.

PEARLS & CONSIDERATIONS

COMMENTS

Since this larval cestode is extremely rare, it is quite difficult to diagnose. A pathologist or parasitologist at a veterinary diagnostic laboratory may be called on to assist in the definitive diagnosis.

PREVENTION

Prevent dogs and cats from roaming and coming into contact with freshwater aquatic environments (large stationary or slow-moving bodies of water) inhabited by aquatic crustaceans. Prevent predation or scavenging of intermediate or transport hosts.

TECHNICIAN TIPS

The importance of proper sample submission cannot be overemphasized. Biopsy specimens must be submitted in 10% formalin.

CLIENT EDUCATION

Dogs and cats should never be allowed to roam freely, thus avoiding contact with infested water or ingestion of infected intermediate hosts or carrion.

AUTHOR: CHARLES HENDRIX

EDITOR: DOUGLASS K. MACINTIRE

Soft-Tissue Sarcoma

BASIC INFORMATION

DEFINITION

A group of common tumors arising from various mesenchymal tissues, classified together because of similar biological behavior and treatment. They include fibrosarcoma, hemangiopericytoma, malignant fibrous histiocytoma, nerve sheath tumor, neurofibrosarcoma, malignant schwannoma, leiomyosarcoma, rhabdomyosarcoma, liposarcoma, myxosarcoma, lymphangiosarcoma, and synovial cell sarcoma. Although it is also a mesenchymal tumor arising from soft tissue, hemangiosarcoma is often excluded from this group because of its aggressive biological behavior.

SYNONYM

Soft part sarcomas

EPIDEMIOLOGY

SPECIES, AGE, SEX: Common in middle-aged to older dogs. Soft-tissue sarcomas at sites other than injection sites are less common in cats.

GENETICS & BREED PREDISPOSITION: In general, soft-tissue sarcomas tend to occur more commonly in larger breeds, but direct inheritance of these tumors has not been reported.

RISK FACTORS

- Certain sarcomas have been associated with metal implants, previous exposure to ionizing radiation, implanted microchips, and parasites *(Spirocerca lupi).*
- Sarcomas at injection sites have been described in dogs but are rare.

CONTAGION & ZOONOSIS: Multiple sarcomas of the head and neck have been reported secondary to combined feline sarcoma virus and feline leukemia virus infection.

ASSOCIATED CONDITIONS & DISORDERS: Hypoglycemia and diabetes insipidus have been reported as uncommon paraneoplastic syndromes in dogs with intestinal leiomyosarcoma.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Most animals present for a progressively enlarging mass noticed by the owner.
- Animals with sarcoma in certain locations will be presented because of clinical signs related to the location of the tumor. Dogs with oral tumors often present with a foul odor from the mouth, difficulty eating or prehending food, oral bleeding, or a visible oral mass. Dogs with intestinal sarcomas will often be presented because of signs related to intestinal obstruction, including vomiting and diarrhea.

PHYSICAL EXAM FINDINGS

- Visible or palpable mass. Regional lymphadenomegaly may be present secondary to inflammation caused by the tumor or (rarely) lymph node metastasis.
- Sarcomas in specific sites may present with physical exam findings related to the location of the tumor (e.g., abdominal pain, weight loss, dehydration).

ETIOLOGY AND PATHOPHYSIOLOGY

- Soft-tissue sarcomas arise spontaneously in dogs and cats. Genetic and environmental factors may be involved in tumor development, but these factors are poorly understood in companion animals.
- Specific lesions and overt clinical manifestations caused by soft-tissue sarcomas depend on location of the primary tumor and invasion into and destruction of surrounding normal structures.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Definitive diagnosis can only be confirmed via histopathologic examination, although additional tests such as diagnostic imaging are often helpful in defining the extent of the tumor. Studies show that an aggressive first surgery is more likely to result in tumor control. Therefore, an incisional biopsy should be performed first to confirm the tumor type, prior to planning definitive treatment.

DIFFERENTIAL DIAGNOSIS

- Mast cell tumors
- Other skin and subcutaneous tumors:
  - Lipoma, histiocytoma, others
- Other masses:
  - Abscess

INITIAL DATABASE

- Fine-needle aspiration and cytologic examination may help identify the type of soft-tissue sarcoma or differentiate from other tumor types.
- Thoracic radiographs to rule out pulmonary metastases
- Radiographs of the affected area may reveal involvement of underlying bone.
- Fine-needle aspirate of draining lymph nodes to help rule out metastasis

ADVANCED OR CONFIRMATORY TESTING

- CT or MRI may be necessary to delineate the local extent of the tumor and plan for surgery or radiation therapy.
- Diagnosis is based on histopathologic evaluation of tissue. Occasionally, special stains may be necessary to differentiate various types of soft-tissue sarcomas, especially with poorly differentiated tumors.
- Histopathologic grade of the tumor is necessary for determining prognosis and treatment of most soft-tissue sarcomas.

TREATMENT

TREATMENT OVERVIEW

- The goal of treatment for soft-tissue sarcomas in dogs or cats is complete eradication of the primary tumor.
- In cases where the tumor cannot be eliminated entirely, the goal of treatment is prevention or delay of the development of metastases.
- Palliative treatment options, such as palliative radiation, may help control pain or discomfort in patients with advanced tumors or when definitive treatment cannot be tolerated.

ACUTE GENERAL TREATMENT

- Surgery:
  - Commonly these tumors appear encapsulated at surgery. This can be misleading because the capsule is usually a pseudocapsule made up of compressed tumor cells, and viable tumor cells are often present beyond the extent of the pseudocapsule.
  - Surgery should be aimed at an aggressive resection of the mass with as wide a margin of normal tissue as possible from around the tumor. In situations where this is not possible because of the size and/or location of the tumor, radiation therapy may be indicated in addition to surgery.
- Radiation therapy:
  - May be used prior to surgery in situations where the tumor is not easily resectable owing to its location or size. In cases where surgery is attempted first but resection is incomplete based on histologic evaluation, these patients should be treated with radiation therapy after surgery.
- Chemotherapy:
  - May be indicated for patients with high-grade tumors, tumors in certain locations, certain tumor types, and in patients that develop metastatic disease
  - Chemotherapy drugs that have been used for soft-tissue sarcoma include doxorubicin, mitoxantrone, platinum drugs, ifosfamide, and combinations of these drugs.
- Hyperthermia:

- Oncologic hyperthermia treatment has been shown to increase response rates for macroscopic tumors treated with radiation therapy. However, such treatment has limited availability, and recurrence of tumors often occurs rapidly after treatment.

POSSIBLE COMPLICATIONS

Complications of treatments for sarcomas depend on types of treatments and location of the primary tumor:

- Surgery may result in wound complications, including infection, dehiscence, or loss of function of a limb.
- Radiation therapy can cause short-term complications in skin and mucosa involved in the radiation field (dermatitis, mucositis). Long-term complications, including bone necrosis and haircoat changes, are uncommon but are permanent when they do occur (see p. 963).
- Chemotherapy complications may include bone marrow suppression, gastrointestinal effects, and haircoat changes along with other side effects caused by specific chemotherapy drugs (see p. 963).

RECOMMENDED MONITORING

Following appropriate local treatment of the primary tumor, follow-up examination should be done on a routine basis to monitor for local recurrence and metastasis. High-grade tumors may require more frequent monitoring for metastasis during and after chemotherapy administration.

PROGNOSIS AND OUTCOME

Prognosis is variable depending on type, location, clinical stage, and histologic grade of tumor:

- Certain tumor types may have higher metastatic rates (e.g., leiomyosarcoma) or more aggressive local behavior (e.g., histologically low grade, biologically high grade sarcomas of the oral cavity).
- Soft-tissue sarcomas located in the abdomen (spleen, intestines) are typically more likely to lead to metastasis.
- Soft-tissue sarcomas in certain locations (e.g., oral tumors) may be more difficult to treat with local therapy (surgery or radiation), resulting in lower rates of local disease control.
- Soft-tissue sarcomas that are large or have metastasized at the time of diagnosis usually lead to a poor prognosis.
- Histologic grading of canine soft-tissue sarcomas is based on: (1) degree of differentiation; (2) mitotic index (0-9 per 10 high-power field (HPF), 10-19 per 10 HPF, >20 per 10 HPF); and (3) percent necrosis (0%, <50%, >50%). High-grade (grade 3) tumors are more likely to lead to metastasis. Typical metastatic rates are considered to be 40% for grade 3 tumors, up to 20% for grade 2 tumors, and 10% or less for grade 1 tumors. It is unclear whether this grading scheme is applicable in feline soft-tissue sarcomas.

PEARLS & CONSIDERATIONS

COMMENTS

Many patients with soft-tissue sarcomas can be successfully treated with wide surgical excision alone. Patients with soft-tissue sarcomas that may be more difficult to treat (oral sarcomas, grade 3 sarcomas, nonresectable tumors, etc.) should be referred for consultation with specialists, including a surgeon, oncologist, or radiation oncologist, to develop a multimodality treatment approach.

PREVENTION

In most cases, prevention of soft-tissue sarcomas is not possible. Early detection and treatment may result in easier treatment and better prognosis.

CLIENT EDUCATION

Owners should be educated to monitor their pets for the emergence of cutaneous or other masses and have them evaluated in a timely fashion. Early detection may allow for easier treatment via surgery and may help avoid the need for radiation therapy.

AUTHOR: JOHN FARRELLY

EDITOR: KENNETH M. RASSNICK

Sneezing

BASIC INFORMATION

DEFINITION

- An explosive expiration of air from the nose for the purpose of clearing the nasopharynx. Sneezing is mediated by a central reflex as a result of stimulation of the nasal mucosa. Occasional sneezing is normal.
- Reverse sneezing is characterized by paroxysmal, forceful, and loud *inspiratory* efforts that are triggered by nasopharyngeal irritation. The syndrome, most commonly seen in small- and toy-breed dogs, is self-limiting and rarely progressive. Reverse sneezing serves to move irritating debris from the nasopharynx into the oropharynx where it can be swallowed (see p. 987).
- All causes of nasal discharge and/or irritation are potential causes of sneezing. The type and duration of the discharge varies with the underlying cause (see Etiology and Pathophysiology below).

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Young cats may have viral upper respiratory infections or nasopharyngeal polyps.
- Young unvaccinated dogs are more likely to have canine viral respiratory infections.
- Younger animals may have congenital deformities.
- Older animals are more likely to have neoplastic or dental-related causes of nasal discharge and sneezing.
- Hunting and working dogs are more likely to have nasal foreign bodies.

GENETICS & BREED PREDISPOSITION: Brachycephalic breeds have upper airway problems that may lead to sneezing and/or nasal discharge. Certain breeds can be affected by primary ciliary dyskinesia or by cleft palate/cleft lip complex.

RISK FACTORS

- Lack of adequate immunization against viral respiratory infections
- Exposure to unvaccinated animals and high-density husbandry situations
- Geographic locations where grass awns are ubiquitous
- Dental disease and poor dental care
- Immunosuppression (fungal disease)
- Compromise of nasal mucosa (secondary bacterial infections)

CONTAGION & ZOONOSIS: Viral upper and lower respiratory tract infections

GEOGRAPHY AND SEASONALITY: Geographic locations where grass awns are ubiquitous

ASSOCIATED CONDITIONS & DISORDERS: Sneezing itself can be a cause of acute nasal trauma (nose hits floor).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Sneezing versus reverse sneezing

HISTORY, CHIEF COMPLAINT: Acute onset of paroxysmal sneezing may suggest nasal foreign bodies or early viral disease. Husbandry and management predispose to certain disorders: for example, recent boarding, exposure to new animals, and/or history of inadequate vaccination (viral infections); hunting and geographic location (nasal foreign bodies); pertinent medical history (dental disease, history of neoplasia, immunosuppression); exposure to irritating aerosols (hairspray, paints, etc.) or anticoagulants (rodenticides, pharmaceuticals).

PHYSICAL EXAM FINDINGS

- Serous, mucopurulent, or hemorrhagic discharge that may be unilateral or bilateral
- Facial deformity
- Exophthalmos
- Maxillary swelling dorsal to carnassial tooth (apical dental [“tooth root”] abscess)
- Oronasal fistula
- Ocular discharge

- Petechiation, ecchymoses
- Pawing at face

ETIOLOGY AND PATHOPHYSIOLOGY

All causes of nasal discharge and/or irritation are potential causes of sneezing. Types of nasal discharge:

- Serous: clear and watery (acellular); due to local irritation, early viral infection, allergic rhinitis, or excessive lacrimation
- Mucoid: clear and thicker (acellular with higher protein content); due to chronic noninfectious irritation and overproduction of mucus by nasal epithelial cells
- Purulent: yellow-tan, thick discharge (neutrophilic with bacteria) usually due to secondary bacterial infection
- Sanguineous: red-tinged (blood mixed with another type of discharge) due to compromise of the nasal mucosa
- Hemorrhagic (epistaxis): frank red blood due to local or systemic causes of bleeding

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

Important diagnostic elements include whether nasal discharge is present and if so, of what type; whether air flow is normal or reduced in one or both nostrils (glass slide fog test); and whether there are systemic signs of illness. These features allow the clinician to choose tests that evaluate the nasal passages specifically (e.g., rhinoscopy) or to opt for conservative treatment and monitor evolution.

DIFFERENTIAL DIAGNOSIS

- Feline viral upper respiratory tract infections (feline rhinotracheitis, feline calicivirus, *Chlamydophila felis*)
- Neoplasia (adenocarcinoma, lymphoma, undifferentiated carcinoma, osteosarcoma, chondrosarcoma, fibrosarcoma, transmissible venereal tumor)
- Foreign bodies
- Apical dental (“tooth root”) abscess
- Oronasal fistula
- Nasopharyngeal polyps
- Canine viral infections (canine distemper virus, canine parainfluenza virus, canine herpesvirus, canine adenovirus types 1 and 2)
- Mycotic infection (*Aspergillus* spp. in dogs; *Cryptococcus neoformans* in cats)
- Parasitic rhinitis (*Cuterebra* spp., *Pneumonyssoides caninum, Linguatula serrata)*
- Bacterial infections (usually secondary)
- Rhinitis (allergic/eosinophilic type I hypersensitivity, lymphoplasmacytic, chronic hyperplastic)
- Congenital defects (cleft palate-cleft lip complex, primary ciliary dyskinesis)
- Trauma
- Inhaled irritants (cat litter dust, aerosols, smoke)
- Epistaxis:
  - Local causes: mycotic infections, neoplasia, foreign body, trauma
  - Systemic causes: inherited or acquired coagulopathies, thrombocytopenia, thrombocytopathia, hypertension, vasculitides
- Nasopharyngeal stenosis

INITIAL DATABASE

- Assessment for unilateral versus bilateral nasal disease by holding a glass microscope slide close to the external nares while the patient breathes on it through its nose (mouth held closed). Presence or absence of steam on the slide suggests unilateral obstruction, bilateral obstruction, or normal air flow. Neoplasia, foreign bodies, and dental disease are often causes of unilateral nasal disease, whereas other local and systemic causes often result in bilateral disease.
- Examination of the oral cavity to look for hard-palate masses; fundic examination to look for evidence of neoplasia, fungal disease, or hypertension and associated retinal hemorrhage
- Eye globe retropulsion ± ocular ultrasound to assess for retrobulbar masses
- Blood pressure measurement to assess for hypertension
- CBC including platelet count to look for evidence of infection, inflammation, or thrombocytopenia
- Serum biochemistry profile, urinalysis
- Feline leukemia and feline immunodeficiency viral testing

ADVANCED OR CONFIRMATORY TESTING

Rocky Mountain spotted fever, *Ehrlichia,* and *Bartonella* testing, prothrombin time, partial thromboplastin time, thoracic radiographs, nasal swabs, fungal titer determinations, nasal radiography, CT (see p. 1233), rhinoscopy (see p. 1335), biopsy, deep tissue cultures, exploratory rhinotomy—as dictated by history, physical exam, and preliminary findings

TREATMENT

TREATMENT OVERVIEW

- Eliminate underlying etiology of sneezing.
- Restore normal nasal function.
- Reduce pain and discomfort.
- Provide supportive care.
- Relieve dyspnea, especially in cats who oftentimes will not readily open-mouth breathe.

ACUTE GENERAL TREATMENT

- If nasal discharge or nasal mucosal edema is causing dyspnea, oxygen therapy may be needed.
- Treatment for underlying coagulopathy (e.g., vitamin K1, 0.25-2.5 mg/kg for first-generation rodenticide intoxication or 2.5-5 mg/kg for second generation, SQ or PO divided q 12 h for 7-21 days, and fresh frozen plasma).
- Correct dehydration and electrolyte abnormalities as necessary.
- Broad-spectrum antibiotics if secondary nasal or dental infection (bacteria are rarely the primary cause of nasal disease, but secondary infection with normal nasal flora is common) or pneumonia (culture and sensitivity from the lower airways is essential if pneumonia is present). *Bartonella* has been implicated as a cause of chronic rhinitis and epistaxis; azithromycin may be used (5-10 mg/kg PO q 24 h. Start at 5 mg/kg and if tolerated, increase by 2.5 mg/kg each day to 10 mg/kg limit. After 1 week, reduce to q 48 h).
- Analgesics if painful (opiates and/or nonsteroidal antiinflammatory drugs [NSAIDs])
- Removal of animal from environmental agents (e.g., smoke, dust, allergens)
- Surgery should be considered for dental disease, neoplasia, nasopharyngeal polyps, cleft palate, foreign bodies, or traumatic causes.
- Radiation and/or chemotherapy for neoplasia
- Chemoembolization (an interventional radiology technique) of nasal tumors can be considered in cases where surgery, radiation, or chemotherapy are associated with excessive morbidity, cost, or a poor outcome.
- Rhinoscopy may be useful for removing a foreign body.
- Fungal: local or systemic treatment
- Parasitic rhinitis: ivermectin, 0.2 mg/kg SQ or PO twice 3 weeks apart, is reported to be successful; avoid in breeds susceptible to toxicosis (collies, Shetland sheepdogs, Old English sheepdogs, and others; see p. 706).
- Decongestants and cleaning of the nares (pediatric Neo-Synephrine, 1 drop in alternating nares q 24 h)
- Nasopharyngeal stenting for nasopharyngeal stenosis
- Embolization for epistaxis

CHRONIC TREATMENT

- Nutrition: cats especially may not eat if unable to smell food; consider coax-feeding (see p. 1377) or placement of a tube (e.g., esophagostomy; see p. 1267) for nutritional support.
- Analgesics
- Antibiotics for secondary infections
- In animals with chronic rhinitis, anti-histamines, inhaled corticosteroids, and systemic NSAIDs may provide some relief.

POSSIBLE COMPLICATIONS

- Anorexia (especially in cats with severe nasal congestion)
- Keratitis (feline viral upper respiratory infections)
- Upper airway obstruction following extubation after general anesthesia
- Hemorrhage following surgery or rhinoscopy
- Dehiscence of surgical site (e.g., cleft palate)
- Progression of underlying disease
- Acute nasal trauma due to paroxysmal sneezing in small, short-legged dogs whose noses may hit the floor while sneezing (e.g., dachshunds)

RECOMMENDED MONITORING

- Respiratory rate and effort; ventilation and oxygenation

- Appetite
- Ongoing hemorrhage
- Volume and nature of discharge
- Monitoring as normal for antimicrobials and NSAIDs
- Appropriate laboratory testing or diagnostic imaging, dependent on underlying disease

PROGNOSIS AND OUTCOME

- Dependent on etiology
- Good if the underlying problem is canine viral upper respiratory tract infection, foreign body, successful surgery, teeth extractions
- Guarded for feline chronic viral upper respiratory tract infections
- Guarded to good for fungal rhinitis, depending on response to therapy
- Poor if neoplasia is not amenable to surgery and radiation therapy. Interventional techniques such as chemoembolization of nasal tumors may be considered in cases where surgery or radiation are not options, or if a less invasive approach is desired.

PEARLS & CONSIDERATIONS

PREVENTION

- Isolation of cats with viral infections
- Appropriate vaccination regime and retroviral testing
- Good dental care
- Limit exposure to irritating aerosols or materials

Snakebite

BASIC INFORMATION

DEFINITION

Injury resulting from a snake biting an animal

SYNONYM

Snake envenomation

EPIDEMIOLOGY

SPECIES, AGE, SEX: Any age or species; either sex

GENETICS & BREED PREDISPOSITION: Large-breed, outdoor dogs appear to have an increased risk.

RISK FACTORS

- Environment: exposure to outdoors in warm climates
- Behavior: curiosity

CONTAGION & ZOONOSIS

- The same snakes that are venomous to dogs and cats are venomous to humans.
- No zoonosis associated with snakebites

GEOGRAPHY AND SEASONALITY

- There are two main families of venomous snakes: Elapidae and Viperidae.
    - Elapids: coral snakes, cobras, mambas, kraits, and the tiger snake; in North America, these are found predominantly in the southeastern areas of the United States.
    - Vipers: rattlesnakes *(Crotalus* and *Sistrus* spp.) and cottonmouths and copperheads *(Agkistrodon* spp.); found throughout the United States
- Increased incidence of bites in summer months (in North America, 90% of bites occur between April and October). Toxicity increased in young or very large snakes during springtime.

ASSOCIATED CONDITIONS & DISORDERS

- Neurologic dysfunction: elapids
- Local tissue damage and possibly systemic bleeding/coagulation: vipers

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Vipers (e.g., rattlesnakes) inflict 99% of the estimated 150,000 annual snake bites of dogs and cats in North America.
- “Dry” bites possible: contain little or no toxic venom (22% of rattlesnake bites are dry; higher proportion in elapids)

HISTORY, CHIEF COMPLAINT

- Observed bite:
    - Dogs, head and neck; cats, abdomen, thorax. Common scenario: the dog cries out after sniffing in the bushes or behind a rock where snake is hidden.
- Unobserved bite: facial or neck swelling and pain after being outdoors without supervision

PHYSICAL EXAM FINDINGS

- Fang marks with swelling and bruising around the area may exist. The animal may show signs of mild discomfort to profound hemorrhagic and neurologic alterations. Fang marks are often difficult to find, especially in longhaired or thick-coated dogs and cats.
- Coral snakes:
    - Leave tiny fang or tooth marks with little or no local swelling
    - Signs may be delayed 1-7.5 hours.
    - Salivation
    - Vomiting
    - Convulsions
    - Quadriplegia
    - Death
- Rattlesnakes:
    - Usually leave two fang marks
    - Swelling
    - Pain
    - Erythema
    - Petechiae or ecchymoses
    - Cyanosis and tissue sloughing

SNAKEBITE Viper (rattlesnake) bite to a dog's muzzle. Note marked diffuse swelling of face and lips.

ETIOLOGY AND PATHOPHYSIOLOGY

- Elapid venom is neurotoxic and hemolytic:
    - Signs appear 1-7.5 hours after the bite was inflicted and progress rapidly.
    - Signs start with salivation, vomiting, and apprehensive behavior.
    - Signs progress to convulsions, quadriplegia, and eventually may lead to death from respiratory paralysis.
- Crotalid venom is vasculotoxic and necrogenic.
    - Bites lead to immediate regional swelling.
    - Area around the bite may have swelling, pain, erythema, ecchymosis, cyanosis, and tissue sloughing.
    - Bites are most often inflicted on the face and head and occasionally on the paws.
    - In severe cases, the tissue around the fang marks turns black within 30 minutes, and the blood oozing from the site is dark and watery.
    - Swelling typically worsens over the first 24 hours after the bite was inflicted, and the swollen tissue may be similar to a hematoma (occasionally requiring transfusion).

SNAKEBITE Viper (rattlesnake) bite to a cat's distal forelimb. Note marked swelling, moist exudation, and dark discoloration of skin, which suggests necrosis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected when a patient develops acute swelling with bruising, often around the face (vipers), or acute neurologic dysfunction (elapids) in a geographic region known to harbor venomous snakes. Identification of puncture marks in the skin from the bite is confirmatory; in many cases the diagnosis remains presumptive.

DIFFERENTIAL DIAGNOSIS

- Other animal attacks
- Scorpion bite
- Insect bite
- Wound of unknown origin
- Intoxication with neurotoxic substance (versus elapid envenomation)

INITIAL DATABASE

- CBC with platelet count: may reveal hemoconcentration, leukocytosis, echinocytosis, or thrombocytopenia
- Serum biochemistry profile: may reveal hypokalemia, high creatine kinase
- Urinalysis: may reveal hematuria or myoglobinuria
- Coagulation profile: prolonged activated clotting time (ACT), prothrombin time (PT), partial thromboplastin time (PTT), and increased fibrin/fibrinogen degradation products (FDPs) possible
- Aerobic and anaerobic bacterial culture and sensitivity (C&S) of the wound

ADVANCED OR CONFIRMATORY TESTING

No test exists that is diagnostic for a snake bite, but echinocytes found on a blood smear are a common finding in animals with envenomation. Echinocytes are “burred” red blood cells (RBCs) that appear soon after envenomation and last 24-48 hours. These cells often precede the massive tissue swelling and necrosis that occur with serious bites.

TREATMENT

TREATMENT OVERVIEW

- Management/prevention of hypotension
- Neutralization of venom (minimizing local and systemic effects)
- Prevention of secondary bacterial infection
- Pain management
- Avoidance of iatrogenic complications, particularly during first-aid efforts in the field

ACUTE GENERAL TREATMENT

- All animals that are bitten by a snake, regardless of their apparent hemodynamic stability, should be hospitalized for a minimum of 8 hours to assess for clinical signs that may first manifest during this period.
- IV fluid therapy:
  - First line of therapy to treat hypotension or hypovolemic shock (see p. 1592) and decreased cardiac output
  - Crystalloids (e.g., lactated Ringer's solution or 0.9% NaCl) at maintenance rates (e.g., 30 mL/lb/d [65 mL/kg/d] plus deficit for extravasated fluid; estimate amount of tissue swelling) if animal is stable; or at shock rates (90 mL/lb/h [200 mL/kg/h]) if animal is in hypovolemic shock.
  - Colloids indicated for animals with hypoalbuminemia; plasma preferred because both albumin and acute phase-proteins are administered (see p. 1347).
- Antivenom (antivenin; polyvalent Crotalidae):
  - Administered immediately for viper bites; increased survival when given closer to time of bite, but beneficial effects noted for at least 60 hours after envenomization
  - A dose of up to 10 to 25 vials is routinely recommended in human cases, but very high cost (up to $400 per vial hospital cost), reduced availability, smaller animal size, and mild extent of some bites generally limit the number of vials used to 1-3.
  - Protocol:
    - Reconstitute antivenin (10 mL diluent into lyophilized antivenin). Warm to body temperature (e.g., armpit method) and not warmer. Gently swirl to dissolve over 10 to 15 minutes; avoid shaking solution.
    - Pretreat the patient (diphenhydramine, 2 mg/kg IM).
    - Dilute antivenin into 50-200 mL IV fluids, and administer test dose IV(10-20 mL over several minutes) while monitoring for anaphylaxis (see pp. 64 and 1111).
    - If no anaphylaxis, administer remainder over 1 hour while continuing to monitor.
- CroFab (polyvalent immune Fabovine) is less antigenic; dissolves more rapidly and is more potent but twice as expensive.
- Antivipmyn: similar to antivenin; obtained from Mexico
- Antibiotics (controversial): chosen empirically at first while culture results are pending; first- or second-generation cephalosporins (e.g., cefazolin, 22 mg/kg IV q 8 h)
- Analgesics: opiates for sedation and analgesia while ensuring that the animal does not develop respiratory depression; buprenorphine (0.01 mg/kg IV q 6 h) or fentanyl at a constant rate infusion (3 mg/kg IV, then 3-6 mg/kg/h)
- Corticosteroids: antiinflammatory doses (e.g., prednisone, 0.5 mg/kg/d PO, maximum 5 days) may be of benefit.
- Antihistamines: not recommended (have been shown to potentiate the toxicity of venom) except in pretreatment doses prior to antivenin administration
- Urgent airway management (critical from time of presentation to 72 hours later): prepare endotracheal tubes and tracheostomy kits when facial, neck, or tongue bites have occurred, even if swelling is initially unimpressive. see p. 1344.

CHRONIC TREATMENT

Surgical débridement of necrotic tissue is necessary in some cases.

NUTRITION/DIET

Most patients can continue to prehend and swallow despite facial bites; if not, placement of a feeding tube should be considered (see p. 1270).

DRUG INTERACTIONS

Antivenin may cause an anaphylactic reaction (see p. 64). Monitor vital signs during infusion; if signs of anaphylaxis develop, temporarily stop the infusion, and then restart the infusion at a slower rate when signs have subsided.

POSSIBLE COMPLICATIONS

Renal failure may result from myoglobinuria, hemoglobinuria, toxic nephropathy, and hypovolemic shock.

RECOMMENDED MONITORING

Monitor respiratory rate and effort as well as blood pressure (BP), electrocardiogram (ECG), coagulation status and urine output.

PROGNOSIS AND OUTCOME 

- The prognosis is worse in animals with high-venom burdens, shock, severe cardiac arrhythmias, hematologic complications, and infection.
- Nevertheless, the spectrum of severity is wide, and the majority of dog or cat snakebite victims survive without permanent

sequelae if treated early and thoroughly.
- Although death may occur in spite of the timely use of crotalid-specific antivenin, a higher survival rate has been found in dogs that received antivenin than in dogs that did not.

PEARLS & CONSIDERATIONS

COMMENTS

- With viper bites, marked worsening of tissue swelling in the 24-48 hours following the bite is common, even with excellent treatment:
  - Warn owners in advance, in order to preempt their perception that treatment is unsuccessful.
  - Prepare airway mobilization material (endotracheal tube or tracheostomy kit) if the snake bit the animal on the head or neck.
- Ineffective first-aid techniques include tourniquet application, incision and suction of the bite, electroshock of the bite, and hot or cold pack application. These maneuvers can harm the animal by fostering infection.
- Effective first aid involves minimizing exertion immediately after the bite (reducing cutaneous blood flow/venom absorption) and immediate transport to a veterinary hospital for diagnosis and treatment as outlined previously.
- Snakebites on digits or in very small animals may require 50% more antivenin on a body weight basis than bites excluding digits or in larger animals:
  - Relatively small volume of body fluid in smaller animals (higher absolute venom concentrations)
  - Difficulty attaining high antivenin concentrations in digits
- Rattlesnakes may bite for up to 30 minutes after they are killed, including death by decapitation. Therefore, the body or head of a snake that has bitten and is then killed and transported for identification should be kept in a rigid, closed container, and the head should not be handled directly.

PREVENTION

The best way to prevent snakebites is to avoid snakes.

- Vipers bite in self-defense or when they are surprised (as occurs in veterinary and human medicine), or to immobilize and consume prey, such as small rodents.
- Vipers may strike with unavoidable speed (8 ft [2.5 m]/sec) but typically for a distance corresponding only to half the snake's length (e.g., half of 3-5 ft [1-1.6 m]).
- Keeping dogs in enclosed areas with cement walls or keeping dogs on leashes while outside may help prevent contact with snakes.
- Keeping cats indoors will help to prevent their contact with snakes.
- In regions where rattlesnakes are common, courses are offered to try to teach dogs to avoid snakes.
- Bitten dogs and cats cannot be counted on to avoid snakes in the future; repeat victims occur.

CLIENT EDUCATION

Most North American snakes bite when surprised or threatened; vigilance and avoidance of snakes during warm months are the best approach to preventing bite incidents.

EDITOR: ELIZABETH ROZANSKI

Smoke Inhalation

BASIC INFORMATION

DEFINITION

Injury to the respiratory system due to breathing of harmful gases, vapors, and particulate matter contained in smoke. Neurologic dysfunction and burns may occur concurrently.

SYNONYMS

Smoke exposure, smoke intoxication

EPIDEMIOLOGY

RISK FACTORS: Exposure to closed-space fires

GEOGRAPHY AND SEASONALITY: More residential fires in winter

ASSOCIATED CONDITIONS & DISORDERS: Carbon monoxide intoxication, acute respiratory distress syndrome (ARDS), burns, secondary bacterial pneumonia, systemic inflammatory response syndrome (SIRS)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Inhalation injury generally manifests in three clinical stages:
  - Hypoxie injury
  - Neurologic compromise
  - Secondary lung injury
- Occasionally, smoke inhalation injury may be confined to the nasal passages and pharynx.

HISTORY, CHIEF COMPLAINT

- Complaint of respiratory difficulties following smoke inhalation
- Weakness, stupor, or coma following rescue

PHYSICAL EXAM FINDINGS

- Dyspnea, coughing, tachypnea, short or shallow respirations, harsh or moist airway sounds, crackles, wheezes, loud laryngeal or tracheal sounds. In milder cases, signs may be limited to the nasal cavity (inflammation-induced nasal congestion, obstruction to nasal airflow).
- Postural adaptations to respiratory distress may be seen.
- Mentation and motor dysfunction may include ataxia, weakness, depression, stupor, or coma.
- Mucous membranes may be hyperemic (due to carboxyhemoglobin [COHb], cyanide [CN], or vasodilation), pale, or cyanotic.
- Dermatologic findings include smoky smell, singed or burnt hair and skin, soot, or skin lacerations.

ETIOLOGY AND PATHOPHYSIOLOGY

Causes of respiratory injury:

- Thermal damage is usually limited to the upper-airway mucosa, owing to rapid heat dissipation. Steam, soot (particles <2.5 mm), and volatile and explosive gases, however, may also cause thermal injury to lower airways.
- Asphyxiation:
  - Atmospheric oxygen deficit due to combustion
  - Carbon monoxide (CO) toxicity: tissue hypoxia from COHb formation and subsequent decrease in the oxygen-carrying capacity of blood. A left shift of the hemoglobin-oxygen dissociation curve also reduces peripheral oxygen delivery.
  - Combustion of plastics, polyurethane, fiber, rubber, and paper produces cyanide gas, which arrests cellular respiration by binding to cytochrome a3.
  - Methemoglobinemia occurs secondary to heat denaturation of hemoglobin and release of oxides and nitrites.

- Pulmonary irritants cause direct tissue injury (dependent on particle size, water solubility, and acidity), bronchospasm, and inflammation. Leukocyte activation with cytokine release and nitric oxide upregulation lead to pulmonary vascular hyperpermeability and edema. Pulmonary hypertension and atelectasis due to acute surfactant inactivation contribute to hypoxemia.
    - Impaired macrophage function and decreased mucociliary clearance may predispose the animal to bacterial pneumonia.
- Neurologic dysfunction: central nervous system (CNS) hypoxia

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis of smoke inhalation is almost always straightforward based on history of known exposure to fire and smoke and compatible clinical signs. Diagnostic testing is useful for monitoring of progression or development, rather than initial diagnosis.

DIFFERENTIAL DIAGNOSIS

- Anaphylaxis
- ARDS
- Asthma (cats)
- Congestive heart failure (CHF)
- Pneumonia
- Pneumothorax
- Pulmonary thromboembolism
- Primary CNS disorders

INITIAL DATABASE

- Arterial blood gas (ABG) and pulse oximetry:
    - ABG may confirm hypoxemia, hypercarbia.
    - Less useful for determining tissue oxygenation in the face of carbon monoxide (CO) exposure and methemoglobinemia unless cooximetry is available
    - With smoke inhalation, standard pulse oximetry cannot evaluate the severity of hypoxemia because it does not differentiate between oxygenated Hb and COHb.
- CBC:
    - Increased packed cell volume (PCV) (hypovolemia, splenic contraction). Dogs with a more severe inhalation injury tend to have a higher PCV (mean: 58%) than milder cases (mean: 50%).
    - Neutropenia: pulmonary neutrophil sequestration.
- Serum chemistry profile:
    - May reflect hypoxic organ damage (e.g., increased hepatic enzyme levels, azotemia)
    - Electrolyte (and lactate) levels: high anion gap acidosis possible
- Thoracic radiography:
    - May be normal after initial smoke inhalation but useful to establish a baseline
    - Findings may include atelectasis, aspiration pneumonia, and pulmonary edema.

ADVANCED OR CONFIRMATORY TESTING

- Bronchoscopy (see p. 1220): may demonstrate the severity of airway damage and indicate impending airway obstruction. A bronchoalveolar lavage (cytologic examination, culture) can be helpful in stable animals to assess for secondary processes such as bacterial pneumonia.
- Transtracheal wash (see p. 1350): if secondary infection is suspected and bronchoscopy is unavailable or not feasible
- Pulmonary function testing: uncommonly used; inhalation injury may decrease functional residual capacity.

TREATMENT

TREATMENT OVERVIEW

Early oxygen supplementation is a cornerstone of treatment to optimize these patients' chances for survival. Close attention should also be paid to maintaining normal tissue perfusion and general nursing care. Additional goals are to maintain airway patency, restore normal gas exchange, and assess for and treat secondary complications such as bacterial pneumonia, ARDS.

ACUTE GENERAL TREATMENT

- High-flow humidified oxygen therapy is crucial to reverse hypoxia and accelerate CO elimination:
  - COHb half-life: 4 hours (room air) versus 1.5 hours (100% oxygen)
- Severe cases: mechanical ventilation with positive end expiratory pressure (PEEP); see p. 1362.
- Administration of IV fluids as needed to maintain normal cardiac output and tissue perfusion
- Blood or plasma transfusions may be necessary (see p. 1347).
- Fluorescein stain corneas for evidence of ulceration
- Nebulization of saline and coupage may facilitate clearance of respiratory secretions.
- Drug therapy:
  - Secondary pneumonia: prophylactic use of antimicrobials is not indicated, as it increases the risk of development of fungal or resistant bacterial pneumonias. Clinicians should monitor for development of bacterial pneumonia (worsening respiratory character or rate, purulent nasal discharge or sputum; radiographic changes; +/− transtracheal wash), justifying sampling and treatment based on cytologic and microbiologic analysis.
  - Corticosteroids: probably contraindicated
  - Nonsteroidal antiinflammatory drugs for analgesia in hemodynamically stable patients only: meloxicam, 0.1-0.2 mg/kg SQ or PO q 24 h; or carprofen, 2.2 mg/kg PO or SQ q 12 h
  - Opioids: hydromorphone, 0.05-0.1 mg/kg IV or IM q 4 h; buprenorphine, 0.01-0.02 mg/kg IV or IM q 6-8 h; or fentanyl, 1-5 mcg/kg/h IV as a continuous rate infusion, all provide effective and relatively safe analgesia.
  - Bronchodilators: albuterol, 90-mg inhaler, 1-2 puffs per large-breed dog q 8 h as needed; or aminophylline, 6-10 mg/kg IM or diluted IV q 8 h, may alleviate reflex bronchospasm.
  - Diuretics: not indicated (decrease intravascular volume without major benefits on pulmonary function and edema)
  - Specific (rarely used) antidotes include:
    - 20% sodium thiosulfate, 30-50 mg/kg IV, q 8-12 h for treatment of cyanide intoxication
    - Sodium nitrite no longer recommended (can cause methemoglobinemia).

NUTRITION/DIET

Nutritional support to preserve body condition and immune status (see pp. 1270, 1267, 1269, and 1273)

POSSIBLE COMPLICATIONS

- ARDS and respiratory failure
- Superimposed bacterial infections: common cause of deterioration
- Immediate or delayed neurologic complications

RECOMMENDED MONITORING

- Careful monitoring of airway patency, gas exchange, hydration, and cardiovascular function
- Repeat thoracic radiographs

PROGNOSIS AND OUTCOME

- The duration of smoke exposure, type of burn material, and availability of immediate oxygen supplementation impact recovery.
- Severe skin burns, other internal organ injury, and deteriorating respiratory function within 24 hours carry a poor prognosis.
- Animals with signs of neurologic dysfunction who are stable or improving at 24 hours have a good prognosis; worsening neurologic function at 24 hours is a poor prognostic indicator.

PEARLS & CONSIDERATIONS

COMMENTS

Substantial pulmonary damage may not manifest until several hours following admission.

TECHNICIAN TIPS

Early oxygen supplementation is essential; it should be administered from the time of triage. Standard monitoring for animals with respiratory distress (e.g., ABGs, pulse oximetry) may be unhelpful in animals with smoke inhalation; monitoring respiratory rate and character and follow-up radiography are superior. Good nursing care is vital, especially for patients with skin wounds (keeping clean

and uncontaminated, changing dressings, pain management) or who have neurologic deficits (protection from self-injury).

Sinusitis and Other Sinus Disorders

Additional Images Available on Website

BASIC INFORMATION

DEFINITION

Mucosal inflammation in, or other diseases of, one or more of the sinuses: either the frontal or the maxillary sinuses in dogs and either the frontal or (even less commonly) the sphenoidal sinuses in cats

EPIDEMIOLOGY

SPECIES, AGE, SEX: Cats:

- No sex predilection
- Young to middle-aged animals for chronic idiopathic (rhino) sinusitis
- Older animals for sinus tumors
- Any age for trauma

Dogs:

- No sex predilection
- Older dogs for frontal sinusitis associated with tumors
- Young adults more commonly with aspergillosis
- Young to middle-aged dogs more often seen with chronic idiopathic sinusitis
- Any age for trauma

GENETICS & BREED PREDISPOSITION

- Cats: any breed
- Dogs: primarily dolichocephalic breeds for frontal sinusitis associated with tumors, aspergillosis, or chronic idiopathic sinusitis

ASSOCIATED CONDITIONS & DISORDERS

- Nasal tumors
- Nasal aspergillosis
- Chronic idiopathic or lymphoplasmacytic rhinosinusitis
- Nasal or frontal sinus trauma
- Abscessation of the roots of the upper fourth premolar tooth (apical dental abscess), causing maxillary sinus empyema
- Feline herpesvirus (rhinotracheitis)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: see Associated Conditions and Disorders, above.

HISTORY, CHIEF COMPLAINT

- Nasal discharge
- Intermittent sneezing
- Focal facial swelling or deformity
- Signs related to local pain:
  - Dullness or lethargy
  - Decreased movements of the head
  - Anorexia

PHYSICAL EXAM FINDINGS

- Unilateral nasal discharge of variable nature: mucoid, mucopurulent or blood-tinged; often bloody with nasal neoplasia
- If nasal cavity affected, diminished air flow through nasal passages/nares
- Focal swelling, firm enlargement, facial deformity, and/or pain with atrophy or lysis of the frontal or nasal bones:

  - Depressions or defects in frontal/nasal bone integrity from osteolysis may be noted during palpation.
  - Dogs with maxillary sinusitis from fourth premolar tooth root abscessation may have a swelling or fistulous tract and drainage from ventral to the eye on the affected side.
- Enlargement of submandibular lymph nodes is possible.
- Percussion of the sinus may induce pain or be associated with reduced resonance.

ETIOLOGY AND PATHOPHYSIOLOGY

- Sinusitis is most often secondary to another primary nasal or frontal sinus disease (as already described in Associated Conditions and Disorders, above) in which disruption of the normal nasal/sinus anatomy impairs mucociliary clearance or obstructs mucus drainage.
- Owing to physical continuity between the chambers, tumors of the frontal sinus can extend into the nasal cavity, and nasal tumors can extend in the frontal sinus.
- Mycotic sinusitis and rhinitis, mostly due to *Aspergillus fumigatus,* can affect both the nasal cavity and sinus, or either independently.
- Chronic lymphoplasmacytic inflammation in dogs can be a sequela to bacterial or mycotic infections (even after successful fungal therapy), can be idiopathic, or possibly could be related to an allergic etiology.
- Chronic lymphoplasmacytic inflammation in cats can be a sequela to bacterial, viral (feline upper respiratory tract infection complex), and (rarely) mycotic infections.
  - Like in dogs, the condition can be idiopathic in cats, possibly related to an allergic etiology.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Sinus diseases are generally associated with nasal diseases and probably secondary to nasal disease in most cases.

DIFFERENTIAL DIAGNOSIS

Nasal diseases of various origins:

- Fungal rhinitis
- Nasal neoplasia
- Dental disease/dental root infection (maxillary sinus)
- Foreign bodies
- Lymphoplasmacytic rhinitis
- Nasal mites
- Chronic viral upper respiratory tract infection in cats

INITIAL DATABASE

- For some cases, plain radiographs of the nasal cavities, sinuses, and dental roots can be helpful in the diagnosis of structural lesions such as neoplasia, fungal rhinitis/sinusitis, and dental disease but will not help discriminate among the various causes of nasal/sinus disease in other cases not involving structural changes.
- Results of a CBC, serum biochemical profile, and urinalysis are often normal.
- For cases in which there is swelling or lysis (which can be palpable) of nasal/facial bones or the frontal sinus area, fine-needle aspirate (FNA) cytologic examination can show neoplasia or inflammation.

ADVANCED OR CONFIRMATORY TESTING

- CT scan and/or MRI of the nasal cavities and sinuses can differentiate neoplasia, fungal rhinitis, and dental disease with more accuracy than plain radiographs but will not confirm the diagnosis in all cases.
- The frontal sinus can be examined by direct rhinoscopy in some dogs, but access to and visualization of the frontal sinus is often possible only in animals with severe turbinate destruction.
- Trephination of the frontal sinus for examination and biopsy may be necessary to confirm the presence of neoplasia, fungal rhinitis, or inflammation, especially if disease is confined to the frontal sinus. Trephination may also have therapeutic value for cases of fungal rhinitis (see p. 96).

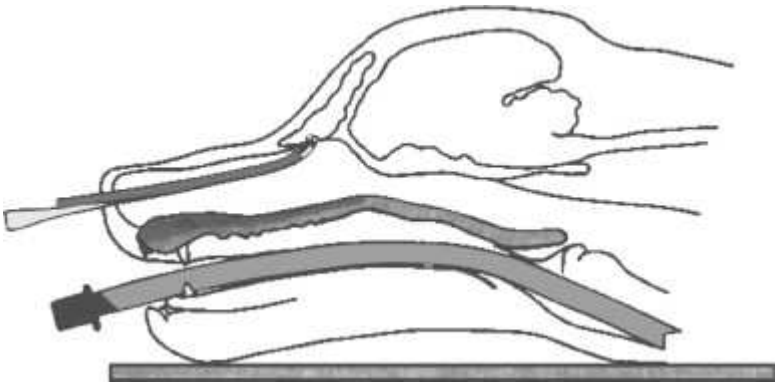
TREATMENT

TREATMENT OVERVIEW

Whenever possible, the best opportunity for resolution of sinusitis is treatment of the underlying primary disease that often exists.

ACUTE GENERAL TREATMENT

- Direct treatment toward the causal agent:
  - Fungal sinusitis/rhinitis: antimycotic therapy (see p. 96 and online chapter: Nasal Infusion of Clotrimazole)
  - Frontal tumors: radiation therapy and, occasionally, surgical resection
  - Traumatic injuries causing fractures of the frontal bone: removal of bone fragments present in the frontal sinus and possibly reconstruction; check patency of the nasofrontal ostium (nasofrontal opening); broad-spectrum antibiotics.
  - Apical dental (tooth root) abscess: surgical extraction of the tooth, including roots, or endodontic treatment
- In acute infection, as well as in chronic idiopathic inflammation with episodes of secondary bacterial infections, oral or injectable antibiotics (e.g., amoxicillin, 20 mg/kg PO q 8 h; cefadroxil, 20 mg/kg PO q 8 h; or amoxicillin-clavulanate, 15 mg/kg PO q 12 h) and possibly mucolytics may be needed.
  - The frontal sinus is a combination of several large cavities surrounded by bone; systemically administered drugs often do not achieve high concentrations in the sinus. Even very high dosages of highly soluble drugs, preferred for systemic therapy, may not reach adequate concentrations throughout the entire sinus cavity.
  - Drug nebulization is unproven; the amount of drug delivered into the frontal sinus is unknown.



SINUSITIS AND OTHER SINUS DISORDERS Diagram demonstrating the standard position for endoscopic imaging of the frontal sinuses in the dog.

(Courtesy Dr. Cécile Clercx, University of Liège.)

SINUSITIS AND OTHER SINUS DISORDERS Endoscopic view of the frontal sinus of a dog. A large, smooth convex mass occupies the center of the image *(arrows),* and its appearance strongly suggests neoplasia. An adjacent blood vessel is seen *(asterisk).*

(Courtesy Dr. Cécile Clercx, University of Liege.)

CHRONIC TREATMENT

In cases of concomitant nasal disease, with loss of the protective filter provided by normal turbinates and decreased mucociliary clearance along the distal third of the nasal cavity, recurrent bacterial secondary infections are common and are treated each time with antibiotics and mucolytics, orally or locally (intranasal administration or aerosol delivery).

POSSIBLE COMPLICATIONS

In animals with chronic sinusitis, repeated episodes of bacterial infection can be expected.

RECOMMENDED MONITORING

Monitoring depends on etiology of the condition and persistence of clinical signs. For example, in lymphoplasmacytic inflammation of the frontal sinus after treatment of aspergillosis, diagnostic workup is warranted in cases of severe recurrence of clinical signs to differentiate between secondary bacterial infection and recurrence of aspergillosis, because the latter must be treated with antifungal agents.

PROGNOSIS AND OUTCOME

- Prognosis and outcome depend on the cause, whether the cause can be eliminated or treated, and whether there are chronic irreversible sequelae of the turbinates and sinus mucosa.
- Poor for most patients with frontal sinus tumors, which are usually malignant
- In chronic sinusitis, total cure is rarely achieved, but response to ongoing therapy is generally good.

PEARLS & CONSIDERATIONS

COMMENTS

- In acute cases, quickly find the cause, using appropriate diagnostic tests, and immediately treat the animal to avoid chronic irreversible sequelae.
- When sinusitis is related to the extension of nasal disease, it is often a chronic condition with consequent remodeling, and total cure is rare; secondary bacterial infections can always occur.

TECHNICIAN TIPS

While of low diagnostic yield, cytologic examination of nasal exudate can occasionally identify another underlying cause (e.g., cryptococcosis, rarely nasal neoplasia) of nasal cavity disease.

CLIENT EDUCATION

Treatment must be repeated when relapses, which are common in chronic idiopathic sinusitis, occur. The disease will rarely totally resolve, and most of the time, mild clinical signs persist despite treatment. If more severe signs persist, repeating a complete diagnostic evaluation is indicated, with the intent of identifying an etiologic cause.

EDITOR: RANCE K. SELLON

Sinus Tachycardia

BASIC INFORMATION

DEFINITION

An accelerated heart rate caused by rapid firing of the sinus node. Sinus tachycardia is a physiologic response to the body's needs (rather than a pathologic condition), triggered by an increase in sympathetic tone. Sinus tachycardia usually appears and subsides gradually over a few seconds; this characteristic helps set it apart from pathologic supraventricular tachycardias, which may appear and subside instantaneously.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Definition of sinus tachycardia depends on the species, breed, and age:

- Dogs > 160 beats per minute (bpm):
  - Toy breeds > 180 bpm; giant-breed dogs > 140 bpm; puppies > 200 bpm
- Cats > 240 bpm

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Primary physiologic sinus tachycardia:
  - Response to exercise, stress (restraint, anxiety), pain
- Secondary physiologic sinus tachycardia:
  - Response to underlying condition/disease:
    - Fever and infection
    - Shock and hypotension
    - Hypovolemia
    - Anemia
    - Hypoxemia
    - Heart failure and cardiac tamponade
    - Hyperthyroidism
    - Catecholamine excess (e.g., pheochromocytoma)
- Pharmacologic sinus tachycardia:
  - Response to drug administration:
    - Vagolytic drugs (atropine, glycopyrrolate)
    - Sympathomimetic drugs (beta-agonists, dopaminergic drugs)
    - Phosphodiesterase inhibitors (aminophylline, theophylline)

HISTORY, CHIEF COMPLAINT: Sinus tachycardia per se does not cause a chief complaint. The chief complaint is typically associated with the respective underlying disease (as already listed).

PHYSICAL EXAM FINDINGS

- Tachycardia
- Also possible, particularly if the cause of the tachycardia is secondary physiologic (underlying diseases listed):
  - Weak pulse or increased capillary refill time (heart failure/decreased cardiac output)
  - Pale or cyanotic mucous membranes (anemia/hypovolemia or hypoxemia)
  - Fever (infection)
  - Palpable thyroid nodule (feline hyperthyroidism)

ETIOLOGY AND PATHOPHYSIOLOGY

- Sinus tachycardia is a manifestation of the so-called fight or flight response governed by the sympathetic nervous system. Its purpose is to contribute to an increased cardiac output.
- Activation of the sympathetic nervous system increases the automatic discharge rate of sinoatrial (SA) nodal cells, either directly by activating the b1 receptors in the SA node or indirectly by stimulating the release of norepinephrine from the

adrenal gland into the circulation.
- Transient sinus tachycardia usually occurs during vigorous exercise, anxiety from restraint, fear, or pain.
- Sustained sinus tachycardia is more likely a compensatory phenomenon associated with a decreased cardiac output, hypoxia, or increased metabolic demand (fever, hyperthyroidism).
- Drug-induced sinus tachycardia (dopamine, sympathomimetics, methylxanthines, anticholinergics)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Sinus tachycardia is suspected (and not pursued diagnostically) when environment/context is appropriate (e.g., in-hospital anxiety). If the heart rate is persistently, seemingly inappropriately elevated, the question of whether sinus tachycardia or another tachycardia is responsible should be raised. In such a situation, an electrocardiogram (ECG) provides the definitive answer.

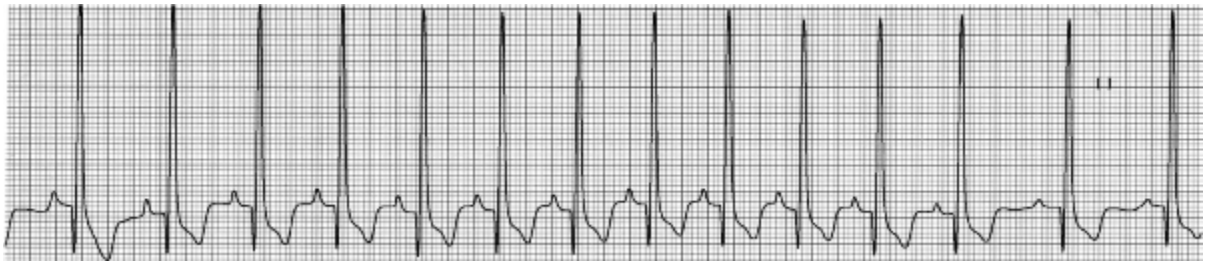
DIFFERENTIAL DIAGNOSIS

By ECG:

- Any narrow complex supraventricular tachycardia (SVT):
  - Sinus node reentry tachycardia
  - Ectopic atrial tachycardia (if normal P wave morphology)
  - In fast sinus tachycardia, the P waves cannot be distinguished from the T waves of the previous beat. In those cases, it can be difficult to differentiate sinus tachycardia from atrioventricular (AV) reentry (bypass tract-mediated supraventricular tachycardia) or AV nodal reentry tachycardia (see the text on vagal maneuver in the Initial Database section below).
  - Atrial flutter with 2:1 or 3:1 conduction
- Sinus tachycardia with bundle branch block can mimic ventricular tachycardia.

INITIAL DATABASE

- ECG (see p. 1253):
  - QRS complexes are similar to normal sinus rhythm.
  - RR interval is shorter.
  - Regular P waves with normal morphology
  - Each P wave is followed by a QRS complex in a 1 : 1 ratio.
  - At very rapid rates, the P waves might become superimposed on the preceding T waves such that the P waves are obscured by T waves.
- Physical tests:
  - Vagal maneuver: a positive response (transient, gradual slowing of sinus tachycardia over a few seconds) may increase the R-R interval enough to allow visualization of P waves. Abrupt termination of a tachycardia during a vagal maneuver (see p. 1359) suggests presence of another type of SVT, such as sinus node reentry or AV node–dependent SVT.
  - Capillary refill time (peripheral perfusion prolonged in shock or with reduced cardiac output)
- Blood pressure (BP) (hypotension)
- Oxygen saturation (hypoxemia)
- Hematocrit and hemoglobin (anemia)
- Thoracic radiography (cardiomegaly, pulmonary edema, or pleural effusion secondary to congestive heart failure [CHF])
- Echocardiography to check for cause of reduced cardiac output or CHF if present



SINUS TACHYCARDIA Electrocardiographic rhythm strip; lead II, 50 mm/sec, 10 mm/mV. Sinus tachycardia in a mixed-breed dog with chronic myxomatous atrioventricular valve disease. Normal sinus rhythm initially; acceleration to a heart rate of up to 200 bpm (sinus tachycardia) is seen in the middle of the strip, with a gradual slowing down again to 150 bpm (sinus rhythm) toward the end of the strip. The R-wave amplitude is tall, indicative of left ventricular enlargement (in this case, secondary to mitral endocardiosis), and

there is mild ST-segment depression, suggesting myocardial hypoxia. Rapid-onset sinus tachycardia, such as in this example, is usually due to catecholamine release in response to environmental stimuli (stress, excitement, etc.).

TREATMENT

TREATMENT OVERVIEW

- Treat underlying cause of sinus tachycardia (if necessary).
- Medical reduction of heart rate (β-blockers) during sinus tachycardia without knowledge of the underlying disorder can be detrimental, since the elevated heart rate might be necessary for maintaining cardiac output.

ACUTE GENERAL TREATMENT

Depends on cause of sinus tachycardia:

- Provide calming environment to reduce anxiety.
- Administer pain medication if indicated.
- Provide oxygen or hemoglobin for hypoxemic or anemic animals.
- Administer fluids or vasopressor agents to stabilize BP for animals in shock.
- Start antimicrobials (if indicated) for sepsis; reduce fever with cool fluid administration.
- Discontinue drugs that are causing sinus tachycardia.

CHRONIC TREATMENT

Address the underlying disease and:

- Manage CHF.
- Control T4 levels (correct hyperthyroidism).
- Treat other signs.

POSSIBLE COMPLICATIONS

- Acute, transient sinus tachycardia can be associated with weakness or syncope, particularly in animals with reduced cardiac function (e.g., dilated cardiomyopathy, advanced mitral/tricuspid endocardiosis) and congestive heart failure.
- Chronic sinus tachycardia may cause tachycardia-induced cardiomyopathy.

RECOMMENDED MONITORING

If the underlying cause has been identified and corrected, the sinus tachycardia should resolve.

PROGNOSIS AND OUTCOME

- Prognosis is good if underlying cause can be corrected.
- Outcome depends on underlying condition.

PEARLS & CONSIDERATIONS

COMMENTS

Sinus tachycardia is a benign “arrhythmia,” and usually should be considered a red flag that indicates an underlying cause needs to be investigated. If the heart rate does not slow down, it can be assumed that the underlying cause is not yet addressed adequately.

CLIENT EDUCATION

Avoid excessive stress or vigorous exercise in animals with reduced cardiac output and CHF.

EDITOR: ETIENNE CÔTÉ

Sinus Bradycardia

BASIC INFORMATION

DEFINITION

Normal sinus rhythm with heart rate less than 60-70 beats per minute (bpm) in dogs and less than 120 bpm in cats

EPIDEMIOLOGY

SPECIES, AGE, SEX: More common in dogs

GENETICS & BREED PREDISPOSITION: Physiologic sinus bradycardia is more common in brachycephalic breeds.

RISK FACTORS

- Variations of normal: athletic dogs, brachycephalic conformation
- Disorders: upper airway disease, respiratory disease, gastrointestinal (GI) disease, systemic disease, central nervous system (CNS) disease, hypothermia, hypothyroidism, sinus node dysfunction, feline dilated cardiomyopathy, end-stage heart failure
- Drug-related: normal response (e.g., β-adrenergic antagonists, diltiazem, amiodarone), inhalation anesthetics, inadvertent administration/toxicity

ASSOCIATED CONDITIONS & DISORDERS: Sinus arrhythmia (normal); sick sinus syndrome (SSS); sinoatrial (SA) block (very rare)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Physiologic: athletes, brachycephalic breeds
- Pathologic: sinus node dysfunction, intoxications, secondary to systemic disease states

HISTORY, CHIEF COMPLAINT

- Often incidental finding: owner auscults/palpates low heart rate.
- Rarely: exercise intolerance, malaise, lethargy, depression, collapse (usually with exertion). When such overt signs occur, they are commonly related to SSS (see p. 1022).

PHYSICAL EXAM FINDINGS

- Cardiac auscultation: reduced heart rate in an alert ± nervous animal:
  - <60–70 bpm in dogs
  - <120 bpm in cats
- Femoral pulse character: may be normal, reduced, or pronounced (depending on underlying etiology and chronicity of bradycardia)
- Malaise, lethargy, depression: if bradycardia is severe

ETIOLOGY AND PATHOPHYSIOLOGY

- Increased vagal tone:
  - Physiologic
    - Brachycephalic conformation (common)
    - Athlete
  - Respiratory disease (upper and/or lower respiratory tract)
  - GI disease: severe vomiting
- CNS disorders:
  - Head trauma
  - Increased intracranial pressure
  - Brainstem lesions

    - Spinal trauma
- Metabolic/systemic disorders:
    - Hypothyroidism
    - Hypothermia
    - Hypoxemia
- Intoxications:
    - Phenothiazines (although phenothiazines may instead induce hypotension and reflex tachycardia).
    - b-Adrenergic receptor antagonists
    - Digitalis
    - Diltiazem (especially injectable)
    - Quinidine
    - Narcotics
    - Amiodarone
    - Inhalation anesthetics
- Primary cardiac disease:
    - Sinus node dysfunction (from SSS)
    - End-stage heart failure
    - Feline dilated cardiomyopathy

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Electrocardiogram (ECG) is required to confirm the presence of sinus bradycardia (and thus rule out other bradycardias, such as atrioventricular [AV] block, if uncertainty exists). Further diagnostic testing is warranted if the patient is exhibiting signs of poor perfusion such as syncope, lethargy, seizures, or other nonspecific systemic disturbances. If signs of underlying disease are absent, the strong possibility of sinus bradycardia as a normal finding should be considered.

DIFFERENTIAL DIAGNOSIS

- Normal (during sleep, healthy dogs routinely have heart rates of 30-40 bpm, and healthy cats routinely have heart rates of 70 bpm).
- Other bradycardias (e.g., AV block, atrial standstill)
- Specific causes: see Etiology and Pathophysiology above

INITIAL DATABASE

- ECG: confirm clinical diagnosis.
- CBC, biochemistry panel, urinalysis may reveal evidence of systemic disease.
- Thoracic and abdominal radiographs to identify underlying respiratory, cardiovascular, or GI disorders
- Abdominal ultrasound to confirm equivocal or subtle abdominal radiographic findings (operator skill dependent)

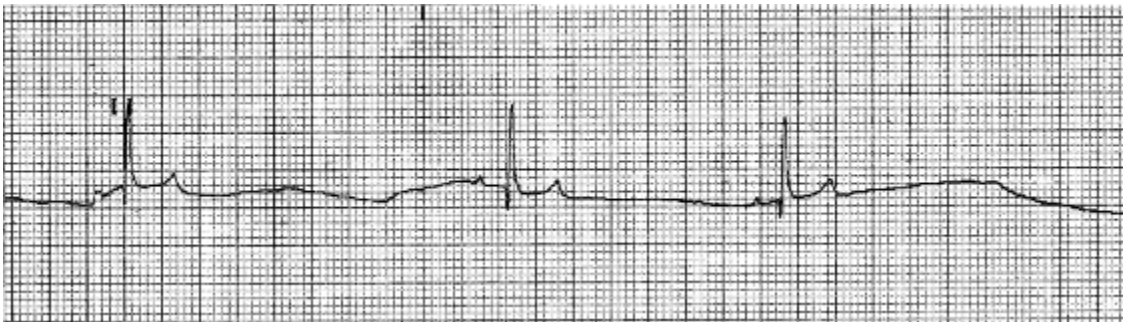
ADVANCED OR CONFIRMATORY TESTING

- Atropine response test to differentiate between vagally mediated bradyarrhythmias and those arising from a conduction disturbance
- Echocardiography to rule out underlying cardiac disease
- Serum digoxin level (if applicable)
- Complete thyroid hormone panel

TREATMENT

TREATMENT OVERVIEW

Treatment of physiologic sinus bradycardia is unnecessary. If systemic disease is identified, treatment of the underlying disease process is indicated. Patients with bradycardia causing overt clinical signs may require acute medical management or pacemaker implantation to increase heart rate, but this is rarely caused by sinus bradycardia (exception: when sinus bradycardia is part of the SSS array of arrhythmias; AV block and premature beats would also be expected concurrently).



SINUS BRADYCARDIA Sinus bradycardia/respiratory sinus arrhythmia. Incidental finding in healthy 5-year-old German shepherd dog. Heart rate = 37 bpm; lead II, 25 mm/sec, 1-cm/mV.

ACUTE GENERAL TREATMENT

- Rarely indicated
- Treat underlying problem (if applicable).
- Discontinue or taper all medications with potential to promote bradycardia.
- For animals with sinus bradycardia that are also showing critical clinical signs (recumbency, unconsciousness, etc.):
  - Administer anticholinergic agent IV (atropine sulfate, 0.04 mg/kg IV; or glycopyrrolate, 0.011 mg/kg IV).
  - If anticholinergic therapy is unsuccessful, consider IV constant rate infusion of isoproterenol (0.4 mg in 250-mL saline; slow drip to effect [prime IV line, start slowly, and increase titration based on response]) or dopamine (2-10 mcg/kg /min).
  - Rarely, emergency cardiac pacing may be required for severe refractory bradycardia.

CHRONIC TREATMENT

- Treat underlying problem (if applicable).
- Discontinue or reduce dosages of all medications with potential to induce bradycardia.
- For animals showing overt signs due to the bradycardia (very uncommon, unless SSS):
  - Propantheline bromide, 0.2-1 mg/kg PO q 8 h (variable response)
  - Theophylline, 10 mg/kg PO q 8 h (variable response)
  - Permanent pacemaker implantation

BEHAVIOR/EXERCISE

Strict exercise restriction for patients with symptomatic bradycardia

DRUG INTERACTIONS

- Propantheline bromide: use this drug cautiously in animals with suspected GI disease or autonomic neuropathy; multiple drug interactions.
- Theophylline: narrow therapeutic window, use cautiously; multiple drug interactions

POSSIBLE COMPLICATIONS

- Medical management failure common when sinus node dysfunction/SSS is present.
- Side effects of propantheline bromide or theophylline administration may be problematic.

RECOMMENDED MONITORING

- None for physiologic sinus bradycardia not causing clinical signs
- The owner monitors for signs of bradycardia: lethargy, exercise intolerance, malaise, collapse.
- Follow-up ECG 1 week after initiation of medical management, then every 1-3 months (as directed by clinical course)
- If pacemaker implantation performed, schedule a follow-up visit as directed (see p. 1022).

PROGNOSIS AND OUTCOME

- Physiologic: excellent. By definition, physiologic sinus bradycardia is not associated with clinical disease.
- Secondary: dependent on response to treatment of primary disorder

- Sinus node dysfunction/SSS:
  - Chronic response to medical therapy is generally unrewarding.
  - Good with pacemaker implantation

PEARLS & CONSIDERATIONS

COMMENTS

- Large- and giant-breed dogs may exhibit normal heart rates as low as 30-40 bpm when asleep.
- Sinus arrhythmia is often identified in conjunction with physiologic sinus bradycardia.
- A life-threatening situation can be the sudden (instantaneous) transition from sinus tachycardia to sinus bradycardia in an unconscious animal, which is associated with impending cardiac arrest.

TECHNICIAN TIPS

- Sinus bradycardia in an anxious or stressed animal (e.g., a hospitalized patient) is more likely to be pathologic and should be brought to the attention of the attending clinician.
- Sinus bradycardia is common in hospitalized patients treated with opiates (e.g., fentanyl, hydromorphone).

AUTHOR: NATHANIEL FENOLLOSA

EDITOR: ETIENNE CÔTÉ

Sinus Arrhythmia

BASIC INFORMATION

DEFINITION

Sinus arrhythmia is a very common form of normal heart rhythm. It is characterized by a physiologic, autonomically mediated cyclical change in sinus rate, with increase in heart rate during inspiration and decrease during expiration. On an electrocardiogram (ECG), the P-P and associated R-R intervals are “regularly irregular” due to fluctuations of the autonomic tone that result in phasic changes of the sinus node discharge rate.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Common in dogs (physiologic)
- Rare in cats (can be pathologic)

GENETICS & BREED PREDISPOSITION

- All dog breeds can display sinus arrhythmia.
- Brachycephalic breeds often have the largest variations in R-R interval (bulldog, pug, boxer, Pekinese, Lhasa apso) owing to increased inspiratory effort.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Respiratory sinus arrhythmia:
  - Physiologic fluctuation associated with respiration
- Nonrespiratory sinus arrhythmia:
  - Cyclic change in P-P interval independent of normal breathing but due to increased vagal tone:
    - Respiratory disease
    - Central nervous system (CNS) disease (increased intracranial pressure)
    - Gastrointestinal (GI) disease

HISTORY, CHIEF COMPLAINT: Respiratory sinus arrhythmia does not cause clinical signs. In animals with nonrespiratory sinus arrhythmia, particularly cats, the chief complaint is related to the underlying disease.

PHYSICAL EXAM FINDINGS

- Normal to “slow-normal” heart rate
- Regularly irregular heart rate by auscultation and pulse palpation
- Also possible but less common:
  - Upper airway noises: stridor, dyspnea, wheezes
  - Neurologic signs: depression
  - GI disturbances

ETIOLOGY AND PATHOPHYSIOLOGY

- Respiratory sinus arrhythmia: sinus node discharge rate is regulated by the autonomic nervous system. Inspiration causes a decrease in vagal tone and an increase in sympathetic tone, resulting in an increased heart rate. Conversely, on expiration there is an increase in vagal tone and a decrease in sympathetic tone, resulting in a decrease in heart rate. The fluctuation in heart rate in phase with respiration and lung volume likely optimizes pulmonary gas exchange by matching perfusion to ventilation within each respiratory cycle.
- Nonrespiratory sinus arrhythmia: autonomic influences can also cause sinus arrhythmia independent of respiration, slowing the heart rate during periods when parasympathetic tone predominates over sympathetic tone.

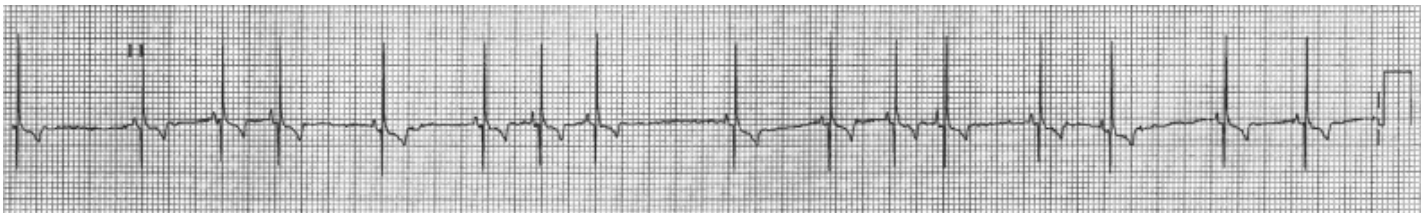
DIAGNOSIS

DIAGNOSTIC OVERVIEW

Sinus arrhythmia is a normal form of sinus rhythm with a “regularly irregular” (cyclical) pattern of increase and decrease in heart rate. Therefore, it is strongly suspected on physical exam alone, and if uncertainty exists, it can be confirmed or ruled out with ECG.

DIFFERENTIAL DIAGNOSIS

- ECG: sinus arrhythmia should be differentiated from (also see Initial Database below):
  - Sick sinus syndrome (SSS): pauses between sinus beats are longer (can be up to several seconds with SSS)
  - Slow atrial fibrillation (no P waves, “irregularly irregular” rhythm)
  - Transient sinus arrest (intermittent nature of pauses instead of cyclic pattern)
  - Atrial premature contractions (APCs): underlying rhythm may be a regular sinus rhythm frequently interrupted by APCs. Differentiation: the P wave of an APC may occur inside the preceding T wave, but such a degree of prematurity does not occur with sinus arrhythmia; APCs do not occur cyclically in concert with the patient's respirations; the heart rate during sinus arrhythmia does not exceed 140 beats/minute, but it commonly does so with APCs/atrial tachycardias.
- By auscultation alone, sinus arrhythmia may be confused with these pathologic arrhythmias. ECG is important to confirm the diagnosis.



SINUS ARRHYTHMIA Electrocardiographic rhythm strip, lead II, 25 mm/sec, 5 mm/mV; healthy dog displaying sinus arrhythmia. Average heart rate is 60-70 bpm; individual R-R intervals vary by close to 100% (range 0.6-1.2 sec).

INITIAL DATABASE

ECG:

- Morphology is similar to normal sinus rhythm:
  - Heart rate is normal to slow (<140 bpm in dogs).
  - P-P interval is variable in a “regularly irregular” fashion.
  - Variability in P-P interval is >10% and can vary up 100%.
  - Normal P wave morphology: P wave is followed by a QRS complex in a 1:1 ratio.
  - P wave amplitude may vary if wandering pacemaker is present (tall P wave after a short P-P interval, low voltage [short] P-wave after a long P-P interval).
- If sinus arrhythmia is concurrent with significant respiratory, CNS, or GI disease, specific diagnostic testing should be recommended based on the relevant abnormalities of the case.

TREATMENT

TREATMENT OVERVIEW

Sinus arrhythmia is a physiologic phenomenon and does not warrant therapy. If confirmation of the rhythm as sinus arrhythmia is needed, administration of a vagolytic agent (atropine) should result in sinus tachycardia and disappearance of sinus arrhythmia. Alternatively, excitement or exercise (sympathetic stimulation) should also result in disappearance of the sinus arrhythmia.

PROGNOSIS AND OUTCOME

Both are good.

PEARLS & CONSIDERATIONS

COMMENTS

Sinus arrhythmia is a physiologic phenomenon, most commonly indicative of a healthy cardiovascular system.

SUGGESTED READING

Hayano J, Yasuma F, Okada A, et al: Respiratory sinus arrhythmia. A phenomenon improving pulmonary gas exchange and circulatory efficiency. Circulation 94:842–847, 1996.

AUTHORS: ANNA R. M. GELZER, MARC S. KRAUS

EDITOR: ETIENNE CÔTÉ

Sick Sinus Syndrome

Additional Images Available on Website

BASIC INFORMATION

DEFINITION

One of the two most common indications for cardiac pacemaker implantation in dogs. It represents diffuse cardiac conduction system disease that displays variable degrees of sinoatrial (SA) nodal dysfunction (sinus bradycardia, sinoatrial block, or sinus arrest) and/or atrioventricular (AV) nodal dysfunction. The subsidiary pacemakers often display depressed automaticity, so prolonged episodes of sinus arrest are accompanied by asystole and syncope. Some dogs may display episodes of supraventricular tachycardia alternating with their bradyarrhythmias, producing a so-called brady-tachy syndrome.

SYNONYMS

Sinus node dysfunction (current term), SSS, bradycardia-tachycardia (brady-tachy) syndrome, chronotropic incompetence, lazy sinus syndrome, SA syncope, sluggish sinus syndrome

EPIDEMIOLOGY

SPECIES, AGE, SEX: Small-breed, older dogs

GENETICS & **BREED PREDISPOSITION:** Middle-aged to older female miniature schnauzers are most commonly afflicted. West Highland white terriers and cocker spaniels also appear to be overrepresented.

ASSOCIATED CONDITIONS & DISORDERS: Sick sinus syndrome (SSS) and chronic degenerative valvular disease often occur in the same animal because of their similar breed and age predispositions, but there is no known link between the two disease processes.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Most dogs with clinical signs from SSS are presented for episodic weakness or syncopal/seizure-like episodes.
- Some animals with severe, long-standing sinus bradycardia may develop congestive heart failure (CHF) and are presented for the evaluation of coughing, respiratory distress, or exercise intolerance.
- Some dogs are diagnosed with bradyarrhythmias and SSS during routine preventive health examination or prior to dental prophylaxis.

PHYSICAL EXAM FINDINGS

- The classic physical examination findings include a detectable bradyarrhythmia with prolonged episodes of asystole due to sinus arrest without activation of subsidiary (AV or intra-ventricular) pacemakers.
- Because of the predisposition for SSS to occur in older, small-breed dogs, many will display variable-intensity, left apical systolic murmurs of mitral insufficiency.
- Dogs with brady-tachy syndrome may have paroxysms of tachycardia followed by audible pauses.
- Unfortunately (as it obscures the diagnosis), some animals will have normal physical examinations without evidence of bradyarrhythmias, because dogs with SSS may still have some response to the elevated circulating levels of catecholamines associated with visits to the veterinary hospital.

ETIOLOGY AND PATHOPHYSIOLOGY

- To date, the etiologic basis for SSS in dogs has not been determined.
- Fibrosis and fatty infiltration with sclerodegenerative processes have been identified within the sinus node, AV node, and bundle of His in humans with SSS.
- Occlusion or degeneration of the sinus node artery could play an important role in the development of this disease.
- The absence of morphologic abnormalities in some humans with sinus node dysfunction suggests that alterations of neural innervation or neural regulation may contribute to the bradyarrhythmias.
- Autoantibodies to proteins isolated from sinus node cells have been identified in humans, suggesting an immune-mediated process in some cases of sinus node dysfunction.
- Changes in ion channels or gap junctions within the sinus node may account for the development of SSS in humans.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

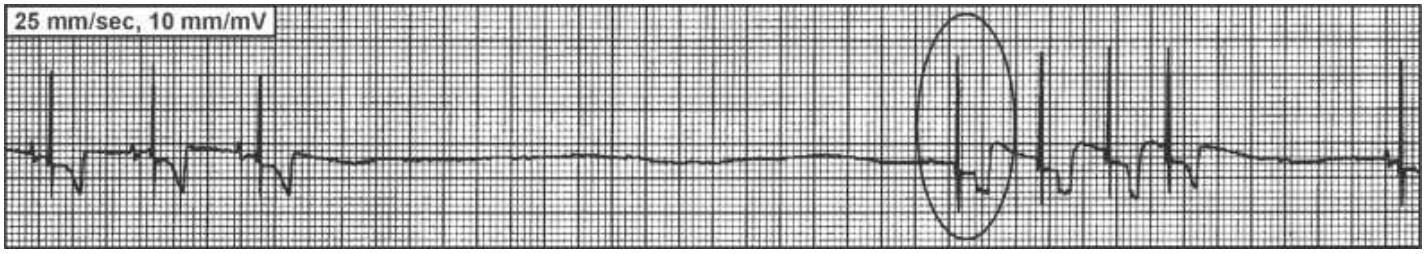
The two most common clinical contexts that would raise the suspicion of this disorder are a history of syncope in a dog of a susceptible breed, or incidental discovery of a bradycardia. The diagnosis is confirmed electrocardiographically. In some patients, an in-hospital resting electrocardiogram (ECG) is sufficient; in others, the intermittent nature of the arrhythmia mandates the use of telemetry or ambulatory ECG.

DIFFERENTIAL DIAGNOSIS

- Other bradyarrhythmias:
  - Third-degree AV block
  - Persistent atrial standstill
  - Vagally mediated bradyarrhythmias
  - Metabolic disorders that may slow SA nodal activity:
    - Hyperkalemia, see p. 556
    - Hypothermia, see p. 587
    - Hypothyroidism, see p. 588
    - Hypoadrenocorticism, see p. 573
    - Dysautonomia, see p. 325
- Seizures of any etiology (see p. 1009)

INITIAL DATABASE

- ECG: characterize the bradyarrhythmia:
  - ECG is the diagnostic test of choice for SSS.
  - Although exact criteria have not been established for the diagnosis of SSS, sinus arrest with or without variable degrees of atrioventricular block or supraventricular tachycardia should raise the suspicion of SSS.
- Atropine response test: determine if the bradyarrhythmia is wholly or partially vagally mediated. If the bradyarrhythmia is vagally mediated (i.e., physiologic), the test reveals a positive response in the form of sustained sinus tachycardia. If it is pathologic, the test reveals no change in the ECG.
  - Obtain initial ECG.
  - Administer atropine, 0.04 mg/kg IV, IM, or SQ.
  - Obtain follow-up ECG approximately 10 minutes later if administered IV, or 20-30 minutes later if administered IM or SQ.
  - An increase of at least 50% in the heart rate is expected when the bradycardia is vagally mediated and therefore physiologic but also occurs in a certain number of dogs with SSS. The absence of any response to atropine in a dog with appropriate signalment and clinical signs is strongly suggestive of SSS.
- CBC, serum chemistry profile, and urinalysis to detect underlying electrolyte imbalances or metabolic disorders that may contribute to bradyarrhythmias or seizures.
- Thoracic radiographs: cardiomegaly or CHF may develop in the face of longstanding bradyarrhythmias, especially when complicated by valvular disease in older small-breed dogs.
- Echocardiography to assess the severity of valvular, myocardial, or structural (including neoplastic) cardiac disease if present.



SICK SINUS SYNDROME A dog with bradycardia-tachycardia sick sinus syndrome displays a prolonged period of sinus arrest followed by a supraventricular escape beat *(circled complex)* and a short run of accelerated supraventricular complexes thereafter.

ADVANCED OR CONFIRMATORY TESTING

- Videotaping of episodes by the owner may help differentiate syncope from seizures if the episodes occur infrequently and are not clearly one or the other based on historic description alone.
- A 24-hour Holter monitor or cardiac event monitor may be indicated in cases where the history, clinical signs, ECG, and atropine response test are inconclusive (see p. 1287).

TREATMENT

TREATMENT OVERVIEW

- Dogs showing no overt clinical signs (arrhythmia was discovered incidentally): periodic monitoring and client education to detect progression of disease
- Dogs showing overt clinical signs such as syncope:
  - Bradycardia: increase the heart rate to alleviate the syncopal episodes.
  - Brady-tachy syndrome: therapy aimed at reducing the supraventricular tachycardia (see p. 111) may be required after resolution of the bradyarrhythmia.

ACUTE GENERAL TREATMENT

- Dogs showing no overt clinical signs: in the absence of syncope, significant cardiomegaly, or CHF, periodic ECGs and client education are

indicated. General anesthesia should be avoided, or if indispensable, should be done with concurrent temporary cardiac pacing (see p. 1320).

- Dogs showing overt clinical signs:
  - Vagolytic drugs display variable and often temporary efficacy in animals with SSS. One option is to begin with a sympathomimetic (e.g., theophylline or terbutaline), and if clinical signs persist, add a parasympatholytic (anticholinergic; e.g., propantheline):
    - Theophylline: 10 mg/kg PO q 8 h
    - Terbutaline (instead of theophylline): 0.2 mg/kg PO q 8-12 h
    - Propantheline bromide: 0.25-0.5 mg/kg PO q 8 h
  - Pacemaker implantation: dogs with overt clinical signs caused by SSS require permanent cardiac pacing if they fail to respond or become refractory to vagolytic drugs.

CHRONIC TREATMENT

- Vagolytic drugs: if animals are responsive, therapy will be maintained lifelong; refractoriness may develop over time, however.

DRUG INTERACTIONS

- Theophylline:
  - Arrhythmias may develop when used with additional sympathomimetics.
  - Cimetidine, erythromycin, allopurinol, thiabendazole, clindamycin, and lincomycin may increase its effects.
  - Phenobarbital or phenytoin may decrease its effects.
  - Enrofloxacin or ciprofloxacin inhibit the metabolism of theophylline and may promote toxicity.
- Terbutaline:
  - Arrhythmias may develop when used with additional sympathomimetics or digitalis glycosides.
  - Tricyclic antidepressants or monoamine oxidase inhibitors (MAOIs) may potentiate the vascular effects.
- Propantheline bromide:
  - Antihistamines, procainamide, quinidine, meperidine, benzodiazepines, and phenothiazines may enhance its activity.
  - Primidone, disopyramide, nitrates, and long-term corticosteroid use may potentiate its adverse effects.
  - May enhance the actions of nitrofurantoin, thiazide diuretics, and sympathomimetics

POSSIBLE COMPLICATIONS

- Tachyarrhythmias, nervousness/anxiety, vomiting, diarrhea, polyuria and polydipsia (PU/PD), and anorexia with administration of sympathomimetics
- Tachyarrhythmias, dry mouth, dry eyes, urinary hesitancy, constipation, and vomiting with administration of anticholinergics such as propantheline bromide
- Pacemakers: lead dislodgement, infection, failure to sense or oversensing, ventriculoatrial conduction, caval obstruction, or skeletal muscle stimulation (if a unipolar pacemaker is implanted)

RECOMMENDED MONITORING

- ECG: periodic monitoring or as dictated by recurrence of syncopal episodes:
  - Animals showing no overt clinical signs: every 3-4 months to evaluate for progression of bradyarrhythmia-tachyarrhythmia; atropine response test may have to be repeated.
  - Animals showing overt clinical signs: whether medical therapy or pacemaker implantation has been performed, ECGs should be repeated every 6 months to assess the long-term response to vagolytic agents or appropriate functionality of the pacemaker.
  - If clinical signs recur, reexamination including ECG is indicated immediately.
- Thoracic radiographs: every 6 months, especially in the face of valvular disease; assessment for progressive cardiomegaly and CHF, assessment of the integrity of the pacemaker.
- Pacemaker interrogation: every 6 months; evaluation of the pacing threshold, lead impedance, and battery life.

PROGNOSIS AND OUTCOME

- The risk of sudden death with SSS appears low, and some affected animals never develop clinical signs.
- If syncope is present, the episodes tend to increase in frequency over time, and the risk of sudden death is greater.
- Medical therapy is usually well tolerated, although the response is variable and in some cases short-lived.
- The prognosis and response to therapy following successful pacemaker implantation are good for animals with SSS. Episodes of syncope tend to resolve, animals become much more suitable anesthetic candidates, and episodes of supraventricular tachycardia can be managed with medications if necessary.

PEARLS & CONSIDERATIONS

COMMENTS

- Seizures and syncope can be very difficult to differentiate.
- SSS should always be on the differential list for older miniature Schnauzers, Westies, and cocker spaniels that display seizure-like activity.
- A normal heart rate at the time of examination does not exclude SSS.
- Even in the absence of syncope during Holter monitoring, many animals with SSS display significant and prolonged episodes of sinus arrest.

Analysis of the Holter recording is still warranted when no episodes have occurred during the monitoring period.

- While ventricular-based pacemakers readily alleviate the clinical signs, atrial-based pacing may be the most appropriate if AV nodal function is normal.

CLIENT EDUCATION

Artificial pacemaker implantation is most commonly performed via a transvenous approach, therefore markedly reducing the pain and recovery time for older dogs.

Shoulder Luxation

BASIC INFORMATION

DEFINITION

Traumatic or congenital scapulohumeral luxation

EPIDEMIOLOGY

SPECIES, AGE, SEX: Traumatic luxation can occur in dogs of all sizes and ages; rare in cats.

GENETICS & BREED PREDISPOSITION: Congenital luxation occurs most often in small dogs. Toy poodles and Shetland sheepdogs appear predisposed.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Any direction for traumatic luxation; in congenital luxation, humerus is usually displaced medially.

HISTORY, CHIEF COMPLAINT: Traumatic luxations cause acute non-weight-bearing lameness. Congenital luxation will cause intermittent or continuous lameness of variable degree and associated pain.

PHYSICAL EXAM FINDINGS

- Animals that have gone through trauma can experience pain and crepitus during shoulder manipulations. Dogs carry the limb in flexion with the foot externally rotated (medial luxation) or internally rotated (lateral luxation). The greater tubercle is displaced relative to the acromion.
- Dogs with congenital luxation may be comfortable during shoulder manipulation; the joint is luxated and reduced easily.

ETIOLOGY AND PATHOPHYSIOLOGY

- Humerus is medially displaced in 75% of cases.
- Medial luxation in small dogs is congenital and associated with developmental laxity or dysplasia of the glenoid cavity; often occurs bilaterally.
- Medial luxation in large-breed dogs is caused by trauma.
- Lateral luxation is caused by trauma and is associated with disruption of the lateral joint capsule, lateral glenohumeral ligament, and infraspinatus tendon.
- Cranial and caudal luxations are rare and are caused by trauma.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Shoulder luxation is diagnosed by physical and radiographic examinations.

DIFFERENTIAL DIAGNOSIS

- Scapular neck or glenoid fractures
- Fracture of proximal humerus
- Bicipital tenosynovitis
- Supraspinatus degeneration or mineralization
- Osteosarcoma of proximal humerus
- Brachial plexus avulsion
- Nerve root signature in the forelimb

INITIAL DATABASE

- Orthopedic and neurologic evaluations

- Radiography of the scapulohumeral joint, orthogonal views
- CBC, serum biochemistry panel, urinalysis: in older dogs or trauma cases
- Electrocardiogram (ECG) and thoracic radiographs if trauma is suspected

ADVANCED OR CONFIRMATORY TESTING

- Evaluate shoulder "drawer movement" by cranial, caudal, medial, and lateral displacement of the humerus relative to the scapula.
- Test medial instability by abduction of the humerus relative to the scapula.
- Stress radiography

TREATMENT

TREATMENT OVERVIEW

The goal is to reserve integrity of the scapulohumeral joint or pain-free use of the affected limb. In the acutely luxated shoulder, closed reduction should be attempted prior to surgery. In congenital luxation with dysplasia, closed reduction is not successful.

ACUTE GENERAL TREATMENT

- Traumatic luxation without glenoid dysplasia can be reduced closed. If the joint reluxates easily during manipulation or in the postanesthetic period, surgery is indicated.
- Surgical options in traumatic luxations or congenital luxations with good joint integrity include primary repair of joint capsule/ligaments and stabilization by transposition of the biceps tendon, or prosthetic suture repair of the glenohumeral ligament. Temporary stabilization with locking plate has also been described.
- Congenital luxations with glenoid dysplasia are not suitable for closed reduction and require surgery if pain or decreased function of the limb is present. Surgical options include excision arthroplasty and shoulder arthrodesis.

CHRONIC TREATMENT

- Conservatively or surgically (biceps tenodesis, ligament prosthesis) managed dogs are immobilized with a spica splint (lateral luxations) or Velpeau sling (medial luxations) for 10-14 days (see p. 1336). Exercise is restricted for 4-8 weeks after splint or sling removal. Physical therapy with passive range-of-motion exercises and swimming are recommended after immobilization.
- Excision arthroplasty cases should be walked using a leash after surgery. Swimming or other vigorous exercise is encouraged starting 10 days after surgery.
- After shoulder arthrodesis, the limb is immobilized in a spica splint until radiographic signs of fusion are present.

NUTRITION/DIET

Dietary management to prevent or treat obesity is beneficial for long-term management.

BEHAVIOR/EXERCISE

After healing is complete, consistent daily low-impact physical activity (walking, swimming, running on soft surfaces) is recommended.

POSSIBLE COMPLICATIONS

- Seroma
- Midsubstance tearing of the biceps tendon after tenodesis
- Articular incongruity causing osteoarthritis
- Suprascapular nerve damage with prosthetic repair
- Fixation failure
- Infection

RECOMMENDED MONITORING

- With conservative management, routine reexamination of the joint is indicated to ensure stable reduction.
- Shoulder arthrodesis cases need monthly radiographic examination starting at week 6 until fusion has occurred.

PROGNOSIS AND OUTCOME

- Animals with biceps tenodesis have good to excellent outcomes in 60% (3/5 dogs), 84% (42/50 dogs), and 93% (11/12 dogs) of cases. A small number of dogs with prosthetic glenohumeral ligament (GHL) repair have had good and excellent results.
- Salvage procedures are rarely performed and may provide adequate function in small dogs; limb amputation is an option in unilateral cases.

PEARLS & CONSIDERATIONS

COMMENTS

- A Velpeau sling is contraindicated for lateral luxations due to lateral translation of the humeral head.
- Radiography helps identify articular fractures or glenoid dysplasia before joint stabilization is attempted.

EDITOR: JOSEPH HARARI

Shock, Hypovolemic

BASIC INFORMATION

DEFINITION

Inadequate circulating blood volume due to intravascular volume loss or redistribution

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Affects all species, ages, and sex
- Underlying causes of shock may differ in different age groups (e.g., trauma may be most common in young to middle aged patients, but internal hemorrhage from a ruptured neoplasm is likely more common in older patients).

RISK FACTORS

- Free-roaming dogs and cats are more likely to sustain trauma.
- Underlying polyuria/polydipsia conditions (e.g., diabetes mellitus, chronic kidney disease) may predispose patients to severe dehydration if access to water is limited.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Absolute with actual loss of intravascular blood volume (hemorrhage)
- Relative with loss of plasma volume (severe dehydration or loss into third space)
- Minimal or no information in veterinary medicine to correlate subtype with prognosis/outcome.

HISTORY, CHIEF COMPLAINT

- Witnessed or suspected trauma (internal or external hemorrhage)
- Acute collapse (any nontraumatic type of volume loss, such as ruptured internal neoplasia or anticoagulant rodenticide intoxication)
- Abdominal distension, typically acute onset (hemoperitoneum, gastric dilatation-volvulus [GDV])
- Vomiting/diarrhea (primary gastrointestinal, commonly obstruction with foreign material or as a manifestation of gastrointestinal hypoperfusion)

PHYSICAL EXAM FINDINGS

- All cases:
  - Quiet or dull mentation
  - Tachycardia, or some cats may develop bradycardia.
  - Weak pulses
  - Pale mucous membranes
  - Tachypnea
- Possible:
  - Distended abdomen (in cases of hemoabdomen or GDV)
  - Signs of external bleeding
  - Signs of severe dehydration: enophthalmos, skin tenting, dry mucous membranes

ETIOLOGY AND PATHOPHYSIOLOGY

- Causes of excess vascular volume loss include:
  - Trauma
  - Ruptured neoplasms
  - Coagulopathies with hemorrhage into body cavities (e.g., anticoagulant rodenticide intoxication)
  - Vomiting ± diarrhea

  - Burns
  - Plasma volume loss into third space (peritoneum or gastrointestinal tract)
- Pathophysiology of hypovolemic shock:
  - A decrease in effective circulating volume leads to decreased tissue perfusion.
  - Decreased tissue perfusion leads to a decrease in oxygen supply to cells.
  - Inadequate energy consumption at the cellular level results in a conversion from aerobic to anaerobic metabolism and decreased adenosine triphosphate (ATP) production.
  - Decreased ATP production alters cellular function, leading to alterations in intracellular calcium homeostasis; this process in turn leads to direct cellular injury, enzyme activation, release of reactive oxygen species, and inhibition of oxidative phosphorylation.
  - Cell death can precipitate a cascade of events, such as activation of the coagulation cascade or bacterial translocation in the gut, which then may result in multiorgan damage and death.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is largely dependent on history and physical examination (suspected possible source[s] of fluid loss) and is confirmed with blood pressure measurement, routine laboratory testing and imaging, and response to treatment.

DIFFERENTIAL DIAGNOSIS

Other forms of shock: distributive (loss of local or systemic vascular resistance), septic, cardiogenic, neurogenic, anaphylactic, hypoxemic, or metabolic shock (specifically disrupted cellular metabolism, such as cyanide toxicity or mitochondrial dysfunction)

INITIAL DATABASE

- Packed cell volume/total solids (PCV/TS) and blood glucose: low or decreasing PCV/TS may indicate blood loss; increased PCV/TS likely indicates dehydration.
- CBC, serum chemistry profile, coagulation profile (prothrombin time and activated thromboplastin time): prolonged clotting times may indicate internal blood loss as a cause for hypovolemia and may raise concerns for anticoagulant rodenticide ingestion. Electrolyte disturbances (hypochloremia) may be present with severe vomiting or upper gastrointestinal obstruction.
- Blood pressure (BP): low BP (<90 mm Hg systolic assessed via Doppler [p. 1209] or direct arterial line [p. 1196]) is consistent with hypovolemic shock.
- Abdominocentesis (see p. 1193)/thoracocentesis (see p. 1338) with fluid analysis: if hemorrhagic effusion is obtained, intracavitary hemorrhage as a cause of the hypovolemia should be considered. Coagulation testing is recommended prior to paracentesis if an effusion is found in a young animal or if there is any possible anticoagulant rodenticide exposure.
- Abdominal and thoracic radiographs: evaluate for peritoneal effusion or gastrointestinal disease/obstruction; also scan for metastatic disease, and evaluate cardiac and pulmonary vasculature size for underlying heart disease and hydration status.
- Lactate analysis: elevated blood lactate (>2.5 mmol/L) supports hypovolemia and decreased tissue perfusion, but extraneous factors (e.g., struggling during phlebotomy) may raise lactate levels. However, increased lactate levels in a collapsed pet are vital clues.
- Mixed venous oxygen saturation: assessment of global tissue oxygenation (decreased oxygen saturation generally reflects decreased tissue oxygen delivery). May be an earlier and more sensitive indicator of patient condition and resuscitative efforts.

ADVANCED OR CONFIRMATORY TESTING

- Abdominal ultrasonography to better evaluate cause in intracavitary effusions or further evaluation for gastrointestinal obstruction (if radiography is inconclusive)
- Histopathologic examination if neoplasia is suspected

TREATMENT

TREATMENT OVERVIEW

- The primary goal is to restore circulating blood volume, thus increasing tissue perfusion. This usually means rapid and continued IV fluid or blood product administration with frequent reevaluation of patient status and parameters.
- Specific treatment of any underlying disease, such as plasma and vitamin K1 for anticoagulant rodenticide intoxication.

ACUTE GENERAL TREATMENT

- The best fluid for restoration depends on:
  - Cause of hypovolemia
  - Serum electrolyte status of animal
  - PCV/TS
- If the animal is bleeding, fresh whole blood or packed red cells ± plasma is the best replacement fluid.
- Give fluids to reach an adequate BP (systolic arterial pressure >90 mm Hg) and central venous pressure (CVP > 5 cm H2O).
- Restoration of volume can include the following fluid types:
  - Crystalloids: requires a replacement fluid (e.g., lactated Ringers, 0.9% NaCl):
    - 40-90 mL/kg IV to reach desired effect
  - Synthetic colloids (e.g., Voluven, Hetastarch):
    - 5-20 mL/kg IV to reach desired effect, up to 50 mL/kg/24 h for Voluven
  - Blood (see p. 1347)
  - Plasma may be required if massive quantities of crystalloids, synthetic colloids, or blood have been given to an animal, and the animal has developed a dilutional coagulopathy.
- Locate and control any source of hemorrhage.

CHRONIC TREATMENT

Unless cause of fluid loss is located and controlled, fluid replacement must continue past initial stabilization to meet ongoing loss and maintenance fluid needs.

POSSIBLE COMPLICATIONS

Complication of prolonged shock include:

- Renal failure
- Loss of gastrointestinal integrity, with bacteria and toxin translocation
- Myocardial dysfunction
- Brain ischemia
- Loss of vascular tone
- Systemic inflammatory response syndrome (see p. 1070)
- Disseminated intravascular coagulation
- Acute lung injury
- Sepsis

RECOMMENDED MONITORING

- Serial BP monitoring, either indirectly or directly, until goal-directed end-point is reached (systolic > 90 mm Hg).
- Monitor heart rate: persistent tachycardia may indicate inadequate fluid loading.
- Recognize that persistent hypotension or tachycardia often implies ongoing hemorrhage, systemic vasodilation, or capillary leakage and the need for continued volume resuscitation and end-point monitoring.
- Monitor PCV/TS for evidence of adequate fluid therapy.
- Utilize trends in central venous pressure as an indicator of volume status (a central multilumen catheter is also recommended for rapid fluid administration and frequent blood sampling). see p. 1227. If the CVP is <5 cm H2O, more fluids should be given. Adequate fluid resuscitation is generally present if the CVP is between 5 and 10 cm H2O.
- Repeat blood gas (including central venous oxygen saturation), electrolytes, and lactate monitoring recommended to ensure return of adequate tissue perfusion and correct electrolyte imbalances.
- Monitor for signs of end-organ damage (e.g., urine output and decreased mentation), as these may carry a poor prognosis.

PROGNOSIS AND OUTCOME

- Determined by the cause of the hypovolemia and the rapidity with which the volume deficit has been corrected
- Prolonged hypotension may cause multiple organ dysfunction, which carries a poor prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- Hypovolemic shock is a potentially life-threatening process that requires early identification and treatment.
- Tachycardia (or bradycardia in the cat) together with low BP and a known cause of fluid loss are hallmarks for diagnosis of hypovolemic shock.
- Essential elements for the successful management of hypovolemic shock are identification of the source of fluid loss and reversal/replacement of the fluid loss.
- Treatment of the underlying cause is the key to long-term success.

TECHNICIAN TIPS

- Treatment of hypovolemic shock requires a concerted effort by clinician and technical staff to quickly obtain diagnostic information, place intravenous (and ideally intraarterial) catheters, prepare IV fluid or blood-product setups, and monitor and frequently recheck patient status and parameters. This can be an exciting and rewarding disease process to treat.
- Repeated reassessment of the initial plan is of utmost importance to ensure adequate resuscitation. This means automatically rechecking the parameters discussed above (mentation, HR, BP, pulse quality, mucous membrane color, and capillary refill time) when initial treatment is completed and alerting the clinician when parameters are persistently abnormal.

Shearing/Degloving Wounds

Additional Images Available on Website 

Client Education Sheet Available on Website 

BASIC INFORMATION

DEFINITION

Soft-tissue injury to the limbs and tail as the result of external trauma

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats of any age and either sex

RISK FACTORS: Dogs and cats that are allowed to roam in unconfined areas without supervision or leash restriction

GEOGRAPHY AND SEASONALITY: Vehicular trauma is the primary cause of external trauma; dogs and cats are most susceptible to injury in areas with high traffic.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES:

Any of the following is/are possible: laceration, contusion, crushing, shearing, penetration, perforation, avulsion, thermal injury, bite

HISTORY, CHIEF COMPLAINT

- An open wound, bleeding, or swelling to the injured area
- Presence of necrotic tissue
- Absence or avulsion of tissue
- Presence of purulent discharge
- Lameness may be noted in association with a limb injury.
- The patient may display pain by vocalization, guarding the injured area, or defensive posturing.

PHYSICAL EXAM FINDINGS

- Open wounds:
  - Skin laceration
  - Partial or complete loss of skin and underlying tissues
  - Avulsion or partial detachment of skin segments
  - Entry or exit wounds secondary to a bite, projectile, or impalement injury
  - Presence of necrotic tissue
  - Older wounds may have variable development of granulation tissue.
- Evidence of previous or ongoing hemorrhage
- Intact skin but the presence of contusion (ecchymosis/bruising)
- Local swelling due to edema, hematoma formation
- Condition and viability of the digital and metacarpal/metatarsal pads; severity of tissue trauma
- Evidence of underlying orthopedic injury:
  - Fracture
  - Joint instability associated with soft-tissue trauma
- Pain:
  - Possibly in association with manual examination of the injury or use of the affected limb(s)
- The overall health status of the animal depends on a variety of factors, including:
  - Body region(s) involved
  - Extent of the trauma
  - Degree of circulatory compromise
  - Blood loss
  - Presence of necrotic tissue/infection

ETIOLOGY AND PATHOPHYSIOLOGY

- Wounds are the result of the transfer and absorption of energy by the body; severity of trauma depends on exact type of trauma and surface area(s) absorbing the trauma.

- Lacerations may be the result of contact with a sharp, bladelike object (glass, metal, etc.) or impact against a hard-edged surface. Bite wounds may create an irregular laceration as a result of the cutting and tearing of tissues.
- Crushing wounds are the result of compression; these can result from impact with a heavy object or contact with a mechanical device; the wounds can also be caused by a powerful bite.
- Cutaneous surfaces may be stripped or avulsed from the extremity, damaging the circulation to the traumatized skin segment. This is often the result of vehicular or bite trauma.
- Shearing wounds may be the result of tangential impact with a hard surface, dragging of a body region on a hard road surface, or entrapment of an extremity beneath the tire of a moving vehicle.
- Assessment of circulation at the time of injury can be difficult. Progressive loss of circulation can result in vascular stasis and necrosis that may not be evident for 4-5 days after the initial injury.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is made from the history and physical exam, although the full extent of bony lesions and other internal injuries may only be appreciated with radiographs and/or ultrasound.

DIFFERENTIAL DIAGNOSIS

Common causes of soft tissue trauma include:

- Vehicular trauma
- Bite wounds
- Penetrating/perforating objects (gunshot, impalement)
- Sharp objects
- Thermal injuries including contact burns

INITIAL DATABASE

- CBC and serum biochemistry profile:
  - Minimum database is indicated.
- Urinalysis would be advisable in pets with extensive trauma or a history/physical findings of renal disease.
- Radiographs (two views) of the injured area:
  - Rule out underlying orthopedic trauma.
- Survey thoracic radiographs:
  - Rule out diaphragmatic hernia, lung contusions, pneumothorax, and other lesions in the face of vehicular trauma.

ADVANCED OR CONFIRMATORY TESTING

The severity of trauma will dictate whether additional diagnostic imaging techniques are required.

TREATMENT

TREATMENT OVERVIEW

Treatment goals:

- Ensure that the animal is hemodynamically stable before inducing general anesthesia, as other injuries (pneumothorax, hemothorax, diaphragmatic hernia, etc.) may be present.
- Assess severity of soft-tissue and orthopedic trauma.
- Assess wound for tissue viability.
- Provide definitive wound care and closure.
- Prevent or manage infection.
- Stabilize local fractures or joint instability.

ACUTE GENERAL TREATMENT

- Cover open wounds with a sterile dressing.
- Initiate systemic antibiotic therapy:

- Empirical therapy to provide broad aerobic coverage (e.g., cefazolin, 22 mg/kg IV q 2 h during the perioperative period)
- Definitive therapy for infected wounds should be based on the results of microbiologic culture and sensitivity (C&S) testing.

- General anesthesia is preferable for definitive wound care because both the wound and manipulations of the wound can be painful.
- Culture of infected wounds may be useful to select the most appropriate antibiotic.
- Liberally remove fur from around the circumference of a shearing wound.
- Povidone iodine or chlorhexidine surgical scrub is used for preparing the skin, alternated with swabbing the area with sterile saline impregnated sponges.
- Aseptically drape the wound.
- Explore the wound and remove nonviable tissue and foreign debris:
  - Perform copious lavage of the wound with sterile saline to remove contaminants:
    - Chlorhexidine solution (1:40 dilution) or povidone iodine solution (1:9 dilution) may be added to the sterile saline.
    - Gentle pressure lavage is useful for removal of contaminants, using a 35-cc syringe and 18-G needle.
- In the absence of infection and necrotic tissue (creating a “surgically clean” wound):
  - Skin borders can be approximated with sutures.
  - If significant incisional tension is present secondary to unresolved edema and swelling, consider partial closure or delayed primary closure.
  - Wound drainage should be established with the use of drains or leaving a portion of the wound open for drainage.
- Joint injury in association with shearing wounds:
  - Repair collateral ligament support using conventional bone screws and braided suture material; stainless steel also may be used. Persistently unstable joints may be candidates for arthrodesis.
  - Perform copious lavage for open joints; in the absence of infection, the joint capsule can be closed if feasible.
- With extensive bruising and swelling, open wound management should be considered until circulation improves, noted by resolution of these two conditions.
- Open wound management varies with severity of trauma and extent of wound. Common options include:
  - Judicious surgical débridement with resection of nonessential tissues of questionable viability
  - Especially with extremity wounds, it may be advisable to delay débridement of skin of questionable viability (daily reassessment) owing to the limited availability of loose elastic skin to facilitate wound closure.
  - Important tissue structures of questionable viability should be managed conservatively until their status becomes apparent. If necrotic, débridement is instituted.
  - Wet-to-dry dressings are considered a form of “mechanical débridement” and may be used effectively in the presence of extensive contamination/local infection. Cotton sponges are moistened with saline (or dilute povidone iodine or chlorhexidine [see above]) and are placed onto the wound. Residual necrotic tissue adheres to the cotton fibers along with partial retention of the exudate. Stripping the partially dry dressing off the wound helps remove this wound debris.
    - The author normally uses wet-to-dry dressings for no longer than 5 days: by then, they usually have accomplished their task.
    - Sedation and analgesics, including topical lidocaine, can reduce the pain associated with their removal and replacement.
  - Other suitable dressings and topical agents:
    - Hydrogel and hydrocolloid products: topical application or in the form of an occlusive dressing. Many of these products include various agents that reportedly “promote” healing.
    - Occlusive dressings are most effective when a healthy granulation bed is forming and infection/tissue necrosis are not present.
    - Absorptive dressings, including the alginates, can be used to promote healing and provide a matrix to absorb discharge.
    - Application of honey (especially Manuka honey) or sugar. These substances are both antibacterial and hydrophilic.
    - Nonadherent (low-adherent) dressings with a topical antimicrobial ointment or gel create an occlusive or partially occlusive environment.
  - A protective bandage is often required to maintain a topical dressing and minimize motion. Thicker absorptive bandages normally are used for facilitating retention of discharged from exudative wounds; lighter bandages are required as discharge progressively decreases as healing progresses.
    - Typically, bandage changes may be needed daily (1-2 times) over the first week of open wound management, with decreasing frequency over the subsequent weeks.
    - Occlusive dressings are normally changed according to the manufacturer's guidelines and the judgment of the clinician; may be changed every 3-5 days. Any cover bandage is changed accordingly.
  - Large open wounds affecting may require closure with skin grafts or skin flaps if contraction and epithelization are not suitable options:
    - In general, wounds affecting less than 90° of the extremity's circumference may heal by second intention, often within 6 weeks after injury.
  - Extensive extremity trauma with severe circulatory compromise and tissue necrosis usually necessitates amputation. The total costs of limb salvage (treatment without amputation) play a role in the decision-making process with many

pet owners.

CHRONIC TREATMENT

- Bandage and dressing changes
- Skin grafts or flaps may be needed for shearing wounds with extensive skin loss as well as nonhealing wounds.

POSSIBLE COMPLICATIONS

- Infection of the soft tissues, underlying bone, or exposed joint
- Failure to heal
- Persistent instability of a shearing wound involving a joint
- Associated fracture nonunion

RECOMMENDED MONITORING

- Bandage care and periodic wound assessment
- Serial radiographs to assess bone healing as needed

PROGNOSIS AND OUTCOME

- Massive trauma to the extremities may necessitate limb amputation.
- Progressive loss of circulation may necessitate serial débridement of the wound or eventual amputation.
- Many shearing wounds will heal by second intention.
- As noted, failure to heal usually necessitates wound closure with a skin graft or flap.
- Severe joint injury/instability may require eventual arthrodesis.
- Wound contracture or the loss and inhibition of function secondary to scarring usually requires surgical intervention combined with physical therapy.
- Loss of the weight-bearing metacarpal or metatarsal pad usually warrants reconstruction, either by digital pad transfer or pad grafts when applicable.

PEARLS & CONSIDERATIONS

COMMENTS

- Most cases of soft-tissue trauma that are presented to veterinarians are relatively simple to manage.
- Confusion occasionally arises with extensive wounds, for which the full extent of the injury is difficult to assess at presentation.
- In the face of infection, open wound management provides optimal drainage and facilitates daily inspection of the entire wound.
- Combined closure techniques can be used effectively together. In some cases wounds can be supported while second intention healing progresses. If the wound does not close after 6 weeks, the wound likely will be smaller; closure may be accomplished using a smaller local flap or skin graft.
- In general, the goal of wound care is to promote formation of a healthy wound bed. In open wound management, the formation of granulation tissue is a key indicator of underlying tissue viability. Moreover, the wound may then be a suitable candidate for surgical closure.
- With the formation of a healthy granulation bed, systemic antibiotics are usually discontinued unless they are indicated for a related/unrelated infection.
- Surgical closure of problematic wounds may be more cost-effective than prolonged open wound management.

PREVENTION

Most wounds occur in pets that are permitted to roam unsupervised. Confining the pet to the house or yard or accompanying the pet on a leash dramatically reduces risks associated with vehicular trauma, bites, and malicious injury.

CLIENT EDUCATION

- Discuss the safety and prevention issues noted above.
- In open wound management, many willing owners can be trained to perform simple bandage changes and manage wound drains. Costs can therefore be reduced.

Shar-Pei Fever

BASIC INFORMATION

DEFINITION

A familial, sterile, systemic inflammatory disorder characterized by recurrent fever, swelling of the tibiotarsal joints, and renal amyloidosis

SYNONYM

Familial amyloidosis of Chinese shar-pei dogs. Resembles familial Mediterranean fever of humans.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Young adults, 1 to 5 years old

GENETICS & BREED PREDISPOSITION: Shar-pei dogs; unknown pattern of inheritance

ASSOCIATED CONDITIONS & DISORDERS: Vasculitis may occur concurrently.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Early stage: fever, tibiotarsal (hock) swelling
- Late stage: signs of renal amyloidosis, hepatic amyloidosis, or amyloid deposition in other organs

HISTORY, CHIEF COMPLAINT

- Early stage: signs due to intermittent fever lasting 24-36 hours (e.g., lethargy, inappetence)
- Late stage: signs of renal and liver failure; signs include vomiting, anorexia, lethargy, polyuria and polydipsia (PU/PD), and weight loss.

PHYSICAL EXAM FINDINGS

- Early stage: fever (103°F-107°F; 39.4-41.7°C); palpable swelling of tibiotarsal joints; swollen muzzle may be present.
- Late stage:
  - Signs of dehydration, halitosis, weight loss, and other manifestations of chronic kidney disease (see p. 207)
  - If nephrotic syndrome is present: ascites, peripheral edema possible; dyspnea may also develop secondary to pulmonary thromboembolism or (rarely) pleural effusion, which is generally small in volume.
  - Liver disease; icterus, hepatomegaly, signs of dehydration, weight loss

ETIOLOGY AND PATHOPHYSIOLOGY

- Elevated levels of the cytokine interleukin 6 alpha (IL-6a) are thought to lead to chronic overproduction of acute-phase reactant proteins (APP), the precursors of amyloid A.
- Amyloid is then deposited in many organs, and its presence in the kidneys usually leads to renal failure and death. Historically, renal amyloid deposition in shar-pei fever was thought to occur mainly in the medulla (unlike most other forms of renal amyloidosis); newer findings suggest that glornerular deposition is common and may surpass medullary deposition.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Shar-pei fever is a diagnosis of exclusion. The diagnosis is suspected in shar-peis presenting with a history of episodes of fever and lameness. A workup is directed toward detecting organ damage and ruling out other causes of fever, polyarthritis, azotemia, or liver disease.

DIFFERENTIAL DIAGNOSIS

- Polyarthritis (see p. 894)
- Lyme disease, ehrlichiosis (see, and 334)
- Other causes of fever (see, p. 389)
- Other causes of renal and liver disease

INITIAL DATABASE

- CBC may show an inflammatory leukogram and (in the presence of chronic kidney disease) nonregenerative anemia.
- Serum biochemistry profile: azotemia (blood urea nitrogen [BUN], creatinine elevation) if renal insufficiency; hypoalbuminemia and hypercholesterolemia with nephrotic syndrome
- Urinalysis: proteinuria possible. If proteinuria is present, culture and sensitivity (C&S) are indicated to rule out urinary tract infection and a urine protein/creatinine ratio to detect pathologic proteinuria, a hallmark of glomerular disease.
- Blood pressure (BP) measurement: to rule out systemic hypertension in cases with renal involvement
- Other tests to consider depending on signs and geographic location: *Borrelia*, *Ehrlichia*, *Leptospira*, and fungal titers; heartworm antigen test; and survey radiographs to screen for evidence of metastatic or fungal disease

ADVANCED OR CONFIRMATORY TESTING

- Abdominal ultrasound exam to evaluate kidney, liver, and other abdominal organs and screen for thrombi from urinary loss of antithrombin
- Renal biopsy: majority of these animals have moderate to severe amyloid deposition in the renal medulla; approximately two-thirds also have glomerular deposition of amyloid. This distribution helps increase diagnostic yield, because glomerular density is greatest in the cortex, and a renal biopsy must be limited to the renal cortex (i.e., the biopsy instrument must be oriented parallel to the long axis of the kidney) to avoid lacerating a renal arcuate artery.
- Consider a liver biopsy (generally safer than renal biopsies), especially if there are clinical and biochemical signs of hepatic dysfunction. Assessment of albumin level, coagulation parameters, and a platelet count must be performed first and abnormalities corrected prior to biopsy.
- Tissue biopsy is the only way to document the presence of amyloid (using Congo red stains).

TREATMENT

TREATMENT OVERVIEW

The three phases of treatment are acute care, prevention of deterioration, and supportive care in advanced cases as follows:

- Supportive care using nonsteroidal antiinflammatory drugs (NSAIDs) during fever and lameness episodes
- Attempt to prevent further amyloid deposition and subsequent organ failure with the use of colchicine.
- Management of chronic kidney or liver disease associated with late-stage disease is difficult and largely supportive.

ACUTE GENERAL TREATMENT

- If fever >105○F, the patient may need hospitalization and intensive antipyretic management (see pp. 389 and 480).
- Presentation in early stage, temperature £105°F (40.6°C): NSAIDs for fever (e.g., carprofen, 2.2 mg/kg PO q 12 h)
- Presentation in late stage, immediate supportive care:
  - Judicious use of IV fluids for volume resuscitation/rehydration and diuresis if renal failure. If nephrotic syndrome is present, fluids may worsen edema and be contraindicated.
  - Antacids if vomiting, anorexia, or other evidence consistent with uremic gastropathy (e.g., famotidine, 0.5 mg/kg PO or IV q 12-24 h)
  - Antihypertensives if systemic hypertension (e.g., enalapril 0.5 mg/kg PO q 24 h and/or amlodipine, 0.125-0.25 mg/kg PO q 24 h)

CHRONIC TREATMENT

- Colchicine, 0.03 mg/kg PO q 24 h for 2 weeks; if no gastrointestinal (GI) signs, may increase to 0.03 mg/kg PO q 12 h
  - Used in people with familial Mediterranean fever; no controlled trials in shar-pei dogs
  - Recommend early in the course of the disease to prevent or delay the development of amyloidosis; no effect on fibrosis once established
- Renal disease: see pp. 450, 205, and 207.
- Liver disease: dogs can respond to supportive care and colchicine therapy.

DRUG INTERACTIONS

Colchicine given with NSAIDs may increase myelosuppressive effects.

POSSIBLE COMPLICATIONS

- Colchicine in humans can cause anorexia, vomiting, diarrhea, renal failure, hepatotoxicity, pancytopenia, and paralysis.
- Vomiting and diarrhea have been reported in dogs taking colchicine and may resolve with dose reduction.

RECOMMENDED MONITORING

Periodic CBC, serum biochemistry profile, and urinalysis with urine protein/creatinine ratio

PROGNOSIS AND OUTCOME

- Early stage: guarded to fair long-term prognosis; colchicine may improve survival.
- Late stage: very poor; most dogs die of renal failure, and thromboembolism and hepatic rupture have also been reported.

PEARLS & CONSIDERATIONS

COMMENTS

- Shar-pei dogs with episodic fever are at high risk of developing amyloidosis.
- The most common cause of renal failure in shar-pei dogs is renal amyloidosis.

PREVENTION

- Removal of affected dogs from the breeding pool
- Colchicine treatment may help prevent or delay amyloidosis once early stage of disease is confirmed with biopsy.

CLIENT EDUCATION

- Closely monitor temperature of an animal during a fever episode.
- Monitor the patient's lab work if treating with colchicine.
- Inform the owner of the guarded long-term prognosis.

Sepsis and Septic Shock

BASIC INFORMATION

DEFINITION

Sepsis is the occurrence of systemic inflammation in response to infection (see p. 1070). It generally implies systemic circulation of infectious agents (e.g., bacteremia). *Septic shock* is defined as sepsis with concurrent hypotension that is refractory to fluid therapy and requires vasopressor therapy.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats of any age and either sex may develop sepsis or septic shock.

RISK FACTORS

- Animals with established infections
- Animals with diseases resulting in immunosuppression (such as hyperadrenocorticism or diabetes mellitus)
- Noninfectious diseases that may predispose an animal to bacteremia include neoplasia, glucocorticoid therapy, trauma, surgery, cytotoxic therapy, IV and urinary tract catheters, burns, and hematologic abnormalities (e.g., leukocyte function defects).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Sepsis and early septic shock initially present a *hyperdynamic phase* characterized by increased metabolic processes: tachycardia, fever, warm extremities, injected mucous membranes, and a bounding pulse. If unchecked, the hyperdynamic phase progresses to a more critical and potentially terminal *hypodynamic phase* of septic shock characterized by normothermia or hypothermia, pallor, cool extremities, a weak or absent pulse, and decreased mentation.

HISTORY, CHIEF COMPLAINT: Complaints vary depending on the source of sepsis. Animals with abdominal sources of sepsis may present with vomiting, anorexia, or abdominal pain, while those with thoracic sepsis often present with a history of coughing, labored breathing/dyspnea, or respiratory distress. Sepsis from an occult source (anywhere in the body) may not produce localizing signs, and some animals with sepsis present with only vague signs of general malaise, such as anorexia and lethargy.

PHYSICAL EXAM FINDINGS

- General:
  - Hyperthermia (>104°F [>40°C]): fever in response to infection (hyperdynamic phase)
  - Hypothermia (<100.4°F [<38°C] in dogs, <100°F [<37.8°C] in cats): advanced stages, usually with visible lethargy, mental depression, or collapse (hypodynamic phase)
  - Tachycardia (although bradycardia may be present in cats with septic shock): by definition, as part of the systemic inflammatory response syndrome
  - Tachypnea, dyspnea: as compensation for metabolic acidosis, as a manifestation of pain, or with primary respiratory disease (e.g., pneumonia) as the source of sepsis/septic shock
  - Pulse and mucous membrane alterations:
    - Injected/red mucous membranes and bounding pulse (hyperdynamic phase)
    - Pale mucous membranes, slow capillary refill time (>3 seconds), weak pulse (hypodynamic phase)
  - Collapse (hyperdynamic or hypodynamic phase)
- Specific signs may indicate the source of infection, such as:
  - Abdominal pain or a distended abdomen (if present, abdominal source of sepsis is suspected)
  - Swollen limb or an infected cutaneous wound

ETIOLOGY AND PATHOPHYSIOLOGY

- Generalized infection leads to the release of inflammatory mediators, including tumor necrosis factor alpha (TNF-α), interleukin 1 (IL-1), and IL-6. These and other inflammatory mediators increase microvascular permeability, cause leakage of fluid from the vascular space, and lead to reduced effective circulating volume.
- Excessive nitric oxide production via the inducible nitric oxide synthase pathway results in arterial and venous vasodilation, reduced systemic vascular resistance, and eventually hypotension. Tachycardia and increased cardiac output occur as compensatory mechanisms for these changes, though these compensatory effects may be negated by reduced myocardial

contractility as a result of inflammatory mediators with myocardial depressant properties (e.g., TNF-α).
- Other physiologic changes in sepsis include stimulation of the coagulation cascade, reduction in endogenous anticoagulants such as protein C and antithrombin, hypoalbuminemia from changes in microvascular permeability and reduced production by the liver, and lung injury secondary to atelectasis or acute respiratory distress syndrome (ARDS).
- Ultimately, if left to progress, these serious changes lead to further reduced tissue perfusion and decreased oxygen delivery to tissues. Deprived of oxygen, tissues sustain terminal cellular injury, leading to the development of multiple organ failure (see p. 732) and death.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Sepsis should be suspected in a patient with two or more of the four following characteristics: an elevated or low temperature, tachycardia, tachypnea, and leukopenia or leukocytosis and/or the presence of bands and a documented infection. Septic shock should be considered in a septic patient who is hypotensive despite adequate fluid resuscitation.

DIFFERENTIAL DIAGNOSIS

Causes of:

- Fever (see p. 389)
- Abdominal pain without an infectious basis (pancreatitis, reno/ureterolithiasis, neoplasia)
- Abdominal distention (organomegaly, neoplasia, obesity, gastrointestinal [GI] obstruction, ascites secondary to cirrhosis or right-sided heart failure, hyperadrenocorticism)

INITIAL DATABASE

- CBC: neutrophilia (medium term) or neutropenia (acute sepsis) and the presence of band forms and toxic changes in neutrophils; thrombocytopenia suggests a hypercoagulable state or early disseminated intravascular coagulation (DIC).
- Serum biochemistry panel:
    - Azotemia (prerenal or renal—correlate to urine specific gravity >1.035 or <1.035, respectively).
    - Elevated liver enzymes (alanine aminotransferase [ALT] and aspartate aminotransferase [AST]) often occur secondary to hepatic hypoperfusion, hepatic thromboembolism, or bacterial showering from a compromised GI tract.
    - Hyperbilirubinemia due to sepsis-induced cholestasis or hemolysis (assess hematocrit)
    - Hypoalbuminemia: common as a result of reduced hepatic synthesis (in favor of acute phase protein production) and increased microvascular permeability
    - Hypoglycemia: common (changes in hepatic gluconeogenesis versus insulin-like growth factor [IGF] production).
- Elevated lactate is an important marker of hypoperfusion and is often elevated in dogs with sepsis.
    - Hyperlactatemia (>3.5 mmol/L) often resolves quickly following initiation of fluid therapy.
    - Increasing lactate despite fluid resuscitation is a negative prognostic indicator and should lead the clinician to seek superior treatment modalities or alternate reasons for deteriorating status.
- Urinalysis with culture and sensitivity (C&S) to help rule out genitourinary source of sepsis. Urine is obtained by cystocentesis to prevent contamination, unless pyometra, ascites, or a bleeding disorder is suspected.
- A coagulation profile helps identify animals with coagulopathy including DIC.
- Diagnostic imaging, including chest and abdominal radiographs and/or abdominal ultrasound, are often necessary to further elucidate the source of sepsis.

ADVANCED OR CONFIRMATORY TESTING

- Abdominocentesis (see p. 1193) should be performed in animals with abdominal effusion and fever. A neutrophilic effusion with intracellular bacteria is diagnostic of septic effusion, which essentially always warrants surgical intervention. The glucose level of septic abdominal fluid is typically <50 mg/dL (<2.8 mmol/L).
- Thoracocentesis to identify septic pleural effusion is indicated in animals with pleural effusion and fever.
- Echocardiography is indicated in animals whose source of fever is difficult to identify, especially when a new-onset murmur is noted in the absence of anemia. Echocardiographic lesions of the aortic valve are often consistent with bacterial endocarditis; less so mitral valve changes, which may be due either to infection or sterile myxomatous valve disease/endocardiosis.
- Blood cultures (four samples: aerobic and anaerobic, both drawn at time 0 and 2 hours later) are indicated in any critically ill animal that develops a fever, neutropenia, neutrophilia with a left shift, a new cardiac murmur, or other signs suggestive of sepsis that cannot be explained by a known preexisting condition.
- Arterial blood gas (ABG) measurement often may identify hypoxemia and metabolic acidosis, conditions commonly associated with sepsis and that may be corrected with treatment.

TREATMENT

TREATMENT OVERVIEW

- Hemodynamic resuscitation to correct intravascular volume deficits and maintain organ perfusion. IV fluids (crystalloids and colloids) are the mainstay of therapy.
- Eradication of the inciting infection using source control measures (e.g., surgery) and systemic antibiotic therapy
- A future direction and goal is modulation of the inflammatory response with interventions that target its specific mediators. Specific agents to target the inflammatory response are not readily available in veterinary medicine but continue to be a subject of intense research in the field of human medicine.

ACUTE GENERAL TREATMENT

- Antibiotic therapy: essential for successful treatment of sepsis. Two commonly used empirical combinations are a cephalosporin (cefazolin, 22 mg/kg IV q 8 h); a fluoroquinolone (enrofloxacin, 10 mg/kg [5 mg/kg in cats] diluted 1:1 in saline and given slowly IV q 24 h); and metronidazole (10 mg/kg given slowly IV q 8 h) or ampicillin (22 mg/kg IV q 6 h) along with an aminoglycoside (gentamicin, 6 mg/kg IV q 24 h, only when rehydrated/optimal renal function). Definitive antimicrobial treatment is based on C&S. Cardiovascular support: IV fluids to address hypotension/hypovolemia; crystalloids (e.g., lactated Ringer's solution, 0.9% NaCl) with or without a colloid (e.g., Hetastarch) are titrated to correct deficits (up to 90 mL/kg per hour initially in dogs and up to 70 mL/kg per hour in cats) until heart rate, blood pressure (BP), mentation, pulse quality, and capillary refill time have normalized. Central venous pressure (CVP) measurement is valuable if available (see p. 1227). If hypoperfusion persists despite appropriate fluid therapy, consider dobutamine (2.5-10 mcg/kg/min IV), dopamine (5-10 mcg/kg/min IV), norepinephrine (0.01-1 mcg/kg/min IV), or vasopressin (0.01-0.04 U/min IV).
- Surgery: after hemodynamic stabilization of the patient, a search for surgically correctable sources of infection is indicated and can be curative. (Coagulation abnormalities: see p. 1549.)
- Support of organ function: increased oxygen delivery to the tissues is critical to prevent organ dysfunction. Provide supplemental oxygen if hypoxemia is present, and mechanical ventilation if Pao2 < 60 mm Hg despite oxygen supplementation. GI dysfunction may lead to gastric ulcer formation or bacterial translocation; gastric protectants (e.g., famotidine, 0.5-1 mg/kg IV q 12 h) are routinely administered to reduce the risk of developing a gastric ulcer, while antibiotic therapy (as described previously) addresses bacterial translocation. Renal dysfunction associated with sepsis and septic shock may lead to oliguria and renal failure. Maintenance of mean arterial BP at >60 mm Hg using IV fluids and vasopressors may reduce the risk of acute renal failure.

NUTRITION/DIET

After stabilization, enteral nutrition is considered superior to parenteral nutrition in preservation of gut function and integrity, but parenteral nutrition should be considered in animals that are not expected to begin eating within several days.

POSSIBLE COMPLICATIONS

Recognized complications of sepsis and septic shock include DIC, MODS, acute renal failure, pulmonary thromboembolism, ARDS, and intractable hypotension leading to cardiac arrest.

RECOMMENDED MONITORING

- Heart rate and pulse quality: hourly or as indicated by case evolution
- Respiratory rate, mentation, BP, and central venous pressure: hourly or as dictated by case evolution
- Continuous electrocardiogram (ECG): all animals with ventricular arrhythmias or those that are persistently tachycardic despite therapy
- Hematocrit, total protein, and electrolyte concentrations; body weight; urine output; and fluid Cytologic examination from indwelling closed suction drains are evaluated daily.
- Repeat CBC and biochemistry profile every 48 hours.

PROGNOSIS AND OUTCOME

- Reported mortality from sepsis in animals ranges from 30%-70%.
- Severity of underlying disease and choice of antibiotic therapy are important factors influencing mortality in animals with sepsis.

Separation Anxiety

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Physical or behavioral signs of distress exhibited by the animal only in the absence of (real absence) or lack of access to the client (virtual absence). Distress can manifest with destruction, elimination, vocalization, withdrawal, and salivation.

EPIDEMIOLOGY

Prevalence has been estimated at 14% of dogs seen in the average United States private practice.

SPECIES, AGE, SEX: Dogs reported > cats; age of onset usually overlaps with social maturity (dogs: 12-36 months old; cats: 24-48 months old)

RISK FACTORS

- Trauma during a client's absence (e.g., fire, burglary) can precipitate a sudden onset of separation anxiety.
- The popular beliefs that dogs with separation anxiety are “spoiled,” are “only dogs,” or have never “learned” to be left alone are incorrect.

ASSOCIATED CONDITIONS & DISORDERS

- Phobias (see p. 875): commonly coexistent
- Probability of separation anxiety given a diagnosis of storm or noise phobia in a dog: 87% and 88%, respectively

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Chief complaints range from minor (a chewed slipper) to major (walls chewed through) destruction, urination, defecation, puddles of saliva, salivary staining, primary self-mutilation (e.g., a chewed leg) or secondary self-mutilation (e.g., injury incurred when breaking out of a crate or through a window).
- Vocalization, while common, is often unrecognized (e.g., no near neighbors).
- Observant clients may see earliest manifestations of separation anxiety begin when signs of impending absence occur (e.g., client putting on a coat, drinking while moving).
- Dogs with separation anxiety have routinely experienced unexplained diarrhea or have been previously considered as candidates for inflammatory bowel disease.
- Some dogs with separation anxiety freeze and withdraw from all action and interaction when left. These animals are underdiagnosed but suffering.

PHYSICAL EXAM FINDINGS: Self-induced during anxiety:

- Broken teeth
- Lingual, nasal, buccal, cutaneous lacerations
- Torn or broken claws
- Abdominal palpation: evidence of ingestion of drywall, plastic, and other such items
- Weight loss possible if chronic condition; clients may not notice that weight loss occurred until the animal begins to recover and gains weight because the anxiety increased activity (e.g., pacing).

ETIOLOGY AND PATHOPHYSIOLOGY

- Multiple mechanisms likely, given the wide variety of anxiety manifestations
- Greater duration of the disorder may lead to more signs, more intense signs, and worse response to treatment.
- Dogs, like humans, may have “susceptibility genes” for the development of problematic anxieties.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is based virtually entirely on history; physical exam findings may be supportive but are not required for the diagnosis to be established.

DIFFERENTIAL DIAGNOSIS

- Generalized anxiety disorder (GAD), panic disorder: many signs are similar to separation anxiety, but in animals with separation anxiety, signs occur only around or during owner's absence.
- Attention-seeking behavior: signs occur only in the owner's presence and generally improve with proper management (ignoring the signs while they occur and rewarding good behavior by interacting with the pet).
- Incomplete housetraining: signs are confined to inappropriate elimination and occur continually (daily for months or more).
- Age-associated destruction and elimination problems (youth or old age)
- Pseudocyesis-like reaction: destructive behavior is typically confined to bedding, occurs after an ovariohysterectomy, and responds to hormonal supplementation.
- Systemic medical conditions can produce changes in behavior, including hyperthyroidism (cats), hypothyroidism (dogs), neurologic disease (some seizure disorders, rare brain tumors, rabies, etc.), and urinary tract disorders.

INITIAL DATABASE

- A complete and detailed history is the cornerstone of diagnosis.
- The most powerful diagnostic tool for separation anxiety is a video camera. Animals should be videotaped when left alone.
  - Identification of distressed but nondestructive animals
  - Identification/ruling out provocative stimuli for the destructive animals
  - Assessment of improvement by comparison with a later videotape
- Neurologic exam: no abnormalities expected.
- CBC, serum biochemistry panel, urinalysis ± thyroid profile: results should be within normal limits but may also reflect ongoing or chronic stress.

ADVANCED OR CONFIRMATORY TESTING

If neurologic signs are present or develop, a full neurologic evaluation including spinal fluid analysis and imaging (CT scan or MRI) may be indicated (see pp. 1311, 1233, and 1302).

TREATMENT

THERAPEUTIC OVERVIEW

The ultimate goal is to change the behavior of the pet so it no longer responds to being left alone with any of the signs of anxiety. Instead, it should be calm in these circumstances.

ACUTE GENERAL TREATMENT

- Separation anxiety is a veterinary emergency. Until medications can take effect, or if clients are unwilling to use medication, pets must not be left alone. Options include dog and cat sitters, daycare, boarding, or bringing the pet to work if possible.
- Reward any spontaneous decrease in reactivity.
- Implement behavior modification designed to teach the pet to relax. Substitute a new and calming rule structure for the pet that panics. Ensure that clients understand what pet anxiety looks like, and teach them to avoid rewarding it. Accidental reinforcement of anxiety-related behaviors occurs frequently (e.g., clients arrive home and think their frantic pet is just glad to see them).
- Clients should not respond to any nonspecific sign of anxiety and only engage with the pet if it is sitting calmly and quietly. Talking to the pet calmly can often help to induce future calmer behaviors. Then clients can add to the behavior modification by gradually teaching the dog or cat that it can be gradually left for incrementally increasing amounts of time.
- Pets should be rewarded with praise and food treats when calm, and the pace of the behavior modification must proceed at an appropriate rate that will allow improvement. If the pet is distressed, the owner is trying to progress too quickly. If panic, noise phobia, or storm phobia coexist (see p. 875), consider alprazolam (dogs, 0.01-0.1 mg/kg [likely most effective range: 0.02-0.04 mg/kg] PO q 4-6 h PRN; cats, 0.0125-0.025 mg/kg PO q 12-24 h PRN; some published sources recommend a tenfold higher dose, which is an error), with a half to a full dose given 2 hours before the expected provocative event and repeated 30 minutes beforehand. If the pet panics when the owner leaves for work in the morning, he/she can give the pet a half to a full dose when awakening in the morning, and then give the same dose 30 minutes prior to departure. An alternative (though more sedative and likely to cause more side effects) is diazepam (dogs, 0.5-2 mg/kg PO q 4-6 h PRN; cats, 0.2-0.4 mg/kg PO q 12-24 h PRN).

CHRONIC TREATMENT

- Dogs should be taught to relax while making eye contact with their owners as a new default behavior when the dogs encounter a situation about which they are anxious or unsure. Clients should learn to monitor facial cues, body postures, pupil size and shape, and respiratory behavior associated with relaxation. Periodic videotaping that clients then watch with their veterinarian is priceless.
- Avoid exposing dogs to circumstances likely to distress them (e.g., boarding dogs in a kennel if they have never enjoyed or experienced this).
- Desensitization to the triggers can be accomplished if two criteria can be met: triggers can be identified, and they can be reproduced faithfully in a systematic and incremental fashion. Beware that many dogs only learn to react earlier if "gradual departure" desensitization programs are inappropriately conducted.
- Dogs and cats should be crated as part of treatment only if they voluntarily and routinely use and enjoy their crates. Crates may represent entrapment to some animals and will make these animals worse.
- Once the pet has improved, it is important that the owners continue the behavior modification as a consistent and kind rule. A decreased or ablated response to an inciting trigger as evidenced by a reduction in or elimination of somatic signs of sympathetic arousal is the desired goal.
- Once developed, humane treatment of separation anxiety will likely require long-term treatment with antianxiety medications:
    - Amitriptyline: dogs, 1-2 mg/kg PO, q 12 h for a minimum of 30 days; cats, 0.5-1 mg/kg PO, q 12-24 h for a minimum of 30 days; tricyclic antidepressant (TCA) drug and first drug of choice in mild cases; inexpensive
    - Clomipramine (Clomicalm): dogs, 2-3 mg/kg PO q 12 h for a minimum of 8 weeks; cats, 0.5 mg/kg PO q 24 h for a minimum of 8 weeks; TCA drug and the only medication licensed for use for separation anxiety. Most successful when the behaviors have a ritualistic component or elimination component.
    - Selective serotonin reuptake inhibitor (SSRI) drugs: fluoxetine (Prozac/Reconcile; dogs, 1 mg/kg PO q 24 h for 8 weeks minimum; cats, 0.5 mg/kg PO q 24 h for 8 weeks minimum) or sertraline (Zoloft; dogs, 1 mg/kg PO, q 24 h for 8 weeks minimum; cats, 0.5 mg/kg PO q 24 h for 8 weeks minimum) can be successful in situations where other medications have been less helpful.
    - The minimal total treatment time for using medication with behavior modification is 4-6 months. Drugs should not be stopped too early.

DRUG INTERACTIONS

- Benzodiazepines, TCAs, and SSRIs can all be combined at lower-than-normal dosages if needed, but the potential for sedation and interaction must be evaluated.
- TCAs and SSRIs should not be given with monoamine oxidase inhibitors (MAOIs) that are found in many flea and tick collars and dips as well as in some cognitive dysfunction medications.

POSSIBLE COMPLICATIONS

- Abrupt cessation of medications with short half-lives is not recommended for the TCAs and SSRIs; wean over 10-14 days.
- TCAs should be used cautiously or not at all in animals with heart disease.
- Cats and dogs receiving serotonergic medications can manifest "serotoninlike syndromes (see p. 1427)," with hyperactivity, unpredictability, and ultimately seizures. This is an extraordinarily rare side effect.

RECOMMENDED MONITORING

- Owners can abuse benzodiazepines. Abuse can be limited by frequent follow-up appointments and not allowing automatic refills.
- Examination, CBC, serum chemistry profile, urinalysis, ± thyroid profile are indicated q 6-12 months for animals receiving long-term medication.
- Clients should learn to monitor heart rate digitally, since the first sign of cardiac side effects of medications can be an unremitting tachycardia.

PROGNOSIS AND OUTCOME

- Prognosis is improved by early diagnosis and aggressive treatment and by client compliance. Frequent and thorough communication between clinician and client so the treatment plan can be adjusted according to the animal's response and needs is essential.
- With chronic separation anxiety, treatment may be lifelong, especially if there are other comorbid anxiety-related conditions.

PEARLS & CONSIDERATIONS

COMMENTS

If a veterinarian is not comfortable treating a case of separation anxiety, the animal should be referred to a specialist (see www.dacvb.org for a listing in the United States).

TECHNICIAN TIP

Most veterinary staffs have no one with formal experience in behavior modification. Resources to help inform support personnel include the Association of Pet Dog Trainers (www.APDT.com) and the Society of Veterinary Behavioral Technicians (www.SVBT.org).

PREVENTION

- Early intervention for diagnosis and treatment
- Veterinarians should screen for behavioral problems as a routine part of every appointment. Otherwise, left untreated, separation anxiety worsens.
- When selecting breeding stock, clients should assess both medical and behavioral patterns of the pet's family members. Liability for anxiety disorders is likely heritable.

CLIENT EDUCATION

- Most behavioral conditions are due to chemical and functional abnormalities. These pets are distressed; they are not vindictive, jealous, spoiled, or disobedient.
- Under no circumstances should pets with behavioral problems be “punished,” physically “disciplined,” or “corrected.” These techniques only render the animal more anxious.
- Clients should expect treatment to be long term (at least 6 months) and possibly lifelong if the condition has been ongoing and/or severe.
- Relapses may occur with treatment discontinuation or added Stressors. When such Stressors are anticipated, premedication may be helpful.

AUTHOR & EDITOR: KAREN L. OVERALL

Semilunar Valve Insufficiency

BASIC INFORMATION

DEFINITION

Diastolic incompetence of the aortic valve and/or pulmonic valve

SYNONYMS

Aortic insufficiency (AI) or aortic regurgitation (AR); pulmonic insufficiency (PI) or pulmonic regurgitation (PR)

EPIDEMIOLOGY

SPECIES, AGE, SEX: May affect dogs and cats of any age and either sex

GENETICS & BREED PREDISPOSITION: Only when associated with an inciting cause (e.g., subaortic stenosis in Newfoundland dogs)

RISK FACTORS

- Aortic insufficiency: subvalvular aortic stenosis, aortic stenosis, ventricular septal defect, tetralogy of Fallot, infectious endocarditis, cardiac catheterization, aortic valve balloon valvuloplasty, aortic dilation
- Pulmonic insufficiency: pulmonic stenosis, patent ductus arteriosus, pulmonary hypertension, infectious endocarditis, heartworm disease, cardiac catheterization, pulmonic valve balloon valvuloplasty

GEOGRAPHY AND SEASONALITY: see Endocarditis, Infective, p. 346; Heartworm Disease, Cat, p. 474; Heartworm Disease, Dog, p. 477.

ASSOCIATED CONDITIONS & DISORDERS

- Severe AI may cause volume overload of the left ventricle and ultimately may lead to left-sided congestive heart failure. Such severe AI is rare in dogs and cats.
- Pulmonic insufficiency, even if severe, essentially never produces volume overload of the right ventricle.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Aortic insufficiency:
  - Isolated AI: uncommon
  - Secondary AI: underlying causes: see Risk Factors above
- Pulmonic insufficiency:
  - Isolated trivial PI: relatively common in dogs of all ages and either sex; uncommon in cats
  - Secondary PI: underlying causes: see Risk Factors above

HISTORY, CHIEF COMPLAINT

- Aortic insufficiency:
  - Often an incidental finding; no overt clinical signs
  - If severe: respiratory distress, cough, exercise intolerance, weakness, collapse
  - Signs of the causative cardiac disorder may predominate
- Pulmonic insufficiency:
  - Virtually never associated with clinical signs
  - If severe: respiratory distress, cough, cyanosis, exercise intolerance, weakness, collapse, abdominal distention
  - Signs of the causative disorder may predominate.

PHYSICAL EXAM FINDINGS

- Aortic insufficiency:
  - No abnormal findings if AI is trivial to mild
  - If moderate to severe:
    - Cardiac auscultation reveals a soft, low-frequency holodiastolic murmur over the left heart base (4th-5th intercostal space [ICS]) with radiation to right hemithorax.
    - Bounding peripheral pulses in some instances (dependent upon quantity of AI and underlying etiology)
  - If sufficiently severe to cause congestive heart failure (CHF): dyspnea, cough, pale mucus membranes, lethargy, pulmonary crackles
- Pulmonic insufficiency:
  - No abnormal findings if PI is trivial to moderate
  - If severe, and/or if concurrent pulmonary hypertension:
    - Cardiac auscultation reveals a low-frequency, diastolic/decrescendo murmur over the left heart base (3rd-4th ICS).
  - If sufficiently severe to cause CHF (rarely under any circumstance, and virtually never without a complicating factor such as pulmonary hypertension):
    - Pulse quality may be decreased.
    - Dyspnea, cough, dull lung sounds, abdominal fluid wave, pale mucous membranes, lethargy

ETIOLOGY AND PATHOPHYSIOLOGY

- Isolated semilunar valvular insufficiency:
  - Usually mild, rarely associated with clinical disease (especially PI)
  - Presumed mild congenital valvular malformation
- Aortic valve incompetence secondary to other causes:
  - Subaortic stenosis:
    - Poststenotic turbulence distorts valve endothelium such that valve closure is ineffective.
  - Valvular aortic stenosis (rare), infectious endocarditis:
    - Malformed valve leaflets do not coapt/close normally.
  - Ventricular septal defect (membranous):
    - Base of aortic valve is poorly supported owing to absent basal septal tissue, causing sagging and partial prolapse of the aortic valve in diastole.
- Pulmonic valve incompetence secondary to other causes:
  - Pulmonic stenosis: malformed pulmonic valve leaflets do not coapt/close normally.
  - Heartworm disease: physical blockage of pulmonic valve closure by worms
- Volume overload and increased end-diastolic ventricular and atrial pressures if AI or PI severe:
  - Predisposes to CHF and ultimately myocardial failure

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Clinically significant semilunar valve insufficiency is suspected when a diastolic murmur is identified on physical examination. More commonly, trivial semilunar valve insufficiency is identified incidentally during an echocardiogram and is of little or no consequence. Doppler echocardiography is necessary to noninvasively confirm the presence of this disease process and define the etiology. Further testing is often indicated if a pathologic disease process is identified; however, isolated semilunar valve insufficiency (in the absence of structural valvular or myocardial lesions) is rarely clinically significant.

DIFFERENTIAL DIAGNOSIS

- Normal
- Differentiate isolated semilunar insufficiency from specific causes (see Etiology and Pathophysiology above).

INITIAL DATABASE

- Echocardiogram: confirm diagnosis, identify underlying conditions, and qualitatively assess degree of insufficiency.
- Thoracic radiographs: normal if insufficiency mild:
  - AI: if moderate to marked: left ventricular enlargement, left atrial enlargement, distended pulmonary veins, pulmonary edema
  - PI: if marked (and especially when associated with severe pulmonary arterial hypertension): right ventricular enlargement, pleural effusion, distended caudal vena cava
  - Findings consistent with primary disorder
- Blood pressure: assess hemodynamic consequence of valvular insufficiency.

- CBC, serum biochemistry panel, urinalysis usually unremarkable with mild insufficiency but varies with underlying etiology

ADVANCED OR CONFIRMATORY TESTING

- Tests to rule out specific acquired diseases such as infective endocarditis and heartworm disease (see pp. 346, 474, and 477)
- Angiogram: confirmation of echocardiographic findings (rarely necessary)

TREATMENT

TREATMENT OVERVIEW

Treatment of semilunar valve insufficiency is oriented towards the underlying etiology and severity of the disease process. Isolated semilunar valve insufficiency rarely requires treatment, whereas treatment of semilunar valve insufficiency secondary to endocarditis (see p. 346) may require aggressive multimodal therapy.

ACUTE GENERAL TREATMENT

- None if insufficiency is mild/moderate
- Treat primary cause of insufficiency if applicable (e.g., antimicrobial therapy for semilunar valve insufficiency secondary to endocarditis)
- Manage CHF if present (see pp. 468, 470)

CHRONIC TREATMENT

- Dependent on underlying cause and presence or absence of CHF
- Prevent progressive cardiac remodeling and myocardial failure.

NUTRITION/DIET

Reduce dietary sodium if CHF present.

BEHAVIOR/EXERCISE

Exercise moderation for patients that develop CHF

POSSIBLE COMPLICATIONS

- Refractory CHF
- Systemic hypotension
- Azotemia (especially in patients with preexisting renal compromise and/or those receiving aggressive diuretic therapy)

RECOMMENDED MONITORING

Implemented as needed based on severity of disorder:

- Systemic blood pressure
- Renal function (with diuretics)
- Serum digoxin levels (measure 6-8 hours post administration)
- Repeat echocardiograms regularly (frequency dependent on the severity of insufficiency).

PROGNOSIS AND OUTCOME

- Excellent for mild to moderate PI and mild AI without evidence of ventricular or atrial dilation
- Guarded to poor for patients with marked AI/PI and CHF

PEARLS & CONSIDERATIONS

COMMENTS

- Auscultation of soft, low-frequency diastolic murmurs may be enhanced by positioning patient in left lateral recumbency and placing stethoscope bell on the dependent side of the chest wall over the heart base.
- The detection of small jets of semilunar valve insufficiency requires a high-quality echocardiograph.
- The presence of mild or moderate aortic insufficiency, even if inaudible, may add weight to a diagnosis of mild subaortic stenosis in a patient with echocardiographic results that are otherwise equivocal.
- With increasingly sensitive color-flow Doppler echocardiography, semilunar valve insufficiency can be detected in a progressively larger proportion of the normal dog and cat population; the volume of insufficiency and its impact on the ventricle are more important than simple presence or absence.

PREVENTION

see Endocarditis, Infective, p. 346; Heartworm Disease, Cat, p. 474; Heartworm Disease, Dog, p. 477.

TECHNICIAN TIPS

Auscultation of diastolic murmurs requires careful auscultation in a quiet environment. Minimizing ambient background noise, limiting respiratory tract interference, and reducing patient movement are strategies that may promote auscultation of diastolic murmurs.

Seizures

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A seizure is the clinical manifestation of abnormal, excessive, and/or hypersynchronous neuronal activity in the cerebral cortex. The location and extent of this abnormal neuronal activity determines the clinical appearance of the seizure. In clinical practice, seizures must be differentiated according to whether they are of extracranial or intracranial origin.

SYNONYMS

Convulsion, epileptic seizure, ictus

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Both sexes, dogs and cats, all ages
- Dogs: 6 months to 5 years (primary epilepsy); older dogs (brain tumor); young dogs (intoxication, metabolic, malformation)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Partial seizures (previously called *petit mat):* focal or asymmetric sensory or motor activity affecting any part of the body (e.g., facial twitching, chomping of the mouth); can be associated with autonomie signs (e.g., salivation, vomiting)
  - Simple (no alteration of consciousness) or complex (alteration in mentation and/or behavioral abnormalities; also called *psychomotor seizures)*
- Generalized seizures (previously called *grand mat):* diffuse, bilateral motor activity with loss of consciousness
- Status epilepticus: continuous seizure activity lasting for 5 minutes or more or repeated seizures with failure to return to normality in between
- Cluster seizures: two or more seizures within 24 hours

HISTORY, CHIEF COMPLAINT

- Any combination of uncontrollable, involuntary, excessive, or reduced motor activity; alteration in consciousness; behavioral disturbance and autonomie signs (e.g., salivation, urination, defecation, piloerection)
- A seizure is transient and starts and ends abruptly.
- Postictal disturbances frequently follow the seizure (e.g., confusion, pacing, blindness, ataxia).
- The motor activity can be bilateral and diffuse (e.g., generalized tonic/clonic seizure) or minor and subtle (e.g., facial twitching).

PHYSICAL EXAM FINDINGS

- The animal is often normal between episodes.
- Complete neurologic examination (see p. 1311) is mandatory:
  - Presence of any neurologic deficits after complete resolution of the seizure (interictal period) is important. Interictal neurologic deficits are an indication of a structural intracranial lesion, such as inflammation or neoplasm.
  - A patient that shows no interictal neurologic deficits, however, may have either a primary brain disturbance as the cause of seizures or, less likely, an extracranial cause for the seizures.
- Evidence of systemic illness is often present in cases where seizures are the result of intoxication (e.g., bradycardia, gastrointestinal [GI] signs) or metabolic diseases (e.g., anorexia, lethargy, vomiting).

ETIOLOGY AND PATHOPHYSIOLOGY

Etiology:

- Intracranial:

- Idiopathic epilepsy: based on exclusion of all known causes
- Primary epilepsy: genetic, common in dogs, rare and poorly documented in cats, possible ion channel mutation
- Persistent interictal deficits: structural forebrain lesion, including infectious encephalitis (e.g., viral, fungal, other), noninfectious encephalitis (e.g., granulomatous meningoencephalitis, necrotizing meningoencephalitis), brain tumor, vascular insult (e.g., stroke, feline ischemic encephalopathy), head trauma, degenerative diseases (e.g., storage disease), and malformation (e.g., cyst, hydrocephalus)

- Extracranial (or reactive): seizure secondary to a transient systemic or toxic insult to a normal brain. Systemic causes include hypoglycemia (e.g., insulinoma), encephalopathy (e.g., portosystemic shunt), and hypocalcemia (e.g., hypoparathyroidism, eclampsia). Many toxins can cause seizures at the advanced stage (e.g., ethylene glycol, metaldehyde, lead). For most toxins, there is progression from shaking to trembling to (finally) seizuring.

Pathophysiology:

- An alteration in neuronal excitability causes a paroxysmal depolarizing shift (PDS). This PDS may be secondary to inadequate neuronal inhibition (neurotransmitters GABA and glycine) or to excessive neuronal stimulation (neurotransmitters glutamate and aspartate) or can be a combination of both.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- Seizure is the most common neurologic disorder in small animals.
- Ensure that the episodes truly are seizures: a thorough history and description are essential. Asking the owner to provide a video clip of the episode can be very useful.
- Once episodes are confirmed to be seizures, all patients undergo a comprehensive medical evaluation, and if no causes of extracranial/reactive seizures are identified, advanced imaging of the brain and cerebrospinal fluid (CSF) analysis are warranted.

DIFFERENTIAL DIAGNOSIS

- Syncope: sudden loss of consciousness and muscle tone, usually without motor activity and without postictal signs (fast and complete recovery). Syncopal events last <1 minute (otherwise fatal), whereas seizures may last several minutes. Clues of a cardiac problem may be present on examination (e.g., heart murmur, arrhythmias).
- Metabolic diseases: seizures are usually preceded by other signs (e.g., confusion, change in behavior, weakness).
  - Hypoglycemia (e.g., insulinoma): diagnosed rapidly with a simple blood glucose evaluation
  - Hypocalcemia: causes muscle cramping, spasms and fasciculation, and weakness and irritability rather than “true” seizures; diagnosed rapidly with simple blood total calcium or ionized calcium evaluation
  - Hepatic encephalopathy: episodes usually last hours, often associated with food intake.
  - Polycythemia: may cause weakness, confusion, collapse, and even a vascular event in the brain; diagnosed rapidly with hematocrit > 60%-65% (sight hounds >70%).
  - Kidney failure: at advanced stages, evident on physical exam (anuria) and/or blood work and urinalysis (concurrent azotemia and isosthenuria)
- Narcolepsy/cataplexy: animal “falls asleep” but can be awakened; usually associated with excitement or food.
- Sleep disorder: excessive “jerky” movements occurring exclusively during sleep. The animal can be awakened and exhibits normal wakening behavior (i.e., no postictal signs).
- Obsessive/compulsive behavior (e.g., “fly biting”): complex behavior that is usually goal directed and/or can be interrupted; more common in dogs. Affected dogs often have other behavioral problems (e.g., separation anxiety).
- Movement disorders: Focal motor signs are not associated with loss of consciousness or postictal signs. One of these signs is the “head bob,” which is occasionally seen in Doberman pinschers, boxers, bulldogs and occasionally in other breeds (movement of the head from side to side or up and down); another sign is dyskinesia in the bichon frise.

INITIAL DATABASE

- Fundic examination (see p. 1313): clues include papilledema (as can be seen with optic neuritis/encephalitis); retinal hemorrhage or detachment (which would suggest hypertension, polycythemia, or coagulopathy); lesions of chorioretinitis suggestive of a systemic infection (e.g., ehrlichiosis, toxoplasmosis, neosporosis, fungal disease).
- CBC, serum biochemistry panel, and urinalysis: evaluate for hypoglycemia, electrolyte imbalance (e.g., hypocalcemia), signs of liver or kidney disease, anemia, polycythemia, and calcium oxalate monohydrate crystals in antifreeze toxicity.
  - Usually normal in cases of primary brain disease
  - After severe seizures or status epilepticus, hyperglycemia (or rarely, hypoglycemia if prolonged seizures last for more than 20 minutes), increased liver enzymes (reduced perfusion or congestion), increased creatine kinase (CK; muscular damage or necrosis), and metabolic acidosis are typical.

- Electrocardiogram (ECG): evaluate for arrhythmias.
- Thoracic and abdominal radiographs: usually unremarkable
- Serum bile acids assay: indicated if hepatic encephalopathy is suspected and/or if a young animal presents with seizures. More than 90% of dogs and cats with portosystemic shunts have abnormal 2-hour postprandial serum bile acid levels.

ADVANCED OR CONFIRMATORY TESTING

- Portable electrocardiogram (ECG; cardiac event monitor or Holter monitor) if distinction between syncope and seizure is unclear on history and physical exam. Helps rule in (severe tachycardia or severe bradycardia occurs during episode) or rule out (cardiac rhythm is normal during episode) a cardiac arrhythmia as the cause of episodic clinical signs. Important prior to proceeding to general anesthesia, as for advanced imaging or CSF tap.
- Advanced imaging of the brain (MRI or CT scan (see p. 1302 and p. 1233)): brain tumor, multifocal lesions suggestive of inflammation, vascular lesion. MRI is slightly more sensitive. Radiographs of the skull are unrewarding except in cases of head trauma or palpable skull abnormalities.
- CSF analysis: often nonspecific but can be helpful in confirming brain disease or inflammation
- Serologic testing (e.g., fungal diseases, *Toxoplasma, Neospora,* and others; selection based on physical findings and initial database)
- Tests for toxins if exposure (e.g., plasma lead concentration, serum cholinesterase level)
- Electroencephalogram (EEG): limited availability; usefulness has yet to be proven.

TREATMENT

TREATMENT OVERVIEW

- Control or elimination of the underlying cause is the overarching long-term goal but is not possible in all cases.
- Reduction in seizure frequency and severity is a principal goal; acceptable seizure control for the owner (e.g., could be <1 seizure per 6-8 weeks) without significant side effects from the medication.
- For cluster seizures (more then two seizures per 24 hours) and status epilepticus: stopping the seizures and preventing others.
- Cluster seizures and status epilepticus are medical emergencies.

ACUTE GENERAL TREATMENT

For emergency situations (cluster or status):

- Identify and address any immediately reversible causes:
  - Hypoglycemia (blood or serum glucose < 40 mg/dL [<2.2 mmol/L]): administration of dextrose 2 g/kg IV. If using 50% dextrose, this equals 4 mL/kg, which must then be diluted with 5-10 times as much 0.9% saline or other sterile isotonic fluid by volume prior to administration to reduce the risk of phlebitis.
  - Hypocalcemia (blood or serum calcium < 6 mg/dL [<1.5 mmol/L]): administration of 10% calcium gluconate IV at a dose of 0.5-1.5 mL/kg or 5-15 mg/kg slowly to effect over a 15- to 30-minute period. Monitor ECG for onset of bradycardia, ventricular arrhythmia, or shortening of the QT interval, any of which justifies temporarily stopping the infusion. Total dose is the amount required to stop clinical signs.
  - Dextrose and calcium should not be administered unless a deficiency is documented.
- To stop the seizure and if reversible causes are absent: diazepam, 0.5-1 mg/kg IV bolus; can be repeated safely if seizure activity persists. Animals receiving phenobarbital may require 2 mg/kg of diazepam. Diazepam lasts only 20-30 minutes; further seizure activity must be prevented by one of the following steps:
  - Diazepam (2 mg/kg) can also be administered rectally either in the hospital or at home by the owner.
- To prevent another seizure:
  - Identify and control any known causes (e.g., antidote if known intoxication: pralidoxime or atropine for organophosphate; others).
  - Administer loading dose of phenobarbital (total mg = desired serum concentration (µg/mL) × BW (kg) × 0.8 L/kg): IV bolus of 10-20 mg/kg slowly; will reach an optimal serum level immediately. Monitor the patient carefully for excessive sedation if combined with diazepam.
  - Administer diazepam as a constant rate IV infusion (CRI): 0.5-1 mg/kg/h; can be added to 0.9% sodium chloride (NaCl) in an in-line burette; reduced by 25% every 4-6 hours if the seizures are controlled. Do not prepare more than 2 hours at a time, because diazepam is adsorbed by plastic and degraded by light.
  - Give diazepam boluses: alternative to a CRI; give 2 IV boluses of 1 mg/kg 30 minutes apart, followed by an IV bolus of 0.5 mg/kg 30 minutes and 60 minutes later.
- If seizures persist, administer propofol via IV bolus of 1-6 mg/kg to effect followed by an IV CRI of 2-8 mg/kg/h; then reduce the dose by 25% every 4-6 hours if the seizures are controlled; adequate monitoring is recommended.
- Provide supportive care and reestablish homeostasis.

- Thiamine (cofactor for glucose metabolism) 25-50 mg IM can be administered.

CHRONIC TREATMENT

Depends on underlying cause. Initiation of long-term, oral anticonvulsant drug therapy (e.g., phenobarbital, potassium bromide) is often required (see p. 353).

POSSIBLE COMPLICATIONS

- Seizures may continue despite adequate anticonvulsant drug therapy.
- Status epilepticus and death
- Hyperthermia, noncardiogenic pulmonary edema
- Neuronal damage if long, severe, or frequent seizures
- Hypersensitivity to phenobarbital; hepatotoxicity, rare bone marrow aplasia or blood dyscrasia, skin lesions (see p. 871)

RECOMMENDED MONITORING

- Phenobarbital serum level 3 weeks after initiation, change in dosage, signs of toxicosis or poor seizure control
- Bromide level after loading dose (if applicable), 3 to 4 months after initiation, and change in dosage; toxicity or poor control
- CBC and serum biochemistry panel every 6 to 12 months

PROGNOSIS AND OUTCOME 

- Good to guarded, depending on the cause:
  - Approximately 25% of dogs are refractory to treatment.
  - Owners should have realistic expectations.
- Many patients need lifetime medication and follow-up appointments.

PEARLS & CONSIDERATIONS 

COMMENTS

- A structural forebrain lesion rather than primary epilepsy should be suspected in seizuring dogs younger than 6 months or older than 5 years, and in seizuring cats.
- Status epilepticus is a medical emergency and needs to be treated intensively.
- Most animals will need long-term or lifelong treatment, and some animals may be refractory to treatment.

AUTHOR: VÉRONIQUE SAMMUT

EDITOR: CURTIS W. DEWEY

Sebaceous Adenitis

BASIC INFORMATION

DEFINITION

Sebaceous adenitis (SA) is a destructive inflammatory disease of the sebaceous glands.

SYNONYM

Granulomatous sebaceous adenitis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Uncommon in dogs, rare in cats; more common in young-adult to middle-aged dogs (1.5-7 years)

GENETICS & BREED PREDISPOSITION: Any breed can be affected, but the condition appears to be inherited in Akita, Samoyed, and standard poodle (autosomal recessive) dogs. Other breeds frequently reported to have SA are English springer spaniel, Hungarian Vizsla, German shepherd, Lhasa apso, Hovawart, and Bernese mountain dog.

ASSOCIATED CONDITIONS & DISORDERS: Pyoderma (see p. 951) and *Malassezia* dermatitis (see p. 682)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- The condition may appear differently in individual breeds, with marked variability depending on severity. Two clinical presentations exist:
  - Generalized SA: in long-coated breeds, such as Akita and standard poodle
  - Multifocal SA: in short-coated breeds, such as Hungarian Vizsla and in cats
- SA can also be subclinical and only identifiable by histologic examination in predisposed breeds.

HISTORY, CHIEF COMPLAINT: Progressive areas of hair loss, poor haircoat, excessive scaling, and musty odor. Pruritus is variable but may be marked, especially if secondary bacterial or *Malassezia* dermatitis is present.

PHYSICAL EXAM FINDINGS

- Generalized SA: presents with dramatic amounts of scaling. Typically, scales are adherent to hairs (follicular castings), coat, and skin and are often dry to the touch. Hypotrichosis on the top of the head, back of the neck, and dorsum is observed as the disease progresses. In chronic cases, hyperkeratotic skin is observed. The dorsal midline and ears are usually the first and most affected areas. In the Akita, where the disease can be more severe, fever, anorexia, and lethargy have been reported.
- Multifocal SA: this clinical presentation seen in Vizlas is strikingly different and presents with coalescing patches of scaly alopecia and annular plaques, with adherent scales developing mainly on face, head and trunk.

SEBACEOUS ADENITIS When hairs are epilated, follicular casts adhere to hair shafts.

(Courtesy Dr. Caroline de Jaham.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Cause and pathogenesis are uncertain, but mechanism may be a genetically inherited cell-mediated immune reaction against the sebaceous glands.
- Initial defect could be a cornification disorder or abnormalities in cutaneous lipid metabolism that affect sebum production.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on physical appearance of large amount of adherent scaling and a dull, sparse haircoat in a predisposed breed. Such findings warrant skin biopsies, which are confirmatory. Deep skin scrapings, fungal cultures, and skin cytologic examination should be done prior to obtaining skin biopsies, to identify complicating/concurrent factors.

DIFFERENTIAL DIAGNOSIS

- Generalized form: cornification disorders (primary seborrhea, ichthyosis), pyoderma, *Malassezia* dermatitis, demodicosis, dermatophytosis, endocrinopathies, leishmaniasis
- Multifocal form: pyoderma, demodicosis, dermatophytosis, zinc-responsive dermatosis, pemphigus foliaceus

INITIAL DATABASE

- Cytologic examinations to assess for presence of secondary bacterial or *Malassezia* infection
- Skin scrapings (for parasites) and dermatophyte culture: generally negative with sebaceous adenitis
- CBC, serum biochemistry profile, urinalysis, and endocrine function tests: no abnormalities expected

SEBACEOUS ADENITIS Note the poor-quality haircoat with adherent scales over the dorsum in this 4-year-old Akita-cross dog.

(Courtesy Dr. Caroline de Jaham.)

ADVANCED OR CONFIRMATORY TESTING

Histopathologic findings are diagnostic. Affected areas show a pyogranulomatous inflammation around the sebaceous glands. Sebaceous glands are in various stages of being destroyed. Marked orthokeratotic hyperkeratosis is present. In late-stage disease, the inflammation resolves, leaving an absence of sebaceous glands.

TREATMENT

TREATMENT OVERVIEW

SA is incurable; however, control of clinical signs (for patient comfort, reduction of risk of secondary infections, and esthetics) can be reached with topical and/or systemic therapy. The mainstay of topical treatment involves the use of keratolytics. Nutritional supplements may be beneficial but are unproven.

ACUTE GENERAL TREATMENT

- Treat bacterial infections with appropriate systemic antibiotic therapy. An acceptable empirical choice initially is cephalexin, 22-30 mg/kg PO q 12 h for 3 weeks.
- There is no gold standard for treatment of SA in dogs; a variety of protocols has been published, all with variable efficacy.
- Mild cases: intensive topical therapy leads to effective (although partial in most cases) control of scaling: keratolytic shampoos and emollient rinses; weekly baby oil soaks prior to shampoo are effective in dissolving the keratin. Weekly baths are needed at first (6-8 wks), but the frequency usually can be decreased to every 2-3 wks when signs improve.
- For more stubborn cases, topical application of 50%-75% propylene glycol as a rinse daily, then decrease frequency as needed.
- For more severe or refractory cases, options include:
    - Synthetic retinoids (isotretinoin, acitretin): 1-3 mg/kg PO q 12-24 h until remission (approximately 6 wks); then the lowest, most infrequent dose (reported effective in Vizsla, variable results in other breeds). Hepatotoxicity, hypertriglyceridemia and keratoconjunctivitis sicca are common, and monitoring is indicated.
    - Cyclosporine: effectively reduces sebaceous gland inflammation, alopecia, and follicular casts at 5 mg/kg PO q 24 h for 4 months, then gradual dose reduction that maintains clinical control. A combination of systemic cyclosporine and topical treatments further improves the skin and coat condition.

NUTRITION/DIET

- Omega-3 fatty acids PO q 24 h (180 mg of eicosapentaenoic acid per 5 kg body weight).
- Vitamin A, 8000-10,000 IU PO q 24 h is listed, but only weak clinical evidence of benefit.

DRUG INTERACTION

Ketoconazole potentiates cyclosporine activity; adjust dosage to reduce risk and monitor serum cyclosporine levels

RECOMMENDED MONITORING

Animals on synthetic retinoids should have liver enzyme activity and triglyceride levels monitored q 1-2 months and tear production monitored q 3 weeks for first 2 months, then q 1-2 months). Cyclosporine serum levels should remain in therapeutic range.

PROGNOSIS AND OUTCOME

- Early diagnosis and treatment improve the prognosis for long-term control.
- Even though the disease is not lethal, dogs with SA are sometimes euthanized because the treatment is lifelong and labor intensive. A clinically and cosmetically acceptable result is sought but not always obtained.

PEARLS & CONSIDERATIONS

COMMENTS

- Subclinical states of SA may progress with time. Early diagnosis can be done with skin biopsies.
- Hair regrowth can be straight rather than curled and of a different color in affected standard poodles.

TECHNICIAN TIPS

Do not scrub—or wipe with alcohol or antiseptic—the biopsy site prior to performing skin punch biopsies. Scales on the skin surface and follicular casts, which are important in making the diagnosis, may be removed. For the same reason, do not shave; gently clip the hair with scissors if necessary. Handle biopsy samples gently, avoiding squeezing or crushing.

PREVENTION

Discourage the breeding of affected animals. Screening is performed via histologic analysis of at least two 6-mm skin biopsies taken from skin with scaling and hair loss, or if no lesions are present, on the dorsal midline between the neck and lumbosacral region. see https://secure.offa.org/sainfo.html for details.

CLIENT EDUCATION

- A clinically and cosmetically acceptable result is not always obtained despite treatment.
- The Orthopedic Foundation for Animals (OFA) provides a database and guidelines on canine sebaceous adenitis. For information and registration: www.offa.org.

Sarcoptic Mange

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A nonseasonal, highly contagious, intensely pruritic cutaneous infestation caused by a small, obligate, burrowing mite, *Sarcoptes scabiei* var. canis.

SYNONYMS

Canine scabies, sarcoptic acariosis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs (all breeds, both sexes, all age) are commonly affected.

RISK FACTORS: The disease is more common in dogs that have been in animal shelters, pet shops, dog shows, boarding, grooming or dog daycare facilities, as well as stray dogs and dogs living in the country where infested foxes or coyotes roam near farm buildings.

CONTAGION & ZOONOSIS

- Transmission occurs most commonly from direct contact with an infested dog or wild canidae but can also occur from a contaminated environment and fomites.
- Humans exposed to an infested dog can develop a pruritic papular eruption which will resolve when the mites are eradicated from the animal. Although quite rare, a dog may acquire the parasite from a human infested with *S. scabiei* var. humanis.
- Dog-to-dog transmission is best avoided by preventing direct contact and administering scabicidal drugs promptly to affected dogs (mites die within several days).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: The primary complaint is pruritus. In more chronic cases, the condition can present as nonseasonal intense pruritus that has responded poorly to various dermatologic therapies, including corticosteroid therapy.

PHYSICAL EXAM FINDINGS

- Typically, the ear margins, elbows and hocks, ventral abdomen, chest, and eventually legs (the dorsum is usually spared) will show intense pruritus, papules, erythema, crusting, excoriations, and alopecia.
- A positive pinnal-pedal reflex (scratching action with the dog's hind limb when the examiner firmly rubs the edge of the dog's pinna between thumb and forefinger) is seen in 82% of dogs with sarcoptic mange but observed in only 7% of dogs with pruritus caused by other diseases.

ETIOLOGY AND PATHOPHYSIOLOGY

- The life cycle lasts approximately 3 weeks, and adult mites usually survive off the host for up to 6 days at room temperature.
- *S. scabiei* var. canis is not totally host specific, given that it has been isolated from foxes, coyotes, and rarely from immunosuppressed cats.
- Infestation with *Sarcoptes* mites (as for many other parasitic infestations) leads to a hypersensitivity reaction, the latter being responsible for the intense pruritus in sensitized dogs. The precise incubation period is not known, but in first-time infections, the first clinical signs are usually expected a few weeks after exposure.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- The diagnosis is suspected from the history and clinical signs; a positive pinnal-pedal reflex is strongly suggestive of the disease. Consider *S. scabiei* infestation when presented with any dog with an apparent sudden onset of intense itching.

DIFFERENTIAL DIAGNOSIS

- Ectoparasites *(Cheyletiella, Otodectes,* fleas, lice, chiggers)
- Hypersensitivities (flea bite and other ectoparasite hypersensitivities, atopic dermatitis, adverse food reaction, contact hypersensitivity)
- Pyoderma
- *Malassezia* dermatitis

INITIAL DATABASE

- Confirmation of the diagnosis relies on a positive skin scraping (mites, mite eggs, or mite fecal pellets) or occasionally on dermatohistopathologic analysis of biopsies or fecal flotation. The ear margins, the elbows or hocks, and unexcoriated papules are the preferred sites for scrapings. However, the mites are notoriously difficult to find.
- Test for the pinnal-pedal reflex.

ADVANCED OR CONFIRMATORY TESTING

- A serodiagnostic (ELISA) test is available in some European countries for the diagnosis of canine scabies. Sensitivity = 82%-92%, specificity = 92%-**96%.**
- Therapeutic trials with reliable scabicides are essential to confirm or rule out scabies in pruritic dogs with negative skin scrapings.

TREATMENT

TREATMENT OVERVIEW

- The goal of treatment is to thoroughly eradicate the mites. Affected and all in-contact dogs should be treated with a scabicide regardless of presence or absence of clinical signs.
- All clinically suspected *S. scabiei* cases should be treated even if multiple skin scrapings are negative.
- Traditional topical scabicides (lime sulfur, amitraz, organophosphates) have been largely replaced by the labeled and off-label use of macrocyclic lactones.

ACUTE GENERAL TREATMENT

- Selamectin (Revolution/Stronghold [Pfizer]) and moxidectin/imidacloprid (Advantage Multi/Advocate [Bayer]) are approved as topical scabicides once every 30 days for 2 treatments, although many veterinary dermatologists recommend a minimum of 3 treatments at 2-week intervals.
- The off-label use of ivermectin, one of the most useful diagnostic and therapeutic tools in canine scabies in the 1980s and '90s, remains a therapeutic alternative but should never be used in collies or related breeds with a high prevalence of MDR1 (ABCB1) mutation (see p. 706). The injectable product (Ivomec 1% injection for cattle and swine [Merial]) is usually given at a dosage of 0.3 mg/kg PO or SQ q 7-14 days for a 4-6 week course of treatment. The 0.5% alcohol based pour-on ivermectin formulation (Ivomec Pour-on for cattle [Merial]) is also effective and practical when applied to the interscapular skin q 14 days at 0.5 mg/kg for 2-3 treatments.
- Concomitant antibiotic therapy may be required if secondary pyoderma is present. Cephalexin at a dose of 22-30 mg/kg PO q 12 h for 30 days typically is a good choice.
- Short-term corticosteroid therapy may be required in severely pruritic dogs. Prednisone can be used at 0.5-1 mg/kg PO q 24 h for the first 2-3 days and then weaned down.
- The use of an environmental acaricidal is generally not required, although grooming equipment and bedding can be treated with an appropriate acaricidal spray.

POSSIBLE COMPLICATIONS

In collies, Australian shepherds, and many other canine breeds carrying the MDR1 (ABCB1) mutation, intoxication can occur with dosages of ivermectin or other off-label macrocyclic lactones that are tolerated by normal dogs. Pretreatment testing for the gene mutation (and/or selection of alternate treatment) is recommended in at-risk breeds (see p. 706).

RECOMMENDED MONITORING

Follow-up examination, including skin scrapings and cytologic analysis, are recommended if clinical signs persist or worsen 1-2 months after initiating scabicidal treatment.

PROGNOSIS AND OUTCOME

- It can take 2 to several weeks for complete resolution of pruritus. In some dogs, an increase in pruritus (probably associated with an immunogenic response to the dying mites) may occur in the first few days after treatment.
- Prognosis is good.
- In humans, the zoonotic infestation is transient, with the pruritic papular eruption resolving when the mites are eradicated from the dog.

PEARLS & CONSIDERATIONS

COMMENTS

- Crusting of the elbows, hocks, and pinnal ear margins accompanied by intense pruritus are strongly suggestive of *S. scabiei.*
- Look for a pinnal-pedal reflex, and treat for scabies if this reflex is noted.
- "Feline scabies" is caused by a different parasite, *Notoedres cati;* however, cats in close contact with dogs affected with *S. scabiei* var. canis may be temporary reservoirs for the mite and occasionally develop transient pruritus. Rarely, immunosuppressed cats may develop persistent pruritic lesions when infested with *S. scabiei* var. canis.
- Owing to cross-sensitization, a positive intradermal skin test response to house dust mite antigen is seen in 75% of dogs with a confirmed diagnosis of scabies. All clinical signs resolve following acaricidal therapy, and all intradermal reaction to dust mites are generally negative within 6 months of the original diagnosis. This illustrates the importance of ruling out scabies prior to testing for atopic dermatitis.

CLIENT EDUCATION

Humans transiently affected with *S. scabiei* mites may develop a pruritic papular eruption, especially on the arms or trunk. This should spontaneously resolve within 3 weeks when the mites are eradicated from the dog. Persistent problems should prompt the person to consult a physician.

TECHNICIAN TIPS

- Sarcoptic mange has zoonotic potential. Therefore, ideally, lesions on affected animals should not be held or touched directly, and the hospital environment should be decontaminated.
- An acaricide (e.g., pyrethrin) is indicated for disinfecting surfaces such as exam tables and floors, but with patients that have low mite burdens, these surfaces may be adequately treated using routine disinfectants.
- Environmental treatment (e.g., home environment) is rarely performed, except for the dog's bedding.

Salt Toxicosis

BASIC INFORMATION

DEFINITION

Salt (sodium chloride, table salt, NaCl) toxicosis results when an excessive amount of sodium has been ingested, intake of potable water is limited, and/or free water translocates from the vasculature into the gut following osmotically active agents.

SYNONYMS

Water deprivation, sodium ion toxicosis, osmotic hypernatremia, salt poisoning

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs (all breeds, both sexes, all ages) are more commonly evaluated for salt toxicosis than cats. RISK FACTORS

- Use of table salt as an emetic, a technique which is now contraindicated for this reason
- Availability of homemade play dough in pet's environment
- Swimming and drinking seawater when availability of potable drinking water is limited (or incidentally during persistent exercise)
- Dehydration (places animals at higher risk)
- Vomiting (inability to maintain hydration despite polydipsia)
- Outdoor dogs in cold climates/frozen water (climate-dependent)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Owner description of typical risk factor (see above)
- Lack of drinking water or vomiting of water after ingesting excessive amounts of salt
- Polydipsia, vomiting, ataxia, tremors, and seizures within 1-4 hours after ingestion

PHYSICAL EXAM FINDINGS

- Polyuria and polydipsia (PU/PD)
- Vomiting, diarrhea, signs of abdominal pain
- Signs of dehydration
- Sinus tachycardia (secondary to dehydration)
- Depression, ataxia, tremors, seizures, potentially altered mentation
- Hyperthermia possible (secondary to tremors, seizures)

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

- Sources of excess sodium chloride for animals include homemade play dough and modeling clay, table salt (used as an emetic or simply ingested), improperly mixed feed or formula, ice melts, paintballs (22% of canine ingestions caused hypernatremia), sea water, hypertonic saline solutions, sodium bicarbonate, and sodium phosphate enemas.
- Osmotically active agents include polyethylene glycol and some sugar alcohols such as glycerol, maltitol, and sorbitol. Sources relevant to veterinary medicine include activated charcoal, paint balls, gummy candies, glaucoma prescriptions, sugar-free candy, and bulk artificial sweeteners.

Mechanism of Toxicosis (also see p. 559):

- Signs of toxicosis appear when serum sodium is >170 mEq/L (vomiting, polydipsia), and central nervous system (CNS) signs such as tremors and seizures begin when serum sodium is > 180 mEq/L (typical normal range in healthy dogs: 145-157 mEq/L).

- Hypernatremia creates a hypertonic state in the extracellular fluid (ECF). Initially, water shifts from the interstitium to the vasculature and then from intracellular fluid (ICF) to the ECF to maintain equilibrium.
- The CNS is particularly vulnerable to initial tissue shrinkage as water leaves the ICF, resulting in microvascular trauma and potential demyelination, with a rapid rise to severe hypernatremia.
- Sodium passively crosses the blood-brain barrier into the cerebrospinal fluid (CSF). Once in the CSF, excess sodium affects neuronal function by inhibiting glycolysis, leading to decreased energy production. Sodium requires active transport to move from the CSF back to the serum; decreased energy production limits this process. In the brain, a compensatory response to dehydration is the formation of idiogenic osmoles or solutes 24 hours or more after onset of hypernatremia. With rapid rehydration, these osmotically active solutes cause an influx of water into the brain, resulting in cerebral edema, seizures, permanent neurologic dysfunction, and possibly death.
- Excess sodium is irritating to gastrointestinal (GI) mucosa and can cause gastroenteritis and dehydration.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A tentative diagnosis is made based on history (excessive sodium intake, water deprivation, and/or ingestion of an osmotically active agent), compatible clinical signs (polydipsia, vomiting, tremors, seizures), or both. Diagnosis is confirmed by documentation of an elevated serum sodium level.

DIFFERENTIAL DIAGNOSIS

Toxicologic (see common sources for excessive sodium chloride ingestion, above)

Spontaneous, nontoxicologic (see p. 559):

- Water deficit:
  - Primary hypodipsia, diabetes insipidus (central/nephrogenic), high ambient temperature, fever, restricted water access
- Hypotonic fluid loss:
  - GI loss, third-space loss (peritonitis, pancreatitis), cutaneous (burns), osmotic diuresis (diabetes mellitus, mannitol infusion), chemical diuretics, acute and chronic kidney disease (CKD)
- Solute gain:
  - Hyperaldosteronism
  - Hyperadrenocorticism

INITIAL DATABASE

- CBC: stress leukocytosis
- Serum biochemistry profile:
  - Hypernatremia: serum sodium >170 mEq/L
  - Hyperchloremia
  - Hyperalbuminemia
  - Decreased serum $Hco3^{-}$ possible (metabolic acidosis)
  - Azotemia possible (prerenal)
- Thoracic radiographs: pulmonary edema possible (with concurrent sodium and water load, especially if there is preexisting heart disease)

ADVANCED OR CONFIRMATORY TESTING

- NaCl can be analyzed in vomitus, food, water; may help determine the source and concentration of NaCl (rarely needed clinically)
- Postmortem: brain sodium (> 1800 ppm)

TREATMENT

TREATMENT OVERVIEW

The cornerstone of treatment is judiciously timed reduction of serum sodium. Patients presented within 24 hours of ingestion may be decontaminated (induction of vomiting, but no administration of activated charcoal) and treatment aims for rapid sodium excretion/dilution. Patient presentation after >24 hours requires careful lowering of serum sodium concentrations to avoid iatrogenic

CNS injury.

ACUTE GENERAL TREATMENT

- Decontamination of patient:
  - Induction of vomiting (see p. 1364) if the animal is not showing clinical signs, and it is performed within 30 minutes of ingestion.
  - DO NOT administer activated charcoal. It does not adsorb NaCl, and some preparations contain substantial amounts of sodium.
- Replacement of water and electrolytes:
  - When the hypernatremia is acute (<24 hours), calculate the amount of free water needed:
  - Free water deficit (liters) = body weight (kg) × 0.6 × ([present serum Na concentration/previous or normal range serum Na concentration] – 1). Replace 50% of the water deficit in the first 24 hours using sterile 5% dextrose solution IV. Replace the remaining deficit in the next 24-48 hours using the same fluid type (5% dextrose), avoiding excessively rapid decreases (see Chronic Treatment, below).
- Facilitation of renal excretion of sodium:
  - 5% dextrose at 3.7 mL/kg/h IV in dogs can decrease serum sodium at about 1 mEq/L/h; 0.45% NaCl with 2.5% dextrose is also suitable (slower decrease).
  - Furosemide, 1-2 mg/kg IM or IV q 6 h (correct dehydration first).
- Supportive care:
  - Control seizures with diazepam: 0.5-2 mg/kg IV PRN.
  - Control tremors with methocarbamol: 55 mg/kg slowly IV PRN.
  - Manage acidosis with sodium bicarbonate (PRN).
  - Warm water enema (5-10 mL/kg) or oral water can help correct free water deficit and thus correct hypernatremia. This works well when hypernatremia is due to osmotically active agents (not readily absorbed, e.g., activated charcoal, glycerol, gummy candies, etc.)

CHRONIC TREATMENT

Do not decrease serum sodium concentration faster than 0.5 mEq/L/h. A rapid drop in serum sodium concentrations can cause water influx into the CNS, and cerebral edema.

POSSIBLE COMPLICATIONS

Permanent CNS damage (osmotic demyelination, microvascular trauma) if excessively rapid correction of longstanding (>24 hours) hypernatremia

RECOMMENDED MONITORING

- Serum electrolytes: cornerstone of diagnostic testing during treatment
- Hydration status/body weight
- CBC (for hematocrit)
- Serum biochemistry profile (serum proteins)
- Acid-base status

PROGNOSIS AND OUTCOME

- Poor if serum sodium > 180 mEq/L and seizures are present
- Good if treated early and intensively

PEARLS & CONSIDERATIONS

COMMENTS

- A widely used homemade play dough recipe contains 2 cups of flour, 1 cup of table salt, and 0.5-1 cup of water; ingestion by dogs is a common cause of severe hypernatremia.
- Minimum lethal dose of NaCl in dog = 4 g/kg; minimum toxic dose = 1.9 g/kg. Equivalents: 1 tsp NaCl = 6 g; 1 lb table salt = 454 g.
- A 10-lb (4.5-kg) dog needs to eat 3.4 tsp (18 g) of homemade play dough to reach a minimum toxic dose of NaCl.
- In patients that are less severely affected, frequent access to small amounts of drinking water may be sufficient to lower serum sodium levels.

TECHNICIAN TIP

Do not use salt to induce vomiting.

Salmonellosis

BASIC INFORMATION

DEFINITION

Infection of susceptible patients with pathogenic *Salmonella* spp.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Many species can be infected, including cats, dogs, and people.
- Cats appear to be more resistant to *Salmonella* infection.
- Younger animals are more commonly affected.

RISK FACTORS

- Young, stressed, or immunocompromised patients
- Feeding raw or undercooked meat products, eggs, or diets
- Overcrowded, unsanitary, or stressful conditions
- Concurrent gastrointestinal (GI) infections
- Antibiotic therapy

CONTAGION & ZOONOSIS

- Infected dogs and cats are a major risk to people, especially immunocompromised persons.
- Risk to people increases if pets are eating raw meat diets.
- Undercooked meat is also a risk for people if ingested.

ASSOCIATED CONDITIONS & DISORDERS: Focal organ infections following clinical or subclinical infection:

- Abscesses, pneumonia, pyothorax
- Meningitis
- Osteomyelitis
- In utero infection resulting in abortion, stillbirth, weak puppies or kittens

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Up to 30% of dogs and 18% of cats are subclinical carriers.
- Acute enterocolitis
- Chronic diarrhea rare
- Septicemia/endotoxemia
- Cats may develop chronic, febrile illness

HISTORY, CHIEF COMPLAINT

- Watery to mucoid diarrhea with or without blood
- Straining or increased urgency to defecate
- Vomiting
- Anorexia and lethargy
- Weight loss

PHYSICAL EXAM FINDINGS

- Fever
- Abdominal pain

- Dehydration, possibly severe
- Pale mucous membranes, tachycardia, tachypnea, weakness, weak pulses if septicemic
- Conjunctivitis in cats

ETIOLOGY AND PATHOPHYSIOLOGY

- *Salmonella* spp: gram-negative, facultative anaerobic, motile, non-spore-forming rods from the family Enterobacteriaceae.
- Most common route of transmission is through contact with infected food, water, or fomites.
- Bacterium survives for long periods, up to 6 weeks, in environment.
- Clinical signs occur secondary to mucosal invasion and epithelial injury:
  - *Salmonella* spp. also produce an enterotoxin, resulting in secretory diarrhea.
- Organism persists in phagocytic cells of intestinal mucosa and mesenteric lymph nodes, liver, and spleen:
  - Results in persistent shedding for 3-6 weeks after infection
- Bacteremia and endotoxemia may occur in association with mucosal invasion, resulting in systemic infection and possibly the systemic inflammatory response syndrome (SIRS).
- Persistence and severity of infection depend on the patient's immune status.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on the isolation of *Salmonella* from feces in conjunction with appropriate clinical signs, or isolation from blood or infected tissues.

DIFFERENTIAL DIAGNOSIS

- Viral diarrhea: parvovirus, coronavirus, rotavirus
- Bacterial diarrhea: *Clostridium, Campylobacter* enteritides
- GI parasites
- Dietary indiscretion
- Septicemia due to other causes

INITIAL DATABASE

- CBC, biochemistry profile, and coagulation changes are generally nonspecific or represent signs of endotoxemia/sepsis:
  - Neutropenia with left shift and toxic neutrophils in acute phase or systemic disease
  - Neutrophilia if chronic illness
  - Nonregenerative, possibly hypo-chromic anemia may be noted.
  - Thrombocytopenia in severe cases, with septicemia leading to disseminated intravascular coagulation (DIC)
  - Hypoproteinemia due to GI loss
  - Sometimes hyponatremia and hyperkalemia (similar to hypoadrenocorticism)
  - Hypoglycemia, azotemia, or hyperbilirubinemia suggest endotoxemia/sepsis.
  - Prolonged coagulation times in severe cases with DIC
  - Fecal flotation, direct smear, and parvoviral ELISA test as needed to address differential diagnosis

ADVANCED OR CONFIRMATORY TESTING

- Fecal bacterial culture:
  - Best results using enrichment broth or selective culture media
  - Positive fecal culture establishes infection but not necessarily that signs are due to salmonellosis, since subclinical carriers are common.
  - Positive culture from blood, bile, or other normally sterile samples is more strongly indicative of salmonellosis.
  - False-negative results are possible, since organism grows fastidiously.
- Serologic testing is used in establishing diagnoses in human salmonellosis but is not routinely used in animals.

TREATMENT

TREATMENT OVERVIEW

Treatment consists of supportive care without antibiotics for mild to moderate cases of gastroenteritis. For severe gastroenteritis or

systemic disease, aggressive therapy with antibiotic use is warranted. No therapy is usually recommended for asymptomatic carriers.

ACUTE GENERAL TREATMENT

- Depends on severity of illness
- Mild cases are often self-limiting and require only supportive therapy.
- Intravenous fluid support, including plasma or colloids if necessary, recommended if dehydrated or septicemia is present
- Antibiotic therapy is controversial:
    - May induce carrier state and prolong fecal shedding of organisms
    - Antibiotics are indicated if severe hemorrhagic diarrhea is present, if the patient is depressed or febrile, if evidence of sepsis exists, if the patient is immunosuppressed and shows GI signs, or if positive blood cultures are obtained. Duration of treatment corresponds to time to resolution of fever, shock, or other signs of complications.
    - The most effective and least likely antibiotic to develop resistance is enrofloxacin (5-10 mg/kg PO or slow IV q 24 h in dogs; 4-5 mg/kg PO or slow IV q 24 h in cats).
    - Others reported to be effective include trimethoprim-sulfa (15 mg/kg PO q 12 h) or amoxicillin (22 mg/kg PO q 8 h).
    - Antibiotic therapy should initially be administered for 10 days, but some cases may require long-term administration.

RECOMMENDED MONITORING

Monitor carefully for signs of sepsis or SIRS (see pp. 1591 and online chapter: Systemic Inflammatory Response Syndrome).

PROGNOSIS AND OUTCOME

- Prognosis for mild cases is good; infections may resolve spontaneously or with supportive care only.
- Prognosis for septicemic patients is guarded; potential disease complications include dehydration, electrolyte imbalances, sepsis, septic shock, SIRS, and DIC.

PEARLS & CONSIDERATIONS

COMMENTS

Patients fed raw food diets are at increased risk of salmonellosis:

- *Salmonella* isolated from 66%-80% of samples of raw food (e.g., bones and raw food [BARF] diet).
- *Salmonella* isolated from 30%-93% of stool samples from dogs fed these diets (thus, there is an increased risk for human exposure and infection).

PREVENTION

- Avoid feeding raw or undercooked meat diets.
- Isolate infected animals, and practice good hygiene.

CLIENT EDUCATION

- Owners should be informed that this is a zoonotic disease, and humans are very susceptible.
- Avoid eating undercooked meats.

Salmon Poisoning

BASIC INFORMATION

DEFINITION

A febrile rickettsial infection of dogs in the Pacific northwestern United States and Pacific coastal Canada, associated with ingestion of raw fish

SYNONYM

Neorickettsia helminthoeca infection

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs: any age, both sexes affected

RISK FACTORS: Exposure to a fresh brackish stream or beach is commonly elicited in the history.

GEOGRAPHY AND SEASONALITY: Infections are limited to the habitat range of the intermediate snail host *(Oxytrema silicula)* in western British Columbia, Washington, Oregon, northern California, and more sporadically in areas where fish carrying the causative organism, *N. helminthoeca,* migrate or are transported. Dogs have the greatest access to dead fish during spawning seasons (late summer to early winter).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute, severe febrile illness 5-7 days after fish ingestion; often fatal
- A more moderate illness may be seen as late as 14-33 days after exposure, particularly with the Elokomin fluke fever disease variant.

HISTORY, CHIEF COMPLAINT

- Acute onset of anorexia and lethargy associated with fever
- Vomiting and bloody diarrhea common
- Oculonasal discharge occasionally reported

PHYSICAL EXAM FINDINGS

- Fever
- Lymphadenopathy
- Signs of hypovolemic shock (tachycardia, collapse, poor pulse quality)

ETIOLOGY AND PATHOPHYSIOLOGY

- Dogs acquire the causative organism (*N. helminthoeca),* and therefore the disease, from a fluke parasite *(Nanophyetus salmincola)* carried in the kidneys of salmon, and rarely other fish or salamanders.
- Rickettsial infection transmitted when flukes mature in the canine gastrointestinal (GI) tract:
  - Fluke maturation in the GI tract involves release of the rickettsiae, which are taken up into macrophages and disseminate to lymph nodes (especially mesenteric).
  - Replication of the organism occurs in the lymph nodes, and this is where the lesions are most profound (other than the inflammatory response that occurs in the GI mucosa when flukes and rickettsiae elicit an immune response).
- Systemic rickettsial replication results in clinical disease in dogs.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is typically based on compatible clinical signs (fever, hemorrhagic gastroenteritis, lymphadenopathy) in a dog with a history of fish ingestion, finding flukes on a fecal exam, or response to doxycycline therapy.

DIFFERENTIAL DIAGNOSIS

- Parvoviral enteritis
- Ehrlichial infections
- Hemorrhagic gastroenteritis
- Sepsis (e.g., due to foreign body perforation, cholangiohepatitis)
- Pancreatitis
- Neoplasia, especially GI lymphoma

INITIAL DATABASE

- CBC and serum biochemical findings are inconsistent but may include thrombocytopenia, lymphopenia, eosinophilia, hypoalbuminemia, and elevated alkaline phosphatase.
- Operculated fluke eggs are most easily seen on fecal sediment exam but may be seen on direct smear or fecal flotation.

ADVANCED OR CONFIRMATORY TESTING

- Giemsa-stained lymph node aspirates may reveal intracytoplasmic rickettsial bodies.
- Abdominal ultrasound often reveals moderate to marked mesenteric lymph node enlargement.

TREATMENT 

TREATMENT OVERVIEW

Affected patients should be hospitalized and treated with intravenous fluids, supportive care, and parenteral then oral doxycycline. The flukes should also be eliminated via treatment with praziquantel.

ACUTE GENERAL TREATMENT

- Hospitalization is recommended for intravenous fluid support and alleviation of vomiting and diarrhea.
- Mild cases: rickettsial infection can be treated with oral doxycycline (10 mg/kg q 12 h) or tetracycline (22 mg/kg q 8 h) for 7-14 days.
- Severe cases, particularly with vomiting/diarrhea: parenteral doxycycline (5-10 mg/kg IV q 12 h until oral form is tolerated) or ampicillin (20-30 mg/kg IV q 6 h). Oxytetracycline (7 mg/kg IV q 8 h × 3 days) has also been effective.
- Praziquantel (10-30 mg/kg PO or SQ once) is effective for elimination of the fluke.

POSSIBLE COMPLICATIONS

Parenteral oxytetracycline has been rarely associated with acute renal failure.

PROGNOSIS AND OUTCOME 

- Prognosis is fair to good in aggressively managed cases; improvement is usually noted within 2-3 days after treatment initiation but may take up to a week.
- Death is likely within 5-10 days if the disease remains untreated.

PEARLS & CONSIDERATIONS 

COMMENTS

- Salmon poisoning is an important cause of fever, lymphadenopathy, and severe GI signs in dogs in the Pacific northwestern United States and Pacific coastal Canada.
- Clinical signs are similar to hemorrhagic gastroenteritis, but affected dogs are typically febrile.
- Fecal direct and sedimentation exams and treatment with doxycycline are recommended in febrile dogs when possible ingestion of raw fish is noted in disease-endemic regions.

PREVENTION

Restrict canine access to raw fish in the Pacific Northwest.

CLIENT EDUCATION

Early aggressive treatment is required for salmon poisoning, or death is likely.

SUGGESTED READING

Gorham JR, Foreyt WJ: Salmon poisoning disease. In Greene CE, editor: Infectious disease of the dog and cat, ed 3, St Louis, 2006, Saunders Elsevier, p 198.

AUTHOR: POLLY B. PETERSON

EDITOR: DEBRA L. ZORAN

Salivary Gland Disorders

BASIC INFORMATION

DEFINITION

- Sialocele: accumulation of saliva that has leaked from a salivary gland or its duct into subcutaneous or submucosal tissue and consequent tissue reaction to saliva
- Sialadenitis: inflammation of a salivary gland
- Sialadenosis: noninflammatory, nonneoplastic enlargement of a salivary gland
- Necrotizing sialometaplasia: squamous metaplasia of the salivary gland ducts and lobules, with ischemie necrosis of the salivary gland lobules
- Salivary neoplasia: benign or malignant lesion arising from salivary glandular or ductal tissue

SYNONYMS

- Sialocele: salivary mucocele; ranula (sublingual sialocele)
- Necrotizing sialometaplasia: salivary gland necrosis or infarction

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Sialocele: typically dogs between 2 and 4 years old; in fewer than 20 of 4000 dogs
- Sialadenitis: typically older dogs
- Sialadenosis and necrotizing sialometaplasia: dogs of all ages, most often 3-8 years old
- Salivary neoplasia: older dogs (mean-10 years old); prevalence in cats almost twice that in dogs

GENETICS & BREED PREDISPOSITION

- Sialocele: German shepherds, miniature poodles overrepresented
- Sialadenosis and necrotizing sialometaplasia: small dog breeds (especially terriers) predisposed
- Salivary neoplasia: spaniel breeds and poodles predisposed

RISK FACTORS: Sialocele: oral trauma and activity of young dogs; however, experimental duct ligation, duct laceration, rupture of the mandibular salivary gland capsule with damage to glandular tissue, and subcutaneous injection of mucocele fluid have not caused salivary mucoceles in healthy dogs, suggesting a developmental predisposition in some dogs.

ASSOCIATED CONDITIONS & DISORDERS: Necrotizing sialometaplasia: *Spirocerca lupi* infestation (esophageal granulomas), megaesophagus, esophagitis, esophageal diverticulum, giardiasis, autoimmune sialadenitis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Sialocele:
  - Sublingual sialocele (ranula): in sublingual tissue
  - Cervical sialocele: in intermandibular or cervical area; most common
  - Pharyngeal sialocele: in pharyngeal wall
  - Zygomatic sialocele: in orbit
- Salivary neoplasia: carcinoma or adenocarcinoma most common

HISTORY, CHIEF COMPLAINT

- Sialocele:
  - Acute, painful intermandibular swelling: initial stage of cervical salivary mucocele resulting from an inflammatory response; uncommon presentation
  - Swelling in the cranioventral neck region: cervical salivary mucocele at later stages when inflammation has subsided (more common presentation); typically found incidentally by owner; slowly enlarging or intermittently large, fluid-filled,

and usually nonpainful.
    - Ptyalism, blood-tinged saliva secondary to masticatory trauma, poor prehension of food, and reluctance to eat: sublingual salivary mucocele
    - Dyspnea/dysphagia secondary to pharyngeal obstruction: pharyngeal salivary mucocele
    - Periorbital mass and either enophthalmos or exophthalmos: zygomatic salivary mucocele (infrequently reported in dogs)
- Sialadenitis:
    - Painful swelling (dependent on location) along the vertical ear canal, caudal to the mandible, or orbital/retrobulbar area, with exophthalmos
    - Lymphadenopathy, fever
    - Pain associated with palpation of the affected gland
    - Pain associated with mouth opening
    - Dysphagia secondary to pain or enlarged inflamed gland that physically inhibits mouth opening
- Sialadenosis:
    - Regional swelling (dependent on location), exophthalmos, but no apparent pain
    - Retching and gulping elicited by mild excitement and occurring several times a day
    - Weight loss, reluctance to exercise, snorting, lip smacking, nasal discharge, hypersalivation, inappetence, depression
- Necrotizing sialometaplasia:
    - Depression, nausea, anorexia
    - Hypersalivation, persistent swallowing, lip smacking
    - Retching, gagging, regurgitation, chronic vomiting, weight loss
    - Cough, tachypnea, dyspnea, abdominal respiration
    - Painful swelling caudal to the mandible, pain associated with mouth opening
- Salivary neoplasia:
    - Sometimes painful swelling (dependent on location) around the vertical ear canal or caudal to the mandible
    - Exophthalmus from orbital or retrobulbar swelling
    - Pain on palpation of the involved gland
    - Pain associated with mouth opening
    - Dysphagia secondary to pain or neoplastic gland that physically inhibits mouth opening

SALIVARY GLAND DISORDERS Sialoceles in dogs: **A**, Sublingual (right-sided). **B**, Cervical (originating from the right side). **C**, Pharyngeal (left-sided). **D**, Nontransparent, stringy, brownish fluid aspirated from a sialocele.

PHYSICAL EXAM FINDINGS: All: see also History/Chief Complaint, above.

- Sialocele:
  - Fluid-filled, generally painless swelling in the cervical, sublingual, pharyngeal, or periorbital region
  - Patient otherwise normal with no signs of systemic disease
  - Sublingual gland most commonly affected
- Sialadenitis:
  - Pain upon palpation of the gland
  - Pain upon gentle retropulsion of the eye through closed eyelids
  - Systemic signs of inflammation: fever, malaise, inappetence
  - Mucopurulent discharge may be noted at the duct opening in the oral cavity.
  - Soft palate asymmetry from an enlarged, inflamed zygomatic salivary gland
  - Zygomatic and mandibular glands most commonly affected
- Sialadenosis:
  - Usually bilateral salivary gland enlargement
  - Mandibular gland most commonly affected
  - Exophthalmos if zygomatic gland affected
  - Hypersalivation, retching, and gulping but no signs of pain
- Necrotizing sialometaplasia:
  - Enlarged, painful, hard salivary gland
  - Mandibular gland most commonly affected
  - Very sensitive upon palpation of pharyngeal area
  - Dyspnea, cough, reverse sneezing

- Hypersalivation, lip smacking, persistent swallowing, retching, vomiting
- Weight loss

- Salivary neoplasia:
  - Painful swelling in the cervical, periauricular, or periorbital region; distinct mass; rarely any fluid accumulation
  - Pain upon gentle retropulsion of the eye through closed eyelids
  - Occasionally cancer cachexia or signs of other paraneoplastic disorders
  - Parotid and mandibular glands most commonly affected

ETIOLOGY AND PATHOPHYSIOLOGY

- Sialocele:
  - Contrary to a true cyst which is lined by epithelium, a sialocele represents a tissue reaction to extravasation of saliva from a gland/duct complex and has a nonepithelial, nonsecretory lining consisting primarily of fibroblasts and capillaries.
  - Damage to salivary gland or duct associated with orofacial trauma may cause leakage of saliva into adjacent tissues. Generally this leakage is self-limiting and does not lead to mucocele.
  - The defect is most often associated with the portion of the sublingual gland/duct complex caudal to the lingual nerve.
- Sialadenitis:
  - Salivary gland inflammation with enlargement. Sialoliths may be a contributing factor, since they can occur in dogs and are reported commonly in humans with sialadenitis. The associated ductal obstruction can lead to inflammation of the glandular tissue.
- Sialadenosis:
  - Sialadenosis: salivary gland enlargement without cytologic or histologic abnormalities. Excessive saliva production may be associated with increased parasympathetic activity or changes in sympathetic innervation.
  - No evidence of cytologic or histologic abnormalities in affected salivary glands; usually no abnormalities noted upon esophageal endoscopy
- Necrotizing sialometaplasia:
  - Squamous metaplasia of salivary gland ducts and lobules, with ischemic necrosis of the salivary gland lobules
  - Neurogenic pathogenesis suspected to be associated with abnormalities of the vagal nerve
  - Associations with *Spirocerca lupi* infestation, megaesophagus, esophagitis, esophageal diverticulum, giardiasis, autoimmune sialadenitis
- Salivary neoplasia:
  - No cyst or mucocele formation unless there is saliva accumulation secondary to ductal obstruction

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Among other signs, the presence of any swelling in the periorbital, sublingual, intermandibular, subhyoid, parotid, pharyngeal, and cranioventral neck regions; exophthalmos; or being unable or reluctant to open the mouth should prompt suspicion of disease of the salivary gland/duct complex. Fine-needle aspiration for cytologic evaluation is valuable (particularly for sialoceles: saliva-like fluid). Definitive diagnosis for all others requires biopsy and histologic evaluation.

DIFFERENTIAL DIAGNOSIS

- Edema, cyst, seroma, hematoma, abscess
- Trauma, foreign body, sialolith
- Lymphadenitis, neoplasia affecting lymph nodes
- Aural or ocular neoplasia

INITIAL DATABASE

- Sialocele:
  - Fine-needle aspiration and cytologic evaluation: clear or nontransparent, stringy, sometimes blood-tinged, often brownish fluid with a very low cellular content
  - Mucin and amylase analyses of the fluid are not reliable diagnostic procedures.
  - If cervical sialocele appears on ventral midline, place patient in exact dorsal recumbency (awake, sedated, or anesthetized):
    - Sialocele usually shifts to the originating side and is more easily mobile on the originating side.
    - Essential for correct identification of the affected side if surgical intervention is contemplated
- Sialadenitis, sialadenosis, necrotizing sialometaplasia, salivary neoplasia:
  - Fine-needle aspiration of gland and cytologic evaluation (zygomatic salivary gland may require per os aspiration)

- Fine-needle aspiration of regional lymph nodes
- Bacterial culture and sensitivity
- Three-view thoracic radiographs to rule out conditions associated with necrotizing sialometaplasia and thoracic metastasis

ADVANCED OR CONFIRMATORY TESTING

- Regional radiographs or ultrasonography if sialolith is suspected or palpated
- Sialography: radiographic contrast study of a salivary gland/duct complex; most common indication for a sialogram is to determine the location of a salivary gland/duct defect in patients with sialocele.
- CT (see p. 1233), MRI (see p. 1302)
- Incisional biopsy for histopathologic evaluation

TREATMENT

TREATMENT OVERVIEW

Combination of immediate relief through aspiration or incision for some disorders is followed by surgical excision, radiation therapy, or others depending on diagnosis.

ACUTE GENERAL TREATMENT

- Sialocele:
  - Needle drainage of mucocele; not recommended as repeat treatment option owing to rapid recurrence and risk of iatrogenic infection
  - Complete removal of involved salivary gland/duct complex with ligation of remaining duct and drainage of sialocele and surgical site
  - Marsupialization of a sublingual or pharyngeal sialocele (creation of a large window in the mucosa overlying the swelling to allow for intra-oral drainage of saliva) is not as effective as removal of the involved gland/duct complex because granulation tissue may result in closure of the window.
- Sialadenitis, sialadenosis and necrotizing sialometaplasia:
  - Surgical removal of the affected salivary gland produces minimal if any improvement.
  - If needle aspirate yielded mucopurulent fluid, per os or percutaneous drainage to alleviate mucopurulent fluid accumulation and associated pressure causing discomfort:
    - Percutaneous drainage using a closed suction system rarely required
    - Per os drainage following stab incision using a #15 scalpel blade through the soft palate into the affected zygomatic salivary gland (hemostatic forceps can be used to enlarge the stab wound and facilitate drainage)
- Salivary neoplasia:
  - Complete excision of a salivary neoplasm: only if entirely intracapsular, otherwise not recommended
  - Surgical debulking procedure recommended if part of a multimodality treatment plan that involves cytoreduction of the neoplasm
  - Pain management

CHRONIC TREATMENT

- Sialadenitis, sialadenosis, and necrotizing sialometaplasia:
  - Pain management, antibiotics (based on culture and sensitivity of the fluid/tissue aspirate), nonsteroidal antiinflammatory drugs, antiinflammatory doses of glucocorticosteroids, and control of internal parasites have resulted in favorable responses in some cases.
  - Phenobarbital administration (1-2 mg/kg PO q 12 h) has resulted in dramatic improvement in some cases, providing more support for a neurogenic pathogenesis.
- Salivary neoplasia:
  - Radiotherapy
  - Surgical debulking

POSSIBLE COMPLICATIONS

- Injury to the lingual nerve during removal of mandibular/sublingual gland/duct complex (lingual nerve is located dorsal and rostral to the gland/duct complex)
- Recurrence of mucocele due to failure of having completely excised all affected gland(s)
- Seroma/hematoma formation due to failure of having appropriately drained the sialocele and surgical site
- Injury to major neurovascular structures during incisional biopsy procedures

- Ocular trauma associated with the zygomatic salivary gland during drainage of mucopurulent fluid
- Failure to completely excise all affected tissue (any salivary neoplasm)
- Ocular complications of radiotherapy if ipsilateral eye is in the treatment field

RECOMMENDED MONITORING

Surgical site for evidence of seroma/hematoma formation

PROGNOSIS AND OUTCOME

- Sialocele: excellent with complete removal of the gland/duct complex, with appropriate drainage of the sialocele and surgical site
- Sialadenitis: excellent/good, depending on identification of initiating cause and response to treatment
- Sialadenosis: excellent/good with phenobarbital treatment
- Necrotizing sialometaplasia: good/guarded, depending on response to medical treatment (such as phenobarbital)
- Salivary neoplasia: guarded/poor; treatment is generally considered palliative.

PEARLS & CONSIDERATIONS

COMMENTS

- Sialocele:
  - Placement of the patient in exact dorsal recumbency can lateralize cervical sialoceles that otherwise seem to be on the ventral midline, which is essential for knowing which side to approach surgically.
  - Sialoliths are concretions of calcium phosphate or calcium carbonate and may occur with chronic sialocele.
  - The intimate anatomic association of the sublingual and mandibular salivary glands and their ducts requires removal of both structures when a sialocele affects one of them.
  - If left untreated, a sialocele may result in:
    - Physical problems associated with a large cranioventral cervical mass
    - Trauma, ulceration, secondary infection
    - Dysphagia (sublingual sialocele), dyspnea/dysphagia (pharyngeal sialocele), exophthalmos, strabismus, and other ocular complications (zygomatic sialocele)
- Sialadenitis, sialadenosis, and necrotizing sialometaplasia:
  - Be careful to differentiate these conditions from salivary neoplasia, as they can have similar clinical signs.
  - Complete surgical excision of affected salivary gland/duct complexes is virtually impossible, often unhelpful, and usually not necessary.
  - Be mindful of the many neurovascular structures in anatomic areas where drainage of salivary glands is required.
  - It is speculative whether sialadenitis or sialadenosis can progress to necrotizing sialometaplasia.
- Salivary neoplasia:
  - Be careful to differentiate this from sialadenitis, sialadenosis, and necrotizing sialometaplasia, as they can produce similar clinical signs.
  - Complete excision of a salivary neoplasm is unlikely and may increase morbidity; generally lesions are large and invasive at the time of diagnosis.
  - Be mindful of the many neurovascular structures in anatomic areas where salivary gland neoplasms are likely to occur.
  - Salivary neoplasia should be staged according to the TNM system (see p. 692) to permit appropriate prognostication and treatment plan.

TECHNICIAN TIPS

Technicians should be able to distinguish lymph nodes from salivary glands upon neck palpation.

Tularemia

BASIC INFORMATION

DEFINITION

Acute zoonotic bacterial infection caused by fastidious gram-negative aerobic intracellular coccobacilli, *Francisella tularensis* subsp. *tularensis* (type A [more virulent]) or subsp. *holarctica* (type B); uncommon to rare in occurrence

SYNONYMS

Rabbit fever, deerfly fever, *Brucella* or *Pasteurella tularensis*

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Affects > 100 species of wild and domestic mammals, amphibians, arthropods, birds, and humans
- Seroprevalence indicates latent infection is common in dogs and cats in endemic areas.
- Clinical disease occurs occasionally in cats and rarely in dogs.
- Cats often severely affected; dogs more resistant and milder signs; puppies and kittens more susceptible than adults

RISK FACTORS: Exposure to ticks or wild rabbits or rodents; humans at greater risk include veterinarians, farmers, hunters, landscapers, meat handlers, cooks, and laboratory personnel.

CONTAGION & ZOONOSIS: Highly infectious zoonotic disease; the infectious dose for humans is <100 organisms via cutaneous or conjunctival exposure and <10 for inhalation. Transmission occurs through direct contact with infected animals, their tissues or excrement, or contaminated fomites; cat bites or scratches; insect bites (mosquitoes, biting flies, ticks); ingestion of contaminated food (esp. meat) or water; inhalation of aerosolized organisms (bacterial cultures, contaminated plant material).

GEOGRAPHY AND SEASONALITY: Throughout the Northern Hemisphere; occurs in distinct endemic areas, with a few cases in bordering areas; sporadic disease with 100-200 human cases per year in the United States

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Subclinical to mild to fatal disease approximately 2-7 days after exposure
- Cats often present with severe acute disease with nonspecific signs: lethargy, anorexia
- Dogs may present with anorexia, lethargy, weakness, and mucopurulent oculonasal discharge
- Recent contact with rabbits or rabbit carcasses is common.

PHYSICAL EXAM FINDINGS

- Cats: usually severe illness characterized by fever, lymphadenopathy, oral or lingual ulcerations, splenomegaly, hepatomegaly, icterus. Occasionally, milder nonfatal form of disease may present as chronic draining cutaneous lesions.
- Dogs: fever, lymphadenomegaly and oculonasal discharge

ETIOLOGY AND PATHOPHYSIOLOGY

- *F. tularensis* is a highly infectious gram-negative intracellular bacterium found in water and mud.
- Two disease cycles are noted: a terrestrial cycle associated with transmission of type A (subsp. *tularensis)* from infected rabbits, ticks (eastern and central United States), and biting flies (western United States); and an aquatic cycle, associated with transmission of type B (subsp. *holarctica)* from infected aquatic mammals (muskrat, beaver, voles) via contamination of water by carcasses or excrement or mechanical transmission by biting insects.
- Transmission occurs through inoculation (cat or insect bite), ingestion, inhalation, or contact with skin or conjunctiva (able to penetrate intact skin).
- At the site of inoculation, the organism multiplies locally and spreads to local lymph nodes, resulting in regional lymphadenopathy.

- Bacteremia with seeding of the organism to multiple organs throughout the body may follow, particularly in cats and humans.
- *Francisella* is an obligate intercellular organism: it invades and replicates in macrophages, facilitating persistence and systemic dissemination.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Tularemia should be considered in acutely febrile patients with regional or generalized lymphadenopathy, especially in endemic areas and/or if oral ulcerations or cutaneous abscesses are present.

DIFFERENTIAL DIAGNOSIS

- Plague *(Yersinia pestis)*
- Pseudotuberculosis *(Yersinia pseudotuberculosis)*
- Nocardiosis
- Mycobacterial infection
- Pasteurellosis

INITIAL DATABASE

- CBC: panleukopenia or leukocytosis with toxic neutrophils, thrombocytopenia
- May have elevated liver enzymes (alanine aminotransferase [ALT]) and hyperbilirubinemia

ADVANCED OR CONFIRMATORY TESTING

- Serologic test: fourfold increase in titer or single markedly high titer (=1:160 in humans); false positives may occur because of cross-reactivity with *Brucella* and *Yersinia*
- Definitive diagnosis: demonstration of organism by PCR, direct fluorescent antibody, or culture of organism from tissue biopsy or aspirate samples (use caution during diagnostic sampling and specimen handling: organism highly infectious).

TREATMENT

TREATMENT OVERVIEW

- Antimicrobial treatment for eradication of *Francisella* organisms and supportive care for accompanying conditions (dehydration, septic shock)
- Cats must be treated early and intensively; treat presumptively while awaiting test results.
- Canine cases are often self-limiting, requiring only supportive care.
- Wear barrier attire and stringently avoid cutaneous contact with infected animals or splatter/aerosolization of patient blood, tissue, and excrement to prevent transmission of disease to contact humans and other animals.

ACUTE AND CHRONIC TREATMENT

- Supportive therapy, including IV fluid administration (see also Sepsis, p. 1014)
- Specific treatment of choice is aminoglycoside antimicrobial (gentamicin, streptomycin). Nephrotoxic: patients must be well hydrated prior to aminoglycoside administration: IV fluid therapy prior to treatment is advised.
- Alternative agents: fluoroquinolones, tetracyclines, erythromycin, chloramphenicol
- Gentamicin, ciprofloxacin, or doxycycline most commonly used for treating humans
- β-Lactam antibiotics, azithromycin are not effective.
- Clinical relapse in humans reported more commonly after treatment with bacteriostatic antimicrobials (tetracycline, chloramphenicol) than with bactericidal agents
- Gentamicin, 4-8 mg/kg IV, SQ, IM q 8-12 h; or 8-12 mg/kg q 24 h for 7-10 days. Ensure hydration and normal renal function prior to treatment to reduce risk of nephrotoxicity; in animals with chronic kidney disease, decrease dose of aminoglycoside or choose another antibiotic.
- Enrofloxacin, 2.5-5 mg/kg PO, SQ, IV q 12-24 h; if IV, dilute with saline and administer slowly.
- Doxycycline, 5-10 mg/kg PO q 12-24 h; or 5 mg/kg IV q 24 h for minimum of 14 days

DRUG INTERACTIONS

- Aminoglycosides: use with extreme caution with other drugs that are excreted by the kidneys or are potentially nephrotoxic or ototoxic. Diuretics or cephalosporins given concurrently with aminoglycosides may increase toxicity.
- Tetracyclines: do not administer rapidly IV (may cause collapse).
- Fluoroquinolones: may alter metabolism of other drugs, leading to toxicity (e.g., theophylline); avoid >5 mg/kg/d enrofloxacin in cats.

POSSIBLE COMPLICATIONS

- Sepsis (see p. 1014)
- Disseminated intravascular coagulation (DIC; see p. 315)
- Renal failure

RECOMMENDED MONITORING

- Monitor for DIC and other complications of sepsis.
- Monitor serum blood urea nitrogen (BUN) and creatinine, as well as urine sediment, of patients receiving aminoglycosides.

PROGNOSIS AND OUTCOME 

- Rapidly fatal in untreated cats with overt clinical signs
- Self-limiting infection in most dogs
- Rapid resolution of fever follows administration of appropriate antibiotic.

PEARLS & CONSIDERATIONS 

COMMENTS

- May be underreported in dogs because of the mild, self-limiting nature of disease.
- Highly infectious and zoonotic
- CDC Class A pathogen; potential bioterrorism agent
- Tularemia awareness is important for veterinarians to (1) recognize, treat, and prevent disease in animal patients; (2) prevent disease exposure to themselves and other people in contact with infected animals; and (3) recognize potential bioterrorism in unexplained increase in cases.
- Tularemia is a reportable disease in most U.S. states; many states require immediate reporting (within 3 hours). Reporting regulations vary by country, state, and within-state region and may change. Veterinarians should verify infectious-disease reporting regulations for the areas in which they practice.

PREVENTION

- Tick, mosquito and biting fly control
- Limit exposure to rabbits, rodents, and other wild mammals.
- Currently, no licensed vaccine, although great effort to develop human vaccine underway.

TECHNICIAN TIPS

- Tularemia is extremely infectious and readily transmitted from infected animals to humans.
- Strict protective measures should be used in handling animals, their bedding, and all laboratory samples.
- Use of hoses to clean cages of infected animals, or blow dryers or fans in the proximity of the patient, is contraindicated. Resulting aerosols may cause exposure by inhalation and subsequent pneumonic tularemia, the most highly fatal form of the disease in people.

CLIENT EDUCATION

- Multiple reports of transmission to humans from infected cats (cat bite, cat scratch, cutaneous contact) and from pet prairie dogs.
- No recorded transmission from infected dog to humans, but the possibility is not excluded.

1ST EDITION AUTHOR: LISA M. TIEBER NIELSON

Tritrichomonas Infection

BASIC INFORMATION

DEFINITION

Infection of the ileocolic and colonic mucosa with the protozoan parasite, *Tritrichomonas foetus,* causing chronic large-bowel diarrhea in susceptible young cats. The organism is a similar but distinct member of the protozoan family that causes early embryonic death and abortions in cattle.

EPIDEMIOLOGY

RISK FACTORS: The predominant risk factors appear to be age and population density. The infection is most prevalent in kittens and cats < 2 years of age housed in shelters and catteries. In one study of cats in a cat show, nearly 30% of the cats were asymptomatic carriers.

CONTAGION & ZOONOSIS: Zoonotic transmission has not been described.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Chronic large-bowel diarrhea that is refractory to standard antibiotic or antidiarrheal therapy and often progresses over time to liquid, fetid small-bowel diarrhea. Infected cats are often in good flesh, have a normal appetite and activity level, and are feline leukemia virus/feline immunodeficiency virus (FeLV/FIV) negative.

PHYSICAL EXAM FINDINGS: There are no specific physical exam findings. Affected kittens may have a reddened, protruding anal mucosa due to recurrent bouts of diarrhea and straining. Affected adult cats may have a normal physical examination, other than abnormal fecal odor and character.

ETIOLOGY AND PATHOPHYSIOLOGY

- *T. foetus* is a single-cell flagellated protozoan found in the colon of domestic cats.
- No cysts are formed, but the parasite is passed in the feces as a trophozoite.
- Infection occurs by direct fecal-oral transmission of the trophozoites.
- The pathophysiologic mechanism has not been described, but in one case, colonic biopsies revealed severe lymphocytic plasmacytic colitis with multifocal disruption of the surface epithelium.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Suspected in cats from population-dense environments presenting with chronic diarrhea. The confirmatory test of choice is a microscopic fecal exam.

DIFFERENTIAL DIAGNOSIS

- Giardiasis or enteritis due to other protozoan parasites
- Intestinal parasitism
- Idiopathic colitis or inflammatory bowel disease
- Bacterial colitis
- Dietary intolerance or sensitivity
- Antibiotic responsive diarrhea

INITIAL DATABASE

- Microscopic evaluation of fresh fecal preparations for trophozoites is diagnostic:
  - Fecal saline suspension (by mixing a speck of feces with a drop of saline on a microscope slide and covering with coverslip) or fecal smear of fresh feces
  - Directed motility of organisms, which are 10-25 µm long and flagellated

- Differentiation: unlike *Giardia* spp., trophozoites of *T. foetus* have an undulating membrane and demonstrate directed movement across the slide. *Giardia* spp. form cysts (which may also be seen on fecal suspensions, smears, and flotations), but *T. foetus* does not. Motility of *Giardia* is "falling leaf" or movement in place, which helps distinguish it from trichomonads.
- Main problem is that chronic diarrhea may make finding trophozoites difficult; in one study, only 20% sensitivity was reported.

- Minimum database (CBC, panel) is typically within normal limits.
- Fecal flotation to rule out other parasites
- Imaging (radiographs and ultrasound): generally unremarkable

ADVANCED OR CONFIRMATORY TESTING

- PCR to amplify *T. foetus* rDNA in the feces
- Protozoal culture of feces using the *T. foetus* pouch. This method can be especially helpful if chronic diarrhea makes finding trophs more difficult as a result of dilution of numbers; it increases the numbers of organisms so easy identification is possible.

TREATMENT

TREATMENT OVERVIEW

Treatment aims to resolve diarrhea and eradicate infection.

ACUTE AND CHRONIC TREATMENT

- Standard antiprotozoal and antidiarrheal therapies are ineffective for the eradication of *T. foetus* infection and the management of associated chronic diarrhea.
- Oral ronidazole (a nitroimidazole antimicrobial), 30-50 mg/kg PO q 24 h for 2 weeks. This powdered drug is not approved for use in cats and must be compounded to achieve appropriate dose forms. Reports indicate resolution of *T. foetus-associated* diarrhea and eradication of the infection (based on PCR studies). However, adverse effects (e.g., neurotoxicity) are relatively common with use of ronidazole, and it must be stopped immediately if signs of neurotoxicity are observed.

PROGNOSIS AND OUTCOME

- Historically, most cats diagnosed with chronic diarrhea resulting from *T. foetus* infection have had apparent resolution of the diarrhea within 2 years of onset. Chronic *T. foetus* infection following resolution of clinical signs appears to have been common.
- There appears to be an inverse correlation between housing density and the interval to the resolution of *T. foetus-associated* diarrhea.

PEARLS & CONSIDERATIONS

COMMENTS

Consider *T. foetus* as a differential diagnosis in kittens or young cats with chronic small- or large-bowel diarrhea, particularly if they are housed with other cats or have come from a shelter or cattery.

AUTHOR & EDITOR: DEBRA L. ZORAN

1ST EDITION AUTHOR: LAURA SMALLWOOD

Trigeminal Neuritis

BASIC INFORMATION

DEFINITION

An idiopathic, self-limiting inflammatory condition that involves the motor and sensory branches of the trigeminal nerve and (on occasion) the sympathetic innervation to the eye (i.e., Horner's syndrome)

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs most commonly affected; rare in cats

GENETICS & BREED PREDISPOSITION: No sex or breed predilection, although golden retrievers have been reported to be overrepresented.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Bilateral paralysis of the masticatory muscles that primarily affects the mandibular branch of the trigeminal nerve

HISTORY, CHIEF COMPLAINT: Acute or subacute onset of an inability to close the mouth. The dog cannot prehend food, may hypersalivate, and has difficulty drinking water.

PHYSICAL EXAM FINDINGS

- Bilateral paralysis of the masticatory muscles
- Affected dogs are bright and alert and do not appear as though they are in pain. They have no other detectable neurologic abnormalities.
- In some cases, there is decreased facial sensation bilaterally, and Horner's syndrome may be observed.
- Trismus/inability to open the mouth does not occur with trigeminal neuritis.

ETIOLOGY AND PATHOPHYSIOLOGY

- Most common neurologic cause of an inability to close the mouth in the dog
- Etiology is unknown, but extensive bilateral nonsuppurative inflammation, demyelination, and, in some cases, axonal degeneration of all portions of the trigeminal nerve and its ganglion, with no brainstem lesions, have been reported at necropsy.
- Complete recovery is observed in 2-3 weeks (rarely, may take several months), with no drug therapy being reported as useful.
- Facial sensation is usually preserved. Occasionally, Horner's syndrome may be observed, presumably because the postganglionic sympathetic axons course with the ophthalmic branch of the trigeminal nerve.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is based on characteristic clinical signs, absence of other neurologic deficits, and elimination of the possibility of orthopedic (mandibular, temporomandibular joint) disorders. Advanced diagnostic testing is generally reserved for cases showing additional or unusual neurologic deficits, when spontaneous resolution does not occur, or if rabies is possible (quarantine/euthanasia).

DIFFERENTIAL DIAGNOSIS

- Rabies
- Traumatic mandibular injury
- Inflammatory or infectious central nervous system (CNS) disease

INITIAL DATABASE

CBC, serum chemistry profile, urinalysis: usually within normal limits

ADVANCED OR CONFIRMATORY TESTING

- Cerebrospinal fluid (CSF) analysis may be normal or show mild increases in protein concentration. Lymphocytic pleocytosis is rarely observed.
- Electromyography may reveal increased insertional activity and other mild changes.
- CT scan or MRI of the brain: within normal limits
- Trigeminal nerve biopsy: not recommended

TREATMENT

TREATMENT OVERVIEW

Spontaneous resolution usually occurs in 2-3 weeks with no treatment.

ACUTE GENERAL TREATMENT

- Maintenance of hydration and alimentation is critical.
- Percutaneous gastrostomy may be helpful in severe cases (see p. 1270).
- Feeding canned food gruel is most helpful, since tongue function is maintained.

CHRONIC TREATMENT

Signs will typically resolve spontaneously in 2-3 weeks but in some cases will take months to totally normalize.

POSSIBLE COMPLICATIONS

- Dehydration
- Weight loss

RECOMMENDED MONITORING

- Hydration status
- Food intake

PROGNOSIS AND OUTCOME

Excellent for recovery

PEARLS & CONSIDERATIONS

COMMENTS

- If signs do not resolve in the 2-3-week period, other differentials should be considered.
- If sensory deficits are observed, the recovery period may take longer.

CLIENT EDUCATION

- Signs are typically self-limiting and should resolve in 2-3 weeks.
- Suggested feeding protocols

Tricuspid Valve Dysplasia

BASIC INFORMATION

DEFINITION

Congenital cardiac abnormality involving the right atrioventricular (AV) valve (tricuspid valve) and characterized by any or all of the following: thickening of leaflets, foreshortening of chordae tendinae, fusing or underdevelopment of right ventricle (RV) papillary muscles, tethering of particularly the septal leaflet to the underlying ventricular muscle, and redundancy of the parietal leaflet

SYNONYMS

Congenital tricuspid valve malformation, Ebstein anomaly (specific form of tricuspid valve dysplasia [TVD])

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats
- Present at birth; however, affected individuals are identified at any age based on when the heart murmur is detected.
- Either sex

GENETICS & BREED PREDISPOSITION: Identified in several breeds, notably Labrador retrievers

ASSOCIATED CONDITIONS & DISORDERS

- Typically an isolated congenital heart defect
- Atrial septal defect (ASD), patent foramen ovale, mitral valve dysplasia, ventricular septal defect (VSD), pulmonic stenosis (PS), and patent ductus arteriosus have coexisted.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Often no clinical signs are detectable by the owner (incidental discovery of heart murmur on routine physical exam).
- Severe forms of the disease cause exercise intolerance, abdominal distension, dyspnea (secondary to pleural effusion), poor appetite, and weight loss.

PHYSICAL EXAM FINDINGS

- Right-sided systolic heart murmur of tricuspid regurgitation (significantly softer or even inaudible over the left precordium)
- Rarely a soft diastolic murmur of tricuspid stenosis
- Tachycardia possible
- Jugular venous distension and pulsation if severe disease
- Abdominal palpation: hepatomegaly and a peritoneal fluid wave if right-sided congestive heart failure (R-CHF) is present
- Femoral pulses: usually normal; weak with severe disease associated with poor cardiac output
- Lung auscultation: usually normal; muffled lung sounds if pleural effusion
- Mucous membrane color: usually normal; pale with poor cardiac output; cyanotic if concurrent patent foramen ovale or septal defect

ETIOLOGY AND PATHOPHYSIOLOGY

- During embryonic development, tricuspid valve leaflets are almost exclusively derived from ventricular myocardium by a process of undermining the RV inner wall:
  - The inner layer of RV myocardium is undermined from the remainder to form a skirt in which perforations appear in the apical portion.
  - These perforations enlarge until only the papillary muscles remain, and the initially muscular chordae tendinae become fibrous.
  - Abnormalities during this process lead to TVD.

- An autosomal dominant mode of inheritance with reduced penetrance has been found to date only in the Labrador breed:
  - Affected Labrador retrievers that have been studied thus far (from different families) all had the same susceptibility locus identified, suggesting a founder effect.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Physical examination findings are highly suggestive; echocardiography is required for confirmation and delineation of the defect's extent/structure, as well as associated defects.

DIFFERENTIAL DIAGNOSIS

- Tricuspid valve endocardiosis/myxomatous valve disease: older dogs; concurrent more severe myxomatous mitral valve disease/endocardiosis generally is present.
- Tricuspid valve endocarditis: very rare in dogs and cats, associated with systemic illness and fever (can be waxing and waning); focal valve thickening or vegetation

INITIAL DATABASE

- Echocardiogram (see p. 1251):
  - Diagnostic test of choice
  - Two-dimensional (2-D) mode defines degrees of tricuspid valve leaflet thickening, adherence of the septal leaflet to the interventricular septum, redundancy of the parietal leaflet, presence of hyperechoic fibrous tissue at the annulus resulting in stenosis, and right atrial and right ventricular dilation.
  - Doppler echocardiography documents the presence and degree of tricuspid regurgitation and presence/severity of tricuspid stenosis.
  - Concurrent defects can be identified.
- Thoracic radiographs:
  - Normal in mild disease
  - Evidence of right atrial and right ventricular enlargement in moderate to severe disease
  - Enlargement of the caudal vena cava and possible pulmonary hypoperfusion in severe disease
  - Hepatomegaly, peritoneal effusion, and less commonly, pleural effusion can occur in severe cases (such as in R-CHF).
- Electrocardiogram (ECG; see p. 1253):
  - Normal in mild disease
  - May exhibit fragmentation or splintering of the QRS complex, with a normal mean electrical axis
  - Less commonly, classic right axis deviation of the QRS complex as seen with right ventricular dilation
  - P waves may be tall and wide.
  - May exhibit ventricular preexcitation or supraventricular tachycardias associated with accessory pathway conduction (e.g., see online chapter: Wolff-Parkinson-White Syndrome).

ADVANCED OR CONFIRMATORY TESTING

- Generally not required
- Holter monitoring to document intermittent tachyarrhythmias (see p. 1287)

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are to control R-CHF if present, control associated tachyarrhythmias, and consider surgical valve reconstruction in severe cases.

ACUTE GENERAL TREATMENT

- Abdominocentesis (see p. 1193) or abdominal drainage (see p. 1192) for severe peritoneal effusion to relieve abdominal pressure that can inhibit diaphragmatic movement
- Cage rest for severe R-CHF
- Antiarrhythmic treatment for acute control of supraventricular tachyarrhythmias

CHRONIC TREATMENT

- Careful diuretic administration for CHF (furosemide, 1-2 mg/kg PO q 8-12 h; spironolactone, 1-2 mg/kg PO q 12 h)
- Low-dose angiotensin-converting enzyme (ACE) inhibition may be helpful (e.g., enalapril or benazepril, 0.1-0.25 mg/kg PO q 12-24 h)
- Pimobendan, 0.25 mg/kg PO q 12 h in the face of RV myocardial failure (very advanced stages)
- Digoxin, 0.0055 mg/kg PO q 12 h, adjusting based on serum digoxin concentrations, for certain supraventricular tachyarrhythmias; consultation with a cardiologist is recommended
- Exercise restriction
- Nutritional management (see below)

NUTRITION/DIET

- A high-quality, reduced-sodium diet (<90 mg sodium/100 kcal) in the face of congestive heart failure
- Nutritional management of cardiac cachexia (adequate calorie intake for disease state, highly digestible foods [see p. 168])

DRUG INTERACTIONS/CONTRAINDICATIONS

- Be careful about compromising renal perfusion, owing to excessive diuretic administration and poor forward cardiac output from the disease.
- Coadministration of spironolactone and ACE inhibitors can theoretically lead to hyperkalemia, although concurrent furosemide administration generally causes potassium wasting.

POSSIBLE COMPLICATIONS

- Excessive diuresis, causing decreased forward output and weakness
- Electrolyte abnormalities and azotemia secondary to diuresis and renal hypoperfusion
- Hypoalbuminemia secondary to cardiac cachexia and continued peritoneal effusion

RECOMMENDED MONITORING

- Monitor for signs of R-CHF (peritoneal effusion, decreased exercise tolerance, decreasing muscle mass).
- Monitor for tachyarrhythmias (ECG, Holter monitoring if necessary).
- If the animal is receiving a diuretic and other CHF therapy, monitor the serum chemistry profile every 5-7 days after medication adjustments are made and every 3 months thereafter.

PROGNOSIS AND OUTCOME

- Better than is typically found in the literature
- Dogs with mild disease and even many with moderate disease can live a normal lifespan.
- Dogs with severe disease will have shortened lifespans, but some can live several years (5 or more years is possible).

PEARLS & CONSIDERATIONS

COMMENTS

- TVD appears to be inherited as an autosomal dominant trait with reduced penetrance in Labradors, meaning it may be transmitted by the sire or the dam, and the extent to which offspring are affected is individually variable.
- Carefully auscult dogs over the right precordium to detect this disease.
- Prognosis in animals with isolated TVD is better than initially thought, although the lifespan of dogs with severe disease is still shortened.
- Major complications in severe disease include CHF and tachyarrhythmias.
- Concurrent congenital heart defects are not common but, if present, generally worsen the prognosis.

Tremors and Myoclonus

BASIC INFORMATION

DEFINITION

- Tremor: involuntary oscillating contraction of opposing muscle groups: may occur during rest or movement and typically disappears during sleep.
- Myoclonus: single or multiple shocklike contraction of a muscle group: may occur singly or repetitively, regularly or irregularly, and does not stop during sleep.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dependent on underlying cause.

- Dogs: puppies (hypomyelination/dysmyelination, familial myoclonus): young adults (see p. 592); older adults (senile tremors)
- Cats: kittens (hypomyelination)

GENETICS & BREED PREDISPOSITION

Dogs:

- Maltese, West Highland white terriers, other small-breed white or nonwhite dogs (see p. 592)
- Doberman pinscher, English bulldog, Shetland sheepdog, boxer: idiopathic head tremors
- Labrador retriever: idiopathic head tremor, familial myoclonus
- Great Dane, mastiff: orthostatic tremor
- Springer spaniel, Samoyed, chow chow, weimaraner, Lurcher, Bernese mountain dog, dalmatian: hypomyelination/dysmyelination
- Scottish terriers: central axonopathy

Cats:

- Siamese: hypomyelination

RISK FACTORS: Exposure to tremorgenic drugs or toxins

CONTAGION & ZOONOSIS: Dogs: distemper virus (dog-to-dog transmission)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Generalized more common than localized
- Resting tremor
- Action tremor
- Intention tremor

HISTORY, CHIEF COMPLAINT

- Tremor may worsen with exercise and abate with rest or sleep.
- Littermates may be affected:
  - Tremor associated with hypomyelination/dysmyelination typically begins between 12 days and 3 weeks of age. Signs worsen with exercise but often resolve with rest.
- Exposure to tremorgenic toxins
- Insulin therapy for diabetes mellitus, suggesting hypoglycemia
- Recent (preceding weeks/months) history of respiratory disease, ill thrift, or adoption from a shelter, suggesting canine distemper-associated myoclonus
- Recent whelping, suggesting hypocalcemia
- Seizures (must be differentiated from tremor/myoclonus)

- Idiopathic head tremors are episodic and may be confused for focal seizures. They are often precipitated by excitement or particular head positions, and owners may describe a characteristic “yes” or “no” movement of the head and normal consciousness with tremors, in contrast to the tonicclonic or gum-chewing motions of seizures.
- Orthostatic tremor is a fine tremor of the muscles that occurs only while standing and subsides when walking, running, or in recumbency.
- Scottish terriers with central axonopathy develop tremors and ataxia at 10-12 weeks of age.

PHYSICAL AND NEUROLOGIC EXAM FINDINGS

- The presence of tremors or myoclonus may be the only abnormality on the physical or neurologic examination.
- Ataxia, paresis, and proprioceptive deficits may be present, suggesting a central (brain, spinal cord) lesion.
- Seizures, stupor, and coma may be seen concurrently with intoxication or metabolic derangement.
- Ocular tremors and menace deficits often accompany idiopathic tremor syndrome.
- Intention tremor (i.e., tremor precipitated by the onset of voluntary movement, such as responding to a command) if associated with a fine head tremor, dysmetria, and nystagmus, is characteristic of cerebellar disease.
- Pelvic limb tremors in older dogs (senile tremors)

ETIOLOGY AND PATHOPHYSIOLOGY

Primary:

- Idiopathic tremor syndrome: immune-mediated (see p. 592)
- Hypomyelination, dysmyelination: congenital
- Lysosomal storage diseases: congenital
- Cerebellar disease
- Idiopathic head tremors
- Senile tremors

Systemic:

- Intoxication (mycotoxins [see p. 144]. hexachlorophene, heavy metals, organophosphates [see p. 792], metaldehyde [see p. 720], pyrethrins [see p. 958], others)
- Drug administration (fentanyl/droperi-dol, epinephrine, metoclopramide, diphenhydramine, isoproterenol, numerous illicit drugs)
- Metabolic (hypocalcemia, hypoglycemia, hepatic or uremic encephalopathy, hyperthyroidism)
- Infectious (canine distemper)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A presumptive diagnosis is often made based on the signalment, history, and clinical findings.

DIFFERENTIAL DIAGNOSIS

- Shivering
- Tetany
- Weakness
- Seizure
- Specific causes according to etiology

INITIAL DATABASE

- Complete physical and neurologic examination
- CBC, serum biochemistry, and urinalysis to assess for metabolic etiologies
- Serum T4 (hyperthyroidism in cats)

ADVANCED OR CONFIRMATORY TESTING

Cerebrospinal fluid (CSF) analysis: may be normal or reveal increased numbers of leukocytes (usually lymphocytes) with increased levels of protein, reflecting a nonsuppurative meningoencephalitis

TREATMENT

TREATMENT OVERVIEW

Identify and treat the underlying cause of tremors.

ACUTE GENERAL TREATMENT

- General and/or specific treatment for intoxication
- Discontinue drug therapy if suspected to be causing tremors.
- Correct metabolic and electrolyte abnormalities.
- Sterile inflammatory tremor syndromes often respond to corticosteroid therapy.
- Orthostatic tremor usually improves with phenobarbital or gabapentin administration.

CHRONIC TREATMENT

- Long-term corticosteroid therapy is often necessary for inflammatory tremor syndromes.
- Supportive care aimed at keeping animals safe and ensuring adequate caloric and water intake.

POSSIBLE COMPLICATIONS

Prolonged tremors may result in hyperthermia, hypoglycemia, dehydration, and anorexia.

RECOMMENDED MONITORING

Follow-up exam and serial diagnostic studies as directed by the animal's clinical progression

PROGNOSIS AND OUTCOME

- Tremors associated with idiopathic tremor syndrome usually resolve within days of the initiation of corticosteroid therapy:
  - Treatment should be continued for 2-3 months.
  - Relapses may occur.
- Male springer spaniels with hypomyelination are nonambulatory and generally do not recover.
- Female springer spaniels and other breeds with hypomyelination/dysmyelination usually recover completely between 2 and 12 months of age.
- Idiopathic head tremors may improve and become less frequent over time and rarely cause any clinical dysfunction.
- Senile tremors also generally do not interfere with normal function.
- Central axonopathy in Scottish terriers is progressive and associated with a poor prognosis.
- Lysosomal storage diseases are usually fatal.
- Toxin and drug-induced tremors resolve if the animal survives the initial event.

PEARLS & CONSIDERATIONS

CLIENT EDUCATION

- Owners should be warned that excitement and exercise often precipitate or worsen tremors.
- Many tremor syndromes have a known or suspected inherited basis, and these animals should not be bred.

AUTHOR: GREG KILBURN

EDITOR: ETIENNE CÔTÉ

Transmissible Venereal Tumor

BASIC INFORMATION

DEFINITION

A contagious, neoplastic disease transmitted by transplantation of viable tumor cells during coitus

SYNONYMS

Canine condyloma, contagious lymphoma, contagious venereal tumor, infectious sarcoma, Sticker's sarcoma, transmissible venereal sarcoma, venereal granuloma

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Species: canids—dogs, foxes, coyotes, jackals
- Age: mostly young, sexually active animals; average age 4-5 years
- Sex: females > males

GENETICS & BREED PREDISPOSITION

- Higher prevalence in mixed-breed dogs

RISK FACTORS

- More commonly occurs in free-roaming sexually active dogs
- Grows more rapidly in neonatal or immunosuppressed dogs

CONTAGION & ZOONOSIS

- By definition, transmissible venereal tumor (TVT) is contagious among members of the family Canidae. It has not been identified as a zoonotic disease, although personal protection apparel (exam gloves, etc.) is recommended when examining and treating TVT lesions.

GEOGRAPHY AND SEASONALITY

- Worldwide distribution
- Greatest prevalence in tropical and subtropical urban environments

ASSOCIATED CONDITIONS & DISORDERS

- Urinary tract infections (UTIs; due to presence of TVT in the vestibulovagi-nal junction of females) and phimosis (males; inability to extrude the penis from the prepuce). Both conditions interfere with voiding of urine.
- Tumors are easily traumatized and ulcerated; secondary bacterial infection is a common sequela.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Initial persistent or intermittent bloody genital discharge (often foul smelling), constant licking, genital malformation, or swelling
- Eventually, masses can be seen protruding either from vulva or penis.
- Clinical signs of TVT typically last 40-100 days but may last longer depending on the tumor size and location, immune status of the animal, and occurrence of secondary bacterial infections.

PHYSICAL EXAM FINDINGS

- Nodular lesions in the external genitalia

- Solitary or multiple masses progressing to cauliflower-like, papillary, multilobulated, or pedunculated masses
- Appearance is typically gray or pinkish gray.
- Texture is firm but friable; masses bleed easily when manipulated, resulting in genital bleeding in both sexes.

Definitive diagnosis is by histologic classification of a biopsy specimen (after formalin fixation and staining with hematoxylin and eosin) and immunochemistry testing to determine degree of malignancy.

TREATMENT

TREATMENT OVERVIEW

The goal of treatment is elimination of the tumor. Spontaneous regression occurs in experimental and clinical cases.

ACUTE GENERAL TREATMENT

- The rationale for surgical removal of the tumor is to induce an immune response as well as mechanically remove the mass. A small TVT may be surgically excised without relapse, but tumor regrowth frequently occurs over a very short period of time following excision of large tumors (>2 cm).
- Chemotherapy with vincristine at 0.025 mg/kg IV (highly corrosive if extravascular) once weekly for 6 weeks until complete tumor regression is the treatment of choice for metastatic or multifocal TVT.
- Radiation therapy is effective (100% cure with a single radiation dose) when appropriate facilities are available.

CHRONIC TREATMENT

Electrochemotherapy with bleomycin has been tried for vincristine-resistant TVT.

BEHAVIOR/EXERCISE

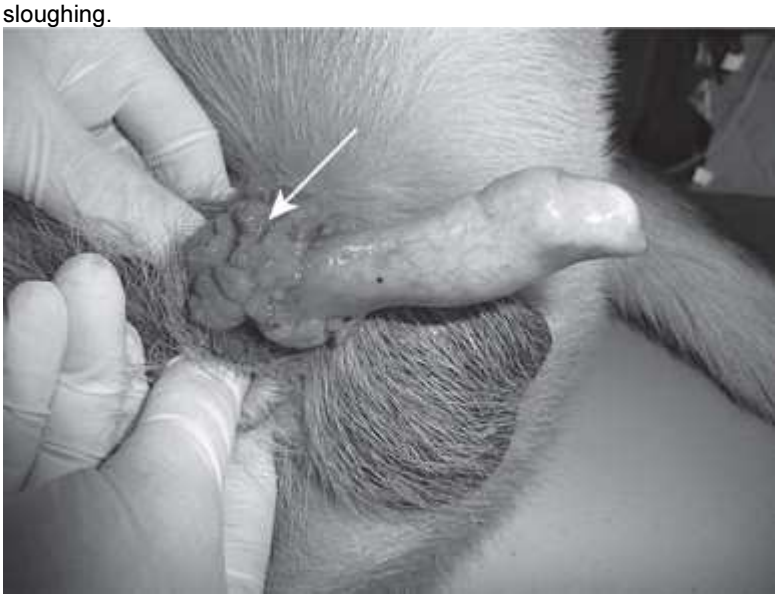
- Breeding should be avoided when TVT is present (contagion risk).
- Erection from excitement with preputial extrusion of the penis with a TVT tumor may result in paraphimosis.

DRUG INTERACTIONS

Severe bronchospasm has been reported in humans when vinca alkaloids are used in combination with mitomycin C.

POSSIBLE COMPLICATIONS

- Extravasation injuries associated with perivascular injection of vincristine can range from irritation to necrosis and tissue sloughing.



TRANSMISSIBLE VENEREAL TUMOR Transmissible venereal tumor *(arrow)* surrounding the bulbus glandis of an intact male dog. Prepuce was difficult to retract over the penis owing to size of tumor relative to size of preputial opening.

- Combined chemotherapy with vincristine presents more side effects (vomiting, diarrhea, and neutropenia) than vincristine alone.

RECOMMENDED MONITORING

- Monitor for efficacy (tumor reduction).
- Monitor for toxicosis, using peripheral neuropathic clinical signs, CBCs with platelets, and liver tests before, during, and after treatment.

PROGNOSIS AND OUTCOME 

Despite the location or pattern of metastasis, the prognosis for TVT is excellent with recommended therapy.

PEARLS & CONSIDERATIONS 

COMMENTS

With any kind of vaginal or preputial bleeding:

- Cytologic examination for TVT cells
- Visual examination of clitoral fossa and preputial fornix for gross TVT lesions

PREVENTION

Pet dogs should avoid contact with stray dogs.

CLIENT EDUCATION

In areas were TVT is endemic, pet dogs should be confined and spayed or neutered to reduce the risk of disease transmission.

AUTHOR: ROSA MARÍA PÁRAMO RAMIREZ

EDITOR: MICHELLE A. KUTZLER

Transitional Cell Carcinoma

BASIC INFORMATION

DEFINITION

Neoplasms arising in the bladder parenchyma of epithelial origin; relatively common in dogs but rare in cats

SYNONYM

TCC

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: typically, older adults (median age 11 years). Females appear at higher risk than males.
- Cats: rarely affects older adults, males at increased risk

GENETICS & BREED PREDISPOSITION: Scottish terriers (up to 20-fold increased risk), Shetland sheepdogs, West Highland white terriers, wirehaired fox terriers, Airedales, beagles, and collies have higher incidence.

RISK FACTORS

- Dogs: female predominance. Exposure to herbicides and insecticides associated with an increased risk; worsened in the presence of obesity, possibly due to accumulation of “inert ingredients.” Spot-on flea products do not appear to increase risk. Cyclophosphamide administration may increase risk.
- Cats: possibly associated with chronic urinary tract infection (UTI). Older cats at greatest risk.

ASSOCIATED CONDITIONS & DISORDERS

- Bacterial cystitis
- Hypertrophic osteopathy
- Urethral obstruction
- Bladder atonia/hypotonia

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Most common form is invasive cancer into muscularis, most often in trigone region
- Early form of superficial cancer may be identified that may be more responsive to therapy.

HISTORY, CHIEF COMPLAINT

- Pollakiuria (common)
- Hematuria (common)
- Stranguria (common)
- Tenesmus (occasional)
- Abdominal pain (occasional)
- Abdominal distension (occasional)
- Lameness and joint thickening (rare; associated with hypertrophic osteopathy)

PHYSICAL EXAM FINDINGS

- Abdominal tenderness +/−
- Caudal abdominal mass +/−
- Urethral mass on rectal exam +/−
- Distended urinary bladder +/−

- Abdominal distension with fluid wave if bladder ruptured (rare)

ETIOLOGY AND PATHOPHYSIOLOGY

- Bladder mass most commonly occurs in trigone region.
- Urethral or prostate involvement is common, often leading to obstruction.
- Lymph node metastasis present in approximately 15% of cases.
- Distant metastasis common (49% at death)
- Metastatic sites include lymph node, lung, liver, kidney, spleen, uterus, gastrointestinal (GI) tract, bone, muscle, cystocentesis needle tracts.
- Secondary bacterial urinary infection common

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Middle-aged to older animals with signs of recurrent UTI should be screened for bladder masses, and dogs of at-risk breeds —particularly Scottish terriers— should be screened early. Diagnosis should be made as early as possible to achieve the best outcome.

DIFFERENTIAL DIAGNOSIS

- Pollakiuria, stranguria, hematuria:
  - UTI
  - Urolithiasis
  - Feline lower urinary tract disease/interstitial cystitis
  - Other bladder tumor such as botryoid rhabdomyosarcoma (in young, large-breed dogs) or leiomyosarcoma
- Abdominal distension/tenderness or abdominal mass:
  - Mass in spleen, mesenteric lymph node, or retroperitoneal space
  - Ruptured splenic or hepatic mass with hemoperitoneum
  - Abdominal trauma or coagulopathy with peritoneal or retroperitoneal bleeding
  - Rectal mass
  - Prostatic abscess, cyst, or neoplasia
  - Pyelonephritis
  - Hydronephrosis or hydroureter
- Radiographic:
  - Other bladder neoplasm or radiolucent urolithiasis
  - Ruptured splenic, renal, or hepatic mass with hemoperitoneum
  - Traumatic bladder rupture
- Ultrasonographic :
  - Papillary cystitis
  - Leiomyosarcoma
  - Botryoid rhabdomyosarcoma
  - Lymphoma (rare)
  - Other rare carcinomas or sarcomas
- Urinalysis:
  - UTI
  - Urolithiasis
  - Other bladder tumor
  - Idiopathic renal hematuria

INITIAL DATABASE

- CBC, chemistry profile: no specific findings supportive of TCC. Azotemia, hyperkalemia may occur with urethral or ureteral obstruction.
- Urinalysis: proteinuria and hematuria are most common. May be complicated by secondary bacterial UTI with pyuria, bacteruria. Cystocentesis has been associated with needle-tract neoplastic cell implantation; recommend catheterization or free-catch for urine collection.
- Veterinary bladder tumor antigen test (VBTA): approximately 85% sensitive for TCC but only 45% specific in the presence of other urinary tract disease. As such, it is a good screening test but does not confirm the presence of TCC.
- Abdominal radiographs: bladder mass is possible to visualize, but this is unusual. Bladder distension may be seen, and with rupture, possible peritoneal or retroperitoneal fluid may be present.

- Thoracic radiographs: metastasis may be present. Pulmonary lesions my be nodular interstitial, unstructured interstitial, cavitated, or alveolar in appearance; bone lesions possible.
- Abdominal ultrasound: bladder mass or wall thickening with possible metastasis to abdominal organs or nodes; prostate or urethra are commonly involved.

ADVANCED OR CONFIRMATORY TESTING

- Cytologic analysis or biopsy from guided diagnostic catheterization or biopsy from cystoscopy necessary for diagnosis
- Contrast cystography/ureterography may be used to delineate ureteral involvement and impending urethral obstruction.
- VBTA does not confirm, only suggests, TCC.

TREATMENT

TREATMENT OVERVIEW

The therapeutic goal is to alleviate clinical signs, control the primary mass, and prevent or delay metastasis

ACUTE GENERAL TREATMENT

- Surgically manage urinary bladder rupture if present (see p. 1135)
- Surgically remove lesions at bladder apex if operable. Surgery may be of greater benefit in cats.
- Address complicating bacterial UTI with antimicrobials (see p. 276).
- Begin chemotherapy to palliate clinical signs and address metastatic disease: See p.677 for conversion table of body weight to body surface area.
  - Piroxicam, 0.3 mg/kg PO once daily if renal function is normal. Can be used alone or in combination with:
  - Mitoxantrone, 5 mg/m^2 IV q 21 days for 4 cycles; *or*
  - Doxorubicin, 30 mg/m^2 IV q 21 days for 4 cycles (dogs); or 1 mg/kg IV q 21 days (cats and small dogs)
  - CBC and blood urea nitrogen (BUN)/ creatinine/urine specific gravity should be checked prior to each dose, and CBC checked 1 week later.
  - Cisplatin cannot be recommended in combination with piroxicam due to nephrotoxicity.
  - Intravesicular therapy of BCG or thiotepa used in humans has been poorly effective in veterinary patients.
- If bladder distended initially, maintain urinary drainage to avoid detrusor hypotonia (see pp. 104 and 1131)
- Address electrolyte imbalances if present secondary to obstruction (see pp. 1131 and 556)

CHRONIC TREATMENT

- Continue piroxicam indefinitely.
- May repeat mitoxantrone after first four doses if clinical signs recur.
- Cumulative doxorubicin doses greater than 180-240 mg/m^2 are associated with increased risk of cardiotoxicity.
- Urinary diversion surgery or intraluminal stenting may prolong life if urethral obstruction is imminent.

NUTRITION/DIET

Feeding vegetables may help prevent bladder transitional cell carcinoma.

DRUG INTERACTIONS

- Avoid combining drugs with similar toxicity profiles, such as cisplatin and piroxicam.
- Piroxicam should not be given in combination with corticosteroids or other nonsteroidal antiinflammatory drugs.

POSSIBLE COMPLICATIONS

- Neutropenia, thrombocytopenia, sepsis, and renal injury secondary to chemotherapy
- GI ulceration or nephrotoxicity secondary to piroxicam
- Urethral or ureteral obstruction secondary to tumor growth

RECOMMENDED MONITORING

- Monitor CBC prior to every chemotherapy treatment and 7-10 days later.
- Monitor BUN, creatinine, and urine specific gravity for renal function every 3-12 weeks.
- Monitor frequently for UTI.

PROGNOSIS AND OUTCOME

This disease is locally aggressive with a significant metastatic potential.

Dogs:

- Median reported survival treated with piroxicam alone is approximately 6-7 months.
- Median reported survival treated with piroxicam and mitoxantrone is approximately 12 months, with or without surgery.
- Median reported survival treated with surgery alone is approximately 3.5 months.

Cats:

- Median reported survival approximately 8.5 months
- Surgical resection may improve prognosis significantly in cats.

PEARLS & CONSIDERATIONS

COMMENTS

- Repeated urinary tract signs or infection, especially in older animals, warrants further screening for TCC
- Early detection is critical for best response to treatment.
- VBTA test may allow early detection in geriatric at-risk breeds of dogs with lower urinary tract signs.
- Definitive diagnosis necessary for prognosis and therapeutic decisions; requires cytologic examination or biopsy.
- Bacterial UTI is a frequent complication.

PREVENTION

see Nutrition/Diet

TECHNICIAN TIPS

Because cystocentesis can allow peritoneal seeding and accelerate metastasis, it should be avoided in older dogs (especially in predisposed breeds) with signs of dysuria prior to screening for TCC by imaging or VBTA.

CLIENT EDUCATION

- Signs are subtle and nonspecific, so advanced diagnostics and imaging are most useful early.
- Urethral obstruction is often the life-limiting complication, and urinary diversion may be beneficial.

AUTHOR: JEFFREY BRYAN

EDITOR: LEAH A. COHN

Transfusion Reactions

BASIC INFORMATION

DEFINITION

Adverse effects from infusion of blood products are well recognized. They are classified as immunologic or nonimmunologic and further categorized as acute (minutes to 48 hours later) or delayed (days to weeks later).

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats of any age and either sex

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute immunologic:
  - Acute hemolytic transfusion reaction (AHTR): antibodies to donor red blood cells (RBCs) are present in recipient plasma (incompatible blood type).
  - Nonhemolytic febrile reaction: recipient antibodies against donor leukocyte or protein antigens
  - Anaphylaxis: recipient hypersensitivity/immune reaction to donor leukocyte, major histocompatibility complex, or protein antigens
- Acute nonimmunologic:
  - In vitro hemolysis: improper handling of blood (freezing, overheating, mixing with nonisotonic solutions, inappropriate infusion devices)
  - Volume overload: excessively rapid or large-volume infusion, particularly in cats, puppies, and small dogs or in those with compromised cardiac or renal function.
  - Contaminated blood: lack of aseptic collection or storage, long transfusion times (>4 hours), and subclinical infection of donor
  - Citrate intoxication: rapid large-volume infusions of whole blood or plasma in small animals or those with liver failure
  - Hyperammonemia: high ammonia levels in stored blood in animals with hepatic failure
- Delayed immunologic:
  - Development of antibody that shortens lifespan of transfused RBCs
  - Occurs within 3 days to several weeks
- Delayed nonimmunologic:
  - Transmission of infectious diseases from donors

HISTORY, CHIEF COMPLAINT: Current (acute reaction) or recent (delayed reaction) transfusion of whole blood, packed RBCs, or platelet-rich plasma

PHYSICAL EXAM FINDINGS: In most instances, the first manifestations of a transfusion reaction include only one or two of the physical signs listed for each. If unnoticed, however, these signs may quickly worsen, with additional signs occurring as the reaction worsens.

- Acute immunologic:
  - RBC: vomiting, fever, anaphylaxis (lethargy, urticaria, pruritus, tachypnea/dyspnea), hemolysis (pallor, tachycardia, weakness), tremors, salivation hypotension (weak pulse), pigmenturia, ventricular arrhythmias, apnea
  - Platelet/leukocyte: fever, vomiting
  - Plasma proteins: urticaria, edema, pruritus, erythema
- Acute nonimmunologic:
  - Contamination: sepsis (fever, weak pulse, tachycardia), hemoglobinuria, vomiting
  - Disseminated intravascular coagulation possible (hemorrhage, thrombosis; see p. 315)
  - Improper collection, in vitro hemolysis: vomiting
  - Volume overload: dyspnea, tachypnea, tachycardia, new-onset cough (dry, soft at first), vomiting (rarely)
  - Citrate toxicity: uncommon; vomiting, tremors, tetany
- Delayed immunologic:
  - RBC: recurrence of clinical signs of anemia sooner than expected (shortened RBC survival)
  - Platelet: melena, epistaxis, ecchymoses (thrombocytopenia: post-transfusion purpura)
- Delayed nonimmunologic:

- Disease transmission; signs reflect pathogen transmitted.

ETIOLOGY AND PATHOPHYSIOLOGY

- Immunologic: specific cellular or protein fraction in blood transfused to sensitized recipient:
  - Acute: animals receiving incompatible blood (A/B incompatibility in cats; or rarely Mik) or dogs sensitized by prior transfusion, usually dog erythrocyte antigen (DEA) 1.1 incompatibility (or rarely other antigens)
  - Delayed: previously transfused animals with antibodies to minor RBC antigens
- Nonimmunologic: results from contamination, improper handling, or cytokine activation in the blood product

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Clinical signs of transfusion reaction usually appear during or immediately after the transfusion. Signs that develop after several days (delayed reaction) may need to be differentiated from recurrence of the disorder that warranted transfusion originally (e.g., hemolysis) and from complications of the disease or its treatment (e.g., sepsis). Additional testing, if necessary, is selected based on the type and severity of the reaction.

DIFFERENTIAL DIAGNOSIS

- Hemolysis: rule out underlying hemolytic diseases (see p. 71).
- Fever: rule out acute hemolytic transfusion reaction, sepsis, underlying inflammatory diseases.

INITIAL DATABASE

- CBC, serum biochemistry panel, urinalysis:
  - Hemoglobinemia (after centrifuging, serum is pink; repeat blood sampling to rule out hemolysis from blood collection).
  - Bilirubinemia (serum often icteric if bilirubin > 1 mg/dL [>17 mmol/L])
  - Leukocytosis
- Urinalysis: hemoglobinuria, bilirubinuria
- Hypocalcemia (citrate toxicity); only ionized calcium is reduced.
- Blood pressure (BP) measurement (see p. 1209): rule out hypotension.
- Thoracic radiographs: if volume overload is suspected (rule out pulmonary edema)

ADVANCED OR CONFIRMATORY TESTING

- Acute hemolytic transfusion reaction: centrifuge recipient blood to check for evidence of hemolysis; repeat major cross match (see p. 1234); Coombs' test on recipient.
- Inspect transfused unit for dark discoloration, clots, air bubbles, or hemolysis to detect contaminated blood; Gram stain and culture (aerobic/ anaerobic).
- Examine blood from bag or administration set for in vitro hemolysis.

TREATMENT

TREATMENT OVERVIEW

Treatment is tailored to the type and severity of the reaction. Often, slowing or stopping the transfusion is sufficient, while in other cases pharmacologic therapy may be necessary (see reaction types below). Identification and correction of the cause of reaction are indicated (when possible), and supportive care should be provided while clinical signs resolve.

ACUTE GENERAL TREATMENT

- Acute hemolytic transfusion reaction: stop the transfusion and treat for shock (IV fluids, vasopressor agents if persistent hypotension, ± glucocorticoids)
- Urticaria: antihistamines (e.g., diphenhydramine, 2 mg/kg IM) and/or short-acting corticosteroids (e.g., dexamethasone sodium phosphate, 0.2 mg/ kg slow IV); temporarily halt transfusion until signs resolve.
- Nonhemolytic febrile reaction without cardiovascular or respiratory compromise (temperature rise of 2○F [1○C]): slow rate of transfusion. Discontinue if fever persists or worsens.
- Volume overload (pulmonary edema): halt transfusion and give IV diuretics (furosemide, 2 mg/kg IV) and oxygen.

- Sepsis: halt transfusion and obtain samples for culture; IV antibiotics; IV fluids.

POSSIBLE COMPLICATIONS

- Acute immunologic hemolytic reactions and reactions to infected blood may be severe and require a rapid and intensive response. Most other transfusion reactions, when detected early, respond well to conservative management.
- Acute hemolytic transfusion reaction/ contaminated blood: arterial hypotension and shock, renal failure, disseminated intravascular coagulation
- Volume overload: hypoxemia

RECOMMENDED MONITORING

- Monitor mentation, temperature, and vital signs throughout and following the transfusion.
- Monitor hematocrit/total protein before and after the transfusion.

BEHAVIOR/EXERCISE

Limit activity during the transfusion.

PROGNOSIS AND OUTCOME

- Stable animals: good with early recognition and intervention
- Severely ill: guarded

PEARLS & CONSIDERATIONS

COMMENTS

- Pretreating with antihistamines or corticosteroids will not prevent immunologic hemolytic reactions.
- Severe reactions usually occur during or shortly after transfusion.
- Most acute hemolytic transfusion reactions can be prevented by using DEA 1.1-negative canine blood donors (in nontyped recipients); and in cats, using matched blood donors.
- With the recent discovery of new RBC antigens (Mik in cats; Dal in dogs), it has been suggested that routine cross-matching should be considered in all cats and all previously transfused dogs requiring blood products.
- Cross-matching detects antibodies against donor RBCs. Nonimmune reactions or reactions due to antibodies attacking white blood cells (WBCs), platelets, or proteins will not be detected by cross-matching.

TECHNICIAN TIPS

- Inspect all units prior to infusion; discard if discolored. Monitor patients closely during the transfusion. Transfusion administration checklists can assist staff in patient monitoring and early recognition of potential reactions.
- All technical staff should be familiar with signs of transfusion reactions.

PREVENTION

- Type all donors, screen for infectious diseases, and use a sterile collection technique.
- Type all recipients if possible.
- Cross-match all cats and dogs that have had previous transfusions.
- Never use outdated or hemolyzed products.
- Consider the animal's underlying diseases when choosing component and administration rate.
- Follow strict guidelines for storage, handling, and administration of blood products.
- Monitor transfusions carefully.

Tracheobronchitis (Infectious): Dogs

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

An acute, highly contagious, generally benign respiratory disease complex of dogs. Common manifestations include cough, oculonasal discharge, and occasionally bronchopneumonia. For more information regarding cats, see p. 1431.

SYNONYMS

Kennel cough, canine respiratory disease complex, canine croup

EPIDEMIOLOGY

SPECIES, AGE, SEX: Common in dogs: puppies more prone to pneumonia. Often infectious tracheobronchitis is a multi-etiology syndrome that can involve viruses, bacteria, *Mycoplasma* spp, and other infectious agents. *Bordetella* spp (see p. 144) can infect multiple species, including felines, wildlife, and rodents.

RISK FACTORS: Exposure to other dogs; affected animals usually have a history of boarding, grooming, or being in environments with many other dogs (e.g., dog parks, veterinary hospitals).

CONTAGION & ZOONOSIS

- Highly contagious among canines
- *B. bronchiseptica* zoonosis can occur, mainly in immunocompromised humans

ASSOCIATED CONDITIONS & DISORDERS: Pneumonia (rare)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Most dogs develop a typical mild "classic" clinical disease characterized by coughing, even though the dog is otherwise normal.
- Unvaccinated puppies or adult dogs may develop a more severe disease with bronchopneumonia and rhinitis.

HISTORY, CHIEF COMPLAINT: Classic:

- Sudden-onset deep, hacking cough often followed by terminal retch (may be misinterpreted by client as vomiting).
- Owners often believe the dog has "something stuck in its throat."
- Appetite and demeanor are not affected, although excessive coughing may cause mild lethargy.

Bronchopneumonia: see p. 887

PHYSICAL EXAM FINDINGS

- Physical exam is often unremarkable in dogs with classic disease, other than an easily inducible cough on tracheal palpation and mild nasal or ocular discharge.
- Bronchopneumonia: fever, depression, tachypnea, dyspnea, cyanosis. Wheezes, crackles, rales on lung auscultation may be present.

ETIOLOGY AND PATHOPHYSIOLOGY

Infectious causative agents include *B. bronchiseptica,* canine parainfluenza virus (CPIV), canine influenza, and canine adenovirus 2 (CAV-2). Other agents that are implicated include canine herpesvirus (CHV) and occasionally canine distemper virus (CDV). Clinical disease is often the result of multiagent infections, and the most frequent multiagent infection includes *B. bronchiseptica* with CPIV or canine adenovirus (CAV, CAV-2):

- CPIV damages the respiratory epithelium of the upper respiratory tract and trachea. Alone, it primarily causes a dry cough and serous nasal discharge. Incubation period is 3-10 days.
- Canine influenza is an emerging viral disease that is highly contagious and typically found in kennels and settings where dogs are in close contact. Since this is an emerging disease with no preexposure, all ages are susceptible.
- CAV-2 replicates and damages epithelial cells in the nasopharynx, tonsils, trachea, and unciliated bronchial epithelium. Incubation period is 3-6 days.
- *B. bronchiseptica* is a gram-negative coccobacillus that replicates on respiratory ciliary epithelial cells and produces toxins that can paralyze cilia and impair local phagocytosis, allowing colonization by opportunistic pathogens. Incubation period is approximately 6 days.
- *Mycoplasma* spp. infections (see online chapter: Mycoplasma/Ureaplasma Infections) can develop secondarily and cause bronchopneumonia.
- Transmission of all three primary pathogens is via airborne transmission or oronasal contact.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Clinical diagnosis is often made based on historical and physical signs, vaccination history, and history of recent exposure to other dogs. However, in more complicated cases, additional tests including blood work and imaging may be indicated to determine the extent and severity of disease.

DIFFERENTIAL DIAGNOSIS

- Pulmonary signs:
  - Fungal pneumonia
  - Aspiration pneumonia
  - Pulmonary neoplasia
  - Pulmonary thromboembolism
  - Lung lobe torsion
- Cough:
  - Collapsing trachea
  - Chronic bronchitis
  - Heartworm disease
  - Nasopharyngeal foreign body
  - *Oslerus osleri* infection
  - Pulmonary or mediastinal neoplasia
  - Pulmonary edema
  - Left atrial enlargement due to chronic left heart disease

INITIAL DATABASE

- For dogs with a simple cough, diagnosis is typically made according to history, physical examination, and possibly response to therapy.
- For dogs with suspected pulmonary involvement, routine blood and urine tests, thoracic radiographs, and transtracheal wash (see p. 1350) are indicated.
- CBC, serum biochemistry panel, and urinalysis are often unremarkable, especially in dogs with simple infection. CBC may show an inflammatory leukogram with left shift in complicated bronchopneumonia.
- Thoracic radiographs are usually normal in dogs with cough only. Puppies and adults with pulmonary signs may show diffuse or focal bronchial or alveolar pattern ± evidence of hyperinflation or atelectasis, or complete lobar consolidation.
- Transtracheal wash cytologic examination is characterized by excessive neutrophils and may demonstrate bacterial colonization.

ADVANCED OR CONFIRMATORY TESTING

Bacterial or *Mycoplasma* spp. isolation, or virus isolation can be performed on nasopharyngeal or tracheal swabs or on transtracheal wash fluid, although such testing is virtually never necessary or helpful in formulating a treatment plan.

TREATMENT

TREATMENT OVERVIEW

- In simple clinical disease, the goal of treatment is cough suppression and prevention of secondary infection; the cough resolves spontaneously, generally in 7-10 days.
- In bronchopneumonia, the goals are to identify and eradicate bacterial agents involved, improve air movement, and maintain respiratory epithelial health.

ACUTE GENERAL TREATMENT

- In patients with simple clinical disease, antibiotic treatment is often not necessary; most dogs with a healthy immune system can recover from the disease spontaneously.
- Antibiotic selection in bronchopneumonia should be based on culture and sensitivity (C&S) results.
- Empirical antibiotics may be used in the absence of C&S or while results are pending. In bronchopneumonia, appropriate antibiotics are given 7-28 days beyond resolution of clinical and radiographic signs, depending on severity of disease. Empirical choices can include one of the following:
  - Amoxicillin/clavulanic acid: 12-25 mg/kg PO q 8-12 h
  - Ampicillin: 30 mg/kg IV or SQ q 6-8 h
  - Azithromycin: 5-10 mg/kg PO q 24 h
  - Trimethoprim-sulfa drugs: 15 mg/kg PO or IV q 12 h
  - Enrofloxacin: 10-20 mg/kg PO, SQ, or IV q 24 h
  - Antibiotics effective against *B. bronchiseptica* include azithromycin, enrofloxacin, and doxycycline, 5-10 mg/kg PO q 12 h
- Antitussives:
  - Hydrocodone: 0.22 mg/kg PO q 6-12 h PRN
  - Butorphanol: 0.5 mg/kg PO, SQ, or IM q 6-12 h PRN
  - Dextromethorphan (available in over-the-counter human cough suppressants): 1-2 mg/kg PO q 6-8 h. Warn owners to avoid products that contain other ingredients such as antihistamines and decongestants.
- Dogs with bronchopneumonia may require further therapy, including bronchodilators, aerosol therapy, and supportive care (see p. 887).

PROGNOSIS AND OUTCOME

Prognosis in dogs with simple disease is excellent. Prognosis for those with bronchopneumonia is guarded to good, depending on age of animal and severity of disease.

PEARLS & CONSIDERATIONS

PREVENTION

- Vaccination (CPIV, CDV, CAV-2: modified live); part of many commercial combination canine vaccines (DHLPP). CPIV vaccine is also available as intranasal formulation with *Bordetella.*
- Parenteral and intranasal vaccines against *B. bronchiseptica:* duration of immunity is variable and can be short (3-6 months).

TECHNICIAN TIPS

- Wear gloves, wash hands, and strictly isolate patients to prevent spread to other hospitalized dogs.
- Clean nasal and ocular discharge with a warm, moist cloth.
- Warm food to enhance smell when offering food (see p. 1377).

CLIENT EDUCATION

- To prevent disease, limit exposure to other dogs, especially in high-density populations such as boarding kennels, shelters, and dog parks.
- If exposure is unavoidable, recommend vaccination 5-14 days prior to potential risk.

1ST EDITION AUTHOR: SHANNON T. STROUP

Tracheal Avulsion

BASIC INFORMATION

DEFINITION

Disruption of the continuity of, or a tear in, the trachea

SYNONYMS

Tracheal laceration, tracheal rupture, tracheal transection

EPIDEMIOLOGY

SPECIES, AGE, SEX: Reported primarily in small dogs and cats; there is no age or gender predilection.

RISK FACTORS

- Choke chains
- Overinflation of an endotracheal tube cuff
- Cervical trauma

ASSOCIATED CONDITIONS & DISORDERS: Can lead to pneumomediastinum, pneumothorax, and/or subcutaneous emphysema

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of trauma or recent general anesthesia and subsequent dyspnea
- Intermittent, continuous, or progressive respiratory distress

PHYSICAL EXAM FINDINGS

- Increased respiratory effort:
  - Decreased heart and breath sounds on thoracic auscultation if pneumothorax is present
- Subcutaneous emphysema: inflated, crepitant subcutaneous space
- Precipitation of severe dyspnea with neck flexion

ETIOLOGY AND PATHOPHYSIOLOGY

- Direct injury to the trachea due to either blunt or penetrating trauma to the cervical or thoracic area
- Violent hyperextension of the head and neck can lead to stretching of the trachea and may cause tracheal transection:
  - The carina and lungs are a fixed point that is stronger than the tracheal wall.
  - As the trachea is stretched, the intrathoracic trachea ruptures cranial to the carina.
- The dorsal tracheal membrane is the most common location for a tear from overinflation of an endotracheal tube cuff.
- Peritracheal tissues can maintain tracheal continuity.
- Initial dyspnea may persist, worsen, or resolve until subsequent stenosis or displacement causes return of clinical signs.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of tracheal avulsion is suggested by a patient with a history of cervical trauma or recent anesthesia, especially in the presence of subcutaneous emphysema, pneumomediastinum, or obvious radiographic disruption of the trachea.

DIFFERENTIAL DIAGNOSIS

- Tracheal foreign body
- Collapsing trachea
- Tracheal stenosis
- Tracheal neoplasia or mass
- Laryngeal paralysis
- Laryngeal collapse
- Tracheobronchitis
- Pneumothorax/pneumomediastinum from other causes
- Pulmonary disease

INITIAL DATABASE

- Results of CBC, serum biochemistry panel, and urinalysis are usually unremarkable.
- Radiographs of the neck (lateral view) may show discontinuity of the tracheal wall. Site of rupture may be obscured by the humeri or scapulae, requiring retaking of radiographs with the fore-limbs repositioned.
- Cervical and/or thoracic radiographs may show peritracheal air accumulation, subcutaneous emphysema, and/ or pneumomediastinum.
    - Pneumothorax is rare.
    - Tracheal stenosis can be seen in chronic cases.

ADVANCED OR CONFIRMATORY TESTING

Tracheoscopy is useful in documenting tracheal rupture, especially tears in the dorsal tracheal membrane, if a radiographic diagnosis is not definitive.

TREATMENT

TREATMENT OVERVIEW

- Stabilize animal.
- Repair or resect damaged trachea or stenosis to resolve respiratory distress.
- Note that surgery is not always needed, and follow guidelines for conservative versus surgical management.

ACUTE GENERAL TREATMENT

- Oxygen supplementation if dyspnea (see p. 1318)
- For animals with respiratory distress, induction of anesthesia or heavy sedation and intubation per os or through a cervical tracheal laceration (if present) are indicated to quickly gain control of the airway:
    - Intubation through a cervical laceration/avulsion is accomplished in similar fashion to tracheostomy.
    - Distal cervical tracheal lacerations may require retrieval of the distal trachea from the thoracic inlet via traction sutures.
- Thoracocentesis may be indicated if pneumothorax is present (see p. 1338).
- Prepare the animal for exploration of all structures in the injured area to determine extent of injury and provide the opportunity for primary repair.
- Treat any other additional wounds.
- Antibiotics are indicated, especially if traumatic injuries are present.
    - Coverage against skin organisms *(Staphylococcus* or *Streptococcus* spp.) is considered most important.
        - Ampicillin, 22 mg/kg PO or IV q 8-12 h; cefazolin, 22 mg/kg PO or IV q 12 h; or clavulanic acid/ amoxicillin, 12.5-25 mg/kg PO q 8-12 h (dogs), 62.5 mg PO q 8-12 h (cats)
        - Enrofloxacin, 5-20 mg/kg PO or IV q 24 h if concerns about gram-negative organisms (maximum 5 mg/kg PO q 24 h in cats)

CHRONIC TREATMENT

- Closure and débridement of tracheal laceration:
    - Surgery is indicated for repair of tracheal defects if:
        - The cause is from injury associated with contamination (e.g., bite wounds or other penetrating injury).
        - The animal is not improving or getting worse with conservative (nonsurgical) treatment.
        - There is stenosis or stricture causing respiratory difficulty.
- Resection of damaged or stenotic trachea and anastomosis of normal ends:
    - Minimize tension.
    - May need to use tracheal tubes/stents

- Use a tape neck splint to hold the neck in a flexed position to reduce tension on the trachea postoperatively:
  - Try to keep the splint in place for 2 weeks if it is needed.

POSSIBLE COMPLICATIONS

- Dehiscence may occur if excessive tracheal suture tension is present.
- Narrowing of the tracheal lumen due to scar tissue may occur secondary to tracheal anastomosis.

RECOMMENDED MONITORING

- Monitor for respiratory distress.
- Drainage of the peritracheal area may be indicated if area is contaminated.
- Small areas of tracheal granulation tissue may be removed through a bronchoscope at periodic examinations during the healing period.
- Removal of tubes/stents is indicated when a healed mucosal surface is present.

PROGNOSIS AND OUTCOME

- Prognosis is good for long-term resolution of clinical signs.
- Stenosis of the tracheal lumen may be a complication postoperatively.

PEARLS & CONSIDERATIONS

COMMENTS

- Trauma is the most common cause of tracheal avulsion in small dogs.
- Overinflation of the endotracheal tube is the most common cause of tracheal rupture in cats:
  - Tracheal tears can occur from over-inflation of either low-volume/high-pressure cuffs or high-volume/ low-pressure cuffs.

TECHNICIAN TIPS

Have a sterile endotracheal tube readily available in case the trachea within the sterile field needs to be intubated. It is also worthwhile to have an extra-long endotracheal tube handy if the avulsed trachea needs to be temporarily bridged.

CLIENT EDUCATION

Recurrence of clinical signs is possible secondary to tracheal stenosis.

Toxoplasmosis/Neosporosis

BASIC INFORMATION

DEFINITION

Infections with *Toxoplasma gondii* or *Neospora caninum,* obligate intracellular coccidian parasites that infect mammals, including humans

EPIDEMIOLOGY

SPECIES, AGE, SEX: Cats and other members of the Felidae family are definitive hosts for *T. gondii*

- Warm-blooded mammals serve as intermediate hosts.
- More severe disease can affect trans-placentally infected kittens.
- Cats of any age can be affected.

N. caninum infections have been seen in dogs, cattle, sheep, goats, horses, and deer but not in cats.

- Dogs are both intermediate and definitive hosts.
- Puppies are more severely affected by disease, but dogs of any age can be affected.
- Cats have demonstrated antibodies to *N. caninum* in field conditions but are not known to develop clinical neosporosis

GENETICS & BREED PREDISPOSITION: All breeds seem to be equally susceptible to toxoplasmosis. German short-haired pointers, Labrador retrievers, boxers, golden retrievers, basset hounds, and greyhounds may be more susceptible to neosporosis.

RISK FACTORS: Immunosuppression (e.g., from glucocorticoids or antineo-plastic drugs) or concomitant illnesses, such as ehrlichiosis, canine distemper, feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), feline infectious peritonitis (FIP), or *Mycoplasma haemofelis* infection. Immuno suppression is not consistently found in cases of neosporosis.

CONTAGION & ZOONOSIS: Toxoplasmosis is zoonotic. The zoonotic potential of *N. caninum* is not known.

- A cat negative for *T. gondii-specific* antibodies is at greatest risk for developing oocyst shedding in feces, and is a danger to a susceptible owner, especially if it goes outside where it may ingest the intermediate host.
- A healthy cat positive for *T. gondii*-specific antibodies is of little risk to its owner, as it is unlikely to shed oocysts again if exposed.

GEOGRAPHY AND SEASONALITY

- Worldwide
- About 30% of cats and dogs in the United States have antibodies against *T. gondii*
- There is a higher prevalence of antibodies against *N. caninum* in rural or farm dogs than urban dogs.

CLINICAL PRESENTATION

In dogs, the clinical presentation of toxoplasmosis and neosporosis may be identical.

DISEASE FORMS/SUBTYPES

- Unaffected cat
- Clinically ill dog (toxoplasmosis or neosporosis) or cat (toxoplasmosis)

HISTORY, CHIEF COMPLAINT

Toxoplasmosis:

- Cats with clinical illness commonly present with anorexia, lethargy, respiratory distress, and ocular signs.
- Dogs and cats can present with anorexia, vomiting, diarrhea, weight loss, lethargy, dyspnea, ocular signs, lameness, and signs of central nervous system (CNS) dysfunction (seizures, paresis, cranial nerve deficits).

- Stillborn kittens

Neosporosis:

- Older dogs may present with dermatitis, respiratory signs (cough, dyspnea), gastrointestinal (GI) signs, or neurologic signs (lameness, seizures).
- In young dogs (<6 months), acute ascending paralysis is typical. Dysphagia, incontinence, and muscle atrophy are also seen.

PHYSICAL EXAM FINDINGS

Toxoplasmosis:

- Prenatally infected kittens: hepatomegaly, ascites, dyspnea, and fever
- Postnatal infection in cats is characterized by uveitis, chorioretinitis, dyspnea, icterus, ascites, fever, stiff gait, hyperesthesia, and neurologic deficits (spinal cord or brain).
- As definitive hosts, most cats with *T. gondii* harbor the organism with no adverse effect and no clinical signs.
- Young dogs (1 year or less) have generalized infections resulting in fever, icterus, dyspnea, and tonsillitis.
- Older dogs more commonly have neuromuscular signs, including muscle atrophy, stiffness, abnormal gait, and multifocal neurologic deficits involving the spinal cord or brain (seizures, ataxia, lower motor neuron [LMN] signs, cranial nerve deficits).
- Arrhythmias or, rarely, heart failure may be present in some older dogs.

Neosporosis:

- Puppies are more severely affected and show ascending rigid paralysis, with hind limbs worse than forelimbs:
  - Muscle atrophy and stiffness, muscle contractures leading to arthrogryposis and hyperesthesia. Cervical weakness, dysphagia, and variable CNS signs may also be seen.
- Older dogs may have LMN flaccid paralysis or show multifocal CNS signs (cranial nerve deficits, seizures, blindness).
- Systemic signs include fever, dyspnea, cough, skin lesions, vomiting, icterus, cardiac arrhythmias, megaesophagus, and regurgitation.

ETIOLOGY AND PATHOPHYSIOLOGY

- *T. gondii* exists in three infectious stages: sporozoites, tachyzoites, and bradyzoites:
  - Sporozoites occur in oocysts, which are excreted in a cat's feces, whereas tachyzoites and bradyzoites occur as tissue cysts.
- Transmission can occur through ingestion of infected tissues or ingestion of oocysts in contaminated food or water; transmission can also occur congenitally.
- The enteroepithelial life cycle (and thus fecal shedding) occurs only in cats.
- Cats are infected by ingestion of intermediate hosts infected with tissue cysts:
  - Bradyzoites are released in the GI tract from tissue cysts during digestion.
  - The bradyzoites penetrate the small intestinal epithelium and initiate asexual stages, eventually forming oocysts. These oocysts are passed in feces.
- The extraintestinal life cycle occurs in all hosts including cats:
  - After ingestion of oocysts or tissue cysts, the organism invades the small intestine and spreads to many extraintestinal tissues through blood and lymph, where it causes a focal necrosis. The CNS, muscles, liver, lungs, and eyes are commonly affected.
  - The organism localizes in tissues as cysts, resulting in chronic infection. These cysts may rupture, resulting in clinical relapses during immunosuppression.
- The life cycle of *N. caninum* involves three infectious stages: tachyzoites, tissue cysts found primarily in the CNS, and oocysts:
  - Tissue cysts and tachyzoites are found in intermediate hosts.
  - Transmission is suspected to occur through ingestion of shed oocysts, ingestion of infected tissues, and transplacentally.
  - Transplacental transmission may be the predominant route in dogs.
  - The organism and associated necrosis may be found in macrophages, polymorphonuclear cells, spinal fluid, and neural cells (brain, spinal cord, peripheral nerves, retina) as well as other cells, causing focal necrosis.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

The diagnosis of either one of these diseases relies mainly on identifying appropriate clinical signs in patients with positive antibody

tests. It is possible (but unusual) to identify the organism in tissue or fluid samples.

DIFFERENTIAL DIAGNOSIS

- Uveitis: infectious (FeLV, FIV, FIP [coronavirus]), immune-mediated, trauma
- Respiratory signs: feline asthma, pneumonia (bacterial, *Mycoplasma,* parasitic, fungal), pulmonary edema, neoplasia, heartworm disease, trauma
- Hepatic: hepatic lipidosis (cats), cholangiohepatitis (cats), infectious hepatitis, neoplasia, toxic hepatopathy
- GI: infectious (bacterial, viral, parasitic), dietary, endocrine (hypoadrenocorticism), obstructive, pancreatitis.
- Neurologic signs: meningoencephalitis (FeLV, FIV, FIP, canine distemper, ehrlichiosis, Rocky Mountain spotted fever, rabies, fungal disease, parasitic disease, thiamine deficiency [cats], immune-mediated disease)
- Neuromuscular: hepatozoonosis, Lyme borreliosis, immune-mediated disease (polyradiculoneuritis, polymyositis)

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis:
  - Nonregenerative anemia, neutrophilic leukocytosis, lymphocytosis, monocytosis, eosinophilia possible (toxoplasmosis)
  - Leukopenia (lymphopenia, neutropenia, degenerative left shift) possible in cats severely affected with toxoplasmosis
- Serum biochemistry profile may show elevated alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase, bilirubin, amylase, lipase, and creatine kinase (CK). Hyperglobulinemia, hypoalbuminemia, and hypoproteinemia may also be present with toxoplasmosis.
- Proteinuria and bilirubinuria may be present in cats with toxoplasmosis.
- Dogs with neosporosis may have elevated CK and AST secondary to muscle disease.
- Liver enzymes may be elevated with hepatic involvement in neosporosis.
- Radiographs:
  - Thoracic radiographs may show a diffuse interstitial to alveolar pattern and mild pleural effusion.
  - Abdominal radiographs may show hepatomegaly, ascites, masses in the intestines, or mesenteric lymph nodes.
- Other tests:
  - Fecal examination with Sheather's sugar solution may not reveal oocysts in clinically ill cats.
  - Cytologic examination of ascitic fluid, tracheal washes, and pleural fluid may reveal tachyzoites.

ADVANCED OR CONFIRMATORY TESTING

Toxoplasmosis:

- Clinical confirmation comes from serologic testing combined with clinical response to medications and exclusion of other causes for clinical signs:
  - Serologic testing: ELISA tests designed specifically for dogs or cats should be used. A fourfold rise in immunoglobulin (Ig) G over a 2-3 week period or a high IgM titer suggest active infection.
  - The presence of a positive IgM may not be reliable, but 80% of cats with clinical disease associated with toxoplasmosis have positive IgM titers.
  - IgG reflects only past exposure (positive in 30% of the cat population), but a positive titer along with appropriate clinical signs may suggest toxoplasmosis.
- Organism detection: *T. gondii* can be detected using PCR on tissue or blood and aqueous humor samples.

Neosporosis:

- Serologic testing with indirect FA, ELISA, and direct agglutination tests can confirm neosporosis:
  - Serologic testing can be done on cerebrospinal fluid (CSF).
  - Organism detection with histologic or cytologic examination
  - *N. caninum* may be found in CSF or tissue samples.
- Both organisms can be grown in cell culture and in mice.
- CSF analysis and aqueous humor may have elevated protein levels and leukocytes in both toxoplasmosis and neosporosis.

TREATMENT 

TREATMENT OVERVIEW

Treatment is predominantly supportive, with antimicrobials as appropriate for the organism. Drugs suppress replication of *T. gondii* and are not completely effective at killing the organism. There is limited information for effective treatment of neosporosis.

ACUTE AND CHRONIC TREATMENT

- Toxoplasmosis: clindamycin is the treatment of choice in dogs and cats.
- Neosporosis should be treated early in the disease with the same drugs used for treating toxoplasmosis. Treatment should continue at least 2 weeks after resolution of clinical signs.
- Clindamycin (dogs): 10-20 mg/kg PO q 12 h for at least 2 weeks
- Clindamycin (cats): 12.5 mg/kg PO q 12 h for a minimum of 2-4 weeks
- Alternatively, trimethoprim-sulfonamide: 15 mg/kg PO q 12 h for 2-4 weeks may be used if the patient cannot tolerate clindamycin. Barring corneal ulceration, uveitis may be treated with 1% prednisolone acetate ophthalmic drops.

POSSIBLE COMPLICATIONS

- Clindamycin may cause anorexia, vomiting, and diarrhea with higher doses.
- Trimethoprim-sulfonamides are associated with bone marrow suppression (anemia, leukopenia, thrombocytopenia), keratoconjunctivitis sicca (KCS), depression, immune-mediated disease, cutaneous drug eruptions, renal failure, GI signs, and hepatotoxicosis (especially in Doberman pinschers). Reduce dose of trimethoprim sulfa in renal insufficiency and avoid use in hepatic disease, anemia, leukopenia, and congenital bleeding disorders.
- In cases of fulminant infection, some patients do get worse after antimicrobials are started.

RECOMMENDED MONITORING

Serial recheck examinations at 2 days and 1 week after initiation of therapy and again at 2 weeks after resolution of signs and prior to discontinuation of therapy

PROGNOSIS AND OUTCOME

- In most cases, clinical signs of systemic illness usually begin to resolve within 1-2 days after institution of therapy.
- Uveitis should resolve in 1 week with therapy.
- Neuromuscular deficits should partially resolve within 2 weeks of initiation of therapy; however, some signs may be permanent. Animals may survive acute disease if treated intensively and rapidly.
- Guarded for complete resolution of neuromuscular signs
- Clinical improvement is not likely in severe cases of neosporosis with muscle contracture.
- Older puppies (>16 weeks) and adult dogs generally respond better to treatment for *N. caninum.*

PEARLS & CONSIDERATIONS

COMMENTS

- Examine and treat all dogs in a litter for neosporosis if one littermate is diagnosed.
- No drug will clear the organism, and relapses may occur.
- Toxoplasmosis-associated chorioretinitis in cats can be treated with topical glucocorticoids.
- Precautions are often adequate for preventing zoonosis, and immunocompromised individuals need not necessarily be separated from their cats.
- Toxoplasmosis in cats with FIV is most often reactivation of latent infection rather than a newly acquired one.

PREVENTION

- Clean litter boxes daily (oocysts need 1-5 days to sporulate and become infective).
- Disinfect litter boxes with boiling water at least once weekly.
- Cover outdoor sandboxes.

CLIENT EDUCATION

- Wash hands and surfaces after handling raw meat or cleaning litter boxes.
- Wear gloves when gardening, and wash vegetables and hands thoroughly to prevent contamination from soil.
- Do not eat undercooked meat or unpasteurized dairy products.
- Boil drinking water from unreliable sources.
- Pregnant women must avoid contact with soil, cat litter, raw meat, and cats excreting oocysts.

Tooth Resorption

BASIC INFORMATION

DEFINITION

Loss of tooth substance due to resorption by osteoclast-like cells (odontoclasts)

SYNONYMS

Feline odontoclastic resorptive lesion (FORL), odontoclastic resorptive/resorption lesion, resorptive/resorption lesion, external root resorption, cervical line erosion/lesion, feline caries, neck lesion. (Note: The term *neck lesion* is a topographical distinction only. The terms *erosion* and *caries* are inappropriate because the dental defect is resorptive in nature and not caused by acidic or bacterial insult.)

EPIDEMIOLOGY

SPECIES, AGE, SEX: Resorption can occur in any mammalian deciduous or permanent tooth, but the condition affecting multiple or all permanent teeth is seen predominantly in domestic cats 4 years of age and older, with reported prevalence rates ranging between 25% and 75%.

GENETICS & BREED PREDISPOSITION: No obvious breed predisposition; purebred cats have been reported to develop tooth resorption at a younger age compared to other breeds.

RISK FACTORS

- Periodontal disease
- Trauma from occlusion
- Dietary composition
- Increased vitamin D levels in commercial diets

GEOGRAPHY AND SEASONALITY: Worldwide

ASSOCIATED CONDITIONS & DISORDERS

- Thickening of bone at the alveolar margin (alveolar bone expansion)
- Abnormal extrusion of teeth (particularly canine teeth)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Tooth resorption is classified based on severity (stages 1-5) and radiographic appearance (types 1-3; see http://avdc.org):

- Dentoalveolar ankylosis (ankylotic fusion between root and bone)
- Root replacement resorption (resorption followed by bone replacement)
- Inflammatory resorption (vascular and inflamed granulation tissue filling a resorptive defect)

HISTORY, CHIEF COMPLAINT: Patients may present with “red spots” on their teeth (crown defect filled with granulation tissue), repetitive lower jaw motions (jaw opening reflex), fractured crowns, root remnants, and missing teeth. These animals may also have difficulty eating hard food and may refuse to drink cold water. The majority of cats are diagnosed with tooth resorption from dental radiography.

PHYSICAL EXAM FINDINGS: Oral examination can reveal crown defects filled with vascular and inflamed granulation tissue, fractured crowns, root remnants, bulging gingiva in areas of missing teeth, thickening of bone at the alveolar margin, and abnormal extrusion of the canine teeth.

ETIOLOGY AND PATHOPHYSIOLOGY

- Suggested causes include periodontal disease, anatomic peculiarities, mechanical trauma, increased vitamin A and vitamin D intake, abnormal calcium homeostasis, and viruses causing immunosuppression.
- Association of multiple tooth resorption in cats with excessive dietary intake of vitamin D:
  - Histologic examination of healthy teeth from cats with tooth resorption on other teeth shows periodontal ligament degeneration, hypercementosis, decreased width of the periodontal space, and dentoalveolar ankylosis, indicating that inflammatory cells may not play a primary role in the development of tooth resorption.
  - A prospective study showed that cats with tooth resorption have significantly increased serum levels of 25-hydroxyvitamin D, compared to cats without tooth resorption; these findings indicate that cats with tooth resorption must have had a higher intake of dietary vitamin D, compared to cats without tooth resorption.
  - Recently the nuclear vitamin D receptor has been implicated in tooth resorption in cats.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Changes may be visible during intraoral examination, but these lesions are only the tip of the iceberg. What lurks below the gum line cannot be appreciated without diagnostic imaging. Full-mouth dental radiography is of utmost importance in identifying and assessing tooth resorption in cats.

DIFFERENTIAL DIAGNOSIS

- Periodontal disease
- Fractured teeth
- Root remnants
- Tooth resorption due to local causes (e.g., apical abscess, orthodontic tooth movement, trauma, neoplasia)
- Caries (dogs)

INITIAL DATABASE

Preanesthetic CBC, serum biochemistry profile, urinalysis

ADVANCED OR CONFIRMATORY TESTING

Full-mouth (intraoral) dental radiographs (see p. 1246)

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are to make the mouth free of pain, preserve masticatory function, and prevent abscess formation and local osteomyelitis.

ACUTE GENERAL TREATMENT

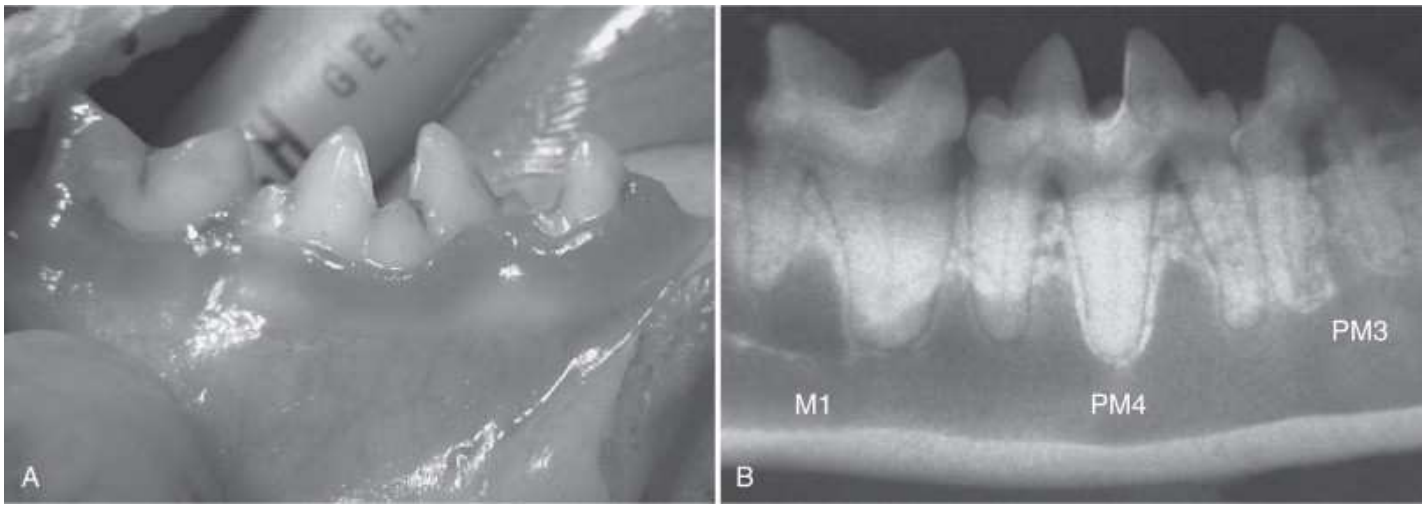
- Closed or open extraction of root remnants and teeth affected by resorption
- Flaps should be closed with synthetic absorbable suture material.
- Administration of antibiotics is not usually necessary after tooth extraction unless another medical condition or extensive tissue trauma at the extraction site is present.
- Pain management: regional nerve block(s) intraoperatively (0.3-0.4 mL of 0.5% bupivacaine per block) followed by opioid medications upon extubation (hydromorphone, 0.1 mg/ kg IM) and opioid medications post-operatively for 3-4 days (butorphanol, 0.2-0.4 mg/kg PO q 8 h; or buprenorphine, 0.01-0.02 mg/kg buccal transmucosal q 8 h); transdermal fentanyl patch (25 mcg) if multiple extractions were performed.

POSSIBLE COMPLICATIONS

- Fractured teeth and roots
- Root remnants
- Regional trauma due to improper extraction technique
- Infection
- Future development of resorption on other teeth

RECOMMENDED MONITORING

- Examination in 2 weeks to evaluate extraction sites
- Clinical examination and full-mouth dental radiography once per year



TOOTH RESORPTION A, Clinical picture of right mandibular third and fourth premolars and first molar in a cat; rostral is to the right. Generalized

moderate gingivitis with focalized gingival hyperplasia; possible tooth resorption on third premolar and first molar; fourth premolar shows gemination (division of a tooth bud, resulting in the formation of partially or completely separated crowns). **B**, Radiograph of same area. Generalized mild to moderate horizontal alveolar bone loss; tooth resorption on third premolar (PM3; inflammatory resorption near cervical region and furcation; dentoalveolar ankylosis and replacement resorption at distal root) and first molar (M1; inflammatory resorption near cervical region on mesial tooth surface); geminated fourth premolar (PM4) does not show obvious radiographic signs of tooth resorption.

PROGNOSIS AND OUTCOME

- Excellent for extraction site healing
- Fair with regard to preventing the development of resorption on other teeth

PEARLS & CONSIDERATIONS

COMMENTS

- Usually more than one tooth is affected.
- Dental radiography is an invaluable tool in diagnosing tooth resorption that is missed on clinical examination.

PREVENTION

There is no reliable prevention strategy available at this time.

CLIENT EDUCATION

Inform clients about the likelihood of development of resorption on other teeth and the need for continued clinical and radiographic monitoring.

Tooth Fractures

BASIC INFORMATION

DEFINITION

Fracture of dental enamel, dentin, and/ or cementum; common in both dogs and cats

SYNONYMS

Dental fracture; “slab” fracture: fracture of the buccal (or lingual/palatal) surface of a tooth

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: canine and maxillary fourth premolar teeth are commonly affected (due to trauma).
- Cats: more commonly in canine teeth (due to trauma) or any other teeth (weakened by tooth resorption; see p. 1104)

RISK FACTORS

- Dogs: chewing on bones, ice cubes, nylon toys, cow hooves, rocks
- Cats: high-rise syndrome (see p. 529 and online chapter: High Rise Syndrome, Craniofacial), vehicular trauma, tooth resorption

ASSOCIATED CONDITIONS & DISORDERS: Attrition (wear from tooth-to-tooth contact), abrasion (wear due to contact of teeth with nondental materials such as bones), pulpitis (pulpal inflammation), displacement injuries (tooth luxation or avulsion; see p. 1100), tooth resorption (commonly seen in cats), and caries (bacterial infection causing tooth demineralization)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: American Veterinary Dental College (AVDC) Tooth Fracture Classification (http://avdc.org/) based on location (crown [portion of the tooth covered by enamel], crown-root, or root) and presence of pulp exposure (uncomplicated or complicated):

- Enamel infraction: incomplete fracture (crack) of the enamel without loss of tooth substance
- Enamel fracture: fracture with loss of crown substance confined to the enamel
- Uncomplicated crown fracture: fracture of the crown that does not expose the pulp
- Complicated crown fracture: fracture of the crown that exposes the pulp
- Uncomplicated crown-root fracture: fracture of the crown and root that does not expose the pulp
- Complicated crown-root fracture: fracture of the crown and root that exposes the pulp
- Root fracture: fracture involving the root

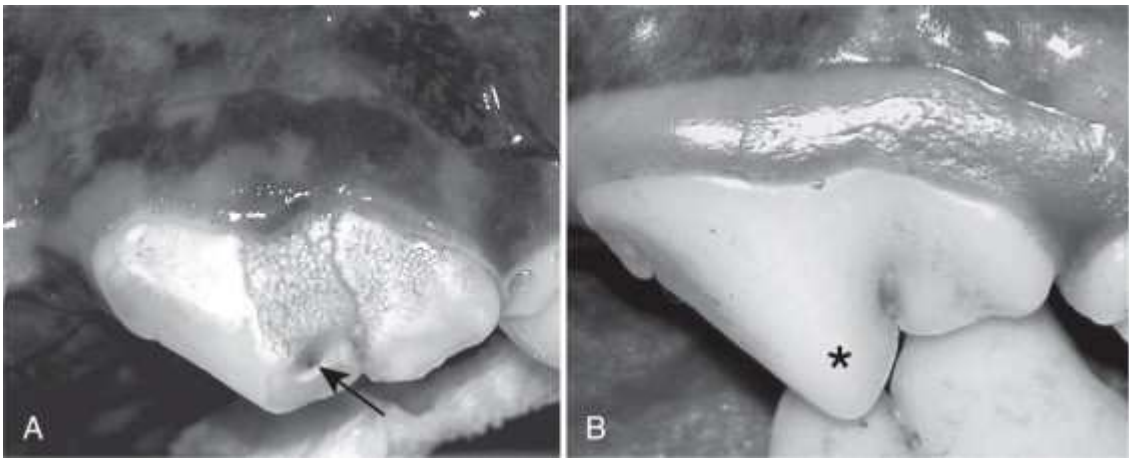
HISTORY, CHIEF COMPLAINT

- Tooth fractures are commonly noted as incidental findings on routine physical examination.
- History of falling from a height, vehicular trauma, fights with other animals, aggressive chewing tendencies, or other unknown trauma

PHYSICAL EXAM FINDINGS

- Commonly no overt clinical signs, especially if fracture is uncomplicated
- Oral bleeding with complicated fractures
- Hypersalivation with acute complicated fractures
- Appetite rarely affected; chewing on opposite side results in greater calculus accumulation on affected side.
- Calculus may obscure a slab fracture of the maxillary fourth premolar; compare with crown height and shape of the contralateral tooth.
- Acute pulp exposure: red spot in tooth defect ± bleeding from exposed pulp, painful on probing
- Chronic pulp exposure: dark brown/ black spot in tooth defect, asymmetric calculus accumulation (greater on affected side),

regional facial swelling ± draining tracts at mucogingival junction or through skin



TOOTH FRACTURES A, Slab fracture of left maxillary fourth premolar in a dog. The main cusp is fractured off; there is pulp exposure *(arrow)* and moderate calculus accumulation. Amount of calculus indicates fracture occurred more than 1-2 months prior to the visit, but bleeding pulp tissue indicates fracture may not be older than 6-12 months. **B**, Normal left maxillary fourth premolar for comparison. The tooth (notably the main cusp *[asterisk])* is structurally intact; mild calculus accumulation in developmental groove.

(Copyright Dr. Alexander M. Reiter.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Uncomplicated fracture: exposure of dentinal tubules causes sensitivity and may allow bacterial access to the pulp. Odontoblasts may respond by forming tertiary dentin, sealing off exposed tubules.
- Complicated fracture: pulp exposure results in pulpitis and bacterial infection; most will develop pulp necrosis and periapical disease (e.g., apical abscess; see p. 10).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Often the diagnosis of a fractured tooth is straightforward from visual inspection, though it may be difficult to determine whether the fracture is complicated or involves the roots from physical examination alone. A sedated/anesthetized oral examination and dental radiography are essential. It is important to avoid waiting for the patient to show clinical signs of oral discomfort, at which time the disease process may be advanced.

DIFFERENTIAL DIAGNOSIS

- Abrasion/attrition
- Tooth resorption
- Caries
- Displacement injury (luxation/avulsion)

INITIAL DATABASE

CBC, serum chemistry panel, urinalysis: generally unremarkable (preanesthetic)

ADVANCED OR CONFIRMATORY TESTING

- Anesthetized oral examination using a dental explorer (#11/12, 17, or 23) to determine pulp exposure
- Dental radiographs (see p. 1246): indicated to identify extent of lesion and state of adjoining teeth. Possible findings include structural crown and/or root defect, arrested root development (open root apex, wide root canal when compared with healthy contralateral tooth), diffuse root canal mineralization, apical root resorption, and/or periapical lucency.

TREATMENT

TREATMENT OVERVIEW

Endodontic or exodontic (extraction) therapy is indicated for fractured teeth with pulp exposure. Fractured teeth with no pulp exposure require radiographic evaluation and monitoring, since they may also develop endodontic disease. A "wait-and-see" approach for fractured teeth with pulp exposure is below the standard of care, because tooth fractures cause discomfort and invite infection of endodontic and periapical tissues.

ACUTE GENERAL TREATMENT

- Uncomplicated crown fractures may not require treatment, or may benefit from sealing dentinal tubules of exposed dentin with a bonding agent. Fractures extending below the gumline (crown-root fractures) may require periodontal surgery to prevent focal periodontal pocketing.
- Acute complicated crown fracture: vital pulp therapy (partial pulpectomy, direct pulp capping, and restoration) within 48 hours of pulp exposure; administer antibiotics (e.g., intraoperative ampicillin, 22 mg/kg IV q 6 h; followed by amoxicillin/clavulanic acid, 14 mg/kg PO q 12 h × 7 days; or clindamycin, 5.5 mg/kg PO q 12 h × 7 days).

CHRONIC TREATMENT

- Chronic, complicated crown fractures (adult animals): root canal therapy or extraction (extraction of large, firmly rooted teeth causes more postoperative morbidity than root canal therapy)
- Recently fractured (<2 weeks) teeth in immature animals (<18 months old) may be treated by vital pulp therapy in an attempt to achieve root lengthening and apical closure (apexogenesis).

POSSIBLE COMPLICATIONS

Uncontrolled force during extraction of crown-root segments can result in:

- Fracture and incomplete removal of the tooth/root, resulting in formation of an apical abscess (see p. 10)
