CLINICAL VETERINARY ADVISOR

Dogs and Cats

SECOND EDITION

Editor-in-Chief

Etienne Côté

Associate Professor
Department of Companion Animals
Atlantic Veterinary College
University of Prince Edward Island
Charlottetown, Prince Edward Island, Canada

With 551 illustrations

3251 Riverport Lane
St. Louis, Missouri 63043

CLINICAL VETERINARY ADVISOR: DOGS AND CATS ISBN: 978-0-323-06864-2

Library of Congress Cataloging-in-Publication Data or Control Number
Clinical veterinary advisor. Dogs and cats / editor-in-chief, Etienne Cote.—2nd ed.
p. ; cm.
Other title: Dogs and cats
Includes bibliographical references and index.
ISBN 978-0-323-06864-2 (hardcover : alk. paper) 1. Dogs—Diseases. 2. Cats—Diseases. 3. Pet medicine. I. Côté, Etienne. II. Title: Dogs and cats.
[DNLM: 1. Cat Diseases. 2. Dog Diseases. 3. Animals, Domestic. 4. Veterinary Medicine—methods. SF 981]
SF991.C658 2011
636.7'089—dc22

2010037649

Publishing Director: Linda Duncan
Acquisitions Editor: Penny Rudolph
Associate Developmental Editor: Lauren Harms
Publishing Services Manager: Catherine Jackson
Senior Project Manager: Rachel E. McMullen
Design Direction: Teresa McBryant

Printed in the United States of America

Last digit is the print number: 9 8 7 6 5 4 3 2 1

Editors

Editor in chief

Etienne Côté, DVM, DACVIM (Cardiology, Small Animal Internal Medicine)

Cardiology, Chief Complaints, Other Topics, Procedures and Techniques, Differential Diagnosis, Drug Formulary

Associate Professor, Department of Companion Animals, Atlantic Veterinary College, University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

Editors

Leah A. Cohn DVM, PhD, DACVIM (Small Animal Internal Medicine)

Urology

Professor, Veterinary Medicine and Surgery, Department of Veterinary Medicine and Surgery, College of Veterinary Medicine, University of Missouri, Columbia, Missouri

Susan M. Cotter, DVM, DACVIM (Small Animal Internal Medicine and Oncology)

Hematologic/Immunologic Diseases

Distinguished Professor of Clinical Sciences

Emerita

Department of Clinical Sciences, Tufts Cummings School of Veterinary Medicine, Tufts University, North Grafton, Massachusetts

Cheryl L. Cullen, DVM, MVetSc, DACVO

Ophthalmology

Associate Professor, Comparative Ophthalmology

Department of Veterinary Clinical and Diagnostic Sciences, Faculty of Veterinary Medicine, University of Calgary, Calgary, Alberta, Canada

CullenWebb Animal Neurology & Ophthalmology Centre, Riverview, New Brunswick, Canada

Curtis W. Dewey, DVM, MS, DACVIM (Neurology), DACVS

Neurology

Associate Professor, Neurology/Neurosurgery, Chief, Section of Neurology, Department of Clinical Sciences, College of Veterinary Medicine, Cornell University, Ithaca, New York

Joseph Harari, MS, DVM, DACVS

Orthopedics

Co-Owner, Veterinary Surgical Specialists, Spokane, Washington

Sherri Ihle, DVM, MS, DACVIM (Small Animal Internal Medicine)

Endocrinology

Associate Professor, Department of Companion Animals, Atlantic Veterinary College, University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

Safdar Khan, DVM, MS, PHD, DABVT

Toxicology

Senior Director of Toxicology Research ASPCA Animal Poison Control Center Urbana, Illinois

Michelle Kutzler, DVM, PhD, DACT

Theriogenology

Associate Professor, Department of Animal Sciences, College of Agricultural Sciences, Oregon State University, Corvallis, Oregon

Douglass K. Macintire, DVM, MS, DACVIM (Small Animal Internal Medicine), DACVECC

Infectious Diseases

Professor of Acute Medicine and Critical Care, Department of Clinical Sciences, College of Veterinary Medicine, Auburn University, Auburn, Alabama

Kathryn E. Michel, DVM, MS, DACVN

Nutrition

Associate Professor of Nutrition, Department of Clinical Sciences, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, Pennsylvania

Karen L. Overall, MA, VMD, PhD, DACVB, CAAB

Behavior

Research Associate, Center for Neurobiology and Behavior, Department of Psychiatry, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, Pennsylvania

Manon Paradis, DMV, MVSc, DACVD

Dermatology

Professor of Dermatology, Department of Clinical Sciences, Faculté de Médecine Vétérinaire, University of Montreal, Saint-Hyacinthe, Québec, Canada

Kenneth M. Rassnick, DVM, DACVIM (Oncology)

Oncology

Assistant Professor of Oncology, Department of Clinical Sciences, College of Veterinary Medicine, Cornell University Ithaca, New York

Alexander M. Reiter, Dipl Tzt, Dr Med Vet, DAVDC, DEVDC

Dentistry/Oral Surgery

Associate Professor of Dentistry and Oral Surgery, Department of Clinical Studies, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, Pennsylvania

Keith Richter, DVM, DACVIM (Small Animal Internal Medicine)

Hepatobiliary/Pancreatic Diseases

Hospital Director and Staff Internist, Veterinary Specialty Hospital of San Diego, San Diego, California,

Lois Roth-Johnson, DVM, PhD, DACVP

Laboratory Tests

President, Dual Boarded, Inc., Eastham, Massachusetts

Elizabeth Rozanski, DVM, DACVECC, DACVIM (Small Animal Internal Medicine)

Emergency and Critical Care

Assistant Professor, Department of Clinical Sciences, Cummings School of Veterinary Medicine, Tufts University, North Grafton, Massachusetts

Rance K. Sellon, DVM, PhD, DACVIM (Small Animal Internal Medicine, Oncology)

Respiratory Diseases

Associate Professor, Department of Veterinary Clinical Sciences, College of Veterinary Medicine, Washington State University, Pullman, Washington

Richard Walshaw, BVMS, DACVS

Soft-Tissue Surgery

Surgical Oncologist, Animal Cancer & Imaging Center, Canton, Michigan

Debra Zoran, DVM, MS, PhD, DACVIM (Small Animal Internal Medicine)

Gastroenterology

Associate Professor and Chief of Medicine, Department of Small Animal Clinical Sciences, College of Veterinary Medicine Texas A&M University College Station, Texas

Contributors

Jonathan A. Abbott, DVM, DACVIM (Cardiology)

Associate Professor, Department of Small Animal Clinical Sciences, Virginia-Maryland Regional College of Veterinary Medicine, Virginia Polytechnic Institute and State University Blacksburg, Virginia

Lisa M. Abbott, DVM, MRCVS

Pet Emergency Treatment Services Limited, Maidstone, Kent, United Kingdom

Sarah K. Abood, DVM, PhD

Assistant Dean, Associate Professor, Department of Small Animal Clinical Sciences, Assistant Dean, College of Veterinary Medicine, Michigan State University, East Lansing, Michigan

Christopher A. Adin, DVM, DACVS

Assistant Professor of Small Animal Surgery, Department of Veterinary Clinical Sciences, College of Veterinary Medicine, The Ohio State University Columbus, Ohio

Darcy B. Adin, DVM, DACVIM (Cardiology)

Associate Veterinary Cardiologist, Cardiology, Medvet, Worthington, Ohio

Sarah Allen, DVM, DACVECE

Veterinarian Emergency/Critical Care, Massachusetts Veterinary Referral Hospital, In Town Veterinary Group Woburn, Massachusetts

Robin W. Allison, DVM, PhD, DACVP (Clinical Pathology)

Associate Professor, Department of Veterinary Pathobiology, Center for Veterinary Health Sciences, Oklahoma State University Stillwater, Oklahoma

Jamie G. Anderson, RDH, DVM, MS, DAVDC, DACVIM (Small Animal Internal Medicine)

Co-Owner, San Francisco Veterinary Specialists, San Francisco, California

Elizabeth Armitage-Chan, MA VetMB, FHEA, DACVA, MRCVS

Anaesthetist, Davies Veterinary Specialists, Higham Gobion, Hertfordshire, United Kingdom

Clarke E. Atkins, DVM, DACVIM (Small Animal Internal Medicine, Cardiology)

Jane Lewis Seaks Distinguished Professor, Department of Clinical Sciences, College of Veterinary Medicine, North Carolina State University Raleigh, North Carolina

Todd W. Axlund, DVM, MS, DACVIM (Neurology)

Neurologist Ohio Veterinary Surgery and Neurology, LLC Akron, Ohio

Lenore M. Bacek, DVM

Resident, Emergency/Critical Care, Department of Clinical Sciences, College of Veterinary Medicine, Auburn University, Auburn, Alabama

Jonathan Bach, DVM, DACVIM (Small Animal Internal Medicine), DACVECC

Clinical Assistant Professor, Department of Medical Sciences, School of Veterinary Medicine University of Wisconsin—Madison, Madison, Wisconsin

Dennis Bailey, DVM, DACVIM (Oncology)

Staff Oncologist Oradell Animal Hospital Paramus, New Jersey

Kerry Smith Bailey, DVM, DACVIM (Neurology)

Staff Neurologist Neurology, Oradell Animal Hospital Paramus, New Jersey

Raviv J. Balfour, DVM, DACVS

Associate Surgeon Animal Surgical and Emergency Center Los Angeles, California

Cheryl E. Balkman, DVM, DACVIM (Small Animal Internal Medicine)

Lecturer, Department of Clinical Sciences, College of Veterinary Medicine Cornell University Ithaca, New York

Carsten Bandt, DVM, DACVECC

Assistant Professor for Emergency Critical Care, Department of Small Animal Clinical Science, College of Veterinary Medicine, University of Florida, Gainesville, Florida

Gad Baneth, DVM, PhD, DECVCP

Professor, Veterinary Internal Medicine The Hebrew University, Veterinary Teaching Hospital, School of Veterinary Medicine, Hebrew University, Rehovot, Israel

Lisa G. Barber, DVM, DACVIM (Oncology)

Assistant Professor, Department of Clinical Sciences, Cummings School of Veterinary Medicine, Tufts University North Grafton, Massachusetts

Georgina Barone, DVM, DACVIM (Neurology)

Staff Neurologist, Long Island Veterinary Specialists Plainview, New York

Kirstie A. Barrett, DVM, DACVIM (Cardiology)

California Animal Hospital Veterinary Specialty Group Los Angeles, California

Cary L.M. Bassett, DVM, PhD, DACVIM (Small Animal Internal Medicine)

Carolina Veterinary Specialists Greensboro, North Carolina

Jeff D. Bay, DVM, DACVIM (Small Animal Internal Medicine)

Staff Internist Upstate Veterinary Specialties Latham, New York

Matthew W. Beal, DVM, DACVECC

Assistant Professor, Emergency and Critical Care Medicine; Director, Emergency Services, Veterinary Medical Center, College of Veterinary Medicine, Michigan State University East Lansing, Michigan

Iveta Becvarova, DVM, MS, DACVN

Clinical Assistant Professor Department of Large Animal Clinical Sciences, Virginia-Maryland Regional College of Veterinary Medicine, Virginia Polytechnic Institute and State University Blacksburg, Virginia

Marie-Claude Bélanger, DVM, MS, DACVIM (Small Animal Internal Medicine)

Associate Professor of Internal Medicine and Cardiology, Department of Clinical Sciences, Faculty of Veterinary Medicine University of Montreal, Saint-Hyacinthe, Québec, Canada

Ellison Bentley, DVM, DACVO

Clinical Associate Professor, Comparative Ophthalmology, Department of Surgical Sciences, School of Veterinary Medicine University of Wisconsin—Madison Madison, Wisconsin

Michael Bernstein, DVM, DACVIM (Small Animal Internal Medicine)

Medical Director VCA South Shore Animal Hospital, South Weymouth, Massachusetts

Adam Birkenheuer, DVM, PhD, DACVIM (Small Animal Internal Medicine)

Assistant Professor, Department of Clinical Sciences, College of Veterinary Medicine, North Carolina State University Raleigh, North Carolina

Marie-Claude Blais, DVM, DACVIM (Small Animal Internal Medicine)

Faculty, Clinical Sciences, Faculté de médecine vétérinaire, University of Montreal Saint-Hyacinthe, Quebec, Canada

Bernard D. Boisvert, BSc (Hons), DVM

Owner, Mission Ridge Animal Hospital St. Albert, Alberta, Canada

Elise Mittleman Boller, DVM, DACVECC

Staff Criticalist, Intensive Care Unit, Department of Clinical Studies, Section of Emergency and Critical Care, Matthew J. Ryan Veterinary Hospital, University of Pennsylvania, Philadelphia, Pennsylvania

John D. Bonagura, DVM, MS, DACVIM (Cardiology, Small Animal Internal Medicine)

Professor Department of Veterinary Clinical Sciences; Cardiology Service Head, The Ohio State University Veterinary Hospital, Member, Davis Heart & Lung Research Institute, College of Veterinary Medicine, The Ohio State University Columbus, Ohio

Betsy R. Bond, DVM, DACVIM (Cardiology)

Staff Cardiologist, The Animal Medical Center New York, New York

Dwight D. Bowman, PhD

Professor of Parasitology, Department of Microbiology and Immunology, College of Veterinary Medicine, Cornell University Ithaca, New York

Søren R. Boysen, DVM, DACVECC

Associate Professor, Faculty of Veterinary Medicine, Emergency and Critical Care, Veterinary Clinical and Diagnostic Sciences, University of Calgary Calgary, Alberta, Canada

David M. Brewer, DVM

Neurology/Neurosurgery Resident, Department of Clinical Sciences, College of Veterinary Medicine, Cornell University Ithaca, New York

Catharina Brömel, DMV PhD, DACVIM (Small Animal Internal Medicine)

Department of Population Health and Reproduction, School of Veterinary Medicine, University of California—Davis, Davis, California

Marjory B. Brooks, DVM, DACVIM (Small Animal Internal Medicine)

Director, Comparative Coagulation Section, Animal Health Diagnostic Center, College of Veterinary Medicine, Cornell University Ithaca, New York

Michael R. Broome, DVM, MS, DABVP

Owner, Advanced Veterinary Medical Imaging, Tustin, California

Andrew J. Brown, MA, VetMB, MRCVS, DACVECC

Assistant Professor, Department of Small Animal Clinical Sciences, College of Veterinary Medicine, Michigan State University East Lansing, Michigan

M. Raquel Brown, DVM, DACVIM (Oncology, Small Animal Internal Medicine)

Adjunct Professor, Department of Veterinary Clinical Sciences, College of Veterinary Medicine and Biomedical Sciences, Texas A&M University College Station, Texas; Staff Oncologist/Internist, Veterinary Oncology and Internal Medicine Austin, Texas

Lisa Brownlee, DVM, MS, DACVIM (Small Animal Internal Medicine)

Assistant Professor Department of Veterinary Clinical Sciences, College of Veterinary Medicine, Oregon State University Corvallis, Oregon

Stephanie R. Bruner, DVM, DACVD

Staff Dermatologist, Greater Cincinnati Veterinary Specialists, Independent Consultant, Antech Diagnostics Cincinnati, Ohio

Jeffrey N. Bryan, DVM, MS, PhD, DACVIM (Oncology)

Assistant Professor, Department of Veterinary Clinical Sciences, College of Veterinary Medicine, Washington State University Pullman, Washington

James W. Buchanan, DVM, M Med Sci, DACVIM (Cardiology)

Emeritus Professor of Cardiology, Department of Clinical Studies, School of Veterinary Medicine, University of Pennsylvania Philadelphia, Pennsylvania

Gareth Buckley, MA, VetMB, MRCVS

Resident Department of Clinical Sciences, Foster Hospital for Small Animals, Cummings School of Veterinary Medicine, Tufts University North Grafton, Massachusetts

Barret J. Bulmer, DVM, MS, DACVIM (Cardiology)

Associate Professor Cardiology, Foster Hospital for Small Animals, Cummings School of Veterinary Medicine, Tufts University North Grafton, Massachusetts

Lyndsay N. Bunting, DVM

Radiation Oncology Resident Department of Surgical Sciences, School of Veterinary Medicine University of Wisconsin—Madison Madison, Wisconsin

William J. Burkholder, DVM, PhD, DACVN

Veterinary Medical Officer, United States Food and Drug Administration, Center for Veterinary Medicine, Division of Animal Feeds Rockville, Maryland

Derek P. Burney, DVM, PhD, DACVIM (Small Animal Internal Medicine)

Chief Operating Officer, Internal Medicine and Critical Care, Gulf Coast Veterinary Specialists, Houston, Texas

Lisa Carioto, DVM, DVSc, DACVIM (Small Animal Internal Medicine)

Clinician Small Animal Internal Medicine, Clinicienne en médecine interne des petits animaux, Centre hospitalier universitaire vétérinaire, Faculté de médecine vétérinaire, Université de Montréal Saint-Hyacinthe, Québec, Canada

Khristen J. Carlson, DVM

Resident Small Animal Internal Medicine, Department of Clinical Sciences, College of Veterinary Medicine Auburn University, Auburn, Alabama

Maureen C. Carroll, DVM, DACVIM (Small Animal Internal Medicine)

Department of Internal Medicine, Angell Animal Medical Center Boston, Massachusetts

Michaela Cautela, DVM

Resident in Neurology/Neurosurgery, Department of Clinical Sciences—Neurology, Hospital for Animals College of Veterinary Medicine Cornell University Ithaca, New York

Tara Chapman, DVM, DACVIM (Small Animal Internal Medicine)

Internal Medicine Alta Vista Animal Hospital Ottawa, Ontario, Canada

Michel Chénier, DMV

Hôpital Vétérinaire Chénier Sainte-Adèle, Québec, Canada

Dennis J. Chew, DVM, DACVIM (Small Animal Internal Medicine)

Professor; Attending Clinician, Department of Veterinary Clinical Sciences, Veterinary Medical Teaching Hospital, College of Veterinary Medicine, The Ohio State University Columbus, Ohio

Jane O. Cho, DVM, DACVO

Veterinary Ophthalmologist, Veterinary Eye Specialists, PLLCArdsley, New York

Ruthanne Chun, DVM, DACVIM (Oncology)

Clinical Associate Professor Department of Medical Sciences, School of Veterinary Medicine University of Wisconsin Madison, Wisconsin

Cecile Clercx, DVM, PhD, DECVIM-CA (Internal Medicine)

Professor Department of Veterinary Clinical Sciences of Companion Animals and Equine, Faculty of Veterinary Medicine University of Liege Liege, Belgium

Joan R. Coates, DVM, MS, DACVIM (Neurology)

Associate Professor Department of Veterinary Medicine and Surgery; Neurology/Neurosurgery Service Section Leader, Department of Veterinary Neurology and Neurosurgery, Veterinary Medical Teaching Hospital, University of Missouri Columbia, Missouri

Leah A. Cohn, DVM, PhD, DACVIM (Small Animal Internal Medicine)

Professor, Veterinary Medicine and Surgury, Department of Veterinary Medicine and Surgery College of Veterinary Medicine University of Missouri Columbia, Missouri

Gary Conboy, DVM, PhD

Associate Professor, Veterinary Parasitology, Department of Pathology and Microbiology, Atlantic Veterinary College, University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

Audrey K. Cook, BVM&S, MRCVS, DACVIM (Small Animal Internal Medicine), DECVIM-CA

Clinical Associate Professor, Department of Small Animal Clinical Sciences, College of Veterinary Medicine and Biomedical Sciences, Texas A&M University, College Station, Texas

Cynthia S. Cook, DVM, PhD, DACVO

Ophthalmologist Veterinary Vision, Inc., San Carlos, California, San Francisco, California

Lilian Cornejo, DVM, DACVIM (Small Animal Internal Medicine)

Clinical Assistant Professor, Department of Clinical Sciences, Cummings School of Veterinary Medicine, Tufts University North Grafton, Massachusetts

Yonaira E. Cortés, DVM, DACVECC

Veterinarian Emergency Medicine/Critical Care Oradell Animal Hospital Paramus, New Jersey

Etienne Côté, DVM, DACVIM (Cardiology, Small Animal Internal Medicine)

Associate Professor Department of Companion Animals, Atlantic Veterinary College, University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

Susan M. Cotter, DVM, DACVIM (Small Animal Internal Medicine, Oncology)

Distinguished Professor of Clinical Sciences Emerita, Department of Clinical Sciences, Cummings School of Veterinary Medicine, Tufts University North Grafton, Massachusetts

Nancy B. Cottrill, DVM, MS, DACVO

Staff Ophthalmologist Massachusetts Veterinary Referral Hospital Woburn, Massachusetts

Laura Ridge Cousins, DVM, MS, DACVIM (Small Animal Internal Medicine)

Upstate Veterinary Specialists, Greenville, South Carolina

Bronwyn Crane, DVM, MS, DACT

Assistant Professor of Theriogenology, Department of Health Management, Atlantic Veterinary College University of Prince Edward Island, Charlottetown,

Prince Edward Island, Canada

Kate E. Creevy, DVM, MS, DACVIM (Small Animal Internal Medicine)

Assistant Professor, Small Animal Internal Medicine, Department of Small Animal Medicine and Surgery, College of Veterinary Medicine, University of Georgia Athens, Georgia

Andrew Cruikshank, DVM, DACVECC

Animal Emergency and Treatment Center, Chicago, Illinois

Ashley Cruse, DVM, DACVIM

Internal Medicine Department, Animal Emergency Referral Center, Torrance, California

Cheryl L. Cullen, DVM, MVetSc, DACVO

Associate Professor, Comparative Ophthalmology, Department of Veterinary, Clinical and Diagnostic Sciences, Faculty of Veterinary Medicine, University of Calgary, Calgary, Alberta, Canada; CullenWebb Animal Neurology and Ophthalmology Centre, Riverview, New Brunswick, Canada

Anne M. Dalby, DVM, DACVIM (Small Animal Internal Medicine)

Animal Emergency and Specialty Center, Parker, Colorado

Sylvie Daminet, DVM, PhD, DACVIM (Small Animal Internal Medicine), DECVIM-CA (Internal Medicine)

Associate Professor, Department of Medicine and Clinical Biology of Small Animals, Faculty of Veterinary Medicine, Ghent University, Ghent, Belgium

Autumn Davidson, DVM, MS, DACVIM (Small Animal Internal Medicine)

Clinical Professor, Department of Medicine and Epidemiology, College of Veterinary Medicine, University of California—Davis, Davis, California

Deborah Groppe Davis, DVM, DACVP

Clinical Pathologist, IDEXX Laboratories North Grafton, Massachusetts

Douglas J. DeBoer, DVM, DACVD

Professor of Dermatology, Department of Medical Sciences, School of Veterinary Medicine University of Wisconsin—Madison, Madison, Wisconsin

Camille DeClementi, VMD, DABVT, DABT

Senior Director, Animal Health Services, American Society for the Prevention of Cruelty to Animals; Adjunct Instructor, Department of Veterinary Biosciences, College of Veterinary Medicine, University of Illinois Urbana, Illinois

Amy E. DeClue, DVM, MS, DACVIM (Small Animal Internal Medicine)

Assistant Professor, Department of Veterinary Medicine and Surgery, College of Veterinary Medicine, University of Missouri Columbia, Missouri

Vincent E. Defalque, DMV, DACVD

Dermatologist, Canada West Veterinary Specialists & Critical Care Hospital, Vancouver, British Columbia, Canada

Alice Defarges, DVM, MSc, DES, DACVIM (Small Animal Internal Medicine)

Faculty, Internal Medicine Department of Clinical Studies Ontario Veterinary College, University of Guelph Guelph, Ontario, Canada

Teresa DeFrancesco, DVM, DACVIM (Cardiology), DACVECC

Associate Professor in Cardiology and Critical Care, Department of Clinical Sciences, College of Veterinary Medicine North Carolina State University Raleigh, North Carolina

Caroline de Jaham, DMV, MSc, DACVD

Director of Professional ServicesDMV Veterinary Center, Montreal, Québec; Associate Professor Faculty of Veterinary Medicine, University of Montreal

Millicent Eidson, DVM, MA, DACVPM

Research Scientist, New York State Department of Health Albany, New York

Bruce E. Eilts, DVM, MS, DACT

Professor of Theriogenology Department of Veterinary Clinical Sciences, Veterinary Teaching Hospital and Clinic, Louisiana State University, Baton Rouge, Louisiana

Amara H. Estrada, DVM, DACVIM (Cardiology)

Associate Professor and Associate Chair for Instruction, Department of Small Animal Clinical Sciences, College of Veterinary Medicine, University of Florida Gainesville, Florida

Michael R.D. Ethier, DVM, DVSc, DACVECC

Director of Emergency and Critical Care Medicine, Intensive Care Toronto Veterinary Emergency and Referral Hospital, Toronto, Ontario, Canada

Stephen J. Ettinger, DVM, DACVIM (Small Animal Internal Medicine and Cardiology)

California Animal Hospital Veterinary Specialty Group Los Angeles, California

Susan Ettinger, DVM, DACVIM (Oncology)

Staff Oncologist Department of Oncology Animal Specialty Center Yonkers, New York

James F. Evermann, MS, PhD

Professor Department of Veterinary Clinical Sciences, Washington Animal Disease Diagnostic Lab, College of Veterinary Medicine Washington State University Pullman, Washington

Patty J. Ewing, DVM, MS, DACVP

Clinical Pathologist Department of Pathology, Angell Animal Medical Center Boston, Massachusetts

John Farrelly, DVM, MS, DACVIM (Oncology), DACVR (Radiation Oncology)

Director of Radiation Oncology, The Animal Medical Center New York, New York

Wenche K. Farstad, DVM, Dr.scient., PhD, DECAR

Professor, Department of Production Animal Clinical Sciences, Norwegian School of Veterinary Science Oslo, Norway

Karen K. Faunt, DVM, MS, DACVIM (Small Animal Internal Medicine)

Vice President, Medical Quality Advancement, Banfield The Pet Hospital Portland, Oregon

Edward C. Feldman, DVM, DACVIM (Small Animal Internal Medicine)

Professor of Small Animal, Internal Medicine and Department Chair, Department of Medicine and Epidemiology, School of Veterinary Medicine University of California—Davis, Davis, California

Nathaniel K. Fenollosa, DVM, DACVIM (Cardiology)

Staff Cardiologist, VCA Shoreline Veterinary Referral and Emergency Center, Shelton, Connecticut

Alberto Fernandez, DVM

Emergency and Critical Care Cape Cod Veterinary Specialists, Buzzards Bay, Massachusetts

Fidelia R. Fernandez, DVM, MS, DACVP (Clinical Pathology)

Veterinary Clinical Pathologist Antech Diagnostics Cary, North Carolina

Janean Fidel, MS, DVM, DACVR (Radiation Oncology), DACVIM (Oncology)

Associate Professor, Department of Veterinary Clinical Sciences, College of Veterinary Medicine, Washington State University Pullman, Washington

Wendy D. Fife, DVM, MS, DACVR

Veterinary Radiologist Diagnostic Imaging, P.C. Boulder, Colorado

Deborah M. Fine, DVM, MS, DACVIM (Cardiology)

Assistant Professor, Department of Veterinary Medicine and Surgery College of Veterinary Medicine, University of Missouri, Columbia, Missouri

Linda S. Fineman, DVM, DACVIM (Oncology)

Veterinary Oncologist Veterinary Medical Specialists Campbell, California

James M. Fingeroth, DVM, DACVS

Senior Staff Surgeon Orchard Park Veterinary Medical Center, Orchard Park, New York; Veterinary Information Network Consultant, Surgery, Neurology, and Oncology Davis, California

James A Flanders, DVM, DACVS

Associate Professor of Small Animal Surgery, Department of Clinical Sciences, College of Veterinary Medicine, Cornell University Ithaca, New York

Polly A. Fleckenstein, DVM, MS, CVA

Veterinary Medical Center of Central New York Veterinary Medical Officer, National Veterinary Response Team—1; NDMS, DHHS, Veterinary Medical Officer, Veterinary Medical, Assistance Team—1; AVMA East Syracuse, New York

Andrea B. Flory, DVM, DACVIM (Oncology)

Co-Chief Department of Medical Oncology, The Animal Medical Center New York, New York

Peter Michael Foley, MSc, DVM, DACVIM (Small Animal Internal Medicine)

Assistant Professor of Companion Animal Internal Medicine, Department of Companion Animals, Atlantic Veterinary College University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

Thierry Francey, Dr.med. vet., DACVIM (Small Animal Internal Medicine)

Vetsuisse Faculty, Department of Clinical Veterinary Medicine, Small Animal Clinic—Internal Medicine, University of Berne Laenggass-Strasse, Bern, Switzerland

Boel A. Fransson, DVM, PhD, DACVS

Assistant Professor, Small Animal Surgery, Department of Veterinary Clinical Sciences, College of Veterinary Medicine, Washington State University Pullman, Washington

Lisa M. Freeman, DVM, PhD, DACVN

Professor, Department of Clinical Sciences, Cummings School of Veterinary Medicine, Tufts University North Grafton, Massachusetts

Laura D Garrett, DVM, DACVIM (Oncology)

Clinical Associate Professor, Oncology Veterinary Clinical Medicine College of Veterinary Medicine University of Illinois Urbana, Illinois

Frédéric P. Gaschen, Dr. med.vet., Dr.med.vet habil., DACVIM (Small Animal Internal Medicine), DECVIM-CA (Internal Medicine)

Professor of Companion Animal Medicine, Department of Veterinary Clinical Sciences, School of Veterinary Medicine Louisiana State University Baton Rouge, Louisiana

Cynthia Gaskill, DVM, PhD

Associate Professor Department of Veterinary Science, College of Agriculture University of Kentucky Lexington, Kentucky

Stephen D. Gaunt, DVM, PhD, DACVP

Professor of Veterinary Clinical Pathology, Department of Pathobiological Sciences, School of Veterinary Medicine Louisiana State University, Baton Rouge, Louisiana

Hans Gelens, DVM, MSc, DACVIM (Small Animal Internal Medicine)

Associate Professor of Internal Medicine, Department of Companion Animals, Atlantic Veterinary College University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

Anna R.M. Gelzer, DMV, DACVIM (Cardiology), DECVIM-CA (Cardiology)

Assistant Professor, Department of Clinical Sciences, College of Veterinary Medicine Cornell University Ithaca, New York

Anne J. Gemensky-Metzler, DVM, DACVO

Associate Professor Department of Veterinary Clinical Sciences, College of Veterinary Medicine, The Ohio State University Columbus, Ohio

Tracy Gieger, DVM, DACVIM (Small Animal Internal Medicine), DACVR

Assistant Professor Department of Veterinary Clinical Sciences, School of Veterinary Medicine Louisiana State University Baton Rouge, Louisiana

Mathieu M. Glassman, VMD

Small Animal Surgery Resident, Department of Small Animal Medicine and Surgery College of Veterinary Medicine, University of Georgia Athens, Georgia

Tony Glaus, PD, DMV, DACVIM (Small Animal Internal Medicine), DECVIM-CA (Internal Medicine and Cardiology)

Head Division of Cardiology, Clinic for Small Animal Internal Medicine, Vetsuisse Faculty, University of Zurich Zurich, Switzerland

Joseph C. Glennon, VMD, DACVS

Staff Surgeon, Veterinary Specialties Referral Center, Pattersonville, New York, Adjunct Associate Professor of Surgery, Albany Medical College Albany, New York

Cristina Gobello, MV, DVM, Sm Anim Special, DECAR

Senior Lecturer, Laboratory of Reproductive Physiology, Department of Basic Sciences Faculty of Veterinary Medicine, National University of La Plata La Plata, Argentina, Researcher, National Research Council, Argentina

Richard E. Goldstein, DVM, DACVIM (Small Animal Internal Medicine), DECVIM-CA

Associate Professor Department of Clinical Sciences, College of Veterinary Medicine Cornell University Ithaca, New York

Kristine L Gonzales, DVM, DACT

Staff Veterinarian Guide Dogs for the Blind, Inc. San Rafael, California

Lillian Good, DVM, DACVECC

Criticalist Pacific Veterinary Specialists Capitola, California

Sonya G. Gordon, DVM, DVSc, DACVIM (Cardiology)

Associate Professor Department of Small Animal Clinical Sciences, College of Veterinary Medicine and Biomedical Sciences, Texas A&M University College Station, Texas

Cecilia Gorrel, BSc, DDS, MA, Vet MB, DEVDC, Hon FAVD, MRCVS

Director Petdent Ltd. Verwood, Dorset and Swindon, Wilthshire, Veterinary Dentistry, Oral and Maxillofacial Surgery Referrals, Veterinary Oral Health Consultancy, Pilley, Hampshire, United Kingdom

Kinga Gortel, DVM, MS, DACVD

Staff Dermatologist, C.A.R.E. Centre Animal Hospital, Calgary, Alberta, Canada

Ruanna E. Gossett, DVM, PhD, DACVP (Clinical Pathology)

Clinical PathologistIDEXX, Inc. West Sacramento, California

Margherita Gracis, DMV, DAVDC, DEVDC

Clinica Veterinaria San Siro Milano, Italy, Clinica Veterinaria Città di Codogno, Codogno (Lodi), Italy

Carlos M. Gradil, DVM, MS, PhD, DACT

Associate Professor Department of Veterinary and Animal Sciences, College of Natural Sciences University of Massachusetts Amherst, Massachusetts

Kristi L. Graham, DVM, MS, DACVIM (Small Animal Internal Medicine)

Staff Internist, VCA-Veterinary Specialty Center, Indianapolis, Indiana

Bradley A. Green, DVM

Internal Medicine Service Puget Sound Veterinary Referral Center, Tacoma, Washington

Pascale Christine Griessmayr, DVM, DACVIM (Oncology)

Oncology Lecturer Department of Clinical Studies School of Veterinary Medicine Matthew J. Ryan Veterinary Hospital, Philadelphia, Pennsylvania

Sophie Alexandra Grundy, BVSc (Hons), MACVSc, DACVIM (Small Animal Internal Medicine)

Internist, Northern California Veterinary Specialists, Sacramento, California

Norma C. Guy, DVM, MSc

Assistant Professor, Companion Animals Department of Companion Animals, Atlantic Veterinary College University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

Sharon Gwaltney-Brant, DVM, PhD, DABVT, DABT

Vice President and Medical Director, ASPCA Animal Poison Control Center, Adjunct Instructor Department of Veterinary Biosciences, College of Veterinary Medicine, University of Illinois Urbana, Illinois

John J. Haburjak, DVM, DACVS

Head, Department of Surgery Veterinary Surgical Centers—Berkeley, Dublin, San Francisco East Bay, California

Jens Häggström, DVM, PhD, DECVIM-CA (Cardiology)

Professor Department of Clinical Sciences, Faculty of Veterinary Medicine and Animal Sciences, University Teaching Hospital Swedish University of Agricultural Sciences Uppsala, Sweden

Edward J. Hall, MA, VetMB, PhD, DECVIM-CA (Internal Medicine)

Professor of Small Animal Internal Medicine, Clinical Veterinary Science University of Bristol, Langford, Bristol, United Kingdom

Michael Hannigan, BVMS, CertSAD, MRCVS

Island Consulting Services Victoria, British Columbia, Canada

Joseph Harari, MS, DVM, DACVS

Co-Owner Veterinary Surgical Specialists Spokane, Washington

Kenneth R. Harkin, DVM, DACVIM (Small Animal Internal Medicine)

Associate Professor Department of Clinical Sciences, College of Veterinary Medicine, Kansas State University Manhattan, Kansas

John R. Hart, DVM, DACVIM (Small Animal Internal Medicine)

Staff Internist, Veterinary Specialty Hospital of San Diego San Diego, California

Katrin Hartmann, Dr Vet Med, Dr Vet Med Habil, DECVIM-CA (Internal Medicine)

Department Head Professor of Small Animal Internal Medicine, Clinic of Small Animal Medicine, Center of Clinical Veterinary Sciences, LMU University of Munich Munich, Germany

Colin Harvey, BVSc, FRCVS, DACVS, DAVDC, FAVD

Professor of Surgery and Dentistry, Department of Clinical Studies School of Veterinary Medicine University of Pennsylvania Philadelphia, Pennsylvania

Timothy V. Hatt, DVM, CCRP

Department Head, Associate Veterinarian, Physical Rehabilitation Oradell Animal Hospital Paramus, New Jersey

Joseph G. Hauptman, DVM, MS, DACVS

Professor of Surgery, Department of Small Animal Clinical Sciences, College of Veterinary Medicine Michigan State University East Lansing, Michigan

Cristine L. Hayes, DVM

Consulting Veterinarian in Clinical Toxicology, Animal Poison Control Center American Society for the Prevention of Cruelty to Animals, Urbana, Illinois

Timothy M. Hazzard, PhD, DVM

Assistant Professor, Senior Research, Department of Animal Sciences College of Veterinary Medicine Oregon State University Corvallis, Oregon

Geoff Heffner, DVM, DACVECC

Criticalist, Intern Director, Director of Emergency and Critical Care Services, Animal Hospital Specialty Center, Highlands Ranch, Colorado

Alicia K. Henderson, DVM, DACVIM (Small Animal Internal Medicine)

Staff Internist, Garden State Veterinary Specialists Tinton Falls, New Jersey

Charles Hendrix, DVM, PhD

Professor Department of Pathobiology College of Veterinary Medicine Auburn University Auburn, Alabama

Kate E. Hill, BVSc (Hons), DACVIM (Small Animal Internal Medicine)

Senior Lecturer Small Animal Medicine, Institute of Veterinary, Animal and Biomedical Sciences, Massey University, New Zealand

Steve Hill, DVM, MS, DACVIM (Small Animal Internal Medicine)

Staff Internist Department of Internal Medicine, Veterinary Specialty Hospital of San Diego, San Diego, California

Mark E. Hitt, DVM, MS, DACVIM (Small Animal Internal Medicine)

Chief of Medicine Atlantic Veterinary Internal Medicine, LLC, Annapolis, Maryland

Daniel F. Hogan, DVM, DACVIM (Cardiology)

Associate Professor, Cardiology, Department of Veterinary Clinical Sciences, School of Veterinary Medicine Purdue University West Lafayette, Indiana

R. Bruce, Hollett DVM, MS, DACT

Associate Professor, Director of Continuing Education, Large Animal Medicine College of Veterinary Medicine University of Georgia Athens, Georgia

Steven R. Hollingsworth, DVM, DACVO

Associate Professor of Clinical Ophthalmology, Department of Surgical and Radiological Sciences, School of Veterinary Medicine University of California—Davis, Davis, California

Cheryl A. Holloway, RVT

Animal Health Technician College of Veterinary Medicine The Ohio State University Columbus, Ohio

Jennifer L. Holm, DVM, DACVECC

Service Director Emergency and Critical Care Angell Animal Medical Center Boston, Massachusetts

Ian Gordon Holsworth, BVSc (Hons), MACVSc (Surgery), DACVS

Surgeon Veterinary Medical and Surgical Group Ventura, California

David Holt, BVSc, DACVS

Professor of Surgery Department of Clinical Studies School of Veterinary Medicine University of Pennsylvania Philadelphia, Pennsylvania

Katherine Albro Houpt, VMD, PhD, DACVB

Professor Emeritus College of Veterinary Medicine Cornell University Ithaca, New York

Bryan Hux, DVM

Resident, Emergency and Critical Care, Department of Clinical Sciences, Small Animal Teaching Hospital, College of Veterinary Medicine Auburn University Auburn, Alabama

Shern Ihle, DVM, MS, DACVIM (Small Animal Internal Medicine)

Associate Professor Department of Companion Animals, Atlantic Veterinary College University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

Edward Jazic, DVM, DACVD

Dermatology for Animals Campbell, California

Albert E. Jergens, DVM, MS, DACVIM (Small Animal Internal Medicine)

Professor, Staff Internist Department of Veterinary Clinical Sciences College of Veterinary Medicine Iowa State University Ames, Iowa

Cheri Johnson, DVM, MS, DACVIM (Small Animal Internal Medicine)

Professor, Chief of Staff Department of Small Animal Clinical Sciences, College of Veterinary Medicine Michigan State University East Lansing, Michigan

Susan E. Johnson, DVM, MS, DACVIM (Small Animal Internal Medicine)

Associate Professor, Service Head, Small Animal Internal Medicine, Department of Veterinary Clinical Sciences, College of Veterinary Medicine The Ohio State University Columbus, Ohio

Spencer A. Johnston, VMD, DACVS

Edward H. Gunst Professor of Small Animal Surgery, Department of Small Animal Medicine and Surgery, College of Veterinary Medicine, University of Georgia Athens, Georgia

Soraya V. Juarbe-Díaz, DVM, DACVB

Veterinary Behaviorist Tampa, Florida

Brett Kantrowitz, DVM, DACVR

Veterinary Medical and Surgical Group Ventura, California

Bruce W. Keene, DVM, MSc, DACVIM (Cardiology)

Professor, Attending Cardiologist Department of Clinical Sciences, Veterinary Teaching Hospital North Carolina State University Raleigh, North Carolina

Ninette Keller, BVSc (Hons), MMedVet (Med)

Senior Lecturer, Faculty of Medicine, Health and Molecular Sciences, School of Veterinary and Biomedical Sciences, James Cook University Townsville, Queensland, Australia

Marc Kent, DVM, DACVIM (Neurology, Small Animal Internal Medicine)

Neurologist Department of Small Animal Medicine and Surgery College of Veterinary Medicine University of Georgia Athens, Georgia

Marie E. Kerl, DVM, DACVIM (Small Animal Internal Medicine), DACVECC

Associate Teaching Professor Department of Small Animal Medicine and Surgery, College of Veterinary Medicine University of Missouri Columbia, Missouri

Frank Kettner, BSc (Hons), BVSc (Hons), MMedVet (Med)

Internist, Medicine Clinic Tygerberg Animal Hospital—Bellville Cape Town, South Africa

Safdar A. Khan, DVM, MS, PhD, DABVT

Director of Toxicology Research, ASPCA Animal Poison Control Center, Urbana, Illinois

Greg Kilburn, DVM, DACVIM (Neurology)

Staff Neurologist/Neurosurgeon, Veterinary Emergency Clinic and Referral Center Toronto, Ontario, Canada

Michael A. Kiselow, DVM, DACVIM (Oncology)

Associate Oncologist Department of Oncology Veterinary Medical Specialists Campbell, California

Barbara E. Kitchell, DVM, PhD, DACVIM (Small Animal Internal Medicine, Oncology)

Professor and Director Center for Comparative Oncology, Department of Small Animal Clinical Sciences, College of Veterinary Medicine, Michigan State University East Lansing, Michigan

Karen L. Kline, DVM, MS, DACVIM (Neurology)

Staff Neurologist Neurology and Neurosurgery, VCA Veterinary Specialty Center of Seattle Lynnwood, Washington

Michael W. Knight, DVM, DABVT, DABT

Senior Toxicologist, Animal Poison Control Center American Society for the Prevention of Cruelty to Animals Urbana, Illinois

Marc S. Kraus, DVM, DACVIM (Small Animal Internal Medicine, Cardiology)

Senior Lecturer Department of Clinical Sciences, College of Veterinary Medicine Cornell University Ithaca, New York

Donald R. Krawiec, DVM, MS, PhD, DACVIM (Small Animal Internal Medicine)

President, Internist, Internal Medicine California Veterinary Specialists San Marcos, California

Michelle Kutzler, DVM, PhD, DACT

Companion Animal Industries Department of Animal Sciences, College of Agricultural Sciences, Oregon State University Corvallis, Oregon

Tracy A. LaDue, DVM, DACVIM (Oncology), DACVR (Radiation Oncology)

Oncologist Southeast Veterinary Oncology Orange Park, Florida

Elizabeth J. Laing, DVM, DVSc, DACVS

Surgical Referral Service Fort Atkinson, Wisconsin

Leigh A. Lamont, DVM, MS, DACVA

Associate Professor of Anesthesiology, Department of Companion Animals, Atlantic Veterinary College University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

Cathy E. Langston, DVM, DACVIM (Small Animal Internal Medicine)

Staff Internist Nephrology, Urology, and Hemodialysis, Animal Medical Center New York, New York

Andrea C. Lantis, DVM, DACVIM (Cardiology)

Assistant Professor Department of Small Animal Clinical Sciences, Virginia-Maryland Regional College of Veterinary, Medicine Virginia Polytechnic Institute and State University Blacksburg, Virginia

Nancy J. Laste, DVM, DACVIM (Cardiology)

Department Head, Cardiology Angell Animal Medical Center Boston, Massachusetts

Susanne K. Lauer, DVM, DACVS, DECVS

Assistant Professor Department of Veterinary Clinical Sciences, School of Veterinary Medicine Louisiana State University Baton Rouge, Louisiana

Richard A. LeCouteur, BVSc, PhD, DACVIM (Neurology), DECVN

Professor Department of Surgical and Radiological Sciences, School of Veterinary Medicine University of California—Davis Davis, California

Alfred M. Legendre, DVM, MS, DACVIM (Small Animal Internal Medicine)

Professor of Medicine and Oncology, Department of Small Animal Clinical Sciences, College of Veterinary Medicine University of Tennessee Knoxville, Tennessee

Bruce E. LeRoy, DVM, PhD, DACVP (Clinical Pathology)

Assistant Professor Department of Pathology College of Veterinary Medicine University of Georgia Athens, Georgia

John R. Lewis, VMD, FAVD, DAVDC

Assistant Professor of Dentistry and Oral Surgery, Department of Clinical Studies School of Veterinary Medicine University of Pennsylvania Philadelphia, Pennsylvania

James D. Lincoln, DVM, MS

Associate Professor of Small Animal Surgery, Department of Veterinary Clinical Sciences, College of Veterinary Medicine Washington State University Pullman, Washington

David S. Lindsay, PhD

Professor of Parasitology, Department of Biomedical Sciences and Pathobiology, Virginia-Maryland Regional College of Veterinary Medicine, Virginia Polytechnic Institute and State University Blacksburg, Virginia

Kathleen Linn, DVM, MS, DACVS

Associate Professor of Small Animal Surgery, Small Animal Clinical Sciences Western College of Veterinary Medicine, University of Saskatchewan Saskatoon, Saskatchewan, Canada

Meryl P. Littman, VMD, DACVIM (Small Animal Internal Medicine)

Associate Professor of Medicine, Department of Clinical Studies School of Veterinary Medicine University of Pennsylvania Philadelphia, Pennsylvania

Remo Lobetti, BVSc, MMedVet (Med), PhD, DECVIM-CA (Internal Medicine)

Internist Bryanston Veterinary Hospital Bryanston, South Africa

Andrea Looney, DVM, DACVA

Senior Lecturer Cornell University Veterinary Specialists, Stamford, Connecticut Senior Lecturer, Department of Clinical Sciences, Cornell University Hospital for Animals, College of Veterinary Medicine Cornell University Ithaca, New York

Kyle G. Mathews, DVM, MS, DACVS

Professor, Small Animal Surgery, Department of Clinical Sciences, College of Veterinary Medicine North Carolina State University Raleigh, North Carolina

Glenna E. Mauldin, DVM, MS, DACVIM (Oncology), DACVN

Western Veterinary Cancer Centre, Western Veterinary Specialist and Emergency Centre Calgary, Alberta, Canada

Janet Kovak McClaran, DVM, DACVS

Staff Surgeon, Co-Director of Post-Graduate Education, The Animal Medical Center New York, New York

Carol McClure, DVM, MS, PhD, DACT

Research Scientist Department of Health Management, Atlantic Veterinary College University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

Brendan C. McKiernan, DVM, DACVIM (Small Animal Internal Medicine)

Staff Internist Southern Oregon Veterinary Specialty Center Medford, Oregon

Maureen A. McMichael, DVM, DACVECC

Associate Professor, Service Chief—Emergency and Critical Care, Department of Veterinary Clinical Medicine, College of Veterinary Medicine University of Illinois Urbana, Illinois

Elizabeth A McNiel, DVM, PhD, DACVIM (Oncology) DACVR (Radiation Oncology)

Assistant Professor Department of Small Animal Clinical Sciences, College of Veterinary Medicine Michigan State University East Lansing, Michigan

Irina Meadows, DVM, DABT

Consulting Veterinarian in Clinical Toxicology, Animal Poison Control Center American Society for the Prevention of Cruelty to Animals Urbana, Illinois

Katrina L. Mealey, DVM, PhD, DACVIM (Small Animal Internal Medicine), DACVCP

Professor Department of Veterinary Clinical Sciences, College of Veterinary Medicine Washington State University Pullman, Washington

Charlotte Means, DVM, MLIS, DABVT, DABT

Senior Toxicologist, Animal Poison Control Center, American Society for the Prevention of Cruelty to Animals Urbana, Illinois

Michele Menard, DVM, MSc, PhD, DACVP

VDIC, Inc. Clackamas, Oregon

Donna Alice Mensching, DVM, MS, DABVT, DABT

Senior Toxicologist, Animal Poison Control Center, American Society for the Prevention of Cruelty to Animals, Urbana, Illinois

Kathryn M. Meurs, DVM, DACVIM (Cardiology), PhD

Professor Veterinary Clinical Sciences College of Veterinary Medicine Washington State University Pullman, Washington

Kathryn E. Michel, DVM, MS, DACVN

Associate Professor of Nutrition, Department of Clinical Studies School of Veterinary Medicine University of Pennsylvania Philadelphia, Pennsylvania

David Benno Miller, BVSc (Hons), MMedVet (Med)

Head Physician Johannesburg Specialist, Veterinary Centre Johannesburg, South Africa

James B. Miller, DVM, MS, DACVIM (Small Animal Internal Medicine)

Professor of Medicine Department of Companion Animals, Atlantic Veterinary College University of Prince Edward Island, Charlottetown, Prince Edward

Island, Canada

Sarah J. Miller, DVM, DACVIM (Cardiology)

Staff Cardiologist Southern California Veterinary Specialty Hospital Irvine, California

Michael B. Mison, DVM, DACVS

Affiliate Assistant Professor Department of Comparative Medicine, University of Washington School of Medicine, Seattle, Washington; Staff Surgeon, Department of Surgery Seattle Veterinary Specialists Kirkland, Washington

Peter Moak, DVM

Assistant Professor Department of Companion Animals, Atlantic Veterinary College University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

Lenore A. Mohammadian, DVM, MSpVM, DACVR

Staff Radiologist, California Veterinary Specialist Carlsbad, California

Lisa E. Moore, DVM, DACVIM (Small Animal Internal Medicine)

Affiliated Veterinary, Specialists Maitland, Florida

Phillip A. Moore, DVM, DACVO

Associate Professor Department of Small Animal Medicine and Surgery, College of Veterinary Medicine University of Georgia Athens, Georgia

Adam Mordecai, DVM, MS, DACVIM (Small Animal Internal Medicine)

Veterinary Specialty Center, Buffalo Grove, Illinois

Sherry J. Morgan, DVM, PhD, DACVP, DABT, DABVT

Senior Project Director Preclinical Safety Abbott Laboratories Alto, New Mexico

Helen M.C. Munro, BVMS MRCVS

Honorary Fellow Veterinary Pathology and Veterinary Clinical Studies, Royal (Dick) School of Veterinary Studies University of Edinburgh Edinburgh, Scotland, United Kingdom

Laura A. Nafe, DVM

Resident Small Animal Internal Medicine, Department of Veterinary Medicine and Surgery College of Veterinary Medicine, University of Missouri Columbia, Missouri

Sarah L. Naidoo, DVM, MS, DACVIM (Small Animal Internal Medicine)

Staff Internist The Emergency Animal Hospital Springfield, Oregon

Jill Narak, DVM, MS

Assistant Professor, Neurology & Neurosurgery, Department of Small Animal Clinical Sciences College of Veterinary Medicine, University of Tennessee Knoxville, Tennessee

O. Lynne Nelson, DVM, MS, DACVIM (Small Animal Internal Medicine, Cardiology)

Associate Professor of Cardiology Department of Veterinary Clinical Sciences, College of Veterinary Medicine Washington State University Pullman, Washington

Nicole Northrup, DVM, DACVIM (Oncology)

Associate Professor Department of Small Animal Medicine and Surgery College of Veterinary Medicine, University of Georgia Athens, Georgia

Dennis P. O'Brien, DVM, PhD, DACVIM (Small Animal Internal Medicine)

Professor of Neurology Department of Small Animal Medicine and Surgery College of Veterinary Medicine, University of Missouri Columbia, Missouri

Mauria A. O'Brien, DVM, DACVECC

Clinical Assistant Professor Department of Veterinary Clinical Medicine, College of Veterinary Medicine, University of Illinois Urbana, Illinois

Karine M. Verstegen-Onclin, DVM, PhD, DECAR

Clinical Assistant Professor Large Animal Clinical Sciences Companion Animal Theriogenology, College of Veterinary Medicine University of Florida Gainesville, Florida

Arthur I. Ortenburger, DVM, MS

Associate Professor of Surgery Department of Health Management, Atlantic Veterinary College University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

João S. Orvalho, DVM, DACVIM (Cardiology)

Cardiology Veterinary Medical Teaching Hospital, University of California San Diego, California

Carl Osborne, DVM, PhD, DACVIM (Small Animal Internal Medicine)

Professor, Department of Veterinary Clinical Sciences, College of Veterinary Medicine, University of Minnesota St. Paul, Minnesota

M. Lynne O'Sullivan, DVM, DVSc, DACVIM (Cardiology)

Associate Professor Department of Clinical Studies, Ontario Veterinary College University of Guelph Guelph, Ontario, Canada

Elizabeth O'Toole, BSc, DVM, DVSc, DACVECC

Consultant Advanced Veterinary Care Toronto, Ontario, Canada

Therese E. O'Toole, DACVIM (Small Animal Internal Medicine)

Assistant Clinical Professor Department of Clinical Sciences, Cummings School of Veterinary Medicine, Tufts University North Grafton, Massachusetts

Karen L. Overall, MA, VMD, PhD, DACVB, CAAB

Research Associate Center for Neurobiology and Behavior, Department of Psychiatry School of Veterinary Medicine, University of Pennsylvania Philadelphia, Pennsylvania

LeeAnn Pack, DVM, DACVR

Assistant Professor Department of Companion Animals, Atlantic Veterinary College University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

Phillip Padrid, DVM

Regional Medical Director, VCA, New Mexico, Arizona, Nevada, Utab, Nebraska Associate Professor of Molecular Medicine, Pritzker School of Medicine University of Chicago Chicago, Illinois; Associate Professor, Small Animal Medicine School of Veterinary Medicine The Ohio State University Columbus, Ohio

Nadia Pagé, DMV MSc, DACVD

Veterinary Dermatologist Centre Vétérinaire DMV Montreal (Lachine), Québec, Canada

Marc Papageorges, DVM, MS, PhD, DACVR

Radiologist VDIC, Inc. Clackamas, Oregon

Manon Paradis, DMV, MVSc, DACVD

Dermatology Professor Department of Clinical Sciences, Faculté de Médecine Vétérinaire, University of Montreal Saint-Hyacinthe, Québec, Canada

Rosa Maria Páramo-Ramírez, MVZ, PhD

Professor, Reproduction Department, Faculty of Veterinary, Medicine and Animal Husbandry, Universidad Nacional Autónomade Mexico—UNAM Ciudad de México, México

Adam P. Patterson, DVM, DACVD

Clinical Assistant Professor of Dermatology, Department of Small Animal Clinical Sciences, College of Veterinary Medicine & Biomedical Sciences, Texas A&M University College Station, Texas

April L. Paul, DVM, DACVECC

Director, Emergency and Critical Care Department, Tufts VETS Walpole, Massachusetts

Michael M. Pavletic, DVM, DACVS

Director of Surgical Services Department of Surgery, Angell Animal Medical Center Boston, Massachusetts

Michael E. Peterson, DVM, MS

Instructor, Toxicology Oregon State University Corvallis, Oregon; Associate Veterinarian Reid Veterinary Hospital Albany, Oregon

Polly B. Peterson, DVM, DACVIM (Small Animal Internal Medicine)

Associate Veterinarian; Intern Director Internal Medicine, VCA Veterinary Specialty Center of Seattle Lynnwood, Washington

Fred S. Pike, DVM, DACVS

Surgeon Veterinary Specialty Hospital San Diego, California

Chantale L. Pinard, DVM, MSc, DACVO

Assistant Professor Department of Clinical Studies Ontario Veterinary College University of Guelph Guelph, Ontario, Canada

Carlos R.F. Pinto, MedVet, PhD, DACT

Associate Professor Service Head, Theriogenology and Reproductive Medicine, Department of Veterinary Clinical Sciences, College of Veterinary Medicine The Ohio State University Columbus, Ohio

Caryn E. Plummer, DVM, DACVO

Assistant Professor of Comparative Ophthalmology, Departments of Small and Large Animal Clinical Sciences, Veterinary Medical Center College of Veterinary Medicine University of Florida Gainesville, Florida

Dan Polidoro, DVM

Staff Surgeon Animal Surgical & Emergency Center Los Angeles, California

Brandy Porterpan, DVM, DACVIM (Small Animal Internal Medicine)

Internist Animal Diagnostic Clinic Dallas, Texas

Thomas Mitchell Potter, DVM

Resident, Small Animal Emergency and Critical Care Department of Clinical Sciences, College of Veterinary Medicine, Auburn University Auburn, Alabama

Barrak M. Pressler, DVM, PhD, DACVIM (Small Animal Internal Medicine)

Assistant Professor of Internal Medicine, Department of Veterinary Clinical Sciences, School of Veterinary Medicine Purdue University West Lafayette, Indiana

Robert Prošek, DVM, MS, DACVIM (Cardiology), DECVIM-CA (Cardiology)

Adjunct Professor of Cardiology, Department of Small Animal Medicine, University of Florida Gainesville, Florida Veterinary Specialists Inc.—Animal Heart Centers, Homestead, Florida Director Veterinary Institute for Interventional Therapy Ft. Lauderdale, Florida

David R. Proulx, BS, MSpVM, DACVIM (Oncology), DACVR (Radiation Oncology)

Head of Radiation Oncology California Veterinary Specialists San Marcos, California

David A. Puerto, DVM, DACVS

Chief of Surgery Department of Surgery Center for Animal Referral and Emergency Services Langhorne, Pennsylvania

Gary Puglia, DVM

Emergency and Critical Care Resident, Department of Clinical Sciences, Cummings School of Veterinary Medicine, Tufts University North Grafton, Massachusetts

Beverly J. Purswell, DVM, PhD, DACT

Professor Department of Large Animal Clinical Sciences, Virginia-Maryland Regional College of Veterinary Medicine, Virginia Polytechnic Institute and State University Blacksburg, Virginia

Richard F. Quinn, DVM, DVSc, DACVO

Veterinary Eye Specialists Denfield, Ontario, Canada

MaryAnn Radlinsky, DVM, MS, DACVS

Associate Professor Department of Small Animal Medicine and Surgery, College of Veterinary Medicine University of Georgia Athens, Georgia

Louisa J. Rahilly, DVM, DACVECC

Emergency and Critical Care Department Supervisor, Department of Emergency and Critical Care, Cape Cod Veterinary Specialist Buzzards Bay, Massachusetts

Gregg Rapoport, DVM, DACVIM (Cardiology)

Assistant Professor, Department of Small Animal Medicine and Surgery, College of Veterinary Medicine University of Georgia Athens, Georgia

Kenneth M. Rassnick, DVM, DACVIM (Oncology)

Assistant Professor of Oncology, Department of Clinical Sciences, College of Veterinary Medicine Cornell University Ithaca, New York

Jennifer E. Rawlinson, DVM, DAVDC

Chief, Section of Dentistry and Oral Surgery, Department of Clinical Sciences, College of Veterinary Medicine Cornell University Ithaca, New York

Carol R. Reinero, DVM, DACVIM (Small Animal Internal Medicine), PhD

Assistant Professor of Small Animal Internal Medicine, Department of Veterinary Medicine and Surgery, College of Veterinary Medicine University of Missouri Columbia, Missouri

Adam J. Reiss, DVM, DACVECC

Veterinarian Department of Emergency/Critical Care, Southern Oregon Veterinary Specialty Center Medford, Oregon

Alexander M. Reiter, Dipl TZt, Dr Med Vet, DAVDC, DEVDC

Associate Professor of Dentistry and Oral Surgery, Department of Clinical Sciences, School of Veterinary Medicine University of Pennsylvania Philadelphia, Pennsylvania

Elaine Reveler, ACT

Veterinary Technologist Small Animal Hospital, Atlantic Veterinary College University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

Keith Richter, DVM, DACVIM (Small Animal Internal Medicine)

Hospital Director, Staff Internist, Veterinary Specialty Hospital of San Diego San Diego, California

Valeria Rickard, DVM

Veterinarian/Chief of Staff North Oatlands Animal Hospital Leesburg, Virginia

Marcella D. Ridgway, VMD, MS, DACVIM (Small Animal Internal Medicine)

Clinical Assistant Professor of Small Animal Medicine, Department of Veterinary Clinical Medicine, Veterinary Teaching Hospital University of Illinois Urbana, Illinois

Wesley J. Roach, DVM

Small Animal Surgery Resident, Department of Small Animal Medicine and Surgery College of Veterinary Medicine, University of Georgia Athens, Georgia

Carlos O. Rodriguez, DVM, PhD, DACVIM (Oncology)

Lecturer Department of Surgical and Radiological Sciences, School of Veterinary Medicine University of California—Davis, Davis, California;Staff Oncologist, San Francisco Veterinary Specialists San Francisco, California

Catherine L. Rogers, DVM, DACVECC

Staff Veterinarian Emergency & Critical Care Medicine, Angell Animal Medical Center Boston, Massachusetts

Elisa Petrollini Rogers, CVT, VTS (ECC)

Assistant Nursing Supervisor Emergency Service, Matthew J. Ryan Veterinary Hospital, College of Veterinary Medicine, University of Pennsylvania Philadelphia, Pennsylvania

Patricia L. Rose, DVM, MS, DACVS, DACVR

Radiologist Veterinary Radiology Ltd. Beachwood, Ohio

Tracey A. Rossi, DVM, DACVIM (Small Animal Internal Medicine)

Southern California Veterinary Specialty Hospital Irvine, California

Lois Roth-Johnson, DVM, PhD, DACVP

President Dual Boarded, Inc. Eastham, Massachusetts

Philip Roudebush, DVM, DACVIM (Small Animal Internal Medicine)

Director of Scientific Affairs and Technical Information Services, Hill's Pet Nutrition, Inc. Topeka, Kansas;Adjunct Professor Department of Clinical Sciences, College of Veterinary Medicine Kansas State University Manhattan, Kansas

Elizabeth A. Rozanski, DVM, DACVECC, DACVIM (Small Animal Internal Medicine)

Assistant Professor Department of Clinical Sciences, Cummings School of Veterinary Medicine, Tufts University North Grafton, Massachusetts

Katrin Saile, DVM, MS

Resident, Small Animal Surgery, Department of Clinical Sciences, College of Veterinary Medicine, Auburn University Auburn, Alabama

Véronique Sammut, DVM, MS, DACVIM (Neurology)

Neurologist Vet Surg and Neurology Woodland Hills, California

Sherry Lynn Sanderson, BS, DVM, PhD, DACVIM (Small Animal Internal Medicine), DACVN

Associate Professor Department of Physiology and Pharmacology, College of Veterinary Medicine University of Georgia Athens, Georgia

Lynne S. Sandmeyer, DVM, DVSc, DACVO

Associate Professor, Ophthalmology Department of Small Animal Clinical Sciences Western College of Veterinary Medicine University of Saskatchewan Saskatoon, Saskatchewan, Canada

John S. Sapienza, DVM, DACVO

Staff Ophthalmologist, Department Chair Ophthalmology, Long Island Veterinary Specialists Plainview, New York

Frédéric Sauvé, DVM, MSc, DES, DACVD

Clinical Instructor Centre Hospitalier Universitaire Vétérinaire, Faculté de médecine vétérinaire, University of Montreal Saint-Hyacinthe, Québec, Canada

Michael Schaer, DVM, DACVIM (Small Animal Internal Medicine), DACVECC

Professor and Special Assistant to the Dean Department of Small Animal Clinical Sciences, College of Veterinary Medicine University of Florida Gainesville, Florida

Mary M. Schell, DVM, DABT, DABVT

Senior ToxicologistASPCA/Animal Poison Control Center Urbana, Illinois

Patricia A. Schenck, DVM, PhD

Section Chief, Endocrine Diagnostic Section, Diagnostic Center for Population and Animal Health; Assistant Professor Department of Pathobiology and Diagnostic Investigation, College of Veterinary Medicine Michigan State University Lansing, Michigan

Mandi Schmidt, DVM

Resident, Cardiology Department of Small Animal Clinical Sciences, College of Veterinary Medicine University of Florida Gainesville, Florida

Johan P. Schoeman, BVSc, DSAM, MMedVet(Med), PhD, DECVIM-CA (Internal Medicine)

Professor of Small Animal Internal Medicine, Head of Department of Companion Animal Clinical Studies, University of Pretoria;Specialist Physician, Onderstepoort Veterinary Academic Hospital Pretoria, South Africa

Diana M. Schropp, DVM, DACVECC

Staff Veterinarian Southern Oregon Veterinary Specialty Center, Medford, Oregon

Danny W. Scott, DVM, DACVD

Professor of Medicine Department of Clinical Sciences, College of Veterinary Medicine, Cornell University Ithaca, New York

Kersti Seksel, BVSc (Hons), MRCVS, MA (Hons), FACVSc (Animal Behavior), DACVB, DECVBM-CA

Adjunct Senior Lecturer Charles Sturt University Wagga Wagga, New South Wales; Director Behavioural Service Sydney Animal Behaviour Service, Sydney, New South Wales;Director Behavioural Service, Melbourne Veterinary Specialist Centre Melbourne, Victoria, Australia

Rance K. Sellon, DVM, PhD, DACVIM (Small Animal Internal Medicine, Oncology)

Associate Professor Department of Veterinary Clinical Sciences, College of Veterinary Medicine, Washington State University Pullman, Washington

Kim A. Selting, DVM, MS, DACVIM (Oncology)

Assistant Teaching Professor Department of Veterinary Medicine and Surgery, College of Veterinary Medicine University of Missouri Columbia, Missouri

Jonathan Shani, BSc, DVM, DECVS

Director of Surgery Department of Surgery Knowledge Farm Beit Berl, Kfar Saba, Israel

Claire R. Sharp, BSc, BVMS (Hons), MS

Assistant Professor Department of Veterinary Clinical Sciences Cummings School of Veterinary Medicine, Tufts University North Grafton, Massachusetts

Darcy H. Shaw, DVM, MVSc, MBA, DACVIM (Small Animal Internal Medicine)

Associate Dean, Professional Services, Department of Companion Animals, Atlantic Veterinary College University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

Scott P. Shaw, DVM, DACVECC

Assistant Professor Department of Clinical Sciences, Cummings School of Veterinary Medicine, Tufts University North Grafton, Massachusetts

G. Diane Shelton, DVM, PhD, DACVIM (Small Animal Internal Medicine)

Professor Department of Pathology;Director, Comparative Neuromuscular Laboratory, School of Medicine University of California—San Diego La Jolla, California

Sharon L. Shields, DVM, DACVS

Surgeon Veterinary Specialty Center Tucson, Arizona

Andy Shores, DVM, MS, PhD, DACVIM (Neurology)

Clinical Professor Neurosurgery and Neurology Department of Clinical Sciences, College of Veterinary Medicine Auburn University Auburn, Alabama

David Sisson, DVM, DACVIM (Cardiology)

Professor of Cardiovascular Medicine, Department of Clinical Sciences, College of Veterinary Medicine, Oregon State University Corvallis, Oregon

Meg Sleeper, VMD, DACVIM (Cardiology)

Associate Professor of Cardiology, Department of Clinical Studies, School of Veterinary Medicine University of Pennsylvania Philadelphia, Pennsylvania

Frances O. Smith, DVM, PhD, DACT

Adjunct Clinical Professor Department of Small Animal Clinical Sciences, College of Veterinary Medicine, University of Minnesota St. Paul, Minnesota; Owner, Smith Veterinary Hospital, Inc., Burnsville, Minnesota; President, Orthopedic Foundation for Animals, Inc. Columbia, Missouri

Mark M. Smith, VMD, DACVS, DAVDC

Center for Veterinary Dentistry and Oral Surgery Gaithersburg, Maryland

Saralyn Smith-Carr, DVM, PhD, DACVIM (Small Animal Internal Medicine)

Associate Professor Department of Clinical Sciences College of Veterinary Medicine Auburn University Auburn, Alabama

Elisabeth L.R. Snead, BSc, DVM, MSc, DACVIM (Small Animal Internal Medicine)

Associate Professor Department of Small Animal Clinical Sciences, Western College of Veterinary Medicine, University of Saskatchewan Saskatoon, Saskatchewan, Canada

Katherine D. Snyder, DVM, DACVIM (Small Animal Internal Medicine)

Lecturer, Internal Medicine and Emergency/Critical Care Department of Small Animal Clinical Sciences, College of Veterinary Medicine and Biomedical Sciences, Texas A&M University College Station, Texas

Mary E. Somerville, DVM, DACVS

Staff Surgeon Animal Surgical Emergency Center, Los Angeles, California

Dennis Spann, DVM, DACVIM (Small Animal Internal Medicine)

Staff Internist, Loomis Basin Veterinary Clinic Loomis, California

Jonathan Spears, DVM, MVSc

Assistant Professor Department of Biomedical Sciences, Atlantic Veterinary College University of Prince Edward Island Charlottetown, Prince Edward Island, Canada

Erick S. Spencer, DVM, MS, DACVIM (Small Animal Internal Medicine)

Clinical Assistant Professor Department of Veterinary Clinical Sciences, College of Veterinary Medicine Washington State University Pullman, Washington

Alan W. Spier, DVM, PhD, DACVIM (Cardiology)

Staff Cardiologist Florida Veterinary Specialists Tampa, Florida

Jörg M. Steiner, Dr Med Vet, PhD, DACVIM (Small Animal Internal Medicine), DECVIM-CA (Internal Medicine)

Associate Professor and Director, Gastrointestinal Laboratory Department of Small Animal Clinical Sciences, College of Veterinary Medicine and Biomedical Sciences, Texas A&M University College Station, Texas

Rebecca L. Stepien, DVM, MS, DACVIM (Cardiology)

Clinical Professor Department of Medical Sciences, School of Veterinary Medicine University of Wisconsin;Clinical Cardiologist Section Head, Cardiopulmonary ServiceU.W. Veterinary Care Madison, Wisconsin

Vladimir Stojanovic, DVM

Resident, Small Animal Internal Medicine, Department of Companion Animals, Atlantic Veterinary Collage University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

Michael Stone, DVM, DACVIM (Small Animal Internal Medicine)

Clinical Assistant Professor Department of Clinical Studies, Cummings School of Veterinary Medicine, Tufts University North Grafton, Massachusetts;Associate Veterinarian, Veterinary Internal Medicine Mobile Specialists North Woodstock, Connecticut

Elizabeth Streeter, DVM, DACVECC

Emergency and Critical Care Medicine Eastern Iowa Veterinary Specialty Center, Cedar Rapids, Iowa

Keith N. Strickland, DVM, DACVIM (Cardiology)

President Veterinary Cardiac Consultations, LLC, Baton Rouge, Louisiana

Shannon Stroup, DVM, MS, DACVIM (Small Animal Internal Medicine)

Associate Department of Internal Medicine, Louisiana Veterinary Referral Center, Mandeville, Louisiana

Jan S. Suchodolski, MedVet, DrMedVet, PhD

Clinical Assistant Professor and Associate Director Gastrointestinal Laboratory, Department of Small Animal Clinical Sciences, College of Veterinary Medicine and Biomedical Sciences, Texas A&M University College Station, Texas

Catherine M. Sumner, DVM

Emergency Medicine/Critical Care Resident, Department of Emergency and Critical Care, Cummings School of Veterinary Medicine, Tufts University North Grafton, Massachusetts; Tufts Veterinary Emergency Treatment Services Walpole, Massachusetts

Graham Swinney, BVSc, FACVSc

Canine Medicine Specialist Veterinary Teaching Hospital University of Sydney; Internal Medicine ConsultantIDEXX Laboratories, Sydney, New South Wales, Australia

Jane Sykes, BVSc (Hons), PhD, DACVIM (Small Animal Internal Medicine)

Professor of Small Animal Medicine, Department of Medicine and Epidemiology, School of Veterinary Medicine University of California—Davis Davis, California

Joseph Taboada, DVM, DACVIM (Small Animal Internal Medicine)

Associate Dean Office of Student and Academic Affairs; Professor of Small Animal Internal Medicine Department of Veterinary Clinical Sciences, School of Veterinary Medicine Louisiana State University Baton Rouge, Louisiana

Lauren R. Talarico, DVM

Neurology/Neurosurgery Resident Department of Clinical Sciences, Hospital for Animals College of Veterinary Medicine, Cornell University Ithaca, New York

Jaime Tarigo, DVM, DACVP

Resident, Clinical Pathology Department of Comparative Biomedical Sciences, College of Veterinary Medicine, North Carolina State University Raleigh, North Carolina

Karen M. Tefft, DVM, DACVIM (Small Animal Internal Medicine)

Assistant Professor of Internal Medicine, Department of Companion Animals, Atlantic Veterinary College University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada

William B. Thomas, DVM, MS, DACVIM (Neurology)

Professor, Neurology and Neurosurgery, Department of Small Animal Clinical Sciences, College of Veterinary Medicine, University of Tennessee Knoxville, Tennessee

Michael Thrusfield, MSc, BVMS, DTVM, CBiol, FSB, DECVPH, MRCVS

Veterinary Clinical Studies Royal (Dick) School of Veterinary Studies, University of Edinburgh Roslin, Midlothian, United Kingdom

D. Michael Tillson, DVM, MS, DACVS

Professor, Small Animal Surgery Department of Clinical Sciences, College of Veterinary Medicine Auburn University Auburn, Alabama

Karen M. Tobias, DVM, MS, DACVS

Professor Department of Small Animal Clinical Sciences, College of Veterinary Medicine University of Tennessee Knoxville, Tennessee

Danna M. Torre, DVM, DACVECC

Veterinary SpecialistVCA Shoreline Veterinary Referral and Emergency Center, Shelton, Connecticut

Nicholas J. Trout, MA, VetMB, MRCVS, DACVS, DECVS

Staff Surgeon Angell Animal Medical Center Boston, Massachusetts

Mark T. Troxel, DVM, DACVIM (Neurology)

Staff Neurologist, Neurosurgeon, Neurology & Neurosurgery Department, Massachusetts Veterinary Referral Hospital Woburn, Massachusetts

David C. Twedt, DVM, DACVIM (Small Animal Internal Medicine)

Professor Department of Clinical Sciences, College of Veterinary Medicine and Biomedical Sciences, Colorado State University Fort Collins, Colorado

Shelly Vaden, DVM, PhD, DACVIM (Small Animal Internal Medicine)

Professor, Internal Medicine Department of Clinical Sciences, College of Veterinary Medicine, North Carolina State University Raleigh, North Carolina

Beth A. Valentine, DVM, PhD, DACVP

Professor Department of Biomedical Sciences, College of Veterinary Medicine, Oregon State University Corvallis, Oregon

Liesel van der Merwe, BVSc (Hons) MRCVS

Faculty of Veterinary Science, Department of Companion Animal Clinical Studies Faculty of Veterinary Medicine, University of Pretoria Onderstepoort, South Africa

Mirinda (Nel) van Schoor, BVSc (Hons), MMedVet (Med)

Senior Lecturer, Small Animal Internal Medicine, Department of Companion Animal Clinical Studies, Faculty of Veterinary Science University of Pretoria Onderstepoort, South Africa

Leen Verhaert, DVM, DEVDC

Practice Assistant Department of Medicine and Clinical Biology of Small Animals, Faculty of Veterinary Medicine, Ghent University Merelbeke, Belgium;Associate, Trivet Veterinary Practice Hove, Belgium

John P. Verstegen, DVM, MSc, PhD, DECAR

Associate Professor Companion Animal Theriogenology, Department of Large Animal Clinical Sciences College of Veterinary Medicine, University of Florida Gainesville, Florida

Dietrich Volkmann, BVSc, MMedVet, DACT

Professor in Theriogenology Department of Veterinary Medicine and Surgery, College of Veterinary Medicine, University of Missouri Columbia, Missouri

Lori S. Waddell, DVM, DACVECC

Adjunct Assistant Professor of Critical Care Department of Clinical Studies, Matthew J. Ryan Veterinary Hospital, School of Veterinary Medicine University of Pennsylvania Philadelphia, Pennsylvania

Stephen Waisglass, BSc, DVM, CertSAD, DACVD

Adjunct Professor Veterinary Dermatologist Dermatology Referral Service Veterinary Emergency Clinic and Referral Centre, Ontario Veterinary College University of Guelph Toronto, Ontario, Canada

Thomas Walker, DVM, DACVECC

Assistant Professor of Pharmacology, Toxicology and Emergency Medicine, Department of Pathobiology School of Veterinary Medicine Ross University St Kitts, West Indies

Richard Walshaw, BVMS, DACVS

Surgical Oncologist Animal Cancer and Imaging Center Canton, Michigan

Aubrey Webb, DVM, PhD

Assistant Professor Department of Clinical Neurosciences, Faculty of Medicine, University of Calgary, Calgary, Alberta, Canada;Cullen Webb Animal Neurology and Ophthalmology Centre, Riverview, New Brunswick, Canada

Craig B. Webb, PhD, DVM, DACVIM (Small Animal Internal Medicine)

Associate Professor Department of Clinical Sciences, College of Veterinary Medicine, Colorado State University Fort Collins, Colorado

Cynthia R.L. Webster, DVM, DACVIM (Small Animal Internal Medicine)

Professor Department of Clinical Science, Cummings School of Veterinary Medicine Tufts University North Grafton, Massachusetts

Lisa P. Weeth, DVM, DACVN

Clinical Nutritionist Red Bank Veterinary Hospital Tinton Falls, New Jersey

Claire M. Weigand, DVM, DACVIM (Small Animal Internal Medicine)

Department of Internal Medicine, Veterinary Emergency and Specialty Hospital, South Deerfield, Massachusetts

Kristin M. Welch, DVM

Resident, Emergency and Critical Care, Foster Hospital for Small Animals, Cummings School of Veterinary Medicine, Tufts University North Grafton, Massachusetts

Sharon L. Welch, DVM, DABVT, DABT

Senior Toxicologist, Animal Poison Control Center American Society for the Prevention of Cruelty to Animals Urbana, Illinois

Elizabeth G. Welles, DVM, PhD, DACVP

Preface

“Not what we have, but what we enjoy, constitutes our abundance.”
-J Petit-Senn

A second edition is both an opportunity and an enigma. It is an opportunity to improve on the original, to make it bigger, more insightful, clearer—simply better. Coming on the heels of a first edition that was very well received, it is a pleasure for us to aim higher. But if the original was a success, the revision is also an enigma, or even a hazard: how do we make a book that keeps the best of the old while adding the most of the new?

The *Clinical Veterinary Advisor: Dogs and Cats,* second edition, has aimed from the very beginning to find the best possible balance in this regard. The basic structure and content of the book should be recognizable to all readers of the first edition. Nevertheless, there are many innovations to be found here. There are all-encompassing changes within the repeating template structure of chapters, and there are also dozens of individual new chapters. Individual overview statements in 800 of the chapters now help guide the reader-practitioner toward implementing recommendations in a practical fashion. A great deal of new information for clients and for technicians is now available. Every chapter that was included in the first edition appears again in the second edition fully revised and updated; some have changed names to remain current (hemobartonellosis now appears as hemotropic mycoplasmosis, hepatocutaneous syndrome is now superficial necrolytic dermatitis, and so on), but users of the first edition can be assured that they will find up-to-date versions of all chapters in this edition. This has indeed been the greatest challenge: keeping the very best, trimming or condensing obsolete or duplicated facts, and introducing worthwhile new material. Doing so has required a herculean effort from authors and editors. George Bernard Shaw faced the same issue when he finished a letter of recommendation for a friend. In a note pinned to the letter, Shaw wrote, “Sorry the letter is so long. I didn't have time to write you a short one.” Similarly, the *Advisor's* authors and section editors had ample material at their disposal, but unlike Shaw, they seem to have spared no effort in distilling the most valuable essentials out of it. Their efforts translate into chapters that are focused, user-friendly, and up to date. Like the unreachable horizon, the permanent goal for which the *Advisor* will continue to strive is for its users to read each paragraph on every page and think “This is exactly what I wanted to know.”

A new edition is justified when there has been substantial change, and updates need to be introduced. These improvements should be evident to all readers through both changes in existing chapters, and the introduction of new chapters. **Over 60 new topics have been created and added to this new edition.** They are summaries of a wide range of disorders such as the MDR-1 (ABCB1) mutation, Xylitol toxicosis, Adulterated diets, Fear due to veterinary visits, Canine influenza, and dozens of others. The novelty of these topics is matched by their clinical relevance, and the appearance of these new chapters is a testament to their importance in veterinary practice. They are presented in the same chronological template format that reflects the way the patient is received and treated: Background information, then chief complaint and history, then physical exam, then analysis (etiology, pathophysiology, differential diagnosis), diagnosis, treatment, and outcome. Every topic has one or more current Suggested Reading sources for additional information, and these have, as much as possible, been drawn from easily accessible journals and textbooks. There are many, many new photographs and illustrations, to convey information graphically for those of us who are visual learners. The photographs in the printed version of the book are also available in color in the online edition of the book.

Over a dozen new Procedures and Techniques have been added, bringing the number of procedure descriptions to over 100. These additions range from the immediately practical (Porcupine quill removal, Breeding soundness exam, Nebulization/coupage/respiratory therapeutics) to the referral-level (Tracheal stent placement, Ethanol ablation of parathyroid nodules, Brain biopsy [stereotactic]). As before, these procedures are described in a step-wise, template-based format, and their inclusion is as much for clinicians involved in actually performing them as for attending veterinarians who plan to refer the patient and simply want to understand what is involved in the procedure.

An important set of specific improvements applied *en masse* to all Section I (Diseases & Disorders) chapters is the addition of clinical guidance statements. Chapters now have two new subsections within their Diagnosis and Treatment sections, called Diagnostic Overview and Treatment Overview, respectively. Briefly, the format of chapters in the first edition allowed for diagnostic tests to be presented in an orderly and clear manner. However, there was a risk of the “laundry list effect”: just because all relevant tests were stated

did not mean that the reader would know how to apply them, or which tests to use when. The information might be encyclopedic, but veterinary practice runs more along the lines of a narrative. In this new edition, authors covering every disease and disorder were tasked with adding a Diagnostic Overview statement to provide basic clinical guidance for achieving a reasonable diagnosis of the disorder in question. The result is a positive and deeply rewarding one. These overview statements now provide the insight of authors not only on what can be done but realistically what should be done to achieve a basic working diagnosis. A typical Diagnostic Overview statement for parvoviral enteritis of dogs, for example, states: “The diagnosis is suspected based on the presence of anorexia, vomiting, diarrhea, lethargy, or a combination of these, typically in a young and usually unvaccinated dog; confirmation requires fecal assay such as a parvovirus ELISA snap test.” It need not be complicated, and is not meant to address every conceivable variation of the disease. Rather, these overviews are a starting point for outlining a reasonable course of action. They offer a summary of expertise, “from the trenches,” of what should be considered when working up a typical patient suspected of having a particular disorder. Similarly, Treatment Overviews aim to address the unspoken questions that come up when looking at a list of possible medications or interventions: which treatments should be applied? In which cases? Overall, these changes are meant to improve what the book has to offer: not just facts, but insights into application of the information provided.

The “health care team” approach is far from an abstract concept. For many of us, our animal health technician colleagues spend as much time with our patients, if not more. To that end, **the *Advisor* now contains hundreds of Technician Tips** that were not available previously. The breadth of this information ranges from nursing care to client counseling, from technical skills required when caring for patients with a certain disorder, to common pitfalls to avoid. The overlap between what a veterinarian needs to know and what a technician needs to know is substantial, and this new chapter section recognizes this important interaction.

Perhaps one of the most innovative changes for this edition relates to client education sheets. These template-based, layperson's vocabulary-based summaries have been highly successful, with many, many positive comments and widespread use. While it was tempting to expand the collection by summarizing more diseases for clients to understand, it was apparent that there was an even greater need in client education: the importance of clients’ grasping not just disease processes, but the actual instructions we give them when they go home. These are the monitoring and treatment activities that we instruct owners to carry out as a follow-through on our care. Sources for information of this type are very few. Client education sheets from most veterinary textbooks are dedicated to informing, but not necessarily empowering, the client; they discuss the entire disease, from mechanism to outcome, rather than concentrating on what we expect the client to be actively doing. Public sources of information, such as dog care manuals or healthy cat books, are useful, but the extent of home medical care they describe is often very limited: how to trim the nails or how to give a tablet may be covered, but how to provide elevated feedings for a patient with esophageal disease usually is not. Niche sources such as websites or specialty books offer an individual approach for specific disorders but not a whole series of “How to” summaries for home care. This is what is missing: information that helps clients carry out the ancillary medical tasks we ask them to do at home after we discharge the patient.

To address this information gap, the *Advisor* now contains a compilation of 50 original medical “How-to” client education sheets. These new information documents cover a wide range of common home management situations, including how to perform range-of-motion exercises on a patient with orthopedic or neurologic disease, how to adapt the home environment for a pet that has become blind or deaf, how to deal with incessant coughing, how to manage a dog or cat that is having a seizure, and how to feed a dog or cat that has an indwelling (PEG or other) feeding tube. The range of topics reaches from the simple (how to remove the scent from a dog or cat that has been sprayed by a skunk) through the mid-range (how to check a bandage or cast for tightness) to the more complex (how to assist appropriately during caesarian section). In many cases, one How-to client education sheet can apply to several diseases and disorders; How to monitor respirations and How to construct and use an Elizabethan collar are such examples. The goal of all of these sheets is to provide a reference that owners can consult when we have asked them to do something specific to help their companion. Variations and modifications to suit individual patients are inevitable, and these information sheets are written to provide a general summary that practitioners can use as a base for this type of information.

Finally, one of the dominant features of the *Advisor* is the solid link between the print and electronic editions of the book. Since it is only possible to obtain both together (neither website access nor the print book is sold individually), the universal access of the web book and the hands-on gratification of opening the print book are literally bound together. This interchange has allowed for some of the less widely used material, or some chapters that overlap substantially with other chapters, to be updated and published only in the web

version of the book for this edition. As a result, the paper book remains portable, and the web book is comprehensive. Over time, the growth of information together with the limitations of a single volume book meant to be portable, means that we may rely on the web book as the vault of information and the paper book as the wallet. It is my hope that this approach will bring about the best of both worlds: new information is introduced without expanding the physical size of the paper book, and all the information can be found, whether one has the paper book handy or not, anywhere at any time online. Even those of us who consider ourselves bookworms will recognize the value of having online availability if we have worked relief shifts at other hospitals where the textbook selection is poor, or have found ourselves in an emergency setting searching for information on an uncommon topic in the middle of the night. Ultimately, this balanced approach is meant to be the answer to the riddle “How do we grow without getting bigger?”

As I noted in the first edition, it would be a pleasure to say that this edition of the *Advisor* will answer every question that comes up in small animal practice. We all know that an honest assessment of any book says otherwise. With the changes we have made, my hope is that past readers will be pleased to find that their early interest in the *Advisor* remains well founded, and that new readers will discover a source of information that speaks to their interests.

Acknowledgments

It has been the selection of information and the careful consideration of what to include that has required the most energy when creating this second edition. To you, the *Advisor's* incredibly dedicated section editors and authors, I offer my heartfelt thanks. From this vantage point I can see perhaps better than anyone the time you took and the effort you expended to create this book. You painstakingly identified relevant new information from the literature and then carefully crafted the material, both old and new, into these compact synopses. For an enthusiastic and learned author, it can be much harder to write less than to write more. All of us know that with writing comes sacrifice: we are busy with many obligations, and much of the work of good writing and editing simply comes when time is available, at night, on weekends, or instead of doing something else. We are willing to do it when there is a positive result: something that shows we made a difference for the better. Ultimately, this collective effort has produced a result of which we deserve to be proud, as I hope you will be. I expect your efforts will be noticed by a great many readers, as they were for the first edition. Many, many readers have commented so favorably on it and this positive feedback is as good a validation as any for showing the effect of your work. Students and veterinarians have told me repeatedly that the *Advisor* is their first "go-to" resource when they want to learn about something they are unfamiliar with; in many hospitals, the book is used so heavily that it has been reduced to tatters (see below) and has had to be re-bound; several board-certified specialists have told me they use the book routinely for information within and outside their specialty; and I have received many, many emails and letters praising your work, simply summarized as: "I think this book is terrific." These testimonials, as much as anything I can say, indicate the far reach of your work and the positive impact of your authorship.

Validation of our work: this is how a book ends up looking when it is used often.

Penny, you and your team deserve perhaps more credit and recognition than have ever been given to a publisher. Under your leadership, the group (Lauren Harms [Developmental Editor], Rachel McMullen [Senior Project Manager], Catherine Jackson [Publication Services Manager], Bruce Siebert [Senior Producer], and Lynn Hoops [Marketing Manager]) has exceeded my every expectation from the earliest planning stages onward. No one could hope for a kinder, more gratifying, and more effective approach for bringing the book together. It has been a pleasure, and my wish for other authors is that they be as fortunate as I have been to work with such a determined, proactive, and fun group.

With or without realizing it, many individuals made this book possible by helping me personally during its creation. My mentor, Steve Ettinger, was unfailing in his constructive criticisms and support. Unbeknownst to him, his candid observations led to many improvements in this edition, both large and small. His positive feedback and kindness during the creation of this book are irreplaceable. Thank you as always, Steve. Elizabeth Charuvastra RN, CEO of Targeted Medical Pharma LLC, stepped in and offered me an editor's dream (office space and support) while I was in California during the final stages of completion of the book. I could not have imagined a better-timed or more welcome gift, Liz. Many, many thanks. Similarly, my good friend and colleague Kirstie Barrett made it possible for me to have an immediately-usable work space during my West coast visit, and for this I am truly grateful. My friend David Edward gets a testimony of gratitude for providing an industrial quantity of PG Tips tea. Many thanks to Richard, Deirdre, and Evan Denis for hospitality during multiple layovers in Toronto. I also wish to thank all readers who sent me feedback aimed at making the second edition better. These messages from the front lines of practice helped reshape some of the content of this edition for the better, as readers will see for themselves.

I thank all members of the Atlantic Veterinary College who contributed directly or indirectly, especially my colleagues who provided feedback, the technical staff (notably Elaine Reveler) who made it possible to generate good images and graphics, and the administration and faculty association who provided the framework and support for my academic work and sabbatical leave to dedicate time to the *Advisor* specifically.

Last and most personally, I thank my family for their support and understanding. An endeavor such as this book is built on sacrifices, and their acceptance of my well-worn refrain, "I can't—I have a deadline," was the epitome of support. François, Diane, Antoine, and above all Jennifer: thank you.

5-Fluorouracil Toxicosis

BASIC INFORMATION

DEFINITION

Adverse effects caused by exposure to 5-fluorouracil (5-FU), a pyrimidine analog-type antineoplastic antimetabolite drug used for palliative management of certain carcinomas in humans and occasionally in dogs.

SYNONYMS

Common brand names: Efudex, Fluoroplex, and Carac. Generic: 2,4-dioxo-5-fluoropyrimidine; 5-fluoro-2,4(1H,3H); pyrimidinedione; 5-FU; NSC 19893; Ro2-9757; CAS 51-21-8.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats of any age, breed, and either sex. Dog cases are more common. Dogs are more likely to develop neurologic effects (seizures) compared to humans. Cats are more sensitive to toxic effects of 5-FU than dogs.

RISK FACTORS

- Preexisting liver or kidney dysfunction can increase risk of toxicity
- Presence of 5-FU in a pet's environment

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of exposure to product containing 5-FU
- Clinical signs begin within 30 minutes to 5 hours of exposure.
- Vomiting, hypersalivation, lethargy, vocalization, diarrhea, tremors, ataxia, seizures
- Some animals show vomiting progressing quickly to seizures; others may show tremors and seizures and no vomiting.

PHYSICAL EXAM FINDINGS

- Seizures (often status epilepticus)
- Vomiting (with or without blood)
- Diarrhea (with or without blood)
- Tremors
- Lethargy
- Ataxia
- Cardiac arrhythmias (all kinds)
- Respiratory depression

ETIOLOGY AND PATHOPHYSIOLOGY

Source

5-FU or similar agents are available for use as injection, topical creams (0.5%-5%) or lotions (1%-5%), and capecitabine (prodrug of fluorouracil) as tablets. Flucytosine is an antifungal agent that must be converted to 5-FU.

Toxicosis occurs after ingestion of products containing 5-FU and occasionally secondary to repeated use in dogs or cats.

Mechanism of Toxicosis

5-FU inhibits RNA processing and function and DNA synthesis and repair, inhibiting cell division. Actively dividing cell lines (bone marrow stem cells, intestinal crypt cells) are most affected.

The mechanism of neurotoxicity may be production of fluorocitrate, which limits cellular energy production by interfering with the Krebs cycle.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

History of exposure and presence of clinical signs consistent with exposure to 5-FU within 30 minutes to 5 hours after exposure

DIFFERENTIAL DIAGNOSIS

Diseases or intoxications that could cause vomiting (see p. 1173) and/or seizures (see pp. 1009 and 1425)

INITIAL DATABASE

- Serum biochemistry profile (elevated liver enzymes, azotemia possible in 24 hours)
- Electrolytes (hypokalemia possible due to severe vomiting, diarrhea)
- CBC with differential (baseline, monitor q 24-72 hours for 20 days); initial leukocytosis followed by evidence of myelosuppression, leukopenia, pancytopenia in 5-20 days. Hematocrit increased due to dehydration then decreased due to gastrointestinal (GI) bleeding.
- Blood gas analysis
- Urinalysis

ADVANCED OR CONFIRMATORY TESTING

- Analysis of 5-FU and its metabolites in plasma is possible but often difficult to obtain in timely fashion for acute toxicoses.
- Necropsy lesions: hemorrhagic colitis, GI mucosal ulceration (throughout), stomatitis, myocardial ischemia, pulmonary edema, hepatic and renal congestion

TREATMENT

TREATMENT OVERVIEW

Stabilize the patient first; control vomiting and seizures. Provide supportive care once the animal has been stabilized.

ACUTE GENERAL TREATMENT

- Decontamination of asymptomatic patient
  - Emesis using activated charcoal with a cathartic if patient is showing no clinical signs and the ingestion is recent (<1 hour)
  - Hemodialysis, peritoneal dialysis, or fluid diuresis may enhance elimination
- Manage vomiting
  - Maropitant, 1 mg/kg SQ q 24 h for up to 5 consecutive days
  - Do not use metoclopramide (contraindicated with GI hemorrhage and seizure disorder)
- GI protection
  - Sucralfate, 0.5 (small dog) to 1 gram (large dog) PO q 8 h
  - Famotidine, 0.5-1 mg/kg IV or PO q 12-24 h; or omeprazole, 0.5-1 mg/kg PO q 24 h
- Manage tremors and seizures (see p. 1009)
  - Seizures are rarely controlled with diazepam alone (dogs: 2-5 mg/kg IV; cats: 0.5-1 mg/kg IV). If seizures persist after diazepam therapy, give phenobarbital IV bolus, 2-5 mg/kg (can be repeated at 20-minute intervals up to two times). May then add phenobarbital IV infusion (2-10 mg/hour IV, titrated to effect) to diazepam; *or*
  - Pentobarbital, 3-15 mg/kg IV slowly to effect; *or*
  - Propofol, 4-6 mg/kg IV or as continuous IV infusion 0.6 mg/kg/min; *or*
  - Gas anesthesia
- Intravenous fluids
- Thermoregulation (correct hypothermia)
- Ventilatory support as needed
- Maintain normal acid-base status and electrolyte balance
- Manage pain
  - Butorphanol, 0.2-0.4 mg/kg q 2-5 h SQ, IM, or IV (dogs); 0.1-1 mg/kg IM, IV, or SQ q 1-3 h (cats); or tramadol, 1-4 mg/kg PO q 6-8 h; or buprenorphine, 0.005-0.05 mg/kg, IM, IV q 4-8 h; *or* fentanyl patch
- Consider giving broad-spectrum antibiotics to prevent secondary infection.
- For neutropenia: filgrastim (Neupogen), 4-6 mcg/kg SQ

CHRONIC TREATMENT

Intensive supportive care may be needed for days/weeks, especially if myelosuppression occurs.

NUTRITION/DIET

Tube feeding or bland diet if GI signs

DRUG INTERACTIONS

Metronidazole may increase toxicity of 5-FU by reducing clearance.

POSSIBLE COMPLICATIONS OF TREATMENT OR DISEASE PROCESS

- Severe brain damage from uncontrolled seizures
- Neutropenia, pancytopenia, myelosuppression (in 5-20 days)

RECOMMENDED MONITORING

- Heart rate, blood pressure
- Respiratory rate and character
- CBC (myelosuppression in 5-20 days), serum biochemistry profile (liver and kidney function)
- Blood gases

PROGNOSIS AND OUTCOME

Guarded to poor, once signs occur. Out of 72 cases of 5-FU toxicosis, 35 dogs died and 11 were euthanized.

PEARLS & CONSIDERATIONS

COMMENTS

- Severe signs or death can result from 5-FU toxicosis; early decontamination and immediate, intensive treatment are essential, and owners should be advised of the seriousness of exposure to 5-FU.
- Estimated toxic dose likely to cause clinical signs in dogs: 8.6 mg/kg PO. Minimum lethal dose in dogs: 20 mg/kg PO. If a 70-lb dog (32 kg) ingests 1 tablespoon (15 g) from a tube containing 5% 5-FU, the dose of 5-FU in this dog will be approximately 23 mg/kg, a potentially lethal dose.

PREVENTION

Keep medications out of pets' reach

TECHNICIAN TIPS

Estimating the ingested amount by obtaining a good history of exposure may predict the prognosis early on.

CLIENT EDUCATION

5-FU toxicosis in pets can be life threatening.

Albretson J: 5-Fluorouracil Toxicosis in dogs. Vet Med 96:270–274, 2001

AUTHOR: SHARON WELCH

EDITOR: SAFDAR KHAN

Abdominal Compartment Syndrome

BASIC INFORMATION

DEFINITION

Impaired organ function resulting from increased intraabdominal pressure (IAP >20 mm Hg). This syndrome is likely underrecognized in veterinary medicine and has a high prevalence in human ICU patients.

SYNONYMS

ACS, increased IAP, intraabdominal hypertension (IAH)

EPIDEMIOLOGY

SPECIES, AGE, SEX

No species, age, sex, genetic, or breed predisposition

RISK FACTORS

- Any patient with abdominal disease or accumulations of fluid, gas, or tissue in the abdominal cavity can develop elevated IAP.
- Specific risk factors include underlying diseases that lead to gas or fluid accumulation in the abdominal compartment (within organs, viscera or as free fluid) or interfere with the abdominal wall's ability to expand and compensate for increased abdominal contents.
    - Abdominal effusion
    - Abdominal neoplasia
    - Abdominal surgery or trauma (most common causes)
    - Abdominal wraps/bandages
    - Decreased abdominal wall compliance (edema, hematoma, muscle activity)
    - Hepatic abscess
    - High-volume fluid resuscitation
    - Ileus
    - Pancreatitis
    - Peritonitis
    - Sepsis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Primary ACS: intraabdominal cause, most commonly postoperative or trauma patients
- Secondary ACS: extraabdominal cause, most commonly sepsis or burn patients that require aggressive fluid resuscitation
- Recurrent ACS: redevelopment of ACS after surgical or medical treatment for primary or secondary ACS

HISTORY, CHIEF COMPLAINT

- Frequent history of abdominal trauma or surgery
- Indications to check IAP are (usually in combination):
    - New or progressive organ failure
    - Particularly azotemia, reduced urine output
    - Elevated central venous, mean arterial, right and left atrial pressures
    - Rising intracranial pressure, altered mentation
    - New vomiting and diarrhea
    - Acidosis, rising blood lactate levels

PHYSICAL EXAM FINDINGS

- Physical examination and abdominal perimeter (girth) measurements are insensitive for detecting elevated IAP.
- Progressive abdominal distension or tympany, jugular vein distension, tachypnea, tachycardia are possible

ETIOLOGY AND PATHOPHYSIOLOGY

- IAP in healthy adults is subatmospheric − 0 mm Hg; IAP in critically ill adults is 5-7 mm Hg.
- IAH is defined as a sustained elevation in IAP = 12 mm Hg.
- ACS (sustained IAP > 20 mm Hg with new organ dysfunction/failure) develops if IAH is not recognized and treated.

- ACS is not a disease, but a distinct syndrome of clinical signs and abnormalities that can have multiple causes.
- At low intraabdominal volumes, the abdominal wall is very compliant. Large increases in abdominal volume result in minor increases in IAP. At higher abdominal volumes, abdominal wall compliance decreases, and even small increases in volume can cause major increases in IAP.
- Increased pressure in the abdomen leads to hypoperfusion and ischemia of abdominal organs and, when severe, direct compression of blood vessels. This leads to alterations in renal (most recognized), hepatic, and gastrointestinal functions. Anuria can occur with IAP > 30 mm Hg. Liver function, including cytochrome P450 function, is impaired. Intestinal edema can develop, as well as bacterial translocation through gastrointestinal walls.
- Reduced ability for the diaphragm to contract against the tense abdomen impairs tidal volume and compromises ventilation, resulting in hypoxia and hypercapnia. Mechanical/positive pressure ventilation is similarly affected.
- Increase in central venous pressure (CVP) and drop in cardiac output (increased systemic vascular resistance, decreased venous return to the heart, compression of vascular structures from increased intrathoracic pressure) result in altered cardiovascular function.
- Intracranial pressure elevations can occur because of elevated CVP.
- Hormonal changes occur in response to the altered cardiovascular state, including elevations in renin-angiotensin activity, antidiuretic hormone, and catecholamine levels.
- Ischemia-reperfusion injury occurs after shock resuscitation and can affect distant organ function.
- Abdominal wall complications can occur secondary to hypoperfusion, including delayed or impaired wound healing, dehiscence, and surgical site infection.
- Recognition of increasing IAP and prevention of ACS are crucial to reducing morbidity and mortality.
- There is no single threshold IAP that will result in organ dysfunction or failure in all patients and can be used for decision making. The critical IAP in most patients is between 10 and 15 mm Hg; at this pressure, initial organ dysfunction develops.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

IAP must be measured to confirm the diagnosis of abdominal compartment syndrome.

INITIAL DATABASE

Most common method of measuring IAP is the intravesicular or “bladder” technique, which is an indirect measurement.

- A water manometer is attached to a stopcock in the evacuation line from a standard urinary (urethral) catheter.
- The urinary bladder is emptied, and a few milliliters of isotonic sterile saline are placed in the bladder (3-10 mL, depending on patient size).
- After 30-60 seconds (to allow the saline to warm and the detrusor muscle to relax, avoiding a falsely elevated reading), the zero mark on the manometer is held at the level of the cardiac atria (level of the umbilicus in lateral recumbency).
- The manometer is filled with saline.
- The stopcock is then opened to the bladder.
- The reading (in mm Hg) is taken when the column of saline reaches a stable level.
- The measurement should be taken at end expiration.
- Abdominal muscle contractions can increase IAP readings. Obese patients may have a higher baseline IAP.
- Alternative measurement techniques include nasogastric balloon catheter (good for continuous measurement), direct intraabdominal catheter/abdominal drain, and venous catheter in the caudal vena cava. These techniques give similar information but can be more cumbersome to place and maintain.
- Trends in pressure parameters may be more important than any single number. It is important to use the same positioning each time a measurement is taken.
- The IAP measured at one point in the abdominal cavity can be assumed to be the pressure throughout the abdominal cavity.
- Imaging can be helpful for looking for underlying causes of IAH but is insensitive at detecting increased IAP.

ADVANCED OR CONFIRMATORY TESTING

- Repeated IAP measurements are essential for monitoring.
- Lactate levels, liver enzyme changes, urine output, blood urea nitrogen, and creatinine levels to identify abdominal organ dysfunction associated with ACS
- Measurements of cardiac output and other cardiovascular parameters and monitoring mentation and intracranial pressure give a more extensive assessment of cardiovascular function and perfusion.
- Abdominal perfusion pressure (APP; mean arterial pressure minus IAP) has been proposed as a more accurate predictor of visceral perfusion. It assesses the severity of IAP, as well as the adequacy of abdominal blood flow, and should be maintained at 50-60 mm Hg in patients with IAH/ACS.

TREATMENT

TREATMENT OVERVIEW

Medical management is crucial to prevention and treatment of IAH. Surgical decompression is the definitive treatment if medical management fails to prevent further increases in IAP and organ dysfunction and failure.

ACUTE, GENERAL TREATMENT

- IAP of 10-20 mm Hg is a mild elevation and should be monitored.
- IAP of 20-35 mm Hg is a moderate to severe elevation.
    - Consider active (centesis or surgical) decompression if pressure continues to rise or if other parameters continue to deteriorate.
- IAP > 35 mm Hg is a severe elevation.

    - ACS is extremely likely.
    - Abdominal decompression is required.
    - If a correctible source is not identified, surgical exploratory laparotomy is indicated.
- Medical Management
    - Sedation, analgesia, and/or neuromuscular blockade to reduce muscle tone secondary to pain, agitation, and ventilator dyssynchrony, which result in increased IAP
    - Not effective at treating severe IAH/ACS
    - Nasogastric or colonic decompression can reduce IAP and treat mild/moderate IAH.
    - Prokinetic motility agents useful in decreasing visceral volume
    - Aim for euvolemia.
    - Hypervolemia can lead to ACS development.
    - Hypertonic crystalloid and colloid resuscitation shown to reduce IAP and decrease risk of ACS
    - Diuretics to mobilize third space fluid accumulation
    - Percutaneous decompression to remove free abdominal fluid or air
    - If this fails to resolve IAH, patient must undergo surgical decompression.
- Surgical Management (VERY rare in companion animals, barring arterial hemorrhage)
    - Direct removal of the fluid or tissue causing the problem
    - Performed when organ dysfunction/failure and IAH are refractory to medical management
    - Open abdomen or temporary abdominal closure techniques often employed in human medicine

CHRONIC TREATMENT

- Placement of abdominal drains or repeated drainages/centeses in chronic conditions to maintain reduced pressure may be necessary. Treatment of the underlying disease is essential.

DRUG INTERACTIONS

Hepatic and renal elimination of drugs may be altered by ACS, requiring dosage adjustment or alternative drug choices.

RECOMMENDED MONITORING

IAP, CVP, blood pressure, blood chemistry, lactate, urine output, diagnostic imaging as indicated by underlying cause and progression of IAP over time

PROGNOSIS AND OUTCOME

Prognosis depends on underlying cause and associated abnormalities, organ dysfunction, and disease. In human medicine, ACS is a significant cause of morbidity and mortality (approaching 70%). Disregard for elevated IAP and delay of surgery are associated with further increases in patient mortality.

PEARLS & CONSIDERATIONS

COMMENTS

- Most critically ill patients should have urethral catheters in place to monitor urine output, which allows for IAP monitoring and early detection of ACS.
- IAH may falsely elevate indirect intracardiac pressure readings due to abdominothoracic transmission of pressure.
- Monitoring and management of patients this ill requires 24-hour care.

TECHNICIAN TIP

IAP is most easily measured in recumbent patients. If the patient is conscious and mobile, care must be taken to prevent the patient from chewing the catheter and retaining the proximal portion in the abdomen or bladder (Elizabethan collar essential).

PREVENTION

Avoid excessive fluid volume resuscitation. Careful monitoring essential, with early preventive action taken if IAP rises.

Abdominal Distention

BASIC INFORMATION

DEFINITION

Enlargement of the abdominal cavity

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dependent on underlying cause

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Abdominal enlargement (rate of distention is extremely variable, varies from acute to chronic and insidious)
- Perceived weight gain
- Decreased activity
- Anorexia
- Tachypnea
- Abdominal discomfort/pain
- When ascites is present and the fluid accumulation is rapid, clinical signs of weakness and dyspnea are more likely to be apparent.
- History may include clinical signs associated with the primary disease (e.g., repeated, unproductive attempts at vomiting if gastric dilatation and volvulus; dyspnea, cough if cardiac disease; icterus if liver disease).

PHYSICAL EXAM FINDINGS

- Visible abdominal enlargement
- Abdominal palpation:
  - Fluid wave may be present (ballottement) with ascites.
  - An abdominal mass or organomegaly (liver, spleen, kidney, etc.) may be palpable.
- Physical abnormalities associated with primary disease may be present:
  - Cardiovascular abnormalities (heart murmur, arrhythmia, gallop sound, jugular distention) should warrant further investigation into the possibility of right heart failure.
  - Marked generalized lymphadenopathy may suggest lymphoma.
  - Muffled heart sounds are consistent with pericardial effusion and tamponade if ascites is present.

ETIOLOGY AND PATHOPHYSIOLOGY

- Ascites: all causes
- Hyperadrenocorticism/Cushing's disease
- Cyst (renal, hepatic)
- Gastrointestinal dilation (food, air, water, foreign material)
- Lipoma
- Lymphadenopathy
- Mass, non-neoplastic (hematoma, granuloma, abscess)
- Neoplasia

ABDOMINAL DISTENTION Dorsal view of a young English bulldog with marked ascites caused by right-sided congestive heart failure due to severe pulmonic stenosis. The abdominal distention hides the dog's weight loss and may be mistaken by the owner as an increase in lean body mass. This degree of abdominal distention was associated with poor appetite, lethargy, and dyspnea in this dog.

ABDOMINAL DISTENTION Same dog 2 hours later when large-volume abdominal drainage was complete. The dog was breathing normally, was more active, and appeared markedly more comfortable. The extent of cardiac cachexia is revealed.

- Pancreatitis
- Parasitic *(Mesocestoides)*
- Peritonitis
- Pneumoperitoneum (peritonitis or postsurgical)
- Pyometra/hydrometra
- Obstipation
- Organomegaly (hepatomegaly, splenomegaly, renomegaly)
- Torsion (splenic, gastric dilation/volvulus, etc.)
- Urinary obstruction/bladder distention

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Apparent on physical examination alone. Careful abdominal palpation and diagnostic imaging help to elucidate the cause.

DIFFERENTIAL DIAGNOSIS

- Normal variation
- Obesity
- Pregnancy

INITIAL DATABASE

- Abdominal radiographs
  - Loss of serosal detail (focal or generalized) is common if ascites is present.
  - May have “ground-glass” appearance (carcinomatosis, peritonitis)
  - Mass lesions, fat, or organomegaly may be apparent or suggested by displacement of gas-filled organs.
  - Free air may be present with peritonitis (ruptured viscus).
- Thoracic radiographs
  - Enlarged cardiac silhouette and/or caudal vena cava if congestive heart failure or pericardial effusion (rule out as cause of ascites)
  - Metastatic pulmonary disease
  - Pleural effusion
- CBC, biochemistry panel, and urinalysis are indicated for any animal with ascites or abnormal abdominal distention. Abnormalities depend on underlying cause and extent of organ damage.
- Abdominal ultrasonography
  - Confirms presence of fluid if present and differentiates fluid from soft tissue or fat
  - Identification of mass lesions, organomegaly, cyst, etc.
- Echocardiography
  - Confirms diagnosis of right heart enlargement or pericardial effusion (rule out as cause of ascites)
- Abdominal paracentesis (see p. 1194) if ascites; obtain fluid for cytology and biochemical evaluation.
- Characterize fluid based on protein concentration, specific gravity, and total cell count.
  - Transudate (pure)
    - Clear and colorless
    - Protein <2.5 g/dL
    - Specific gravity <1.018
    - Cells <1000/mm^3: neutrophils and mesothelial cells
  - Modified transudate
    - Red or pink; may be slightly cloudy
    - Protein 2.5-5.0 g/dL
    - Specific gravity >1.018
    - Cells <5000/mm^3: neutrophils, mesothelial cells, erythrocytes, and lymphocytes
  - Exudate (nonseptic)
    - Pink or white; cloudy
    - Protein 2.5-5.0 g/dL
    - Specific gravity >1.018
    - Cells 5000-50,000/mm^3: neutrophils, mesothelial cells, macrophages, erythrocytes, and lymphocytes
  - Exudate (septic)
    - Red, white, or yellow; cloudy
    - Protein >4.0 g/dL
    - Specific gravity >1.018Cells 5000-100,000/mm^3: neutrophils, mesothelial cells, macrophages, erythrocytes, lymphocytes, and bacteria
  - Hemorrhage

        - Red
        - Protein >5.5 g/dL
        - Specific gravity 1.007-1.027
        - Cells consistent with peripheral blood; usually does not clot
    - Chyle
        - Pink, straw, or white
        - Protein 2.5-7.0 g/dL
        - Specific gravity 1.007-1.040

ADVANCED OR CONFIRMATORY TESTING

- Fine-needle aspirate or needle biopsy (mass, enlarged organs, etc.). Biopsy not recommended if area is infected (abscess, pyometra) or likely to hemorrhage (e.g., suspected hemangiosarcoma).
- Prothrombin time if anticoagulant intoxication is suspected as cause of ascites (paracentesis contraindicated if coagulopathy is suspected)
- CT, MRI
- Abdominal exploratory may be indicated.

TREATMENT

TREATMENT OVERVIEW

Treatment of underlying disease and therapeutic abdominal drainage if large-volume ascites is causing the abdominal compartment syndrome (see p. 4)

ACUTE GENERAL TREATMENT

- Treatment of underlying disease:
    - Chemotherapy if lymphoma
    - Pericardiocentesis if pericardial effusion is present
    - Drug therapy for congestive heart failure
- Removal of fluid if discomfort or respiratory difficulty is present (see p. 1192).
- Surgery may be indicated for neoplasia, pyometra, peritonitis, and some causes of hemorrhage (e.g., ruptured splenic or hepatic hemangiosarcoma).

PROGNOSIS AND OUTCOME

Dependent on underlying cause

PEARLS & CONSIDERATIONS

COMMENTS

- Approach to patient with abdominal distention is to determine the nature of the primary problem.
- Thoracic radiographs should be part of the routine evaluation for a patient with ascites so as not to overlook the possibility of cardiac, pericardial, or metastatic disease–or pleural effusion.
- The cause of abdominal distention may be benign (obesity, intraabdominal lipoma, cyst).

EDITOR: ETIENNE CÔTÉ

Aberrant Adrenocortical Disease (Increased Adrenal Sex Hormone Production)

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Clinical signs of hyperadrenocorticism are present, but cortisol test results are normal, and one or more of the adrenal sex hormones is/are increased.

SYNONYMS

Atypical hyperadrenocorticism, sex hormone abnormality

EPIDEMIOLOGY

SPECIES, AGE, SEX

Middle-aged/old dogs and cats

ASSOCIATED CONDITIONS AND DISORDERS

Hyperadrenocorticism

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Pituitary dependent
- Adrenal dependent: adrenal carcinoma has mainly been reported (two cats and six dogs with hyperprogesteronism)

HISTORY, CHIEF COMPLAINT

Identical to hyperadrenocorticism (see p. 548)

PHYSICAL EXAM FINDINGS

Identical to hyperadrenocorticism (see p. 548)

ETIOLOGY AND PATHOPHYSIOLOGY

- The adrenal gland(s) secretes an excessive amount of one or more adrenal sex hormones.
- Adrenal tumors (particularly adenocarcinomas) may secrete adrenal sex hormones owing to disruption of adrenal tissue.
- Progestagens can act as glucocorticoid agonists.
- Cortisol concentrations may be normal to subnormal with sex hormone-secreting adrenal tumors, as high progestagen concentrations can suppress cortisol secretion.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The disorder is suspected when typical signs of hyperadrenocorticism are identified, but specific diagnostic tests (e.g., ACTH stimulation) are inconsistent with hyperadrenocorticism. Confirmation is obtained with identification of elevated serum levels of adrenal sex hormones.

DIFFERENTIAL DIAGNOSIS

- Polyuria/Polydipsia (see p. 902)
- Polyphagia (see p. 899)
- Alopecia (see pp. 54 and 56)

INITIAL DATABASE

Hyperadrenocorticism (see p. 548)

ADVANCED OR CONFIRMATORY TESTING

- Adrenocorticotropic hormone (ACTH) stimulation test with sex hormone panel (progesterone, 17-hydroxyprogesterone, estradiol, androstenedione, testosterone):
  - Dogs with nonadrenal illness may have mildly increased adrenal sex hormones.
  - Substantial overlap in sex hormone serum concentrations between healthy, nonadrenally ill, and hyperadrenocorticism patients make sex hormone assays ineffective screening tests for hypercortisolism.
  - Approximately 71% sensitivity and specificity for 17-hydroxyprogesterone concentrations if a cutoff greater than 8.5 ng/mL is used for diagnosing atypical hyperadrenocorticism
- Low-dose dexamethasone suppression test to rule out typical hyperadrenocorticism ± endogenous ACTH concentrations, CT, MRI (see p. 548)

TREATMENT

TREATMENT OVERVIEW

Resolution of clinical signs is the goal of treatment; medications are typically used for controlling pituitary-based disease, and surgical excision is the treatment of choice for primary adrenal tumors.

ACUTE GENERAL TREATMENT

- See Adrenal Neoplasia (Adenoma/Carcinoma), p. 43
- Pituitary-dependent (see p. 548)

CHRONIC TREATMENT

- As for hyperadrenocorticism, p. 548
- The following recommended by some, with anecdotally supported results (see http://www.vet.utk.edu/diagnostic/endocrinology/pdf/TreatmentInfoAtypicalCushingsRevised201001.pdf):
  - Melatonin (3-6 mg/dog PO q 12 h, based on body weight); inhibits aromatase and 21-hydroxylase enzymes
  - Melatonin implants (www.melatek.net) 8, 12, 18 mg for dogs weighing <25, 25-50, and >50 lb, respectively
  - Lignan (from flaxseed hulls or HMR lignan) ≈ 2 mg/kg PO q 24 h; phytoestrogenic activity inhibits aromatase
- Elimination of exogenous (e.g., hormone cream) or endogenous (ovarian remnant, cryptorchid testicle) sources of androgens

DRUG INTERACTIONS

See Hyperadrenocorticism, p. 548; Adrenal Neoplasia (Adenoma/Carcinoma), p. 43

POSSIBLE COMPLICATIONS

See Hyperadrenocorticism, p. 548; Adrenal Neoplasia (Adenoma/Carcinoma), p. 43

RECOMMENDED MONITORING

Medical therapy: ACTH stimulation testing every 3 months

- Mitotane (o,p '-DDD) therapy: sex hormone concentrations (and cortisol if also increased) should decrease to normal.
- Trilostane therapy: progesterone and 17-hydroxyprogesterone concentrations may increase concurrent with resolution of clinical signs and a decrease in cortisol concentrations.

PROGNOSIS AND OUTCOME

- Survival data unknown but subjectively similar to dogs with typical hyperadrenocorticism
- Adrenal tumor: good if surgically resectable
- Pituitary-dependent: good with treatment

PEARLS & CONSIDERATIONS

COMMENTS

- Limited information is available regarding this disease and the sensitivity and specificity of adrenal sex hormones in nonadrenal illness.
- Adrenal sex hormones are also increased in dogs with typical hyperadrenocorticism (i.e., hypercortisolemia).

TECHNICIAN TIP

On both the pre- and post-ACTH stimulated serum, 2 mL of serum are required. Centrifuge, separate, and freeze the serum as soon as possible. Avoid submission of hemolyzed samples.

SUGGESTED READING

AUTHOR: KATE HILL

EDITOR: SHERRI IHLE

Abortion, Dog

BASIC INFORMATION

DEFINITION

- The expulsion of one or more fetuses before full term pregnancy. Uncommon; in the dog, resorption is more common. Occurs more often during the fetal period.
- Induction of abortion (pregnancy termination): see p. 912.

SYNONYMS

Fetal loss, pregnancy wastage

EPIDEMIOLOGY

SPECIES, AGE, SEX

Female dog; no specific age

GENETICS & BREED PREDISPOSITION

Inbreeding (inbreeding coefficient >0.25): early embryonic death, conceptus resorption

RISK FACTORS

- History of previous pregnancy loss
- Malnutrition (pregnancy ketosis)
- Endocrinopathies (hypothyroidism, hypoluteoidism, diabetes mellitus)
- Infection *(Brucella canis, Listeria monocytogenes, Streptococcus canis, Escherichia coli, Campylobacter* sp., *Leptospira* sp. *Salmonella* sp., *Mycoplasma* sp., canine herpesvirus 1, canine parvovirus 1 [minute virus of canines], bluetongue virus, canine distemper virus, canine adenovirus [infectious hepatitis], *Toxoplasma gondii, Leishmania infantum)*
- Unsolicited treatment with endocrine disruptors, embryotoxic or teratogenic compounds (e.g., antifungal agents such as itraconazole or polyester textiles in contact with skin).
- Inadequate vaccination or deworming programs

CONTAGION & ZOONOSIS

- *Brucella canis* is zoonotic. *Salmonella* sp. and *Leptospira* sp. have zoonotic potential.
- Canine herpesvirus 1 and minute virus of canines: transmission through direct contact via aerosol or contact with aborted fetuses and/or placentas. Male-to-female venereal contact is not a significant means of viral transmission.

GEOGRAPHY AND SEASONALITY

- Canine brucellosis: endemic in parts of North and South America; eradicated in Europe since 1996.
- Canine herpesvirus: worldwide incidence; serologic prevalence of 60%-80%.

ASSOCIATED CONDITIONS & DISORDERS

Abortion may be secondary to fetal death.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Pregnant bitch whelps prematurely with live or dead pups, or no pups are born at term.
- Abnormal vulvar discharge during pregnancy (bloody or purulent discharge), fever, or signs of abdominal pain may be noted by owner.
- Usually abortion in the bitch goes unnoticed by the owner because the dam may consume the pups and the aborted tissues.
- Death may occur in one or more fetuses, whereas the remainder may continue to develop normally.
- Late-term abortions (between days 45 and 59) are typical of *B. canis*.

PHYSICAL EXAM FINDINGS

- Often unremarkable
- Vulvar discharge occurs normally in pregnant bitches and is clear to mucoid or pink-tinged and odorless; purulent, hemorrhagic, greenish, blackish, or malodorous vulvar discharge may indicate pregnancy complications that could lead to abortion.

ETIOLOGY AND PATHOPHYSIOLOGY

- Canine pregnancy requires normal luteal function throughout its duration. Any toxic or hormonal substance that induces endogenous release of prostaglandin F-2 alpha (PGF2a) and subsequent luteolysis may cause abortion (e.g., bacterial toxins [coliforms, *Staphylococcus* sp.], adrenergic agonists [e.g., phenylephrine]).
- Fetal survival requires normal placental function and placental relaxin production. Relaxin concentration declines rapidly after the death of all fetuses but may remain elevated for some days after the loss of pregnancy.
- Pathogens that influence placental function (e.g., herpesvirus placentitis) may cause abortion.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected when the pregnancy is previously confirmed on ultrasound or by radiography, and the bitch then presents nonpregnant or expelled fetuses have been observed.

DIFFERENTIAL DIAGNOSIS

- Pseudocyesis (false pregnancy). Ultrasound evaluation on days 23-25 following breeding to confirm pregnancy and fetal heart beat.
- Vulvar discharge due to vaginitis or metritis (pyometra). Ultrasound evaluation of uterine disorders may be useful on days 23-25 of anticipated gestation.

INITIAL DATABASE

- Serologic testing of affected dam.
  - *B. canis:* Rapid slide agglutination test (RSAT) is an excellent screening test, but false-positive results occur. To reduce cross-reactivity and false positive results, 2-mercaptoethanol can be added to the RSAT. Dogs in a positive kennel or household that are negative on first test should be retested once a month for 3 consecutive months to confirm negative status. Vaginal secretions or semen can be tested by PCR to determine a positive *B. canis* status before seroconversion occurs.
  - CHV-1: A serum neutralization test or ELISA test with a positive result greater than 1:16 is indicative of prior infection (exposure).
- Virus or bacterial isolation from microbial cultures from fetuses, placenta, milk, or vaginal secretions.
  - *B. canis:* Repeated samples may be necessary. Antibiotics are usually ineffective because of the intracellular location of the infectious organism.
  - In acute CHV-1 infections, viral isolation from infected tissues is possible for 2-3 weeks. Nasal or vaginal swabs may also be tested by PCR. Typically titers show 1:64-1:640. Two blood samples (acute and convalescent) at 1-month intervals are suggested to confirm a decline or rise in titer.
- Fetal gross necropsy (e.g., subcapsular hemorrhages in the kidneys indicative of CHV1) and visual inspection of associated fetal membranes
- Histologic assessment of fetal organs, liver, spleen, thymus, kidneys, adrenals, intestines and stomach, heart, lung, thymus, and brain
- Bacteriologic cultures from fetal organs and reproductive tract of the bitch
- Serum progesterone level of dam must be >2-3 ng/mL (6-9 nmol/L) to sustain pregnancy. Concentrations below this threshold for more than 48 hours may lead to pregnancy loss. Lower level at any time of pregnancy until day 55 indicates hypoluteoidism (luteal dysfunction/failure).
  - When reported, hypoluteoidism generally occurs on days 25-35 past breeding (i.e., at the initiation of the fetal period). Since low progesterone level may occur secondary to fetal death, the diagnosis of hypoluteoidism is based on a low serum progesterone level, positive effect of progesterone supplementation in a bitch that once aborted, and absence of other risk factors, such as a possible genetic etiology.
- Thyroid hormone analyses: May reveal subclinical hypothyroidism aggravated to a clinically significant disease during periods of stress, such as pregnancy (see p. 588).
- Routine laboratory testing: CBC and serum biochemistry profile
  - Normal hematocrit values: 45%-55% (nonpregnant) compared to 30%-35% (pregnant; due to an increase in plasma volume). Nonspecific
  - Mild mature neutrophilia and hemoconcentration is normal in pregnant bitches, but an elevated presence of nonsegmented neutrophils or monocytosis is abnormal.

ADVANCED OR CONFIRMATORY TESTING

- Ultrasonography may reveal fetal death before onset of abortion.
- Contact diagnostic laboratories for further recommendations for specific pathogens. For *B. canis*, blood culture with bacteriologic isolation provides a definitive diagnosis and may be attempted after 5 weeks. If the RSAT is positive, an agarose gel immunodiffusion (AGID) test on cytoplasmic protein antigens can be performed 12 weeks post infection and is the most accurate serologic test available.
- Toxicology of organs and/or blood when a specific toxin or drug is suspected

TREATMENT

TREATMENT OVERVIEW

- Acute supportive treatment of the bitch (e.g., intensive treatment of infection) is the main aim of treatment, since the prognosis for saving the ongoing pregnancy is poor.
- *B. canis*-infected dams should be euthanized or at least surgically sterilized, owing to the location of the organism in reproductive tissue. Premises should be cleaned, kennelmates should be quarantined, and humans should avoid direct contact with excretions or aborted material from potentially infected animals because of the zoonotic nature of *Brucella* sp.
- In cases of hypoluteoidism (see serum progesterone above), progesterone supplementation may be attempted to try to prevent abortion of remaining fetuses.

ACUTE GENERAL TREATMENT

- Supportive: intravenous fluids (e.g., lactated Ringer's solution) and antibiotics if fever.
- Antibiotics: empirical pending culture and sensitivity results (if clinically feasible). Typical choices include amoxicillin (22 mg/kg PO q 8 h), cephalexin or cefadroxil (20 mg PO q 8-12 h) or pivampicillin (30 mg/kg PO q 12 h). Enrofloxacin (5 mg/kg SQ, IM, or PO q 24 h) or trimethoprim/sulfadiazine (15 mg/kg PO q 12 h) are broad spectrum but potentially teratogenic.
- See p. 909

CHRONIC TREATMENT

With confirmed hypoluteoidism, options include:

- Progesterone in oil 2 mg/kg IM q 48 h until 10 days before term
- Altrenogest 0.09 mg/kg PO q 24 h is an alternative.
- Micronized progesterone (Prometrium [Solvay Medical Pharmaceuticals, Marietta, GA, USA]) has been recommended; 10 mg/kg PO q 24 h. Supplementation should be stopped at least 2 days prior to expected term (i.e., 60-61 days after the LH peak, to allow parturition).

If antibiotics are used in *B. canis*-infected dogs, antibiotic treatment should be continued for at least 4 weeks, based on culture and sensitivity results and clinical state.

NUTRITION/DIET

See p. 909. A good-quality maintenance diet is indicated.

BEHAVIOR/EXERCISE

Controlled physical activity during pregnancy

DRUG INTERACTIONS

Glucocorticoids are unpredictable abortifacient drugs in dogs.

POSSIBLE COMPLICATIONS

Supplementation with progesterone analogs (i.e., altrenogest) before sexual differentiation of the fetus is not recommended because of potential masculinization of female fetuses; nor is it recommended if the whelping date is unknown. Failure to discontinue supplementation at the appropriate time can cause prolonged gestation, fetal death, and lactation failure.

RECOMMENDED MONITORING

- If suspicious of possible abortion, weekly monitoring of progesterone concentrations and fetal viability with abdominal ultrasound examinations can be valuable.
- If abnormal vaginal discharge is observed during gestation, the pregnancy should be monitored by ultrasound to assess the viability of the fetuses, and supportive therapy should be initiated.

PROGNOSIS AND OUTCOME

- Poor for saving most ongoing pregnancies. Usually there is no problem in subsequent pregnancies, except in cases of *B. canis* infections and occasionally in herpesvirus-infected bitches with recrudescent infection.
- Bitches with hypoluteoidism may experience recurrent abortion, but the ongoing pregnancy is saved in most cases with supplementary progesterone.

PEARLS & CONSIDERATIONS

COMMENTS

- Abortion is uncommon in the bitch; embryonic death with fetal resorption or mummification is more common.
- Usually abortion in the bitch goes unnoticed by the owner, as the bitch may consume the aborted tissues.
- Infectious agents are the most common causes of canine abortion.
- The diagnosis of abortion should prompt a search for an underlying cause.

PREVENTION

- A canine herpesvirus 1 vaccine is available in Europe (Eurican herpes 205 [Merial, Lyon, France]). Vaccination should be given 1 month prior to estrus, followed by vaccination within 8 days after mating. If titers are below 1:128 at midpregnancy, a third vaccination may be given 10 days prior to parturition.
- Limit contact with external dogs at breeding and during pregnancy.
- Isolate pregnant bitches from showing or performing dogs during pregnancy, especially if herpesvirus is endemic in the area.
- Maintain an adequate vaccination and deworming program.

TECHNICIAN TIP

Educate clients on normal pregnancy (see p. 909) and preventive measures for breeding animals.

CLIENT EDUCATION

- Accurate pregnancy diagnosis should be done in bitches on days 25-30 post breeding (ultrasonography or relaxin test). See p. 909.
- Regular medical evaluation of breeding dogs
- Genetic counseling to avoid inbreeding

Burns

BASIC INFORMATION

DEFINITIONS

- *Burns* are the injuries that result from exposure to flame, extreme heat, scalding, inhalation, and chemical or electrical trauma. Burns produce clinical syndromes ranging from self-limiting injury to devastating long-term incapacitation and potentially death.
- *Eschar:* a thick, coagulated crust or slough that develops as a result of a burn
- *Compartmentalization:* a condition associated with third- and fourth-degree burns in which swelling within tissue compartments creates strictures that can decrease thoracic wall motion and ventilation or cause ischemic injury to limbs
- *Transition zone:* region between completely devitalized tissue and normal tissue

EPIDEMIOLOGY

SPECIES, AGE, SEX

Animals of any signalment are susceptible to burn injury. Debilitating conditions such as chronic renal disease or immunoincompetence carry increased risks for fatal complications.

RISK FACTORS

Both temperature and duration of exposure contribute to the degree of thermal injury. Common sources of companion animal burns include heating pads, hot water bottles, fire, exhaust systems, and hot pipes.

ASSOCIATED CONDITIONS & DISORDERS

Early gram-positive and later gram-negative infections are common in burn wounds.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- First-degree (superficial) burns:
  - Epidermis
  - Typically thickened, erythematous, and desquamated
  - Typically painful
- Second-degree (deep partial thickness) burns:
  - Superficial layers of dermis
  - Typically edematous and erythematous
  - Typically wet and very painful
- Third- and fourth-degree burns:
  - Superficial layers of dermis (third-degree) and subcutaneous layers, tendon, and bone (fourth-degree)
  - Typically waxy and leathery in appearance
  - Typically less painful than first- or second-degree
  - Third- and fourth-degree burns carry a greater risk of wound sepsis, coagulation disorders, limb ischemia, or compression severe enough to cause ventilatory compromise or abdominal problems.
- Electrical burns (see p. 342):
  - High-voltage: associated with compartmental syndromes and ischemia
  - Low-voltage: seldom associated with complication
- Chemical or tar burns usually involve the superficial dermis layers.

HISTORY, CHIEF COMPLAINT

- History and chief complaint reflect acute trauma.
- Recent anesthetic procedures should prompt suspicion of heating blanket or heating lamp burn.
- With acts of malicious intent, history may be unknown.

PHYSICAL EXAM FINDINGS

- Physical examination findings depend on the location and extent of the burn.
- Burns from contact may not initially be apparent until rapid skin and hair loss occur 2-3 days later.
- Thermal burn resulting from a heating blanket or lamp will present as a defined injury reflective of the size of the blanket and the positioning of the animal during recumbency.
- Animals with extensive burns may present in hypotensive shock or with hypothermia.
- The presence of singed whiskers or burn debris in the mouth is strongly suggestive of inhalation (see p. 1027).
- Respiratory distress can occur rapidly from pharyngeal and laryngeal edema, progressive upper airway obstruction, pulmonary edema, inhalation of burn debris, or carbon monoxide toxicity.
- Corneal trauma may be present.

ETIOLOGY AND PATHOPHYSIOLOGY

- Localized wound inflammation results in release of inflammatory mediators and capillary leakage, causing extravasation of fluid.
- If systemic inflammation or vasculitis occurs, fluid losses may be severe and result in hypotension or cardiac collapse necessitating intensive IV fluid resuscitation.
- Burns are colonized initially by normal flora. Due to large volume of dead tissue and impaired blood supply and antimicrobial delivery, large burn areas are at high risk of infection. Initial organisms are gram-positive cocci, but in 3-5 days, gram-negative bacteria colonize the wound. Débridement and topical antibiotics are essential to treatment.
- Sepsis may result from wound infection, nosocomial infection due to the presence of multiple invasive catheters, or the development of pneumonia.
- Systemic inflammation may result in coagulopathy, including disseminated intravascular coagulopathy
- Inhalation injury: see Smoke Inhalation, p. 1027

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Thorough history including initial time and duration of exposure typically will be suggestive or conclusive of thermal injury; however, the full extent of burns may not be apparent immediately after the injury. Determination of the severity of the burn and appropriate treatment course requires examination of the lesion, including underlying and surrounding normal tissue. Diagnostic testing for related disorders (e.g., smoke inhalation) is applied as indicated in each case.

DIFFERENTIAL DIAGNOSIS

- Severe bacterial pyoderma
- Immune-mediated disease
- Fungal infection
- Abscess
- Aspiration pneumonia
- Sepsis

INITIAL DATABASE

- CBC, including manual platelet count
- Serum biochemistry profile
- Urinalysis
- Coagulation panel, including prothrombin and partial thromboplastin times
- Survey radiographs
- Bacterial cultures if evidence of pneumonia

ADVANCED OR CONFIRMATORY TESTING

- Wound culture if infected
- Brain CT or MRI if unexplained alteration in mentation

TREATMENT

TREATMENT OVERVIEW

Wound management is vital to preventing septic complications and minimizing tissue loss. Intravenous fluids, broad-spectrum antimicrobials, and in some cases supplemental oxygen are cornerstones of treatment. Overall goals of treatment are to maintain a patent airway, adequate mean arterial blood pressure and plasma oncotic pressure, and adequate urine production.

ACUTE GENERAL TREATMENT

- Intensive IV fluid resuscitation with crystalloid fluids (e.g., 0.9% NaCl) during the initial 8-12 hours of injury to maintain adequate mean arterial blood pressure and urine production at 1-2 mL/kg/h
- Maintenance of airway patency in presence of pharyngeal or laryngeal edema, with early elective intubation if necessary
- First- and second-degree burns may be self-limiting. Greasy or oil-based dressings (e.g., Vaseline-impregnated gauze) should be avoided.
- Third- and fourth-degree burns may require early escharotomy (débridement/burn excision) or fasciotomy to limit wound sepsis, stricture, or limb ischemia.
- In cases with concurrent smoke inhalation, supplemental oxygen provided within the first 12 hours of injury will help treat carboxyhemoglobinemia. Mechanical ventilation may be required to maintain oxygen saturation.
- Broad-spectrum antimicrobial coverage if evidence of pneumonia until culture results are available (e.g., ampicillin, 22 mg/kg IV q 8 h, plus enrofloxacin, 3 to 5 mg/kg IM or off-label use [diluted 1 : 1 in 0.9% sterile saline and given slowly IV] q 12-24 h; maximum 5 mg/kg q 24 h in cats).

CHRONIC TREATMENT

- First- and second-degree burn wounds may require little débridement. Application of antimicrobial topical creams such as silver sulfadiazine or 0.5% silver nitrate is recommended.
- Small eschars should be débrided for primary closure early in the course of wound care.
- Large eschars not amenable to primary closure should be débrided, allowed to form granulation tissue, and grafted. Open wound management presents a high potential for wound sepsis and is thus not advised if avoidable. See Shearing/Degloving Wounds (p. 1016) for details of wound treatment.
- Serious burns involving the limbs should be débrided to avoid limb ischemia, and treated with variations of splinting to avoid contracture.
- Intravenous fluid therapy should be titrated to replace losses/correct dehydration, maintain arterial blood pressure, and sustain appropriate urine production.
- Systemic inflammation and leaky vessels may result in protein loss and severe hypoalbuminemia. Judicious use of synthetic colloids (Hetastarch 20 mL/kg/24 h or Voluven 40 mL/kg/24 h) may be required to maintain colloid oncotic pressure and mean arterial blood pressure. Transfusion with fresh frozen plasma is recommended in cases of coagulopathy (see Transfusion Reactions, p. 1111). Serum electrolytes should be monitored.
- In cases of severe inhalation injury, maintenance of long-term intubation or tracheostomy may be required until resolution of burn trauma and associated pharyngeal, laryngeal, and airway edema.
- Mechanical ventilation may be required for management of direct lung injury from inhalation of carbon debris, aspiration pneumonia, or pulmonary edema.

NUTRITION/DIET

Parenteral or enteral nutrition should be instituted early in patients with large burns, as increased metabolic demand and protein losses can be significant (see p. 1267 and p. 1322).

BEHAVIOR/EXERCISE

- For third- and fourth-degree burns, especially when involving tissues affected by motion (limbs, axilla, inguinal region, flank, etc.) strict rest for 3-4 weeks may be necessary.
- Physical therapy or hydrotherapy may be beneficial to patients with large body surface regions affected.

POSSIBLE COMPLICATIONS

- Wound infection
- Aspiration pneumonia
- Nosocomial infection
- Sepsis
- Limb ischemia from wound contracture
- Coagulopathy

RECOMMENDED MONITORING

- Mean arterial blood pressure
- Central venous pressure
- Quantification of urine production
- Oxygen saturation
- CBC, serum biochemistry profile, coagulation tests

PROGNOSIS AND OUTCOME

- Outcome is generally good with first-and second-degree burns and more guarded with third- and fourth-degree burns.
- Prognosis is guarded to poor with inhalation injury.
- Prognosis relies on response to fluid resuscitation in severe burn injury. Prognosis improves with appropriate and successful wound management and worsens with development of complications like nosocomial infection and sepsis.

PEARLS & CONSIDERATIONS

COMMENTS

- Third- and fourth-degree burns, and/or inhalation, are best treated in a tertiary care facility with 24-hour intensive care management and surgeons skilled in surgical burn management, including skin grafting.
- Severe eschars causing constriction of ventilatory muscles or limb ischemia require early débridement and primary would closure or grafting to limit wound infection and reduce the risk of compartmentalization.
- Large burns resulting in marked protein loss may be best treated with fresh frozen plasma transfusion to replenish proteins for tissue repair, oncotic support, coagulation factors, and acute phase proteins.
- Respiratory distress in a patient with evidence of inhalation (e.g., burned whiskers) may be due to pharyngeal or laryngeal edema and warrants intubation to obtain and maintain airway patency.
- Iatrogenic thermal burns as a complication from heating pads or lamps during anesthetic procedures may be the most common type of burn injury not resulting in death.
- Burn injury resulting in death occurs most commonly from house fires or malicious acts.

PREVENTION

- Use of circulating warm water or warm air blankets should be used for surgical or hospitalized patients rather than electric heating blankets.
- Patients should not be placed in direct contact with hot water bottles for warming.
- Duration of time in contact with the warming device influences the extent of injury; therefore, the patient or the warming device should be repositioned frequently.

TECHNICIAN TIPS

Always place a towel or blanket between a patient and a warming device.

Budd-Chiari-Like Syndrome and Cor Triatriatum Dexter

BASIC INFORMATION

DEFINITION

Uncommon cardiovascular defects that partially obstruct the flow of blood into or through the right atrium

- Cor triatriatum dexter (CTD):
  - Congenital cardiac defect resulting from persistence of the embryologic right sinus venosus valve
  - The result is a membranous division of the right atrium, which obstructs hepatic venous return to the heart.
  - Cranial vena caval flow is unaffected.
- Budd-Chiari syndrome (BCLS):
  - Originally described as hepatic postsinusoidal hypertension secondary to inflammation and thrombosis of small hepatic veins.
    - Result: obstruction of venous return to the heart, resulting in ascites, hepatomegaly, and abdominal pain.
  - Currently, it is often used loosely to describe obstruction of venous return to the right heart caused by such diverse entities as cor triatriatum dexter, right atrial neoplasia, and caudal vena cava obstruction secondary to masses or traumatic kinking/fibrosis.
    - These disorders are more appropriately referred to as *Budd-Chiari-like syndromes*.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Canine: most often in patients <2 years old; males more commonly affected than females
- Feline: no cases reported (see p. 259)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- CTD: membrane can cause partial or complete division of right atrium. If the membrane is complete, blood flowing into the caudal chamber must pass to the cranial chamber via a vascular connection with the azygos vein.
- Budd-Chiari-like syndrome: obstruction to venous flow may be acquired (e.g., caudal vena cava trauma and subsequent fibrosis) or congenital.

HISTORY, CHIEF COMPLAINT

- Lethargy
- Inappetence
- Severe abdominal distention

PHYSICAL EXAM FINDINGS

- Hepatomegaly
- Ascites
- Abdominal discomfort
- Distention of superficial abdominal vasculature
- Muscle wasting (cardiac cachexia)

ETIOLOGY AND PATHOPHYSIOLOGY

- Obstruction of venous return elevates intrahepatic pressure
- Increased pressure causes leakage of protein and fluid from the hepatic sinusoids, resulting in high-protein ascites (modified transudate)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Clinical presentation of right-sided congestive heart failure should generally lead to the suspicion of other more common cardiac disorders. However, the diagnosis is established during the echocardiographic examination (generally an unexpected finding).

DIFFERENTIAL DIAGNOSIS

- Pericardial effusion
- Right atrial tumor
- Tricuspid dysplasia
- Cor pulmonale (pulmonary hypertension)
- Dilated cardiomyopathy (biventricular)
- Arrhythmogenic right ventricular cardiomyopathy

INITIAL DATABASE

- Ascites without jugular distention supports the diagnosis of CTD or BCLS over other causes of right heart failure signs.
    - Primary intraabdominal causes of ascites (e.g., hemoabdomen, portal hypertension) are important differential diagnoses.
- Fluid analysis of the ascites indicates a modified transudate: high protein (>2.5 g/dL), relatively low nucleated cell count (usually <5000 cells/mcL).
- Thoracic radiographs most often show normal cardiac silhouette and lung fields; enlargement of the caudal vena cava is expected if CTD or BCLS is causing ascites.
- Serum biochemistry panel will often show mild elevation in hepatic enzymes; complete blood count may show a stress leukogram; urinalysis is unremarkable.
- Electrocardiogram may show tall P waves consistent with right atrial enlargement.

ADVANCED OR CONFIRMATORY TESTING

- CTD: two-dimensional echocardiography will display a membrane dividing the right atrium. Doppler echocardiography will demonstrate blood flow through an opening in the membrane if the membrane is perforate.
- BCLS: two-dimensional echocardiography may reveal evidence of an obstruction or may be normal, necessitating other modalities.
- Abdominal ultrasound demonstrates ascites, hepatomegaly, distended hepatic veins, and the absence of a primary intraabdominal cause for the ascites (e.g., mass).
- Angiography is an alternate imaging technique to define blood flow and diagnose causes of BCLS other than CTD.
- Pressure measurements of the hepatic veins, caudal vena cava, and right atrium normally should be approximately equal (normal: 0-5 mm Hg). A drop in elevated pressure measured from the liver to the right heart indicates an obstruction is present.

TREATMENT

TREATMENT OVERVIEW

Correction of the underlying problem may be partial (balloon dilation) or comprehensive (open-heart surgery), with availability of appropriate facilities and barring owners' financial restrictions. Treatment of right-sided congestive heart failure aims to alleviate clinical signs of fluid retention.

ACUTE GENERAL TREATMENT

- Abdominocentesis will improve patient's comfort level (see p. 1193)
- CTD has been successfully corrected with both surgery and balloon dilation.
- Budd-Chiari-like syndromes: surgery may be indicated, depending on the underlying cause.

CHRONIC TREATMENT

If definitive treatment is not possible, furosemide (1-4 mg/kg PO q 12 h) and an angiotensin-converting enzyme inhibitor (e.g., enalapril, 0.5 mg PO q 12-24 h) should be administered along with periodic abdominocentesis to control fluid accumulation.

DRUG INTERACTIONS

Electrolyte depletion and dehydration may result from overzealous diuretic administration.

POSSIBLE COMPLICATIONS

- Surgery is highly invasive, and therefore the risk of mortality is increased with an inexperienced surgeon.
- Balloon dilation of CTD may not create a sufficient opening in the membrane to alleviate clinical signs.

RECOMMENDED MONITORING

- Ascites should resolve with successful reduction/removal of obstruction.
- Renal and hepatic function should be periodically monitored if medical therapy is chosen.

PROGNOSIS AND OUTCOME

- Excellent with successful reduction/removal of the obstruction
- Medical management alone is unlikely to be satisfactory on a long-term basis if clinical signs (e.g., marked abdominal distention from ascites) are already present.

PEARLS & CONSIDERATIONS

COMMENTS

- Jugular distention is *not* present with CTS and other BCLS, unlike other cardiovascular diseases that cause signs of right heart failure.
- Diseases that result in signs of right heart failure are the most common causes of a modified transudate in the abdomen of dogs. Therefore, a modified transudate ascites should always prompt a cardiac workup.

CLIENT EDUCATION

- Advise that surgery or balloon dilation offers the best chance for cure.
- Medical therapy is palliative but is unlikely to be satisfactory on a long-term basis.

Brunfelsia Toxicosis

BASIC INFORMATION

DEFINITION

An acute poisoning resulting from the ingestion of *Brunfelsia* spp. and characterized by nervous system effects including tremors, ataxia, and seizures, often accompanied by vomiting and/or diarrhea

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs are the most commonly affected species; there is no age or sex predilection.

RISK FACTORS

All parts of the plant are toxic; berries and seeds contain more toxin.

GEOGRAPHY AND SEASONALITY

- *Brunfelsia* spp. grow best in a warm, coastal environment. Most cases in the United States are reported from coastal California, Gulf Coast states (Texas and Louisiana), and Florida. In other regions, the plant may be kept indoors as a tub plant and moved outdoors in the summer.
- The plant flowers starting in mid-spring, and berries and seeds are present from summer to fall.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Observed ingestion of the plant
- Vomiting/diarrhea containing plant material/berries/seeds
- Rapid onset of clinical signs, within 30 minutes to a few hours

PHYSICAL EXAM FINDINGS

- Initial signs include agitation or excitement.
- +/− Gastrointestinal (GI) signs such as vomiting and diarrhea
- Tremors
- Muscle rigidity
- Tonic-clonic seizures

ETIOLOGY AND PATHOPHYSIOLOGY

Source

- The genus encompasses several dozen species of shrubs or trees. The most commonly encountered are: *B. americana, B. australis, B. grandiflora*, and *B. pauciflora*.
- Common names include lady-of-the-night, yesterday-today-tomorrow, morning-noon-and-night, and kiss-me-quick.
- Several biologically active tremorgenic compounds such as hopeanine and brunfelsamidine are present in all parts of the plant.

Mechanism of Toxicosis

- Exact mechanism not known. Both hopeanine and brunfelsamidine are potent tremorgens and convulsants in laboratory animals. These compounds seem to interfere with neurotransmission in a manner similar to strychnine.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A clinical diagnosis is made based on history, presence of the plant in the environment, plant material in the vomitus or diarrhea, and rapid onset of neurologic signs (tremors, seizures, and ataxia).

DIFFERENTIAL DIAGNOSIS

- Toxicologic
  - Strychnine, metaldehyde, tremorgenic mycotoxins, stimulant toxicities (e.g. methylxanthines, amphetamines), lead
- Spontaneous, nontoxicologic
  - Seizure disorders including epilepsy, canine distemper, intracranial neoplasia, metabolic (hypoglycemia, hepatic encephalopathy)

INITIAL DATABASE

CBC, serum biochemistry profile, urinalysis. Expected to stay within normal limits. Useful for ruling out other possible causes.

TREATMENT

TREATMENT OVERVIEW

Treatment is aimed at early decontamination of the patient (inducing emesis, administration of activated charcoal), controlling tremors and seizures if present, and supportive care Decontamination can be performed but care must be taken to avoid complications (see below) from these procedures.

ACUTE GENERAL TREATMENT

- Decontamination techniques (Note: vomiting should be induced only in patients showing no clinical signs. It can also trigger seizures.)
  - Hydrogen peroxide 3%: 2 mL/kg to maximum of 45 mL. Repeat once in 15 minutes if no emesis.
  - Apomorphine: 0.03-0.04 mg/kg IV, IM. The tablet can also be crushed and mixed with water and instilled in the conjunctival sac. Rinse eye after vomiting occurs.
  - Gastric lavage (see p. 1281) or enterogastric lavage may be helpful in symptomatic animals to remove plant material, especially berries/seed pods.
  - Activated charcoal: 1-2 g/kg PO +/− a cathartic such as sorbitol. Activated charcoal can be given without first inducing emesis in patients showing clinical signs and can be instilled following gastric or enterogastric lavage. Monitor serum sodium to avoid or manage activated charcoal-associated hypernatremia.
- Control muscle tremors and seizures.
  - Diazepam: 1-2 mg/kg IV may control seizures but generally does not control tremors.
  - Methocarbamol: 100-200 mg/kg slow IV to effect and repeated as needed for tremors. Do not exceed 330 mg/kg in a 24-hour period
  - If tremors and seizures are not controlled with the above agents, pentobarbital (3-15 mg/kg slow IV to effect), propofol (4-6 mg/kg IV followed by a CRI), or gas anesthesia may be needed to avoid muscle contraction–associated hyperthermia, which can become severe.
  - Animals should be kept in a dark, quiet environment; stimulation may worsen the signs.
- Ancillary care
  - Fluid diuresis for intravascular volume and to lessen risk of pigment nephropathy from possible rhabdomyolysis associated with tremors and seizures
  - Monitor and treat hyperthermia secondary to seizures and tremors.
  - Respiratory support (intubation and ventilation) may be needed in severe cases.

PROGNOSIS AND OUTCOME

- Good prognosis if presented early; guarded if seizures are difficult to control during the initial presentation. Tremors may continue for several days.

PEARLS & CONSIDERATIONS

COMMENTS

- All species of *Brunfelsia* are considered toxic.
- The flowers on the plant change from dark purple to lavender to white over a few days, and all three colors may exist on the same plant at the same time. This change is the reason for the common names yesterday-today-tomorrow, morning-noon-and-night, or kiss-me-quick.
- The signs can be mistaken for strychnine toxicity. However, strychnine's signs rarely continue for longer than 48 hours.
- Dogs are attracted to berries and seeds.

PREVENTION

Remove the plant from pet's environment.

TECHNICIAN TIPS

Dogs, particularly large breed ones, should have well-padded bedding to avoid pressure sores due to prolonged immobility.

CLIENT EDUCATION

Make clients aware of *Brunfelsia* toxicity potential and how to avoid having their dogs come in contact with the plant.

EDITOR: SAFDAR KHAN

Brucellosis, Dog

Additional Images Available on Website

BASIC INFORMATION

DEFINITION

Infection with gram-negative coccobacillus or rod-shaped bacteria, *Brucella canis*

EPIDEMIOLOGY

SPECIES, AGE, SEX

Any sexually mature canine; no gender predisposition

RISK FACTORS

Housing or breeding with infected animals

CONTAGION & ZOONOSIS

Transmission between naïve and infected dogs (including via frozen semen), whether in stray, feral, or pet population. Reportable zoonosis in some U.S. states if confirmatory tests are positive. Human cases rare but possible from close physical contact with infected dog, especially if the human is young, pregnant, or immunocompromised.

GEOGRAPHY AND SEASONALITY

Worldwide distribution

ASSOCIATED CONDITIONS & DISORDERS

Diskospondylitis, anterior uveitis, lameness, weight loss, lethargy, behavioral changes, splenomegaly, lymphadenopathy, orchitis, epididymitis, testicular atrophy, azoospermia

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Female
  - Failure to conceive
  - Abortion at 45 to 55 days of gestation, possibly with no other signs
  - Birth of stillborn, partially autolyzed, or weak pups
  - Persistent, highly infective mucopurulent or serosanguineous vulvar discharge for 1-6 weeks postpartum
  - Pattern of successive abortions followed by a normal whelping of live or dead pups
- Male: scrotal swelling, decreased libido, back pain, testicular atrophy(chronic infections), poor semen quality

PHYSICAL EXAM FINDINGS

As for History, above. Variable additional manifestations. Either gender can present with lymphadenopathy, signs of recurrent uveitis, lameness, or paraspinal pain with paresis or paralysis.

ETIOLOGY AND PATHOPHYSIOLOGY

- Bacteria penetrate exposed mucous membranes of oral cavity, conjunctiva, nasal tissue, penis, or vaginal vault.
- Organisms shed through highly contaminated vaginal discharge (following abortion), urine, milk of lactating bitch, semen, prostatic fluid, vaginal fluid during estrus, and lochia of parturition.
- Culture in rough or mucoid phase on primary isolation.
- Phagocytized, *Brucella canis* remains intracellular within regional and other lymph nodes and blood for months to years. Bacteremia within 1-4 weeks after infection; episodic for months to more than 5 years.
- Clinical signs of reproductive tract disease in bitches due to placentitis and metritis and, in male dogs, due to epididymal

inflammation and subsequent autoimmune destruction of testicular tissue.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

If exposure to *B. canis* is suspected from a reproductive history or subsequent physical examination, a blood sample is drawn for screening test, and protective care is assumed for human or canine contact with the animal. If preliminary results are positive, isolation and further client communication about treatment options continue as a precaution until confirmation test results on blood, body fluids, or tissue are received.

DIFFERENTIAL DIAGNOSIS

- Abortion: see p. 7
- Infertility/poor semen quality/azoospermia: improper timing of breeding, subclinical uterine infection, testicular or prostatic disease
- Scrotal enlargement: orchitis, epididymitis, torsion of spermatic cord, hernia, testicular neoplasia, abscess, varicocele, hydrocele, hematoma

INITIAL DATABASE

Screen blood sample with card or rapid slide agglutination test with 2-mercapto-ethanol (RSAT with 2-ME; D-Tec, Synbiotics, San Diego CA) or submit to diagnostic laboratory for overnight result (immunofluorescent assay [IFA], tube agglutination test [TAT]; see figures). Positive from 8-12 weeks post infection. Negative results reliable unless dog exposed <2 months; then retest. False positives are common. Any positive result should be sent for a confirmation test (agar gel immunodiffusion [AGID]).

ADVANCED OR CONFIRMATORY TESTING

- AGID test uses cytoplasmic antigens, is very specific, and will identify a positive dog from 8-12 weeks post infection until 3-4 years after achieving abacteremia.
- Bacterial culture of blood is definitive. Positive cultures occur 2-4 weeks post infection, whereas positive titers do not occur until 8-12 weeks post infection. Small number of circulating organisms may require multiple samples from disease-related tissue (lymph node, bone marrow, placenta, eye, fetus) or fluid (semen, lochia, urine, milk). False negatives are possible depending up on the phase of bacteremia and previous antibiotic therapy.

TREATMENT

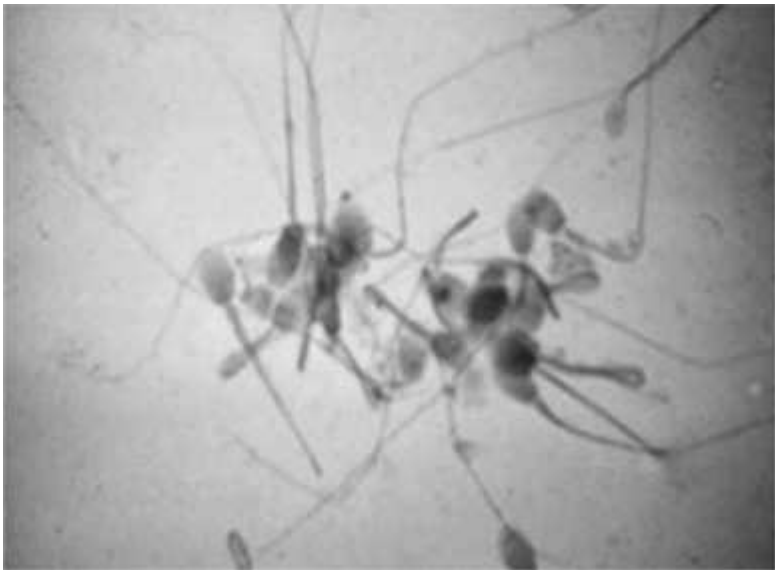
TREATMENT OVERVIEW

Goals of treatment are to:

- Minimize spread to other animals and humans through immediate quarantine, testing, and removal or euthanasia of affected dog(s).
- Stop progression of systemic disease in affected animals by surgical neuter, extended antimicrobial use, semi-isolation, and retesting.

ACUTE GENERAL TREATMENT

- Euthanasia should be treatment of choice in most cases.
- Alternatively, ovariohysterectomy/castration decreases the potential reservoirs of organisms from steroid-dependent tissues. Emphasis should be given to recurrence of symptoms and discouraging exposure of affected dogs to children, immunocompromised individuals, and pregnant women within that household or area.
- Antibiotic therapy is lengthy, expensive, and requires consistent owner compliance. Failures or relapses occur. No regimen is 100% effective. Animals should never be considered cleared of the organism. Combination of multiple drugs is better than any single antibiotic. Tetracycline (30 mg/kg PO q 12 h) or doxycycline (10 mg/kg PO q 12 h) for 1 month, in combination with gentamicin (5 mg/kg SQ q 24 h × 7 days, repeated every 3 weeks). Rifampin (5.5 mg/kg PO q 24 h) has been added in some cases. Enrofloxacin alone (5 mg/kg PO q 24 h for 4 weeks) has been reported in limited use.
- Intermittent serologic testing months after cessation of antibiotic(s).



BRUCELLOSIS, DOG Sperm agglutination.

(Courtesy Dr. Leland Carmichael.)

CHRONIC TREATMENT

- Animals should not be housed with persons susceptible to infection.
- Periodic antibiotic therapy as described previously may be beneficial in decreasing titers but not in eliminating the disease or its potential relapse.
- Quarantine kennel or facility. No animals in or out. Test all animals, including older pups. Repeat test monthly until 3 consecutive months of negative results. Remove or euthanize all positive dogs. Be aware of client's costs, financially and emotionally. Isolate any incoming animals for 8-12 weeks and test before introduction into the house or kennel.

DRUG INTERACTIONS

Cautious use with combinations of antibiotic categories; check renal function, antimicrobial sensitivities, dosages, and availability.

POSSIBLE COMPLICATIONS

Renal failure from long-term gentamicin use. Relapse or additional clinical signs as bacteremia persists.

RECOMMENDED MONITORING

Dogs diagnosed with brucellosis should be considered infected for life. Neutered dogs should be periodically treated with antibiotics to decrease risk of bacteremia and subsequent shedding. Otherwise, euthanasia is indicated for any dog that has a confirmed positive test.

PROGNOSIS AND OUTCOME

- Poor prognosis, guarded at best
- Dogs remain affected for life because of the intracellular location of *B. canis*, ongoing fluctuation of serologic titers, and ineffective bactericidal treatment.
- No infected dog should be used for breeding, even if treated with antibiotics.

PEARLS & CONSIDERATIONS

COMMENTS

- Dogs with a negative screening test (RSAT or TAT), especially those that show no overt clinical signs, are considered *not* infected with *B. canis* unless tested within 12 weeks post exposure.
- Blood samples from any dog testing positive from a preliminary test should be immediately checked by AGID. A dog with a

negative AGID result is considered *not* infected.

PREVENTION

- All intact male and female dogs should be screened for *B. canis* if accidentally bred by a stray or feral dog, exposed to aborted tissue or body fluids, and before breeding or semen shipment.
- Quarantine required by certain state regulatory agencies for facility if a positive test result occurs; enforced for minimum of 2 months until negative results reported

TECHNICIAN TIPS

- Obtain a thorough reproductive history from owners of intact dogs.
- Educate clients about annual testing with consequence of euthanasia if infected.
- Perform RSAT or Card test with in-date kit or submit blood to diagnostic laboratory.
- Test both dogs before breeding.
- Wear gloves during examination or treatment, especially mucous membranes, and isolate any dog with relevant clinical sign(s) until tested negative.

CLIENT EDUCATION

- Public health concern; incurable, zoonotic disease for intact dogs
- To reduce introduction of *B. canis* and subsequent loss of breeding stock or pet, continue regular testing annually early in the estrous cycle and before breeding or collecting semen for shipment.
- Use of common disinfectants on premises

AUTHOR: R. BRUCE HOLLETT

EDITOR: MICHELLE A. KUTZLER

1ST EDITION AUTHOR: MARGARET ROOT KUSTRITZ

Bronchoesophageal Fistula

BASIC INFORMATION

DEFINITION

A communicating tract between the esophagus and a bronchus

SYNONYM

Esophageal fistula

EPIDEMIOLOGY

SPECIES, AGE, SEX

- An uncommon disease that occurs primarily in dogs; occasional cases in cats have been reported.
- Most reported cases have been described in young dogs (<7 years old) of either sex.

GENETICS & BREED PREDISPOSITION

- Most cases of bronchoesophageal fistula have been seen in small-breed dogs; this predisposition also reflects the increased prevalence of esophageal foreign bodies in small-breed dogs. Conceivably, however, any breed could be affected in the presence of appropriate risk factors.
- Congenital bronchoesophageal fistula has also been described in dogs and cats, although the genetic basis for the disease has not been established.

RISK FACTORS

An esophageal foreign body is the single biggest risk factor for the subsequent development of a bronchoesophageal fistula.

ASSOCIATED CONDITIONS & DISORDERS

- Focal pneumonia/aspiration pneumonia
- Esophageal diverticulum

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Congenital
- Acquired

HISTORY, CHIEF COMPLAINT

- Chronic cough is the most common clinical sign; coughing after drinking water is seen in some but not all cases. The cough is often responsive to therapy with antimicrobials but typically recurs at some point after cessation of antimicrobial therapy.
- Regurgitation
- Anorexia, lethargy, depression
- Tachypnea, increased respiratory effort
- Weight loss

PHYSICAL EXAM FINDINGS

- Cough
- Fever
- Tachypnea, increased respiratory effort
- Increased bronchovesicular sounds, or diminished breath sounds from pleural effusion, may be appreciated during thoracic auscultation; thoracic auscultation may also be normal.

ETIOLOGY AND PATHOPHYSIOLOGY

- Congenital:
  - Failure of tracheobronchial tree to completely separate from gastrointestinal tract during embryologic development.
- Acquired (more common form of bronchoesophageal fistula):
  - Esophageal perforation from an esophageal foreign body is the usual cause. The foreign body can perforate the esophagus itself, or perforation may result from pressure necrosis of the esophagus.
  - Esophageal diverticulum formation that predisposes to entrapment of an esophageal foreign body and subsequent perforation of the esophagus can also lead to a bronchoesophageal fistula.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis should be suspected in patients with a history of esophageal foreign bodies and recurrent bouts of antimicrobial-responsive respiratory disease.

DIFFERENTIAL DIAGNOSIS

Other causes of chronic cough include:

- Aspiration pneumonia secondary to other esophageal diseases
- Other causes of recurring pneumonia such as seen with immune deficiencies (e.g., immunoglobulin A [IgA] deficiency) or abnormalities in pulmonary defense mechanisms (e.g., ciliary dyskinesia/immotile cilia syndrome)
- Respiratory foreign bodies
- Respiratory neoplasia
- Inflammatory respiratory diseases (e.g., chronic bronchitis, eosinophilic bronchopneumopathy)

INITIAL DATABASE

- CBC: inflammatory leukogram; mild nonregenerative anemia possible (anemia of chronic inflammatory disease)
- Thoracic radiographs can have several abnormalities:
  - Localized alveolar, interstitial, or bronchial changes; the right caudal and right middle lung lobes are most commonly affected.
  - Esophageal foreign body
  - Esophageal diverticulum
  - Pleural fluid

ADVANCED OR CONFIRMATORY TESTING

- Contrast esophagrams will demonstrate the fistula in most cases. Performing a contrast esophagram with fluoroscopy is considered more sensitive for the detection of small fistulas and for differentiating a fistula from aspirated contrast agent.
- Esophagoscopy/bronchoscopy are considered less sensitive than contrast esophagrams but will be helpful in some cases. Bronchoscopy can help rule out other causes of focal pneumonia such as respiratory foreign bodies or bronchial neoplasia.
- Respiratory washes (transtracheal wash, bronchoalveolar lavage) will be important in some cases—particularly those with a history of having received multiple antimicrobials—to guide appropriate antimicrobial selections.

TREATMENT

TREATMENT OVERVIEW

- Remove or close communication between esophagus and airway.
- Control pulmonary infection.

ACUTE GENERAL TREATMENT

Surgical resection of the fistula, with primary closure of the esophageal defect; remove esophageal foreign body if present.

CHRONIC TREATMENT

Antimicrobials for pneumonia, with selection best guided by culture and sensitivity testing of respiratory washes, especially for patients that have received repeated courses of antimicrobials.

POSSIBLE COMPLICATIONS

- Complications of treatment or the primary disease have not been described for those animals that survive.
- Complications of untreated bronchoesophageal fistula include persistent or recurring pneumonia, pleuritis, and pulmonary parenchymal abscessation.

RECOMMENDED MONITORING

- Clinical signs
- Thoracic radiographs for radiographic resolution of pneumonia
    - Treating for 7-10 days beyond radiographic resolution of pneumonia is commonly recommended, as radiographic resolution often lags behind clinical resolution.

PROGNOSIS AND OUTCOME

A good prognosis is expected if respiratory complications are not serious. For patients with severe respiratory complications, the prognosis is guarded.

PEARLS & CONSIDERATIONS

COMMENTS

Administration of a dilute concentration of barium sulfate (20%-30% weight/volume) for an esophagram can facilitate demonstration of a bronchoesophageal fistula. The use of oral iodinated contrast agents for the documentation of bronchoesophageal fistulae has been discouraged because of the potential for more local adverse effects (cough, pulmonary edema) and the lower degree of radiographic contrast achieved with these substances (see Barium Esophagram, Dynamic, p. 1205; Upper Gastrointestinal Radiographic Contrast Series,p.1351).

TECHNICIAN TIPS

The presence of an esophageal foreign body poses risks of aspiration pneumonia, including during contrast studies. Changes in respiratory rate or character could signal an aspiration event.

PREVENTION

- Limit opportunities for foreign body ingestions, particularly in small-breed dogs.
- There are no means of preventing a congenital bronchoesophageal fistula, but affected dogs probably should not be bred.

AUTHOR & EDITOR: RANCE K. SELLON

Bronchitis: Chronic, Sterile

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A common noninfectious airway disease of older adult dogs. The hallmark is a chronic cough lasting longer than 2 months and not attributable to a known cause.

SYNONYMS

Chronic bronchial disease, chronic bronchitis, chronic obstructive pulmonary disease (COPD), noninfectious sterile bronchitis, old dog sterile bronchitis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Most common in dogs; rarely reported in cats
- Mainly middle-aged to older dogs of either sex

GENETICS & BREED PREDISPOSITION

Primarily a disease of small-breed dogs but should not be overlooked in large-breed dogs

RISK FACTORS

Inhaled environmental irritants such as cigarette smoke, room deodorizers or carpet cleaners, and wood-burning stoves or fireplaces can exacerbate chronic sterile bronchitis.

GEOGRAPHY AND SEASONALITY

There may be seasonal exacerbations in individual pets, although no specific seasonality is described for all dogs.

ASSOCIATED CONDITIONS & DISORDERS

- Pneumonia
- Collapsing trachea
- Bronchiectasis
- Pulmonary hypertension and cor pulmonale

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- The primary clinical sign is a dry, hacking cough.
- Cough can be moderately productive (expectoration of mucus):
  - Not specifically diurnal or nocturnal
  - May have loud, “goose-honk” character
  - Often triggered by physical exertion, especially if it involves the dog's pulling on a leash (tracheal pressure from collars)
- Owners may note posttussive retching or gagging and mistakenly describe this as “vomiting.”
- In severe cases, signs may include:
  - Exercise intolerance
  - Syncope
  - Tachypnea
  - Cyanosis

PHYSICAL EXAM FINDINGS

- Cough:
  - The characteristic finding of this disorder
  - Commonly with sterile chronic bronchitis, the cough occurs less frequently or not at all when the dog is in a veterinary facility (sympathetically mediated bronchodilation due to anxiety).
- Tracheal sensitivity:
  - Applying light to moderate external pressure on the trachea using the fingers may elicit a cough.
  - In affected dogs, it may be possible to elicit a cough with tracheal pressure. However, many other respiratory disorders also have this feature, even if the airway is *not* the source of the problem (e.g., dogs with cardiogenic pulmonary edema virtually always cough in response to tracheal pressure). Therefore, the finding of tracheal sensitivity is nonspecific.
- Auscultatory abnormalities (increased bronchovesicular sounds, crackles, wheezes):
  - Crackles can often be heard on auscultation of the lungs in patients with sterile chronic bronchitis. They can be erroneously attributed to congestive heart failure, particularly in dogs with existing (asymptomatic) heart murmurs; therefore, both conditions should be investigated when crackles are heard, especially in a dog in which a heart murmur is auscultated.
- Tachypnea

ETIOLOGY AND PATHOPHYSIOLOGY

- Airway inflammation characterized by cellular infiltrates, glandular hyperplasia, smooth muscle hypertrophy, and loss of ciliated epithelial cells provokes cough.
- Although inhaled irritants and environmental pollutants could be partially responsible, definitive underlying causes have not been identified.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspect in middle-aged to older dogs with chronic, intermittent cough. A true diagnosis is typically made after exclusion of other causes of chronic cough.

DIFFERENTIAL DIAGNOSIS

- Pneumonia
- Collapsing trachea
- Congestive heart failure
- Respiratory neoplasia
- Heartworm disease
- Canine infectious tracheobronchitis

INITIAL DATABASE

- Thoracic radiograph abnormalities can include:
  - Mild to moderate diffuse interstitial pattern
  - Hyperinflation of lung field (“air trapping”); (see p. 98)
  - Bronchial markings (“doughnuts,” “tram lines”)
  - If pulmonary hypertension present, other possible abnormalities include:
    - Right-sided cardiomegaly
    - ± Enlarged, tortuous pulmonary arteries
- Normal thoracic radiographs do not exclude the possibility of sterile chronic bronchitis:
  - Lateral cervical radiographs should be obtained in suspected cases to avoid misdiagnosis of sterile chronic bronchitis as a result of overlooking cervical collapsing trachea.

ADVANCED OR CONFIRMATORY TESTING

- Cytologic examination of samples collected by bronchoalveolar lavage or transtracheal wash often demonstrates a predominance of nondegenerate neutrophils:
  - Occasionally, a predominance of eosinophils is seen.
  - Although bacterial infection is uncommon with this disease, quantitative culture of airway samples is recommended to exclude secondary infection or colonization exacerbating the disease.
- Bronchoscopy often reveals inflammation, hyperemia, edema, and in some patients, proliferation of the mucosa and accumulation of secretions in the tracheobronchial tree.

- Collapse or hypoplasia of the trachea or bronchi may also be appreciated in cases in which sterile chronic bronchitis coexists with collapsing trachea.
- Arterial blood gas measurement: consider if severe dyspnea/respiratory distress (uncommon). May reveal:
  - Hypoxemia
  - Hypocarbia
    - Hypercarbia from respiratory failure may be seen in advanced cases and usually signals a grave prognosis.

TREATMENT

TREATMENT OVERVIEW

The goal of therapy is to reduce cough, suppress airway inflammation, reduce airway obstructions, and minimize the potential for secondary infections. Complete resolution of cough is virtually never possible. The therapeutic goal is reduction of frequency and severity of cough so the animal is more comfortable.

ACUTE GENERAL TREATMENT

- Bronchodilators, antiinflammatory medications, and cough suppressants are indicated in acute exacerbations.
  - Cough suppressants are indicated to decrease coughing frequency and severity. Cough suppressants should not be used if the cough is moderately productive or if there is suspicion of an underlying infection.
    - Hydrocodone, 0.22 mg/kg PO q 6-12 h
    - Butorphanol, 0.25-1 mg/kg PO q 6-12 h; the higher dosage may cause sedation. The oral dosage is many times greater than the injectable dose and should *not be* used for calculating injectable doses of butorphanol.
    - Diphenoxylate hydrochloride and atropine, 0.2-0.5 mg/kg diphenoxylate PO q 12 h
- Antiinflammatory medications:
  - Prednisone/prednisolone 0.5 mg/kg q 12 h for 5-7 days to induce remission of cough
  - Decrease prednisone dose by half every 7 days and, when possible, move to alternate-day dosing to achieve minimum dose necessary to control clinical signs.
- Bronchodilators:
  - β^2 agonists:
    - Terbutaline (total amount per dose): small dogs 0.625-1.25 mgPO q 12 h, medium dogs 1.25-2.5 mg PO q 12 h, large dogs 2.5-5 mg PO q 12 h.
    - Albuterol: 0.05 mg/kg PO q 8 h.
  - Methylxanthines:
    - Not all long-acting theophylline products have equivalent bioavailability in dogs. Implications are that failure to respond to a certain product should prompt the consideration of switching bronchodilators (to a different brand of theophylline or a different class of bronchodilator altogether [e.g., a β^2 agonist]), and that certain individuals may develop signs of toxicosis when receiving doses that are well tolerated by others.
      - Extended-release theophylline (Inwood Laboratories) is recommended at 10 mg/kg PO q 12 h.
      - Aminophylline or theophylline 10 mg/kg PO q 8 h
- Oxygen therapy is indicated if hypoxemia is present (usually in patients with respiratory distress, which is uncommon).

CHRONIC TREATMENT

- Eliminate sources of airway irritation (see Risk Factors above).
- Weight loss:
  - Obesity is a common exacerbating factor, potentially leading to the Pickwickian syndrome (respiratory compromise due to obesity).
  - Weight loss helps increase lung volume and compliance.
- Bronchodilators, either oral or inhaled, are often used for decreasing airway resistance.
  - Doses for oral management are listed under Acute General Treatment above.
  - Metered-dose inhaler of albuterol (β^2-agonist): one puff (90 mcg) by inhalation q 12-24 h (see p. 1289)
- Cough suppressants decrease cough frequency and severity:
  - Antitussives should not be used if cough is moderately productive or if there is suspicion of underlying infection. Doses are listed under Acute General Treatment above.
  - For long-term use, dose is typically titrated to reduce or eliminate cough, without reaching levels that produce drowsiness.
  - Cough suppressants may be administered daily at first (days to weeks) to obtain palliation of cough, and then reduced or dosed intermittently on an as-needed basis to manage flare-ups of coughing.
- Antiinflammatory medications, either oral or inhaled corticosteroids, are often required:
  - Dose for oral management is listed under Acute General Treatment above.
  - Metered dose inhaler of fluticasone: one puff (110-220 mcg) by inhalation q 8-12 h (see p. 1289)

- The decision to incorporate antibiotic therapy should be based on cytologic evaluation and culture of airway samples.

BEHAVIOR/EXERCISE

- Minimizing the use of collars and using harnesses for restraint can help reduce cough caused by tracheal irritation.
- Eliminating/reducing possible inhaled irritants (cigarette smoke, room deodorizers, carpet cleaners) may help decrease clinical signs related to tracheal irritation.

DRUG INTERACTIONS

Fluoroquinolone antibiotics inhibit the metabolism of methylxanthine bronchodilators such as theophylline and aminophylline; their concurrent use can result in toxic plasma levels of the bronchodilator.

POSSIBLE COMPLICATIONS

- Bronchiectasis
- Pulmonary hypertension and right-sided congestive heart failure

RECOMMENDED MONITORING

Clinical signs

PROGNOSIS AND OUTCOME

- Guarded:
  - Complete resolution of the disorder (and its associated cough) is essentially never possible because sterile chronic bronchitis is a progressive disease.
  - However, it is rarely life threatening. Properly managed and treated, many or most patients with sterile chronic bronchitis can enjoy an excellent quality of life and normal life expectancy.
- Long-term complications of bronchitis can include bronchiectasis and pulmonary hypertension.

PEARLS & CONSIDERATIONS

COMMENTS

- Middle-aged to older small-breed dogs often have mitral or tricuspid endocardiosis. The combination of cough, heart murmur, and pulmonary crackles on auscultation, and some degree of cardiomegaly from valvular insufficiency radiographically, can lead to the erroneous diagnosis of a cardiogenic cause for the cough, when in fact the cause is sterile chronic bronchitis and concurrent (but compensated, clinically insignificant) mitral or tricuspid endocardiosis.
  - Dogs with sterile chronic bronchitis, in contrast to dogs with congestive heart failure, often have normal or lower than normal heart rates.
  - Similarly, dogs with sterile chronic bronchitis often have respiratory sinus arrhythmia, whereas dogs with acute pulmonary edema virtually never do (sinus tachycardia instead).
  - If pulmonary crackles are auscultated, yet there is no heart murmur, extra care should be taken to differentiate sterile chronic bronchitis from congestive heart failure (pulmonary) through radiographs, be cause the two diseases often present with very similar clinical features.
  - The diagnosis of sterile chronic bronchitis should be exclusive of any signs of pulmonary edema on thoracic radiographs. In the absence of thoracic radiographs, the diagnosis of congestive heart failure/pulmonary edema in a coughing dog cannot be made, and long-term treatment with diuretics is not supported.
- Hydrocodone cough suppressants may be difficult to obtain. Of those available, many are combined with other medications (acetaminophen, guaifenesin, and various antihistamines) that may not be safe or routinely recommended.
- Medications delivered by metered dose inhaler are now well-recognized and accepted for treating this disorder (see p. 1289).
  - The proposed advantage is minimization of the adverse effects of oral treatment.
- Obesity is a common complicating factor. For this reason (and many others related to various adverse effects of long-term use), corticosteroid administration of more than a few days' duration should be avoided as much as possible.

TECHNICIAN TIPS

When preparing for respiratory washes, be sure to use solutions that do not contain bacteriostatic additives. If available, pre-warm solutions for respiratory lavage in a 37°C incubator (or suitable alternative).

CLIENT EDUCATION

The clinical signs of sterile chronic bronchitis can be controlled in many dogs, but cure is unlikely.

AUTHOR: LAURA RIDGE COUSINS

EDITOR: RANCE K. SELLON

Bronchiolar and Pulmonary Neoplasia

BASIC INFORMATION

DEFINITION

Neoplastic growth originating in the bronchi or lower airways

SYNONYM

Lung cancer, primary lung tumors, primary pulmonary tumors

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Rare in dogs (1.24% of dogs at necropsy) and cats (0.38% at necropsy)
- Older animals:
  - 9.3 to 10.9 years in dogs
  - 11 to 12.5 years in cats
- No sex predilection

GENETICS & BREED PREDISPOSITION

No breed predisposition known, but increased incidence in boxer dogs and tricolor cats found in single studies

RISK FACTORS

Weak links to urban environment, secondhand smoke, brachycephalic conformation

ASSOCIATED CONDITIONS & DISORDERS

- Hypertrophic osteopathy
- Digital, ocular, or muscular signs secondary to metastasis common in the cat

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Malignant:

- Adenocarcinoma, squamous cell carcinoma, bronchial gland carcinoma, alveolar cell carcinoma
- Variety of sarcomas also possible
- Rarely carcinoids and plasma cell tumors of the airways

Benign:

- Papillary and bronchial adenoma
- Hemangioma
- Fibroma
- Myxochondroma
- Blastoma

HISTORY, CHIEF COMPLAINT

- Nonproductive cough most common complaint
- Dyspnea, lethargy, tachypnea less common
- Occasionally spontaneous pneumothorax or hemothorax
- Occasionally present for secondary problems: thickened and painful limbs or digital pain

PHYSICAL EXAM FINDINGS

- Can be normal
- Increased respiratory rate and/or effort possible
- Easily elicited cough with tracheal palpation (nonspecific)
- Lung auscultation is often normal, although silent areas may be noted over large masses.

ETIOLOGY AND PATHOPHYSIOLOGY

- Inhalation of carcinogens provoking malignant transformation is suspected.
- Dogs trained to smoke cigarettes (through a tracheostomy) or that inhaled radioactive substances developed lung tumors at a dramatically increased rate.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

The diagnosis of pulmonary neoplasia is often suspected in a patient with a chronic cough unresponsive to antibiotics and one or more masses apparent on thoracic radiographs. The presence of such masses does not definitively establish a diagnosis of pulmonary neoplasia.

DIFFERENTIAL DIAGNOSIS

- Metastatic disease (usually multiple nodules of similar size)
- Malignant histiocytosis (usually also includes disease at other locations)
- Tumors of pleura, mediastinum, or heart base
- Abscess, fungal or bacterial disease
- Lymphoid granulomatosis
- Eosinophilic granulomatosis
- Foreign body granuloma
- Hematoma or infarct
- Lung lobe torsion
- Bronchial foreign body (causes lung lobe collapse/atelectasis)
- Mediastinal masses

INITIAL DATABASE

- CBC, serum biochemistry profile, and urinalysis are often normal.
- Thoracic radiographs:
    - Primary lung tumors usually appear as single nodules or one large nodule/mass and several smaller nodules.
    - Cats can have more diffuse infiltrative patterns within a lung lobe.

ADVANCED OR CONFIRMATORY TESTING

- Thoracic CT is the best modality to identify the full extent of disease, including detection of metastatic lesions and tracheobronchial lymph node enlargement, and assess possibility of surgical removal.
- Bronchoscopy and brush biopsy of bronchial lesions or transthoracic needle aspiration of peripheral lesions may yield sufficient cells for cytologic diagnosis.
    - Transthoracic needle biopsy carries acute risks of pneumothorax, hemothorax, and acute death, and a long-term risk of tumor seeding of the needle track.
    - Nonspecific inflammation is a common cytologic feature of respiratory samples obtained from patients with pulmonary neoplasia and thus does not rule out neoplasia.
    - Thoracoscopic lung biopsy can also be used.
    - Lung lobectomy and histopathology are often performed prior to definitive diagnosis by other means for patients with solitary lesions and no evidence of metastatic disease.

TREATMENT 

TREATMENT OVERVIEW

After appropriate staging, removal of the primary tumor is recommended for patients with solitary resectable lesions.

ACUTE GENERAL TREATMENT

- If dyspneic, give oxygen.
- Fluid or air in the thorax should be evacuated if respiration is impaired by pleural effusion or pneumothorax, respectively (see p. 1338).

CHRONIC TREATMENT

- Single nodule/mass:
  - The appropriate therapy for a single isolated nodule is surgical resection.
- If metastatic disease is identified (within lung parenchyma, pleura, hilar nodes, or distant sites), or the tumor is not removable because of size or other factors, surgery should not be attempted.
  - Incomplete removal of lung tumors will not increase quality of life or lifespan.
  - Chemotherapy can be considered for malignant tumors.
    - Vinca-alkaloid and platinum-containing drugs are most often recommended for carcinomas, but pulmonary carcinomas are generally poorly responsive to chemotherapy.
    - Doxorubicin-based protocols may be helpful for patients with sarcomas.
- Radiation therapy for palliation of clinical signs can be considered if tumor is confined to one area.

POSSIBLE COMPLICATIONS

Pneumothorax, hemothorax, pleural effusion

RECOMMENDED MONITORING

Thoracic radiographs for tumor progression, return (postoperatively), or response to therapy

PROGNOSIS AND OUTCOME

- Small tumors carry better prognosis.
  - Median survival after resection of tumors <5 cm diameter is 20 months; >5 cm diameter is 8-9 months
- Adenocarcinoma has a better prognosis than squamous cell carcinoma or undifferentiated carcinomas (median survival 251 days versus 160 days).
- Hilar lymph node enlargement is associated with a poor prognosis (median survival 60 days versus 12 months if no lymph node enlargement).

PEARLS & CONSIDERATIONS

COMMENTS

Patients with lung tumors should always be evaluated fully before attempting surgical resection. If the tumors are small, peripherally located, and there is no obvious lymph node enlargement, surgery should be recommended, and survival after resection could be greater than 1 year.

PREVENTION

There is no means of preventing the development of lung tumors in dogs and cats, although limiting exposure to second-hand smoke may help.

TECHNICIAN TIPS

- Whenever thoracic radiographs are taken, the whole thorax (don't cut off caudal lung regions, for example) should be imaged with at least two orthogonal views (e.g., lateral and ventrodorsal) to be able to examine the entire lung field so as to not miss lesions that may represent metastasis; both lateral views (three-view thorax) are better still for detection of metastasis. When solitary tumors of the lung are found at a small size, before the animal is showing signs, the prognosis will be greatly improved.
- If aspiration cytology is considered necessary to the evaluation, commonly used materials will include 22- or 23-gauge needles of 1 to 1½ inches length. If ultrasound guidance is used to aspirate, the hair over the lesion should be clipped, and skin prepped as if for surgery.

CLIENT EDUCATION

Since prognosis improves with early identification and surgical resection of lung tumors while small, surgery should not be postponed any longer than necessary. Most dogs that have a thoracotomy for lung lobe resection are able to be discharged from the hospital within 36-72 hours.

AUTHOR: JANEAN L. FIDEL

EDITOR: RANCE K. SELLON

Bronchiectasis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Irreversible, pathologic dilation of airways due to destruction of the elastic and muscular components of the airway walls

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs are apparently affected more commonly than cats.
- Young animals are affected if associated with a congenital abnormality (rare); animals are older if associated with chronic inflammation (e.g., chronic bronchitis), infection, or neoplasia.
- Either gender can be affected.

GENETICS & BREED PREDISPOSITION

American cocker spaniels, West Highland white terriers, miniature poodles, Siberian huskies, and English springer spaniels may have an increased risk.

RISK FACTORS

- Congenital defects (e.g., primary ciliary dyskinesia)
- Acquired diseases, such as:
  - Chronic bronchitis
  - Eosinophilic bronchopneumopathy
  - Bronchopneumonia
  - Immunodeficiency diseases
  - Neoplasia

ASSOCIATED CONDITIONS & DISORDERS

- Chronic bronchitis
- Eosinophilic bronchopneumopathy
- Bronchopneumonia

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Focal, multifocal, and diffuse distribution
- Cylindrical, saccular, and cystic forms

HISTORY, CHIEF COMPLAINT

- Incidental radiographic finding in the absence of clinical signs (especially in cats)
- Cough
- Tachypnea
- Respiratory distress
- Other signs that reflect underlying disease (e.g., nasal discharge with ciliary dyskinesia)

PHYSICAL EXAM FINDINGS

- Cough may be inducible on tracheal palpation; however, an inducible cough is not specific for bronchiectasis.
- Other findings may be referable to underlying disease (e.g., fever with bacterial pneumonia).

ETIOLOGY AND PATHOPHYSIOLOGY

- Congenital or acquired conditions lead to a cycle of damage to the bronchial epithelium and/or their cilia, inflammation, impairment of mucociliary function, and secondary infection.
- Cellular damage, inflammation, and infection perpetuate the cycle of airway wall destruction, leading to bronchiectasis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is usually accomplished by survey thoracic radiographs; however, advanced diagnostic imaging (e.g., CT) and/or histopathology may be necessary to detect subtle lesions. If a diagnosis of bronchiectasis is made, it is important to perform a thorough diagnostic workup to identify underlying/concurrent diseases.

DIFFERENTIAL DIAGNOSIS

Physical exam (cough or respiratory distress):

- Other airway diseases (e.g., chronic bronchitis, eosinophilic bronchopneumopathy, secondary bacterial bronchitis)
- Pneumonia (infectious, aspiration, eosinophilic, foreign body)
- Neoplasia
- Pulmonary thromboembolism
- Cardiogenic or noncardiogenic pulmonary edema
- Pleural effusion
- Pneumothorax
- Interstitial lung disease

INITIAL DATABASE

- CBC: neutrophilia may support underlying infection
- Eosinophilia may be present with eosinophilic bronchopneumopathy
- Thoracic radiographs:
    - Bronchiectasis has a pathognomonic radiographic appearance.
    - Morphologic classification:
        - Cylindrical form: dilated bronchi with nontapering ends; most common form (70% of canine cases)
        - Saccular form: “cluster of grapes” appearance to airways; indicates advanced disease
        - Cystic form: rounded ends of the very small bronchi; end stage of saccular form
    - Spatial classification:
        - Focal, multifocal, or diffuse distribution pattern
        - In dogs, multiple lung lobes are affected in 89% of cases; right cranial lung lobe overrepresented (93%)
    - Evidence of concurrent/underlying pulmonary disease is frequently present.
    - Radiographs may be unremarkable in the early stages of disease.

ADVANCED OR CONFIRMATORY TESTING

- CT may help detect subtle lesions.
- Bronchoscopy and bronchoalveolar lavage or fine-needle aspiration of the lung (cytology and culture) are useful in identification of underlying/concurrent diseases.
- Specialized functional and immunologic studies such as mucociliary scintigraphy, immunoglobulin A (IgA) concentrations, and others may be needed to evaluate patients for suspected congenital disease.
- Lung biopsy is sometimes needed to identify underlying/concurrent disease.

TREATMENT

TREATMENT OVERVIEW

Treatment should focus on identifying and treating an underlying cause of chronic inflammation (e.g., chronic bronchitis, infection) if present. Bronchiectasis is an irreversible dilation of the airways and is therefore not a curable disease (with the exception of focal disease treated by lobectomy). Long-term management is focused on decreasing inflammation, enhancing mucociliary clearance, and appropriate antimicrobial treatment of secondary infections.

ACUTE GENERAL TREATMENT

Address underlying illness and secondary complications (e.g., bacterial bronchopneumonia).

CHRONIC TREATMENT

- Humidification or nebulization enhances mucociliary function by increasing water content of the mucociliary blanket.
- Bronchodilators are unlikely to be helpful.
- Glucocorticoids:
  - Oral (e.g., prednisone, 0.25-0.5 mg/kg/d) preferred initially to control inflammation
  - Continuation of glucocorticoids is based clinically on the underlying disease contributing to bronchiectasis.
- If bronchiectasis is due to resolved pneumonia or obstructive disease, then glucocorticoids may not be indicated.
- If bronchiectasis is secondary to noninfectious inflammatory disease (e.g., chronic bronchitis), inflammation often will need to be controlled with long-term, low-dose glucocorticoids.
  - The metered dose inhalant glucocorticoids (e.g., flunisolide: empirically start at 110 mcg/actuation, one puff using a spacer q 12 h; decrease to 44 mcg/actuation, one puff using a spacer q 12 h thereafter) may minimize systemic side effects in the long term (see p. 1289).
- Treat recurrent secondary bacterial infections if present, ideally based on culture and sensitivity.
- In cases in which bronchiectasis is confined to a single lung lobe (e.g., due to a prior bacterial pneumonia), lobectomy may be curative.
- Cough suppressants are contraindicated, as they further impair mucociliary clearance.

BEHAVIOR/EXERCISE

- Minimize exposure to irritants such as dust, smoke, and aerosols.
- HEPA-type air filters

POSSIBLE COMPLICATIONS

Attempting to control inflammation with glucocorticoids may impair immunologic clearance of secondary infection. Additionally, bronchiectasis is itself associated with impaired mucociliary function, which also predisposes to bacterial infections. Frequent use of antibiotics may lead to development of bacterial resistance.

RECOMMENDED MONITORING

- Clinical signs at home
- Physical examination
- Thoracic radiography
- Repeated airway cultures as indicated

PROGNOSIS AND OUTCOME

- If disease is focal and the lobe removed (e.g., bronchiectasis secondary to chronic obstruction from neoplasia or a foreign body) and the underlying disease is cured, prognosis is excellent.
- Otherwise, the disease cannot be cured and must be treated chronically by balancing antibiotics for secondary infections and anti inflammatory doses of corticosteroids. In the absence of life-threatening infection or serious underlying disease (e.g., neoplasia), long-term survival is possible.

PEARLS & CONSIDERATIONS

COMMENTS

- Bronchiectasis is always secondary to an underlying condition, although the primary disease may have resolved by the time of evaluation (e.g., bacterial pneumonia).
- Management of secondary bacterial infections should be done on the basis of culture and sensitivity whenever possible to prevent development of antibiotic resistance.

PREVENTION

The best means of preventing bronchiectasis is early identification and treatment of the diseases that predispose to its development.

TECHNICIAN TIPS

- When preparing for respiratory washes, be sure to use solutions that do not contain bacteriostatic additives. If available, pre-warm solutions for respiratory lavage in a 37°C incubator (or suitable alternative).
- Needle aspiration of the lung is commonly performed with 23-gauge needles and a 6- or 12-mL syringe in the dorsal lung fields defined by rib spaces 6-8.

CLIENT EDUCATION

Owners must understand that aside from focal disease treated with lobectomy, this is not a curable disease; in multifocal and diffuse cases, recurrent secondary bacterial infections are common and can potentially be life threatening.

Bromethalin Toxicosis

BASIC INFORMATION

DEFINITION

A neurotoxic syndrome resulting from ingestion of bromethalin rodenticide.

SYNONYMS

(2,4-dinitro-*N*-methyl-*N*-[2,4,6-tribromo-phenyl]-6-[trifluoromethyl] benzeneamine). Sold under numerous trade names, including: Assault mouse/rat Place Pack, Fastrac Mouse Seed Place Pacs, Green thumb mouse killer, Hot Shot Sudden Death Brand Mouse Killer, Purina Assault Meal, Rampage Rodenticide Place Pacs, Real-Kill Mouse Killer Placepacs, Real-Kill Rat and Mouse Killer All Weather Bars, Real-Kill Rat and Mouse Killer Pellets, Real-Kill Rat Killer Placepack, Top Gun Pellet Rodenticide Place Pack, Vengeance, Trounce, No Pest

EPIDEMIOLOGY

SPECIES, AGE, SEX

Cats much more sensitive than dogs; ingestion more common in dogs than cats; all breeds, both sexes susceptible; young animals may be more sensitive

GEOGRAPHY AND SEASONALITY

Intoxication common year round but more prevalent during fall or winter months

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Dogs ingesting doses close to or greater than the LD50 (dog, 2.4-5.6 mg/kg; cat, 0.4-0.7 mg/kg bait formulation) may develop a convulsant syndrome (acute form) with onset of seizures within 24 hours.
- Dogs consuming less than the LD50 can manifest a paralytic syndrome (subacute/chronic form) in 1-7 days.
- Cats typically develop a paralytic syndrome regardless of amount ingested.

HISTORY, CHIEF COMPLAINT

- History or evidence of exposure
- Central nervous system (CNS) depression, hind limb weakness, or ataxia without evidence of pain
- Twitching, seizures

PHYSICAL EXAM FINDINGS

- Convulsant syndrome (acute form):
  - Focal or generalized seizures (possibly triggered by environmental stimuli)
- Tremors:
  - +/− Hyperthermia
- Paralytic form (sub-acute form):
  - Hind limb weakness, ataxia
  - Depression, tremors, areflexic hind limb paralysis, decreased proprioception, seizures
  - Cats may also show nystagmus, anisocoria, opisthotonos, and occasionally abdominal distension from paralytic ileus

ETIOLOGY AND PATHOPHYSIOLOGY

- Baits are sold as bars, pellets, seed, and worm. Mole baits sold as 5-g worm (0.025%, or 1.25 mg bromethalin in 5 g). Other commercial products contain 0.01% bromethalin, or 2.84 mg bromethalin per 1 oz of bait.
- Bromethalin and its major metabolite, desmobromethalin, are potent uncouplers of oxidative phosphorylation.
- Cerebral and spinal edema secondary to decreased ATP production and failure of Na^+/K^+-ATPase pumps.

- Elevated cerebrospinal fluid pressure causes neurologic dysfunction.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is generally presumptive and based on history of observed or suspected exposure to the bait followed by typical neurologic effects within 1-7 days after the exposure. Advanced or confirmatory tests are rarely conclusive for this intoxication.

DIFFERENTIAL DIAGNOSIS

- Convulsant form:
  - Primary CNS disease
  - Metaldehyde toxicosis
  - Strychnine toxicosis
  - Zinc phosphide toxicosis
  - Ethylene glycol toxicosis
  - Tremorgenic mycotoxins (moldy food ingestion)
- Paralytic form:
  - Neuromuscular disease (polyradiculoneuritis, tick paralysis, botulism, myasthenia gravis)
  - 2,4 D or other phenoxyacetic acid herbicide exposure in dogs
  - Copperhead snake envenomation in cats
  - Spinal cord/CNS trauma
  - Intervertebral disk disease

A/C, Activated charcoal.

RECOMMENDATIONS FOR DOGS

Time Since Exposure (Hours)	Dose Ingested (mg/kg)	Treatment
<4	0.1-0.49	Emesis or 1 dose of A/C
>4	0.1-0.49	One dose of A/C
<4	0.5-0.75	Emesis and 3 doses of A/C over 24 hours
>4	0.5-0.75	3 doses of A/C over 24 hours
<4	>0.75	Emesis and 3 doses of A/C a day for 48 hours
>4	>0.75	3 doses of A/C a day for 48 hours

A/C, Activated charcoal.

RECOMMENDATIONS FOR CATS

Time Since Exposure (Hours)	Dose Ingested (mg/kg)	Treatment
<4	0.05-0.1	Emesis or 1 dose of A/C
>4	0.05-0.1	1 dose of A/C
<4	0.1-0.3	Emesis and 3 doses of A/C over 24 hours
>4	0.1-0.3	3 doses of A/C over 24 hours
<4	>0.3	Emesis and 3 doses of A/C a day for 48 hours
>4	>0.3	3 doses of A/C a day for 48 hours

INITIAL DATABASE

- The diagnosis is generally presumptive, based on clinical presentation, physical examination, and history if available.
- CBC, serum biochemistry panel, diagnostic imaging: no significant changes

ADVANCED OR CONFIRMATORY TESTING

Rarely performed

- CSF tap: increased pressure; no inflammatory changes
- CNS edema, demyelination, and vacuolization on histopathologic exam
- Bromethalin can be detected in tissues postmortem (liver, kidney, brain, and fat).

TREATMENT 

TREATMENT OVERVIEW

In patients presented prior to the onset of clinical signs: induction of emesis followed by administration of activated charcoal. If signs are present, treatment is based on need (e.g., control seizures if present, provide supportive care).

ACUTE GENERAL TREATMENT

Emesis and/or activated charcoal (A/C) treatment recommendations (see Pearls, below, for concentration in products):

CHRONIC TREATMENT

Treatment for subacute cases

- Supportive care for clinically ill patients (fluids, nutritional support, seizure control, etc.)
- Cerebral edema may not respond well to furosemide, mannitol, or corticosteroids.
- Diazepam, barbiturates, and other anticonvulsants for CNS signs

POSSIBLE COMPLICATIONS

Permanent CNS damage/dysfunction due to demyelination and vacuolization

RECOMMENDED MONITORING

Animals with a suspected or confirmed exposure to bromethalin but without overt clinical signs need to be monitored for an onset of hind limb weakness or other CNS signs for 7 days postexposure.

PROGNOSIS AND OUTCOME 

- Good with decontamination of patient prior to the onset of signs
- Guarded if signs develop; recovery may take days to weeks
- Poor if paralysis or seizures develop

PEARLS & CONSIDERATIONS 

COMMENTS

- Commercial products contain 0.01% bromethalin or 2.84 mg/oz bromethalin.
- Presence of blue-green to turquoise dye in the stool over the past few days may provide evidence of ingestion, especially if exposure was not witnessed. However, presence of dye in the stool is not specific for the type of rodenticide (bromethalin, anticoagulant, vitamin D analog, etc.) involved.
- Doses of 0.95-1.05 mg/kg in dogs and 0.24 mg/kg in cats can be lethal.
- Vitamin K1 therapy, used for anticoagulant rodenticides, is not indicated for bromethalin ingestion.
- Potential for relay toxicosis (intoxication through consumption of prey that has itself ingested the toxin) appears low except for those cats whose diet consists largely of rodents.

TECHNICIAN TIP

The various rodenticides (see p. 83), bromethalin, and cholecalciferol (see p. 200) cannot be differentiated by appearance alone (in vomitus or even prior to ingestion).

PREVENTION

Placement of baits in areas not accessible to dogs and cats

Breeding Management

BASIC INFORMATION

DEFINITION

Diagnostic and treatment approaches that optimize a bitch's reproductive performance

SYNONYMS

Breeding timing, estrus monitoring

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs, postpubertal, female

GENETICS & BREED PREDISPOSITION

- Breeding animals should be tested for heritable disorders; >400 genetic diseases have been identified in dogs.
- Bitches requiring elective caesarean section (e.g., brachycephalics) require intense monitoring to establish the time of their luteinizing hormone (LH) surge during estrus.

RISK FACTORS

- Advanced age of dam and/or sire
- Use of cooled or frozen semen
- Dam's or sire's history of unsatisfactory fertility
- Degenerative and/or infectious conditions within the reproductive tract

CONTAGION & ZOONOSIS

Brucella canis (see p. 162)

GEOGRAPHY AND SEASONALITY

Bitches cycle at any time of the year (except basenji—late summer/early fall).

ASSOCIATED CONDITIONS & DISORDERS

Estrus induction, artificial insemination, pregnancy diagnosis.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Owner desires litter from dam and wants to maximize fertility and fecundity.

PHYSICAL EXAM FINDINGS

Physical exam should be unremarkable. Overt signs of estrus should be evident:

- Swollen, edematous vulva
- Serosanguineous vaginal discharge
- Perineal stimulation results in lateral deviation of the tail (“flagging”), elevation of the vulva, and lordosis

ETIOLOGY AND PATHOPHYSIOLOGY

- Developing follicles secrete estradiol initially (proestrus), followed by progesterone after the LH surge has occurred (estrus).
- Follicles ovulate 2 days after the LH surge, and oocytes are fertile another 2 days later.
- Oocytes remain fertile for 4 days.
- Breeding should occur between 3 and 8 days after the LH surge.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

For optimal timing of breeding, determine the day of the preovulatory LH surge by detecting the first day on which serum progesterone concentration exceeds 2 ng/mL or by measuring serum LH concentrations directly. Additional value may be found in vaginal cytology and vaginoscopy (see p. 1361), both of which are inexpensive, provide immediate results, and may be performed on site but are less accurate than hormone assays. Therefore, a typical protocol for a bitch whose signs of estrus are subtle involves daily vaginoscopy or vaginal cytology until characteristic changes of early estrus are noted at which time serum progesterone is measured q 24-48 h.

DIFFERENTIAL DIAGNOSIS

- Persistence of estrous behavior: granulosa cell tumor, endocrine-secreting anovulatory follicle(s)
- Discharge from an open pyometra
- Vaginal or uterine trauma resulting in bleeding

INITIAL DATABASE

- Vaginal cytologic evaluation:
  - Start 0 to 5 days after the onset of vaginal bleeding and continue q 48 h to monitor estrogenization of the vaginal mucosa.
  - Use a cotton swab moistened with saline, and extended with hemostat or artificial insemination pipette to reach through a vaginal speculum for collection of cells from cranial vagina.
  - The vaginal cytology will contain 100% superficial cells (cornified; large, angular, often with folded edges) during estrus, many of which still have nuclear remnants or pyknotic nuclei.
  - Presence of 50% or more cornified cells can be used as the threshold for beginning measurement of serum progesterone levels.
- Serum progesterone concentration
  - Start determining serum progesterone concentration once there is maximal development of the squamous epithelium and/or the vaginal cytology contains 100% superficial cells.
    - Refrigeration of whole blood during the first 2 hours after sample collection significantly decreases measured serum progesterone concentrations in dogs.
    - When whole clotted blood is not centrifuged immediately after collection, it must not be refrigerated for at least 2 hours, because this will affect serum progesterone concentrations.
  - The day of LH surge (d0) is the day preceding the first day on which serum progesterone concentration exceeds 2 ng/mL.
  - Progesterone can be measured by laboratory assays (RIA or chemiluminescence) or by patient-side semiquantitative ELISA assay.
- *Brucella canis* testing is essential (see p. 162).

ADVANCED OR CONFIRMATORY TESTING

- Vaginoscopy (see p. 1361)
  - Start 0 to 5 days after onset of vaginal bleeding; continue q 48 h to monitor estrogenization of the vaginal mucosa.
  - Tubular Plexiglas speculum, 10-20 mm inner diameter, 15-25 cm length.
  - Maximal development of the squamous epithelium (evident as paleness) and edema (evident as swollen, rounded folds) of the vaginal mucosa coincides with peak estradiol concentrations, just before LH surge.
- Serum LH concentration
  - Commercial kits are available for semiquantitative assessment of serum LH concentrations.
  - Once- or twice-daily testing is required; LH concentrations will only remain elevated for 18-24 h.

TREATMENT

TREATMENT OVERVIEW

Breeding management is preventive. Therefore, under most circumstances, treatment as such is not indicated. Proactive strategies help to optimize efficacy of breeding.

ACUTE GENERAL TREATMENT

- Breeding strategies
  - Natural service, fresh or shipped (cooled) semen artificial insemination:
    - Breed on days 4 and 6 after LH surge.
    - Inseminate vaginally, using a 5-mm-thick plastic pipette that is advanced to the caudal end of the cervix (confirm placement by abdominal palpation).
    - Once the pipette is placed, the semen is injected slowly through a syringe attached to the pipette, the pipette is withdrawn, and a finger is placed into the vestibulum and used to massage the floor of the cranial vestibulum ("feathering") for 1-10 minutes (vaginal contractions result and facilitate movement of semen through the cervix).
    - Elevation of the bitch's hindquarters (theoretical benefit of gravity) is often practiced but does not improve fertility.
  - Artificial insemination with frozen or poor-quality fresh/cooled semen:
    - Breed between days 5 to 7 after LH surge.
    - Perform laparotomy and inject semen through uterine wall into the uterine lumen, or perform transcervical catheterization and inject semen directly into uterine lumen (see p. 1346).
      - Transcervical catheterization can be performed either via an endoscopically guided transcervical catheter (dedicated equipment) or with a Norwegian catheter that can be guided through the cervix using abdominal palpation (advanced skill and experience needed).
      - Transcervical catheterization allows for repeat inseminations on multiple days.
      - With frozen semen, more than one insemination at daily intervals and a lower sperm dose produces better results than a single, well-timed insemination with a high sperm dose.
    - Two to four daily vaginal inseminations with frozen-thawed semen extended with prostatic fluid have yielded excellent results as well.
    - Natural copulation can be simulated by the use of a dedicated insemination catheter that allows for the insufflation of a large cuff that seals the vagina to prevent backflow of semen after insemination (MAVIC, Minitube of America).

BEHAVIOR/EXERCISE

- Unrestricted exercise
- To prevent unintentional matings, estrous bitches must not have contact with intact male dogs.

POSSIBLE COMPLICATIONS

- For surgical artificial insemination, clients must be warned that no anesthetic protocol is totally safe, and about 8% of all elective soft-tissue surgeries result in postoperative complications (e.g., infection, wound dehiscence, delayed healing) despite the use of modern techniques and procedures aimed at preventing such complications.
- Inappropriate timing of artificial insemination or use of poor-quality semen can result in a reduction of expected litter size.

PROGNOSIS AND OUTCOME

Average pregnancy rates after artificial insemination with fresh, chilled, or frozen-thawed semen vary greatly between 45% and 90%.

PEARLS & CONSIDERATIONS

COMMENTS

- Animals should be tested for brucellosis and heritable disorders before breeding.
- Semen quality should be assessed in advance of insemination.
- In-house test kits for semiquantitative determination of serum progesterone and luteinizing hormone concentrations of bitches are available for use when veterinary diagnostic laboratory services are not available.
- The day of LH surge (d0) is the day preceding the first day on which serum progesterone concentration exceeds 2 ng/mL.

TECHNICIAN TIP

Follow instructions very carefully when performing in-house or patient-side serum progesterone or LH tests, as results are a cornerstone of success.

CLIENT EDUCATION

- Days 3-8, or days 4 and 6, after the LH surge are the most fertile days for breeding bitches, but pregnancies can result from breeding up to 3 days earlier or 2 days later using fresh semen.
- Estrus monitoring is also used to predict the most likely whelping date: 65 (±1) days after the LH surge or 57 (±1) days after cytologic diestrus (D1).

EDITOR: MICHELLE A. KUTZLER

Brain Neoplasia

BASIC INFORMATION

DEFINITION

- Primary brain tumors include meningioma (discussed separately; see p. 715), glioma (astrocytoma, oligodendroglioma), choroid plexus tumor, ependymoma, medulloblastoma, olfactory neuroblastoma, and primitive neuroectodermal tumor.
- Secondary brain tumors include pituitary tumors, tumors that invade by direct extension into the brain (e.g., nasal tumors), and metastatic tumors to the brain (e.g., hemangiosarcoma, lymphoma [latter is discussed separately]; see p. 671).

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Occurs in both dogs and cats of both sexes
- Incidence reported as high as 2.6% in dogs and 2.8% in cats
- Brain tumors typically occur in older dogs (most > 5 years old) and cats. Median age: 9 years (dogs), 11 years (cats).

GENETICS & BREED PREDISPOSITION

- Canine: Dolichocephalic breeds (e.g., golden retriever, German shepherd dogs) tend to develop meningiomas. Brachycephalic breeds (e.g., boxer, Boston terrier) appear prone to developing gliomas.
- Feline: no breed predisposition. Meningioma is the most common brain tumor in cats.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Meningioma: tumor of the arachnoid membrane
- Glioma: tumor of the cells that form the interstitial tissue of the central nervous system (CNS)
- Choroid plexus papilloma: tumor of the cells of the choroid plexus, the intracranial vascular structure responsible for the formation of cerebrospinal fluid
- Ependymoma: tumor of the ependymal cells that line the ventricular system

HISTORY, CHIEF COMPLAINT

- A brain tumor should be suspected in any older patient with an insidious onset of slowly progressive neurologic signs, and in any patient older than 5 years with a recent onset of seizures.
- Historic findings depend on lesion location. Clinical signs are often insidious and progressive; however, recent onset of clinical signs is possible.
- The most common chief complaints include seizures, circling, behavior change (aggression), altered consciousness, and nonspecific signs such as inappetence and lethargy.

PHYSICAL EXAM FINDINGS

- Neurologic exam findings vary depending on lesion location (see p. 1311).
- Findings generally reflect a focal lesion with asymmetric clinical signs. However, a large case series found that half of canine brain tumors occupy more than one anatomic region of the brain (e.g., forebrain and brainstem).
- Cerebral brain tumors: seizures, contralateral menace and postural reaction deficits, behavior change, contralateral hemiparesis, altered mental status
- Brainstem brain tumors: ipsilateral cranial nerve deficits, hemiparesis or tetraparesis or tetraplegia, altered mental status, central vestibular dysfunction
- Cerebellar brain tumors: hypermetria, intention tremors, truncal sway, broad-based stance, paradoxical vestibular dysfunction

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology is unknown.
- Usually occur as solitary masses. Multiple tumors may be seen with metastatic disease.

- Most commonly reported in the supratentorial compartment (rostral to the tentorium cerebelli, including the cerebrum and diencephalon)
- Biological behavior (benign versus malignant) is generally irrelevant because neoplasia of the brain is detrimental via space-occupying effects.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Neoplasia of the brain is suspected based on signalment, history, and neurologic examination results. Confirmation requires intracranial imaging (CT or MRI).

DIFFERENTIAL DIAGNOSIS

- Infectious diseases (bacterial, viral, fungal, protozoal)
- Inflammatory diseases (e.g., granulomatous meningoencephalomyelitis)
- Cerebrovascular infarction if clinical signs are acute, nonprogressive, and asymmetric
- Toxin and metabolic diseases if clinical signs are acute, nonprogressive, and symmetric

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis: usually normal
- Thoracic and abdominal radiographs: usually normal but performed to rule out extracranial neoplasia

ADVANCED OR CONFIRMATORY TESTING

- CT or MRI:
  - MRI is markedly superior for soft-tissue detail (brain, spinal cord) and has higher resolution than CT. As a result, this is the current gold standard for brain imaging.
  - CT is an adequate imaging modality, is superior for bone lesions (e.g., skull tumors), much faster, and may be cheaper than MRI.
  - Focal mass identified for most brain tumors; however, multiple tumors may be identified with metastatic neoplasia.
  - CT and MRI features are variable between tumor types.
- Cerebrospinal fluid (CSF) analysis:
  - Used as an adjunct to advanced imaging, primarily to assess encephalitis
  - With brain neoplasia, results are generally nonspecific and reveal normal to mildly elevated protein.
  - Albuminocytologic dissociation (elevated CSF protein with normal white blood cell count) can occur but is not pathognomonic.
  - Neoplastic cells are rarely identified within the CSF; however, the presence of lymphoblasts within the CSF supports a diagnosis of CNS lymphoma.
- Histopathologic analysis of tissue is required for definitive diagnosis. Tissue samples can be obtained via surgical excision or stereotactic brain biopsy.

TREATMENT

TREATMENT OVERVIEW

Definitive treatment involving surgical excision and/or radiation therapy and/or chemotherapy

ACUTE GENERAL TREATMENT

- Surgical excision: used for removing or debulking the tumor, if accessible, and for providing a definitive histologic diagnosis
- Radiation therapy: used as an adjunctive treatment to surgery or as a primary treatment
- Chemotherapy: most agents are not effective because the blood-brain barrier (BBB) prevents chemotherapeutic agents from entering the brain and spinal cord. The exception to this is nitrosourea drugs.
  - Nitrosourea agents such as lomustine (CCNU; 60-90 mg/m^2 PO q 6 wk) or carmustine (BCNU 50 mg/m^2 IV q 6 wk), which can cross the BBB, appear to have some effect in canine gliomas and canine CNS lymphoma.
  - The most serious potential adverse effects are bone marrow suppression (anemia, thrombocytopenia, leukopenia) and hepatotoxicity.
  - The use of hydroxyurea (20 mg/kg PO q 24 h) has been shown to significantly increase survival times in dogs with

meningiomas, compared with use of prednisone alone. Side effects at this dose are typically mild to nonexistent.

- Cluster seizures or status epilepticus: diazepam, 0.5 mg/kg IV (can be repeated at 5-minute intervals for a maximum of three doses). If diazepam is initially effective, but seizures recur, consider diazepam IV constant rate infusion (0.25-0.5 mg/kg/h) or loading dose of phenobarbital IV (to effect, up to 16-20 mg/kg total dose). A seemingly effective newer alternative therapy is intravenous levetiracetam.
- Cerebral edema/brain herniation: mannitol, 0.5 g/kg IV slowly over 10-15 minutes; furosemide (2 mg/kg IV) has synergistic effects with mannitol and can be given if needed.

CHRONIC TREATMENT

- Seizures: anticonvulsants should be used if there is more than one seizure every 6-8 weeks.
  - Phenobarbital: 2-4 mg/kg PO or IV q 12 h
  - Potassium bromide: 20-50 mg/kg PO q 24 h; dose can be divided q 12 h to reduce nausea and vomiting. (See p. 1009 and p. 353 .) Use with caution in cats; frequently causes reversible clinical signs consistent with bronchial asthma, but in rare cases has been fatal.
- Cerebral edema: prednisone, 0.5 mg/kg PO q 12 h initially, then taper to lowest dose that will control clinical signs.

DRUG INTERACTIONS

- Drug interactions or altered metabolism of medications have been reported between corticosteroids and amphotericin B, furosemide, thiazide diuretics, digitalis glycosides, cyclosporine, phenytoin, phenobarbital, and mitotane.
- Corticosteroids should not be given concurrently with nonsteroidal antiinflammatory drugs or other potentially gastric ulcerogenic medications.
- Phenobarbital may cause excessive sedation in dogs with intracranial mass lesions, even at low doses.

POSSIBLE COMPLICATIONS

Progression of clinical signs, including status epilepticus, brain herniation, and sudden death

RECOMMENDED MONITORING

- Serial neurologic exam every 4-6 weeks
- Serum phenobarbital blood level 2 weeks after starting medication, or any change in dosage, or immediately after loading dose
- Serum bromide blood level 3-4 months after starting medication, or any change in dosage in dogs and 2 months in cats, or immediately after loading dose

PROGNOSIS AND OUTCOME

- In general, the prognosis is fair to guarded in both dogs and cats.
- In dogs, several small-scale reports have shown a median survival time of approximately 2-4 months with supportive care and nonspecific treatment only, 6-12 months with surgery alone, 7-24 months with radiation therapy alone, 6 months to 3 years with surgery and radiation, and 7-11 months with chemotherapy alone.
- There are no large-scale reports of survival times in cats, with the exception of meningiomas (see p. 715). However, the long-term prognosis for cats with other brain tumors is likely similar to that for dogs.

PEARLS & CONSIDERATIONS

COMMENTS

With neoplasia of the brain, asymmetric neurologic deficits are much more common than symmetric deficits. Symmetric neurologic deficits make other diagnoses more likely.

TECHNICIAN TIPS

Postoperative craniotomy patients are very vulnerable to brain trauma, and comprehensive care (e.g., padding of cage walls, prevention of self-trauma through gentle restraint and padding over the surgical site) can make the difference between a excellent outcome and a life-threatening complication.

PREVENTION

No known method to prevent disease

CLIENT EDUCATION

- Warn owner of corticosteroid side effects (e.g., polyuria, polydipsia, polyphagia, weight gain, gastrointestinal ulceration, iatrogenic hyperadrenocorticism).
- Phenobarbital and KBr: Short-term side effects include sedation/lethargy and pelvic limb weakness and ataxia. Long-term side effects include polyuria, polydipsia, polyphagia, weight gain. Less common adverse effects include hepatotoxicity and blood dyscrasias for phenobarbital and pancreatitis for KBr.
- See other sources for additional information.

EDITOR: CURTIS W. DEWEY

Brachycephalic Airway Syndrome

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A syndrome of anatomic and functional abnormalities of the upper airway found in brachycephalic (short-nosed) dogs; results in variable degrees of upper airway distress

SYNONYMS

Brachycephalic syndrome; brachycephalic upper airway syndrome; upper airway syndrome

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Brachycephalic airway syndrome occurs almost only in dogs.
- Mean age at presentation: 3 to 4 years.
- Age at presentation variable:
  - Young dogs (3-12 months old); clinical signs often associated with stenotic nares
  - Middle-aged dogs with increasingly severe respiratory problems over several years

GENETICS & BREED PREDISPOSITION

Breeds predisposed: English and French bulldogs, Boston terrier, pug, boxer, Pekinese, shih tzu (shih tzu: rarely elongated soft palate, frequently stenotic nares).

RISK FACTORS

Deterioration/decompensation producing severe dyspnea:

- Hot, humid weather
- Hot ambient temperature (e.g., in car with inadequate ventilation)
- Exertion

GEOGRAPHY AND SEASONALITY

More likely to trigger owner concern during summer, when increased ambient temperatures and activity can lead to episodes of severe dyspnea.

ASSOCIATED CONDITIONS & DISORDERS

- Three primary anatomic components of the brachycephalic airway syndrome:
  - Stenotic nares
  - Elongated soft palate
  - Hypoplastic trachea
  - Any or all may be present in any given brachycephalic dog
- Secondary airway changes that can develop due to increased airway resistance include:
  - Laryngeal saccule eversion
  - Laryngeal collapse
    - Seen in older dogs with chronic, severe, untreated brachycephalic syndrome
- Obesity: aggravating factor
- Noncardiogenic pulmonary edema (see p. 933), acute respiratory distress syndrome (see p. 34):
  - Occurs if patient inspires forcefully and excessively against severe upper airway obstruction
  - Can cause persistence of cyanosis/hypoxemia despite relief of upper airway obstruction

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of exercise intolerance, cyanosis, or collapse
- Gagging or coughing
- Stertor (heavy snoring) most common, stridor (high pitched) less common

PHYSICAL EXAM FINDINGS

- Stenotic or narrowed nares
- Stertor or stridor; increased inspiratory sounds
- Increased expiratory sounds on auscultation if concurrent pneumonia, bronchitis, or noncardiogenic pulmonary edema
- If in severe respiratory distress: cyanosis, stridor or apnea, hyperthermia

ETIOLOGY AND PATHOPHYSIOLOGY

- Breeding selection has led to dorsoventral flattening and rostrocaudal shortening of the skull and nasal passages of these dogs. The result is increased negative pressure in the nasal passages and pharynx during inspiration.
- These anatomic characteristics coupled with redundant and edematous nasopharyngeal and oropharyngeal soft tissues contribute to increased airway resistance and obstruction.
- If untreated, stenotic nares and an elongated soft palate increasingly interfere with breathing.
- Excessive negative nasopharyngeal pressure results in laryngeal saccule eversion and laryngeal collapse (inward folding of the epiglottis and arytenoid cartilages).
- As the nasopharyngeal mucosa becomes edematous and inflamed, it contributes to upper airway obstruction.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The characteristic inspiratory stertor in brachycephalic breeds is suggestive of the diagnosis on physical examination alone. Confirmation requires a sedated oropharyngeal examination and cervical and thoracic radiographs.

DIFFERENTIAL DIAGNOSIS

- Upper airway mass: neoplasia, polyp, granuloma, foreign body, abscess
- Laryngeal paralysis
- Cervical or laryngeal trauma
- Coagulopathy resulting in laryngeal hematoma
- Collapsing trachea

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis: generally unremarkable
- Lateral cervical radiographs: length of soft palate, hypoplastic trachea
- Inspiratory and expiratory thoracic radiographs (to assess for complications and rule out differential diagnosis):
    - Tracheal collapse
    - Chronic small airway disease
    - Pneumonia
    - Noncardiogenic pulmonary edema

ADVANCED OR CONFIRMATORY TESTING

Rapid-acting anesthetic induction and oropharyngeal/laryngeal examination (e.g., propofol, 4-6 mg/kg given slow IV to effect): be prepared to intubate and ventilate if necessary, given propofol's apnea-inducing qualities:

- Determine if soft palate excessively long
- Presence of laryngeal saccule eversion
- Presence of laryngeal collapse

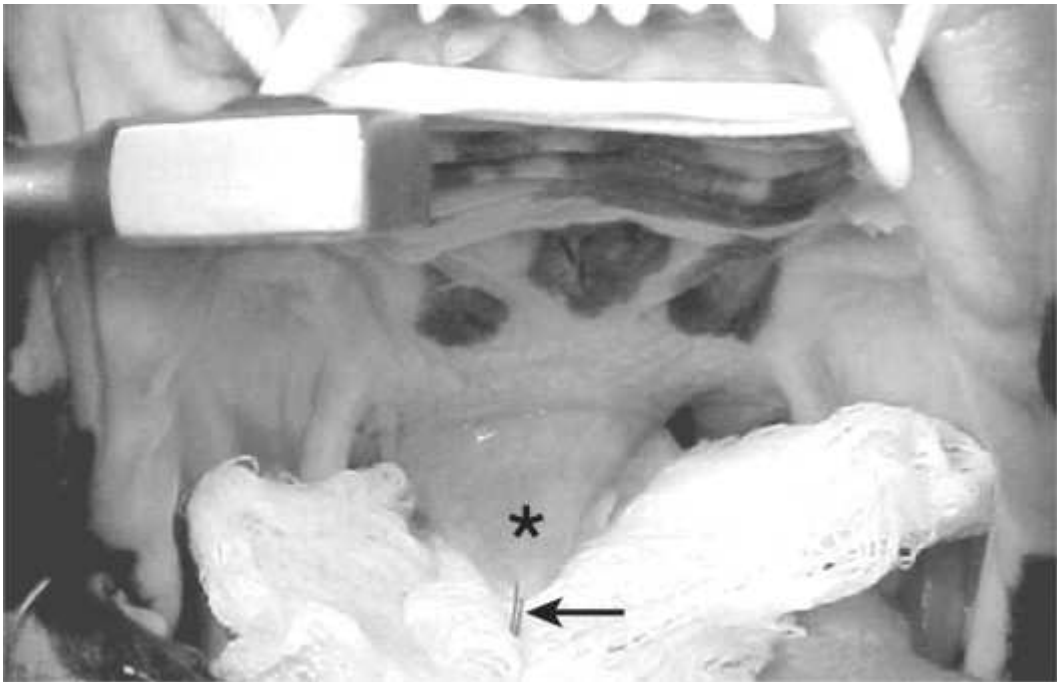
TREATMENT

TREATMENT OVERVIEW

- Immediately, if severe dyspnea:
  - Relieve upper airway obstruction via sedation with or without endotracheal intubation or tracheostomy.
  - Minimize patient's anxiety, and thus reduce the risk of noncardiogenic pulmonary edema, hyperthermia, and worsening dyspnea.
- Long-term:
  - Relieve upper airway obstruction via surgical correction.

ACUTE GENERAL TREATMENT

- Stenotic nares:
  - Remove excessive cartilaginous tissue of alae (wings) of nostrils by excision.
- Elongated soft palate:
  - Shorten soft palate by removing excessive or redundant palatal tissue to improve glottal airflow, eliminate excessive negative pressure, and improve functional glottal size.
  - Soft palate resection using sharp transection and suture, or CO2 laser
- Everted laryngeal saccules: excise everted mucosal tissue.
  - Traction and amputation of everted mucosa with scissors, scalpel, or CO2 laser
- Laryngeal collapse:
  - Cannot be surgically corrected
  - Permanent tracheostomy may be necessary
- Hypoplastic trachea: no surgical treatment
- Complications: treatment as required should they occur



BRACHYCEPHALIC AIRWAY SYNDROME Preoperative open-mouth view of the elongated soft palate *(asterisk)* of a French bulldog with brachycephalic airway syndrome. A stay suture *(arrow)* is placed through the caudal tip of the soft palate in preparation for resection.

(Courtesy Dr. Richard Walshaw.)

BRACHYCEPHALIC AIRWAY SYNDROME Postoperative view of the same dog. Resection of the elongated soft palate is complete, creating a pharynx with a more normal conformation. Consequently, the larynx *(arrows)* is more easily seen, illustrating the improvement brought by the soft palate resection.

(Courtesy Dr. Richard Walshaw.)

CHRONIC TREATMENT

- Avoid exposure to high ambient temperatures and humidity and other sources of stress.
- Maintain optimal body weight.

POSSIBLE COMPLICATIONS

- Hyperthermia (see p. 480)
- Noncardiogenic pulmonary edema (see p. 933). Sedate early to reduce the risk of this complication.
- Aspiration pneumonia (see p. 885)
- Excessive shortening of soft palate may result in nasal reflux of food or water or, more rarely, aspiration pneumonia.
- Laryngeal saccule eversion and collapse may develop if upper airway obstruction persists.

RECOMMENDED MONITORING

Owner should be aware of any recurrent signs of upper airway obstruction (exercise intolerance, coughing, gagging, stridor, or stertor), which might indicate progressive degenerative changes in upper airway (laryngeal collapse).

PROGNOSIS AND OUTCOME

- Guarded prognosis if acute, severe dyspnea: a life-threatening state may exist, but with a good response to treatment, full resolution of signs is possible.
- Good to excellent long-term prognosis after correction of stenotic nares and resection of elongated soft palate, provided secondary changes have not developed
- Variable (poor to good) prognosis if laryngeal collapse has developed or if dog has a hypoplastic trachea, depending on degree of airway obstruction

PEARLS & CONSIDERATIONS

COMMENTS

- Early detection and surgical treatment are recommended for best outcome and avoidance of secondary changes/complications.
- Lifestyle modifications are often necessary to minimize episodes of airway distress:
  - Maintain ideal body weight.
  - Avoid stressful situations.
- Hypoplastic trachea is often a subclinical problem, but if severe it may affect long-term prognosis and outcome after surgery.

PREVENTION

- Because brachycephalic syndrome is breed-associated and heritable, it is not preventable in a given patient.
- Episodes of respiratory distress may be minimized by avoiding stress, moderating exercise, preventing obesity, avoiding exposure to high ambient temperatures, and early surgical treatment for elongated soft palate and stenotic nares.
- Correction of stenotic nares in the puppy may reduce the severity of brachycephalic syndrome later in life.

TECHNICIAN TIPS

Hospitalized patients with brachycephalic syndrome require preoperative and postoperative intensive care and constant monitoring. Respiratory obstruction is a potential problem at any time. Technicians caring for these patients perioperatively should be familiar with and comfortable performing:

- Orotracheal intubation in a brachycephalic dog
- Oxygen administration
- Administration of prescribed sedative and analgesic drugs
- Tracheostomy care
- Cardiopulmonary resuscitation

CLIENT EDUCATION

- Discuss breed association and heritability in brachycephalic dogs.
- Syndrome is progressive and exacerbated by stress, obesity, and exposure to high ambient temperatures.
- Early surgical intervention is important for most successful outcome.

1ST EDITION AUTHOR: ELLEN DAVIDSON DOMNICK

Brachial Plexus Abnormalities

BASIC INFORMATION

DEFINITION

Dysfunction of the peripheral nerves or nerve roots of the brachial plexus (C6-T2 spinal segments)

EPIDEMIOLOGY

RISK FACTORS

Dependent on disease subtype:

- Trauma
- Antigenic stimulation/allergy

ASSOCIATED CONDITIONS & DISORDERS

With concurrent traumatic injuries:

- Shock, hypotension, head trauma, pneumothorax
- With neoplasia, intervertebral disk disease: +/− signs of unilateral C6-T2 myelopathy

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Traumatic brachial plexus injury:
  - Neurotmesis: complete avulsion of brachial plexus nerves
  - Unilateral or bilateral; can involve some or all nerves in the brachial plexus
    - Axonotmesis: partial brachial plexus avulsion (endoneurium remains intact)
    - Neurapraxia: stretching/transient damage to nerve(s), without avulsion
- Brachial plexus neuritis:
  - Idiopathic inflammatory neuropathy of the brachial plexus
- Nerve sheath tumors (see p. 763)
- Lymphoma (rare)

HISTORY, CHIEF COMPLAINT

- Thoracic limb lameness, paresis, or paralysis (acute or chronic onset)
- History of trauma or antigenic stimulation (e.g., vaccination, allergic hypersensitivity [see p. 64 and p. 402])

PHYSICAL EXAM FINDINGS

- Variable, depending on nerve root(s) affected
- Abnormalities may include:
  - Focal muscle atrophy
    - Evident 5-10 days post injury
  - Neurologic deficits in thoracic limb(s): normal pelvic limbs
    - Thoracic limb monoparesis/monoplegia, or bilateral thoracic limb paresis/plegia
    - Proprioceptive deficit of affected limb(s)
    - Hyporeflexia/areflexia
    - Loss of nociception (superficial or deep pain sensation) to various autonomous zones of thoracic limb(s): evaluate all autonomous zones and all digits for sensory loss (see p. 1412)
  - Ipsilateral loss of cutaneous trunci reflex
    - May occur with lateral thoracic nerve injury (C8-T1 spinal nerve roots)
  - Ipsilateral Horner's syndrome
    - May occur with injury of the sympathetic pathway (T1-T3 spinal nerve roots)

ETIOLOGY AND PATHOPHYSIOLOGY

- Brachial plexus injury/avulsion: trauma to the thoracic limb(s) that results in abduction, caudal displacement, or extreme flexion/extension of the shoulder joint; results in traction injury to the nerve roots of the brachial plexus as they attach to the spinal cord
- Complete avulsion more common than partial, caudal nerve root avulsion more common than cranial
- Brachial plexus neuritis: idiopathic inflammatory response; theories include antigenic stimulation by vaccination, allergic reactions, or diet hypersensitivities (particularly diets containing horse meat).
- Neoplasia

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on evidence of thoracic limb hypotonic and hyporeflexive monoparesis/monoplegia with normal pelvic limbs. History may include trauma or recent vaccination. Electrodiagnostic testing and advanced imaging (CT/MRI) may confirm etiology and provide prognostic information.

DIFFERENTIAL DIAGNOSIS

- Neoplasia
- Musculoskeletal injury:
  - Fractures
  - Dislocations
  - Muscle avulsions
- Central cord syndrome:
  - Injury or dysfunction of the central spinal cord parenchyma (grey matter)
  - Very rare; reported sporadically with spinal trauma, disk herniation, intramedullary neoplasia, syringomyelia
- Other focal neuropathies (e.g., early stages of rabies encephalomyelitis or acute canine polyradiculoneuritis/Coonhound paralysis)

INITIAL DATABASE

- Neurologic examination (see p. 1311)
- Cutaneous sensory evaluation (autonomous zones) and deep pain assessment (see p. 1412)

ADVANCED OR CONFIRMATORY TESTING

- Electrodiagnostic testing (see online chapter: Electromyography and Nerve Conduction Velocity): may confirm loss of function but generally not essential for diagnosis
  - Abnormal spontaneous muscle activity seen with electromyography
  - Decreased motor or sensory nerve conduction velocities
- Myelography, CT, and MRI: often not effective in diagnosing brachial plexus injury; however, may rule out other compressive myelopathies or neuropathies
- Brachial plexus ultrasonography: not effective for diagnosing brachial plexus injury; may be useful to localize neoplasia located within the brachial plexus

TREATMENT

TREATMENT OVERVIEW

Treatment mainly consists of maintaining joint mobility and preventing muscle contracture and self-mutilation of affected limb(s) while awaiting return of neurologic function and ability to ambulate.

ACUTE GENERAL TREATMENT

- Supportive care/trauma resuscitation
- Prevent self-mutilation and external trauma to affected limb(s):
  - Booties to protect paw from abrasions and scuffing
  - E-collar to prevent licking, chewing, or other self-mutilation

- Neuropathic analgesia (i.e., gabapentin 10 mg/kg PO q 8 h) may help prevent paresthesia and self-mutilation.
- Corticosteroids may be beneficial in brachial plexus neuritis; however, insufficient information exists to confirm their efficacy.

CHRONIC TREATMENT

- Prevent self-mutilation.
- Physical therapy (see p. 1329): prevent muscle contracture and maintain range of motion/extensor ability should neurologic function return:
  - Target-all joints, including carpus and digits.
  - Perform range of motion (ROM) exercises for 10-15 minutes 3-5 times daily.
- Limb amputation: treatment of choice for permanent unilateral brachial plexus avulsion or if documented or highly suspected nerve sheath tumor
- Euthanasia is warranted in permanent bilateral avulsions.
- Limb-sparing treatments for brachial plexus avulsion have been attempted, including nerve root transplantation, transposition, neurotization, and muscle transposition. Treatment results are generally unsatisfactory. Transposition and neurotization of the intact contralateral C8 ventral root in dogs shows some promise, but at this time, recovery of neurologic function remains limited.

NUTRITION/DIET

Avoid diets containing horse meat.

POSSIBLE COMPLICATIONS

- Paresthesias/sensory nerve injuries promote self-mutilation.
- Abrasions may occur on the dorsum of the paw from scuffing/dragging the affected limb during ambulation, creating a potential portal for infection.
- Peripheral nerve sheath tumor that goes on to invade the vertebral canal

RECOMMENDED MONITORING

Serial assessment of cutaneous sensation and motor function every 2-4 weeks

PROGNOSIS AND OUTCOME

- Loss of deep pain sensation suggests avulsion and warrants a grave prognosis for return of function.
- Preservation of deep pain sensation warrants a guarded to good prognosis for return of function over weeks to months.
- Lack of any neurologic improvement over a 4-week period suggests permanent deficit.
- Brachial plexus neuritis has a guarded prognosis; recovery is possible.

PEARLS & CONSIDERATIONS

COMMENTS

- Physical therapy is imperative in cases with potential for recovery.
  - Splints or bandages are generally not recommended because they impair mobility.
- Evaluate all digits for deep pain sensation; peripheral nerve deficits may be localized and identified in only one digit.
- Neoplasia may present as an acute onset/trauma event.

PREVENTION

Minimize risk of motor vehicle trauma (e.g., riding in open truck beds where pets could jump or be thrown from the vehicle).

CLIENT EDUCATION

- If recovery is possible/attempted, train clients to perform effective physical therapy or encourage referral for formal rehabilitation.
- If amputation is necessary, discuss benefits of amputation and how well pets adapt.
- Discuss importance of maintaining pet at a lean body weight and the negative impact of concurrent osteoarthritis or hip dysplasia on their pet's ability to ambulate.

Botulism

BASIC INFORMATION

DEFINITION

An acute, rapidly progressive generalized lower motor neuron (LMN) paralytic disorder caused by ingestion of an exotoxin produced by the bacterium *Clostridium botulinum*

EPIDEMIOLOGY

SPECIES, AGE, SEX

Any breed, either sex. Cats appear highly resistant to botulism (no natural cases reported).

RISK FACTORS

Ingestion of contaminated food or carrion.

CONTAGION & ZOONOSIS

There are seven antigenically identified types of botulinum neurotoxins (A-G). Dogs: type C. Large animals: type B. Humans: types A, B, F.

ASSOCIATED CONDITIONS & DISORDERS

Aspiration pneumonia, ventilatory failure (respiratory arrest)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Lower motor neuron paresis/paralysis that is often ascending
  - Begins as weakness in the pelvic limbs and can progress to quadriplegia
- History of ingestion of carrion or other source of anaerobic bacterial contamination
  - The incubation period after ingestion ranges from hours to 6 days.
  - Botulism is especially likely if multiple animals are affected.

PHYSICAL EXAM FINDINGS

- Decreased LMN reflexes (patellar, others) and muscle tone in all limbs
- Cranial nerve abnormalities (decreased/absent palpebral and menace, decreased jaw tone and gag, mydriasis, voice change)
- Level of consciousness maintained, pain perception preserved
- In severely affected animals, decreased abdominal and intercostal muscle tone is observed, which can require ventilation or lead to death from ventilatory failure.
- Tail wag is maintained.
- Parasympathetic dysfunction can also be observed (heart rate changes, regurgitation due to megaesophagus).

ETIOLOGY AND PATHOPHYSIOLOGY

- *C. botulinum* is a gram-positive, saprophytic, spore-forming bacterial rod in soil.
- Clinical signs develop after ingestion of the preformed toxin; it is absorbed from the stomach and small intestine and enters the lymphatics, where it is transported by an unknown mechanism to the neuromuscular junction of cholinergic nerves.
- A metalloprotease (botulinal toxin) prevents the presynaptic release of acetylcholine at the neuromuscular junction. Toxin binding is quick, irreversible, and independent of temperature and neural activity. Cell membrane receptors have a high affinity for the toxin (species and individual variation in sensitivity to toxin).
- The severity of the signs varies with the amount of toxin ingested and individual susceptibility.
- The blockage of release of acetylcholine from the presynaptic membrane results in progressive, symmetric, ascending lower

motor neuron paresis/paralysis.
- Duration of illness in the dog: 14-24 days

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is based on a history suggestive of toxin ingestion and the resultant clinical signs. Toxin identification may be undertaken to confirm the diagnosis, but treatment, which is supportive and may be urgently required, is initiated based on neurologic deficits and history.

DIFFERENTIAL DIAGNOSIS

- Early tick paralysis
- Early polyradiculoneuritis

INITIAL DATABASE

- CBC, serum biochemical analysis, and urinalysis: usually normal
- Neurologic examination consistent with diffuse lower motor neuron dysfunction
- Thoracic and abdominal radiographs may occasionally reveal megaesophagus (with or without signs of aspiration pneumonia) and carrion skeletal remains in the gastrointestinal tract, respectively, but radiographic abnormalities are not required to make the diagnosis of botulism.

ADVANCED OR CONFIRMATORY TESTING

- Confirmatory diagnosis is based on finding the toxin in serum, feces, vomitus, or food samples.
- Preferred method of toxin identification is the mouse neutralization test.
- Other in vitro tests (radioimmunoassay, passive hemagglutination, enzyme-linked immunosorbent assay and polymerase chain reaction) exist but have not replaced the mouse test to date.
- Electrophysiologic testing (see p. 1255):
    - Marked reduction in muscle action potential amplitude evoked by electrical stimulation of the motor nerve
    - Normal or only mildly reduced nerve conduction velocities
    - Normal electromyography

TREATMENT

TREATMENT OVERVIEW

Treatment consists principally of supportive care during spontaneous recovery.

ACUTE GENERAL TREATMENT

- Antitoxin (type specific) must be administered before the botulinal toxin binds to receptors at the myoneural junction.
    - Type C polyvalent antitoxin (dog): 10,000-15,000 IU/dog IV or IM, 2 doses given 4 hours apart
    - Anaphylaxis (see p. 64) is a potential risk; intradermal skin testing is recommended prior to administration.
    - Antitoxin may be effective to prevent further toxin binding if ongoing intestinal absorption/circulation.
- Antibiotic use is debated; penicillin and metronidazole have been given to dogs and humans to reduce potential intestinal growth of *C. botulinum*, but use is controversial (disease occurs due to ingestion of preformed toxin; these drugs could alter gastrointestinal flora).
- Antibiotics if secondary infection (i.e., aspiration pneumonia; based on culture and sensitivity testing).

CHRONIC TREATMENT

Long-term physical rehabilitation (see p. 1329), frequent turning, and soft bedding are essential.

DRUG INTERACTIONS

Avoid aminoglycosides (associated with neuromuscular blockade)

POSSIBLE COMPLICATIONS

- Aspiration pneumonia
- Decubital ulcers
- Muscle atrophy and fibrosis
- Ventilatory failure

RECOMMENDED MONITORING

- Respiratory rate and character; temperature and pulse
- Chest radiographs
- Serial neurologic examinations

PROGNOSIS AND OUTCOME 

- Good to guarded.
- Recovery usually occurs 2-3 weeks after regrowth of terminal motor branches; dependent on severity of signs and complications.
- Complete recovery can occur spontaneously in moderately affected animals.

PEARLS & CONSIDERATIONS 

COMMENTS

- The index of suspicion for botulism increases markedly if more than one animal is affected simultaneously.
- Referral may be necessary if long-term supportive care and ventilatory support are needed.

PREVENTION

- Prevention of access to carrion and spoiled food
- Thorough cooking of any foods fed to dogs and cats
- Botulinal toxin is destroyed by heating to 80°C for 30 minutes or 100°C for 10 minutes.

CLIENT EDUCATION

See Prevention above.

AUTHOR: KAREN L. KLINE

EDITOR: CURTIS W. DEWEY

Borreliosis

BASIC INFORMATION

DEFINITION

Borreliosis is a bacterial disease that infects humans, mammals, and birds. It is caused by a unicellular, spiral-shaped, gram-negative spirochete, transmitted primarily by *Ixodes* ticks.

SYNONYMS

Lyme disease, Lyme borreliosis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Susceptibility: humans, dogs, cats
- Younger dogs more commonly affected.

GENETICS & BREED PREDISPOSITION

- Breeds associated with outdoor activities
- Labradors, golden retrievers, and Shetland sheepdogs appear predisposed to Lyme nephropathy.

RISK FACTORS

Tick exposure in endemic areas

CONTAGION & ZOONOSIS

- Direct transmission does not occur from pets to humans.
- Seropositive dogs/cats are sentinel carriers.

GEOGRAPHY AND SEASONALITY

- In 2005, 89% of human cases reported in the US were from 10 northeastern and mid-Atlantic states (PA, NY, NJ, MA, CT, RI, MD, DE, VA, NH); 6% were from upper Midwest states (WI, MN).
- Most cases are reported between May and November.

ASSOCIATED CONDITIONS & DISORDERS

Lyme nephropathy can develop in predisposed animals. Tickborne co-infections are common, especially anaplasmosis (p.66).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of tick exposure in a Lyme-endemic area
- Most seropositive dogs (95%) show no clinical signs. In highly endemic areas, 70%-90% of healthy dogs are seropositive. Illness in seropositive cats is rare.
- Less than 5% of seropositive dogs show the syndrome “Lyme arthritis” (anorexia/fever/arthritis). This occurred 2-5 months after tick exposure in experimental beagle puppies (self-limiting), whereas adults showed no clinical signs.
- No experimental model exists for the less common syndrome “Lyme nephropathy” (protein-losing nephropathy [PLN] with glomerulotubular damage). Patients with this syndrome may present with signs of nephrotic syndrome, hypertension, thromboembolic events, and/or renal failure signs (vomiting/anorexia).

PHYSICAL EXAM FINDINGS

- No abnormalities is most common.
- Lyme arthritis: warm, swollen, painful joint(s), fever (103-106°F, [40-41°C]), lymphadenopathy.
- Lyme nephropathy: dehydration (renal failure), ascites/edema (nephrotic), aortic thromboembolism/dyspnea (thromboembolic events), retinal hemorrhage/detachment (hypertension).

ETIOLOGY AND PATHOPHYSIOLOGY

- *Borrelia burgdorferi* is a small micro-aerophilic spirochete.
- The agent in North America is *B. burgdorferi sensu stricto*.
- The organism multiplies in the tick, entering the host at the end of the tick's bloodmeal (when it regurgitates) after 48-72 hours of attachment.
- Replication in the skin at the tick bite site is followed by interstitial tissue migration.
- Clinical signs appear to be due to an immune-mediated pathogenesis (e.g., Lyme-specific antigen-antibody complexes are in glomeruli of dogs with Lyme nephropathy).
- A persistent carrier state is likely both in healthy-appearing carriers and clinically ill patients.
- Vectors are *I. scapularis* (deer tick) in the eastern United States and *I. pacificus* in the western United States. The white-footed deer mouse is the main reservoir and preferred host of larval and nymphal ticks. There is no transovarial transmission. Migratory birds are also carriers and disseminate infective ticks.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- A presumptive diagnosis of borreliosis includes (1) evidence of natural exposure antibodies, (2) clinical signs consistent with borreliosis, (3) consideration of other differentials, and (4) response to treatment, although Lyme nephropathy may not respond well.
- Overdiagnosis should be avoided; in endemic areas, many dogs with no clinical signs are seropositive. Response to treatment does not confirm diagnosis and may occur by inadvertent treatment of causative co-infections (e.g., Rocky Mountain spotted fever [RMSF], anaplasmosis, ehrlichiosis, bartonellosis, leptospirosis), or the antiinflammatory/antiarthritic properties of doxycycline.
- All seropositive (clinical and nonclinical) dogs should be monitored for proteinuria. Treatment is not recommended for nonclinical, nonproteinuric seropositive carrier dogs. The dog's sentinel status is an opportunity to educate the owner about tick control and public health aspects of Lyme disease.

DIFFERENTIAL DIAGNOSIS

- Lyme arthritis versus other causes for lameness
  - Septic arthritis, tickborne arthritides (anaplasmosis, ehrlichiosis, RMSF, bartonellosis), immune-mediated polyarthritis, systemic lupus erythematosus, rheumatoid arthritis
  - Degenerative joint disease, intervertebral disk disease, trauma
  - Panosteitis, osteomyelitis, polymyositis, neoplasia
  - Cardiopulmonary, metabolic, neurologic disease
- Lyme nephropathy
  - Proteinuria: urinary tract infection, neoplasia, calculi
  - PLN: genetic, infectious, immune-mediated, amyloidosis, neoplasia
  - Other causes for hypertension, hypercoagulable state, edema/effusions, and/or renal failure

INITIAL DATABASE

To confirm exposure and rule out other causes of lameness/fever or PLN:

- CBC and serum biochemistry profile: no specific findings expected unless Lyme nephropathy: hypoalbuminemia, hypercholesterolemia, ± azotemia, hyperphosphatemia, anemia, thrombocytopenia possible.
- SNAP-4Dx (IDEXX Laboratories) for heartworm antigen and antibodies to C6 peptide (specific for natural exposure to *B. burgdorferi*), *E. canis/chaffeensis*, and *A. phagocytophilum/A. platys*. This test replaces previous two-tier testing with Western blot for differentiating natural exposure from vaccine-induced antibodies, because the C6 peptide of the VlsE antigen is not found in any Lyme vaccines.
- IgM/IgG titers are not warranted. Experimentally infected dogs did not show signs of Lyme disease until 2-5 months, well after seroconversion (there is no acute stage when they are seronegative), so paired acute/convalescent titers are unnecessary.
- All Lyme-positive dogs should be screened for proteinuria by urinalysis, microalbuminuria testing, or urine protein/creatinine ratio. Lyme nephropathy cases may also have glycosuria and/or active sediment due to tubular damage.
- Radiographs of leg(s) involved (nonerosive arthritis)

- Arthrocentesis: nonseptic suppurative inflammation
- Abdominal ultrasound and chest radiographs to rule out neoplasia

ADVANCED OR CONFIRMATORY TESTING

- Serology: C6 Quant (IDEXX Laboratories). C6 antibody is detected 3-5 weeks post exposure, before clinical signs appear; paired titers are not necessary. C6 > 30 proves natural exposure (not cause) and is not an indication for treatment in nonclinical, nonproteinuric dogs. Magnitude of titer is not predictive of or correlated with illness.
- PCR or paired serology for other infectious diseases: RMSF (if acute presentation), anaplasmosis/ehrlichiosis, bartonellosis, babesiosis, leptospirosis.
- Renal biopsy: glomerulonephritis, tubular necrosis/regeneration, interstitial lymphoplasmacytic inflammation.

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are:

- Avoidance of treating patients that have positive titers alone (exposure) in the absence of compatible clinical abnormalities
- Resolution of lameness and fever if present
- Palliative/supportive care for complications of PLN

ACUTE GENERAL TREATMENT

- Doxycycline (10 mg/kg PO q 12-24 h)or amoxicillin (11 mg/kg PO q 8-12 h). Treatment for clinical cases is continued for 4 weeks to try to eliminate the carrier state. Treatment is not recommended for nonclinical, nonproteinuric carriers.

CHRONIC TREATMENT

- The length of time antibiotics are needed to clear the carrier state is unknown.
- Treatment for Lyme nephropathy often includes long-term combination doxycycline, angiotensin-converting enzyme inhibitor (e.g., enalapril, 0.5 mg/kg PO q 12-24 h), low-dose aspirin (0.5 mg/kg PO q 12 h), and omega-3 fatty acids. Immunosuppressive therapy protocols are being studied.
- Supportive care of renal disease may include antiemetics, phosphate binders, intravenous fluids/colloids, antihypertensives, and other agents
- Some dogs with Lyme arthritis do not improve with antibiotics alone. Corticosteroids are added for suspected immune-mediated polyarthritis (e.g., prednisone, 1 mg/kg PO q 12 h, tapering to 0.5 mg/kg PO q 48 h).

RECOMMENDED MONITORING

- Lyme nephropathy is uncommon even in seropositive retrievers, but it is recommended to continue screening (duration/frequency unknown) all Lyme-positive dogs for proteinuria whether treated or not.
- If treated, C6 Quant is recommended at 0 and 6 months; the new baseline is for comparison if signs recur. High pretreatment titers usually drop > 50%; lower titers may not. Qualitative C6 (SNAP-4Dx) often remains positive post treatment.
- For Lyme nephropathy: Monthly monitoring of hematocrit, serum creatinine, serum albumin, urine protein/creatinine ratio, and blood pressure measurement are decreased to every 3-6 months if clinically stable.

PROGNOSIS AND OUTCOME

- Prognosis is good for Lyme arthritis. Most dogs respond immediately without recurrence.
- Prognosis is guarded to poor for Lyme nephropathy, especially in hypoalbuminemic/dehydrated/azotemic cases; life expectancy may be days to weeks.

PEARLS & CONSIDERATIONS

COMMENTS

In humans, the *Borrelia* vaccine was removed from the market because of poor sales over concern about possible immune-mediated

sequelae in genetically predisposed individuals.

PREVENTION

- Tick prevention and control are paramount.
- Lyme disease vaccines are controversial because the most serious forms of Lyme disease in dogs have an immune-mediated pathogenesis.

CLIENT EDUCATION

Proper tick removal and tick control.

1ST EDITION AUTHOR: KHRISTEN J. CARLSON

Boric Acid Toxicosis

BASIC INFORMATION

DEFINITION

Toxicosis resulting from ingestion of inorganic compounds of boron used in ant or roach baits, flea products for dogs and cats, cleaning compounds, buffering agents, eye washes, and as an anticaking agent. While ingestions are common, toxicosis is uncommon because of the relatively large amount of product that needs to be ingested. However, clinically significant ingestions are characterized by vomiting, diarrhea, anorexia, lethargy, and (rarely) renal damage.

SYNONYMS

Borax, boric acid, orthoboric acid, sodium biborate, sodium borate, sodium perborate, sodium pyroborate, sodium tetraborate

EPIDEMIOLOGY

SPECIES, AGE, SEX

- All breeds of cats and dogs are susceptible.
- Cats may be exposed after walking through the agent when it is placed on small pieces of cardboard or in small cups in cupboards or closets, or when flea powders containing boric acid are used topically.

RISK FACTORS

Preexisting kidney disease may increase the risk of nephrotoxicosis from large ingestions.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of using a boric acid–containing product on the animal or in the house (for fleas or control of other insects)
- Vomiting
- Hypersalivation
- Anorexia
- Lethargy

PHYSICAL EXAM FINDINGS

- Findings tend to be nonspecific
- Common:
  - Hypersalivation
  - Lethargy
  - Vomiting, diarrhea
- Possible:
  - Oliguria/anuria
  - Anorexia
  - Ataxia (rare)
  - Seizures (rare)

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

- Some ant baits may contain less than 1% boric acid, whereas some roach products can contain 100% boric acid.
- Boric acid–containing formulations are available as powders, liquids, or gels.
- Borates have been used in pharmaceutical preparations (mouthwash, toothpastes, cosmetics), as toiletries, in cleaning compounds, and as insecticides.

Mechanism of Toxicosis:

- The exact mechanism is unknown. Boric acid is considered cytotoxic to all cells.
- Rapidly absorbed after oral ingestion through mucous membranes, as well as through abraded skin.
- Concentrated in the kidneys before excretion, excreted unchanged in the urine.
- Half-life in dogs is 12 hours, but total elimination may take up to 7 days.
- No death or serious systemic toxicosis reported in dogs when given 1.54-6.51 g/kg of borax or 1-3 g/kg of boric acid. Examples:
  - 20 ounces (570 g) of a 5.4% boric acid ant bait would have to be ingested by a 20-kg dog to reach a dose of 1.5 g/kg.
  - Similarly, 1.1 ounces (31 g) of a 99% boric acid agent would need to be ingested by a 20-kg dog to reach a dose of 1.5 g/kg.
  - In either case, systemic signs are not likely, except for possibly vomiting and diarrhea.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis rests on history and physical exam: suspected or witnessed exposure and presence of gastrointestinal disturbance signs (vomiting, diarrhea) that are typically self-limiting.

DIFFERENTIAL DIAGNOSIS

Toxicologic:

- Garbage toxicosis
- Dietary indiscretion
- Nephrotoxic agents (ethylene glycol, pharmaceuticals, lilies [cats], grapes and raisins [dogs])

Spontaneous Nontoxicologic:

- Infectious enteritis (parvoviral, coronaviral, bacterial, etc.)
- Foreign body

INITIAL DATABASE

- CBC: microcytic hypochromic anemia
- Serum biochemistry panel: azotemia, hyperchloremia, hypernatremia, hyperkalemia, and metabolic acidosis may be noted in severe cases; rarely, elevated liver enzymes.
- Urinalysis: in severe cases causing oliguria or anuria with tubular necrosis, albuminuria, hematuria, proteinuria, and epithelial casts (acute renal failure), or isosthenuria concurrently with azotemia (chronic kidney disease) may be noted

ADVANCED OR CONFIRMATORY TESTING

Boric acid may be detected in the urine, cerebrospinal fluid, blood, and plasma.

TREATMENT

TREATMENT OVERVIEW

Treatment is aimed at inducing emesis in large exposures and providing supportive care as needed, notably in uncommon instances of systemic effects. Most cases are self-limiting (signs resolve within a few hours).

ACUTE GENERAL TREATMENT

- Decontamination of patient:
  - Emesis (see p. 1364): induce vomiting in cases involving large ingestions. Activated charcoal not useful in binding boric acid.
  - Bathe the animal for dermal exposures, using diluted liquid dishwashing detergent.
- Supportive care:
  - Control excessive vomiting with metoclopramide at 0.022-0.044 mg/kg PO, SQ, or IM, barring gastrointestinal

obstruction
- Gastrointestinal protectants: sucralfate, 0.5-1 g q 8 h PO, and famotidine, 0.5 mg/kg PO, SQ, or IM q 12-24 h for 5-7 days
- IV fluid diuresis for 24-48 hours in cases involving large ingestions
- Treat renal failure as needed (see p. 31).
- Control seizures with diazepam, 0.5-2 mg/kg IV unless underlying cause is metabolic (e.g., hypoglycemia, hypocalcemia, hepatic encephalopathy)

CHRONIC TREATMENT

- Chronic problems not expected
- Renal injury is uncommon and when it occurs, generally responds to fluid therapy and supportive care.

POSSIBLE COMPLICATIONS

May exacerbate preexisting kidney disease

RECOMMENDED MONITORING

- Recheck renal parameters (blood urea nitrogen, creatinine, urinalysis) at 24 and 48 hours postexposure.
- If renal parameters are within normal limits at that time, further problems not expected.

PROGNOSIS AND OUTCOME

Excellent in animals with signs limited to vomiting/diarrhea after a low-dose exposure

PEARLS & CONSIDERATIONS

COMMENTS

- Activated charcoal adsorbs boric acid poorly (boron compounds do not adhere well to charcoal). A 30:1 ratio of activated charcoal to boric acid was needed to absorb 38% of boric acid in an in vitro study; 5 to 10 times the normal activated charcoal dose would be required to be effective (risk of severe hypernatremia), so activated charcoal is not recommended as a routine part of treatment of boric acid toxicosis.
- In general, boron compounds have a wide margin of safety, and in most cases of toxicity, only vomiting and diarrhea are noted.
- Ant baits containing 1%-5% boric acid are not expected to cause a serious problem in dogs or cats.
- Concentrated boric acid product greater than 50% should be avoided, but products containing less than 5.4% concentration are considered relatively safe.

PREVENTION

Avoid using highly concentrated boric acid products directly on animals or in the house (on the carpet especially if cats are around) where direct exposure to pets is likely.

Bordetellosis

BASIC INFORMATION

DEFINITION

An inclusive term for diseases caused by *Bordetella bronchiseptica*, a highly contagious aerobic gram-negative cocco-bacillus that is a primary respiratory pathogen for dogs and cats and can cause acute or chronic respiratory disease

SYNONYMS

Infectious tracheobronchitis, kennel cough, canine respiratory disease complex. *B. bronchiseptica* is considered a contributing agent in the acute canine respiratory disease syndrome known by these names.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs, cats, rabbits, pigs
- Young animals more susceptible to disease, especially severe disease, than adults

RISK FACTORS

Increased incidence in dogs and cats exposed to other animals with respiratory infection or housed with large numbers of other animals (shelters, boarding kennels, breeding facilities)

CONTAGION & ZOONOSIS

- *B. bronchiseptica* is highly contagious: animal-to-animal contact, aerosol, or fomites. Infected animals shed the organism in nasal and oropharyngeal secretions for 3 months or longer post infection. Infection can be transmitted between species. *B. bronchiseptica* is a rare cause of zoonotic disease: human infection can occur opportunistically (respiratory disease, pleuritis, meningitis, peritonitis) in infants or immunocompromised people.
- *B. bronchiseptica* can be isolated from the upper respiratory tract of healthy dogs and cats: up to 10% of healthy household dogs and 5%-11% of healthy household cats are *Bordetella* positive.

GEOGRAPHY AND SEASONALITY

Probable worldwide distribution, occurs year-round

ASSOCIATED CONDITIONS & DISORDERS

- Bordetellosis is often part of a disease complex that can include co-infections with canine parainfluenza, canine adenovirus-2, canine distemper, *Mycoplasma* spp., and/or *Streptococcus* spp. in dogs and feline rhinotracheitis (feline herpesvirus), feline calicivirus, and other pathogens in cats.
- Bordetellosis is generally limited to the upper respiratory tract; in some cases, pneumonia can occur.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Typically includes exposure to multiple non-housemate animals (kennel/animal shelter, dog show) several days before onset of coughing
- Chief complaint in dogs is usually acute-onset nonproductive hacking cough, including fits of coughing that result in terminal retch.
- Chief complaint in cats is sneezing and oculonasal discharge + cough.
- Severe or complicated cases may be dyspneic, anorectic.

PHYSICAL EXAM FINDINGS

- Spontaneous or inducible cough
- ± Conjunctivitis
- ± Nasal or ocular discharge
- ± Submandibular lymphadenomegaly
- ± Mild to moderate fever, increased lung sounds (pneumonia) in severe cases

ETIOLOGY AND PATHOPHYSIOLOGY

- The organism colonizes respiratory epithelium of the nasal cavity and trachea and can establish persistent (often subclinical) infections.
- Infection occurs via contact of the organism with the upper airway and attachment/adherence to the respiratory epithelium by direct binding to cilia, inducing stasis of the cilia and reducing mucociliary escalator clearance of bacteria and other particulate matter from the airways.
- Airway colonization induces an inflammatory response and increased mucus production.
- *Bordetella* spp. produce multiple factors, allowing *Bordetella* to persist chronically and predispose the host to secondary infections.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

Bordetellosis often is a suspected diagnosis that goes unconfirmed. Since many infections are mild and self-resolving, the urgency of establishing a diagnosis of bordetellosis specifically is low, and treatment is often initiated based only on clinical signs of upper respiratory infection.

DIFFERENTIAL DIAGNOSIS

Dogs:

- Other agents of infectious tracheobronchitis: canine parainfluenza, canine influenza, canine adenovirus, canine herpesvirus, canine distemper, *Mycoplasma* spp. infection, *Streptococcus* spp. infection
- Chronic bronchitis
- Collapsing trachea
- Traumatic tracheitis
- Airway foreign body
- Mechanical or chemical airway irritant
- Other causes of pneumonia: fungal infection, aspiration

Cats:

- Other upper respiratory infections/agents: feline rhinotracheitis (feline herpesvirus 1), feline calicivirus infection, *Chlamydophila felis* infection, other pathogenic causes of pneumonia

INITIAL DATABASE

- CBC: often unremarkable; neutrophilia with left shift or toxic neutrophil changes may be seen with pneumonia.
- Thoracic radiographs: usually unremarkable; pneumonia in severe/complicated cases

ADVANCED OR CONFIRMATORY TESTING

- Bacterial culture and sensitivity: many healthy animals are culture positive.
  - Nasal or oropharyngeal swabs for bacterial culture: should be plated on selective medium to decrease overgrowth by other respiratory flora.
  - Transtracheal wash or bronchoalveolar lavage if pneumonia or lower airway disease suspected
- Serologic testing not helpful; many healthy animals have positive titers
- PCR assays available that differentiate *Bordetella* spp. including *B. bronchiseptica;* no routine clinical application

TREATMENT 

TREATMENT OVERVIEW

- Treatment goals are initiation of appropriate antibiotic therapy and supportive care.
- Cough suppressants are often indicated to break the cough cycle but are contraindicated in cases with pneumonia or productive cough.

ACUTE GENERAL TREATMENT

- Antimicrobials:
  - Should be based on culture/sensitivity, especially since *Bordetella* spp. show high level of antimicrobial resistance
  - Options for empirical treatment pending culture results:
    - Doxycycline (5 mg/kg PO q 12 h) is the antimicrobial of choice (most *Bordetella* isolates are susceptible). Treat adults for 14-21 days, young (growing) animals for 7-9 days (reduces risk of discoloration of teeth); *or*
    - Amoxicillin-clavulanate (12.5-25 mg/kg PO q 12 h); *or*
    - Trimethoprim-sulfonamide (15-30 mg/kg PO q 12 h); *or*
    - In severe cases, other options include gentamicin, enrofloxacin, and cefazolin.
    - Antimicrobial therapy helps alleviate clinical signs but does not alter shedding in recovered carriers.
- Antitussives:
  - For suppression of dry, nonproductive cough in milder cases (animal is otherwise well); titrate dose to reduce cough without causing sedation
    - Butorphanol 0.05-1 mg/kg PO q 8-12 h; *or*
    - Hydrocodone 0.22 mg/kg PO q 8-12 h
  - Contraindicated with pneumonia
- Bronchodilators:
  - May be indicated in patients with pneumonia
- Nebulization therapy:
  - Nebulization with sterile saline may help hydrate airway secretions and facilitate clearance, but patient must have adequate systemic hydration as a prerequisite.
  - Nebulization with antibiotic solutions (gentamicin, kanamycin, or polymyxin B) has been suggested for refractory cases to reduce *Bordetella* populations in the trachea and bronchi, but unpredictable dose delivery to airways.
- Glucocorticoids:
  - Antiinflammatory doses administered short term may reduce cough.
  - E.g., prednisolone 0.25-0.5 mg/kg PO q 12-24 h for 3-5 days
  - Does not shorten course of disease
  - May exacerbate disease in immunocompromised animals
  - Do not use in cases with severe/complicated disease
- Adequate systemic hydration very important to facilitate clearance of respiratory secretions

DRUG INTERACTIONS

Reduce dose of trimethoprim-sulfa and avoid gentamicin in patients with renal disease. Tetracyclines may cause discoloration of dental enamel in young animals.

POSSIBLE COMPLICATIONS

Pneumonia may develop secondary to *Bordetella-induced* impairment of respiratory defenses. Sulfonamides (trimethoprim-sulfonamide) may induce keratoconjunctivitis sicca, hypersensitivity reactions, crystalluria, renal tubule obstruction, polyarthritis, and GI signs.

RECOMMENDED MONITORING

- Serial thoracic radiographs, CBC, and arterial blood gas to monitor patients with pneumonia
- Monitor tear production before and during treatment in patients receiving sulfonamides.
- Monitor BUN, creatinine, and urinalysis in patients receiving gentamicin.

PROGNOSIS AND OUTCOME

- Disease is usually self-limiting; uncomplicated cases resolve within approximately 2 weeks.
- Severe (potentially fatal) pneumonia may occur in young or debilitated animals.

PEARLS & CONSIDERATIONS

COMMENTS

- Shedding of organisms may continue for 3 months or more after resolution of clinical signs. Transmission of infection to other animals and immunocompromised people may continue during that time; suitable precautions (avoidance of direct or indirect contact) should be taken.
- *B. bronchiseptica* is the evolutionary progenitor of *B. pertussis*, a human-specific pathogen that is the causative agent of whooping cough.

TECHNICIAN TIP

Caution is warranted when preparing a vaccine: erroneous SQ injection of intranasal vaccine in dogs has caused severe acute hepatic injury.

PREVENTION

- Limit transmission by quarantine of new animals and isolation of infected animals.
- Decrease stress, provide adequate hygiene and care.
- Disinfect cages and other surfaces (1:32 dilute bleach solution).
- Vaccination:
    - Parenteral and intranasal (IN) vaccinations are available for dogs, intranasal for cats.
    - Effective in reducing infection rate and severity of clinical signs
    - IN: rapid onset of immunity within 72 hours post vaccination; duration 1 year
    - Vaccinate at least 5 days prior to anticipated exposure (boarding) if possible.
    - Some IN vaccines may be used as early as 2 weeks of age.
    - Intranasal vaccines may induce cough and/or nasal discharge.
    - Animals receiving live vaccines will shed bacteria that may cause infection ± disease in susceptible animals and humans.
- Natural immunity lasts at least 6 months post infection.

Blue-Green Algae Toxicosis

BASIC INFORMATION

DEFINITION

Syndrome of sudden-onset neurologic signs or acute liver failure in dogs caused by ingestion of blue-green algae (BGA) toxins

SYNONYM

Cyanobacteria toxicosis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: all breeds, ages, and both sexes susceptible
- Cats: none reported

RISK FACTORS

BGA blooms are favored by stagnant water, warm water temperatures, ample sunlight, and high nutrients from fertilizer, animal waste, and sewage runoff.

GEOGRAPHY AND SEASONALITY

Blooms occur mostly in summer or fall.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute neurotoxic syndrome
- Subacute hepatotoxic syndrome

HISTORY, CHIEF COMPLAINT

- History of swimming in or drinking water from a pond, lake, or river
- Vomiting, diarrhea, weakness, and collapse (>6 hr after exposure): hepatotoxic syndrome
- Salivation, vomiting, diarrhea, dyspnea, tremors, muscle fasciculations, ataxia, weakness, seizures, and death (>15 min after exposure): neurotoxic syndrome

PHYSICAL EXAM FINDINGS

- Presence of algae on the muzzle or on the fur elsewhere on the body is common. Bluish-green and slimy, or may be dried if later presentation.
- Hepatotoxic syndrome: see History, Chief Complaint above; plus pale mucous membranes, poor capillary refill time, tachycardia or bradycardia, signs of abdominal pain, rapid weak pulse, hypothermia, and shock
- Neurotoxic syndrome: see History, Chief Complaint above

ETIOLOGY AND PATHOPHYSIOLOGY

- BGA are microscopic organisms that form colonies visible to the naked eye, rely on photosynthesis for energy, and have a cell wall similar to gram-negative bacteria.
- Accumulations of large amounts of BGA in lakes, ponds, or rivers are known as *waterblooms*. BGA blooms exist worldwide and are light to dark green or sometimes reddish-brown. Wind propels toxic algae to the shoreline, where animals are exposed to the organism by ingestion when they drink BGA-contaminated water.
- Common toxin-producing genera of fresh and brackish water BGA include *Microcystis*, *Anabaena*, *Oscillatoria*, *Aphanizomenon*, *Nodularia*, and *Nostoc* spp.

- Acute hepatotoxic syndrome:
  - Most commonly described poisoning by BGA; caused by low-molecular-weight cyclic heptapeptides and pentapeptides known as *microcystins* and *nodularins*. Microcystin-LR (MCLR) is the most toxic and the most frequently encountered of approximately 50 similar peptides.
  - After ingestion, BGA toxins are released from the cells and preferentially absorbed from the ileum.
  - Once inside hepatocytes, toxins inhibit protein phosphatases (PP) types 1 and 2A (PP1 and 2A), causing hyperphosphorylation of cytosolic and cytoskeletal proteins, leading to cytoskeletal disruption, damage, and necrosis.
  - Death is possibly due to massive intrahepatic hemorrhage, hypovolemia, and liver failure.
- Peracute neurotoxic syndrome; responsible toxins are:
  - Anatoxin-a: an alkaloid and potent postsynaptic depolarizing neuromuscular blocking agent that affects nicotinic and muscarinic acetylcholine receptors
  - Anatoxin-a(s): inhibits peripheral (but not central) cholinesterase irreversibly and is the only known naturally occurring organophosphorus cholinesterase inhibitor (similar to organophosphate pesticides)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A tentative diagnosis is based on history of exposure (drinking or swimming in a pond) and rapid onset of clinical signs (vomiting, shock, liver failure, or neurologic signs). Given the potential speed and intensity of progression, treatment may be initiated on this basis. Toxicosis can be confirmed by purification and identification of toxins, but turnaround time means these methods are not clinically useful to an affected patient (e.g., rather for preventative purposes or medicolegal reasons).

DIFFERENTIAL DIAGNOSIS

- Differentiate from other hepatotoxic agents: amanita mushroom, sago palm, acetaminophen
- Primary hepatic diseases (see p. 503)

INITIAL DATABASE

- Hepatotoxic syndrome:
  - CBC: leukocytosis and thrombocytopenia
  - Serum biochemistry panel: increased levels of all liver enzymes, glucose, and possibly creatine phosphokinase. Hypoglycemia is possible after hyperglycemia.
  - Serum bile acids: increase commonly occurs early.
  - Coagulation profile: whole blood clotting time may be normal; prothrombin time and activated thromboplastin times increase twofold to fourfold.
- Neurotoxic syndrome:
  - Owing to rapid effect of the toxins, no significant serum biochemical changes are expected.

ADVANCED OR CONFIRMATORY TESTING

- Postmortem (hepatotoxicosis): rounding of hepatocytes, disruption of hepatic cords, loss of sinusoidal integrity, intrahepatic hemorrhage, and centrilobular necrosis
- Microscopic identification of toxigenic algae. Obtain large specimen (1-2 L) of the algae by straining the cells out of the water with cheesecloth. Specimens can be sent for identification, purification, and quantification of algal toxins, for mouse bioassay, or for ELISA to Dr. Wayne Carmichael's laboratories. Call before shipping specimens. Information available at: http://www.wright.edu/biology/faculty/carmichael/labhome/labhome.htm.

TREATMENT

TREATMENT OVERVIEW

Early decontamination (induce emesis and give charcoal) of patients not showing clinical signs. For overtly ill patients, treatment of muscarinic and central nervous system (CNS) signs, prevention/treatment of liver damage, and supportive care are cornerstones of therapy.

ACUTE GENERAL TREATMENT

- Decontamination of patient:

- Emesis: only in animals not showing any clinical signs (see p. 1364)
- Activated charcoal 2-4 g/kg PO
- Cholestyramine (200-300 mg/kg PO) may be more effective than charcoal (more expensive and must be obtained from a pharmacy).
- The noncompetitive bile-acid transport inhibitors, rifampicin, and bile salts such as cholate and deoxycholate can inhibit uptake of microcystins. Their utility, however, in clinical algal toxicoses has yet to be determined.

- Control muscarinic and neurologic signs:
  - Atropine sulfate for muscarinic signs (0.04-0.1 mg/kg IV PRN)
  - Diazepam for seizures 0.5-2 mg/kg IV PRN; other antiseizure medications (e.g., barbiturates) if diazepam is ineffective
- Supportive care:
  - Control severe vomiting with metoclopramide (0.1-0.4 mg/kg PO, SQ, or IM q 6 h), only if intestinal obstruction has been ruled out (if present, usually unrelated to BGA) or use maropitant 1 mg/kg SQ q 24 h or 2 mg/kg PO q 24 h for 5 days.
  - Treat signs of acute hepatic failure (see p. 503, and p. 501). Typical therapeutics may include:
    - Lactulose
    - *S*–adenosyl methionine (SAMe)
    - Dietary management
    - Vitamin K1
    - Plasma and/or whole blood transfusions as needed
    - IV fluids (possibly including 5% dextrose)
    - Broad-spectrum antibiotics for secondary infection

POSSIBLE COMPLICATIONS

Permanent hepatic insufficiency

RECOMMENDED MONITORING

- Serum chemistry profile, especially liver-specific enzymes (ALT, AST, GGT, alkaline phosphatase)
- Serum bile acids
- CBC
- Hematocrit
- Body temperature
- Blood glucose

PROGNOSIS AND OUTCOME

Poor prognosis with systemic signs of acute hepatic damage or severe neurologic dysfunction

PEARLS & CONSIDERATIONS

COMMENTS

- In dogs, BGA poisoning is a sporadic but recurrent cause of acute illness and death.
- Lethal doses of purified MCLR: rat, 160 mg/kg IP; mouse, 100 mg/kg

IP; LD50 of purified anatoxin-a in mouse = 200 mg/kg IP and anatoxin-a(s) = 30 mg/kg IP.

Blindness

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Loss of vision

SYNONYMS

Amaurosis, central blindness: loss of vision due to a lesion in the central nervous system

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats; any age and sex may be affected, depending on etiology.

GENETICS & BREED PREDISPOSITION

Several, depending on causative disorder (see p. 448, p. 644, p. 985)

RISK FACTORS

- Age: older animals may be predisposed to diseases associated with blindness, including neoplasia (intracranial, intraocular, optic chiasmal), cataracts, and retinal detachment (see p. 985)
- Outdoor access may predispose to infectious diseases associated with blindness (see p. 141)

CLINICAL PRESENTATION

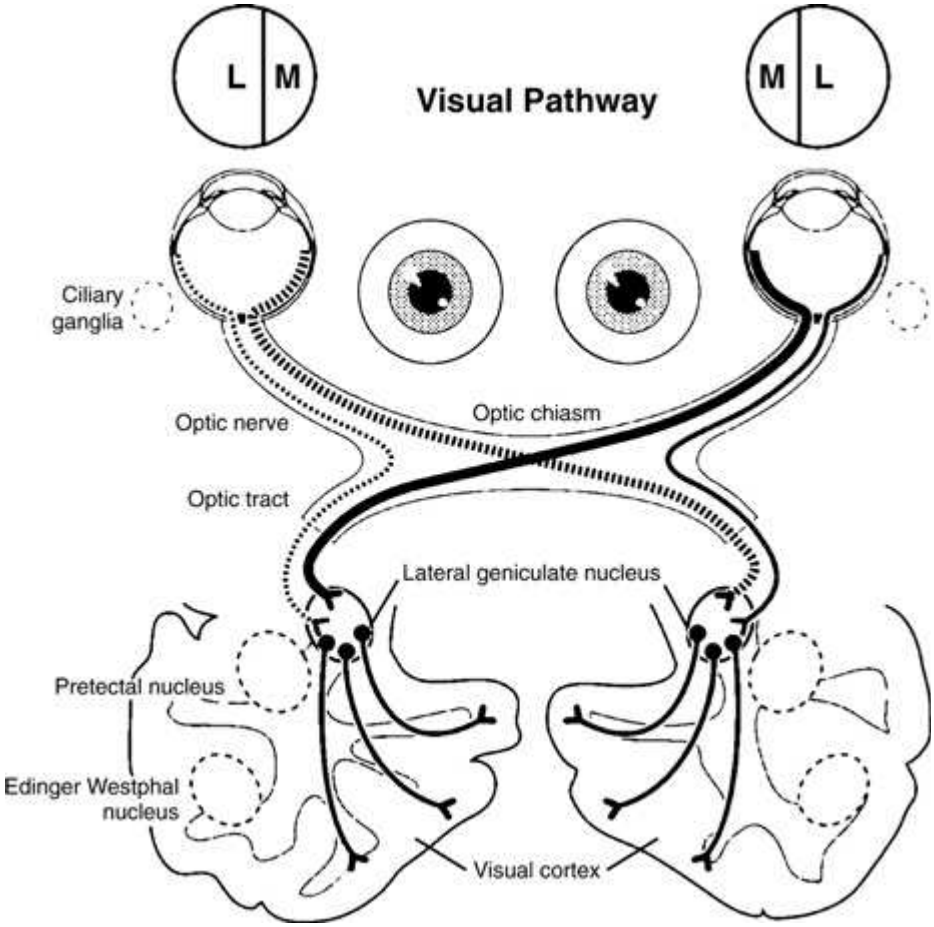
DISEASE FORMS/SUBTYPES

- Unilateral or bilateral
- Sudden or progressive
- "Red eye" blindness: associated with visible conjunctival redness on physical examination:
  - Glaucoma (see p. 448), severe uveitis (see p. 1151), cataracts (see p. 181), lens luxation (see p. 644), complex corneal ulceration (see p. 250), orbital disease (see p. 790)
- Non-red, noninflamed eye ("quiet eye") blindness: no conjunctival or scleral redness is observed in the blind eye(s):
  - Prechiasmal/chiasmal blindness
    - Lesion affecting retina, optic nerve, optic chiasm
    - Associated with dilated pupils and pupillary light reflex (PLR) abnormalities
  - Postchiasmal/cortical blindness
    - Lesion affecting optic tracts, lateral geniculate nucleus (LGN), optic radiations, or visual cortex of the cerebrum
    - Pupil size and PLRs usually normal unless optic tracts affected along portions common to PLR and vision pathways (see figure) and/or unrelated, concurrent iris condition (see p. 944)
    - The PLR fibers split from the vision pathway just before the LGN.

HISTORY, CHIEF COMPLAINT

- Variable depending on the underlying cause, whether the blindness is unilateral or bilateral, and sudden or progressive in onset
- In cases of sudden blindness, all or some of the following may be reported:
  - Disorientation (see p. 314)
  - Suddenly starts bumping into objects within familiar or unfamiliar environments
  - Inability to find food bowl, toys, and the like
  - Lethargy
  - Anxiety
- In cases of progressive blindness, all or some of the following may be reported:
  - Occasionally bumping into objects in own environment

- Frequently bumping into objects in unfamiliar or suddenly altered environment
- Vision deficits in dim light and/or darkness (loss of night vision/nyctalopia) (e.g., progressive retinal degeneration/atrophy; see p. 983)
- Patients may be lethargic and/or anxious but generally adjust and compensate better with progressive vision loss, especially if slowly progressive.



BLINDNESS Anatomy of visual pathway from the eye to the visual cortex of the cerebrum. Circles adjacent to "Visual Pathway" title indicate visual fields. *M*, Medial; *L*, lateral.

PHYSICAL EXAM FINDINGS

- See also: Ophthalmic Examination p. 1313, ; Neurologic Examination,p. 1311
- "Red eye" blindness (see p. 448 ,p. 1151 , and p. 790)
- Non-red, quiet eye blindness
  - Prechiasmal/chiasmal blindness:
    - Menace response (blink in response to hand motion toward the eye) absent
    - Dazzle reflex (blink in response to a bright light) absent
    - Pupil(s) dilated or fixed and dilated
    - PLR(s) decreased (i.e., sluggish and incomplete) or absent
    - ± Anisocoria (asymmetry between the size of the pupils), especially seen in unilateral lesions where only the affected pupil is more dilated)
  - Postchiasmal/cortical blindness:
    - Menace response variable depending on localization and severity of lesion
    - Menace response absent or decreased in contralateral eye if a unilateral lesion present
      - Small percentage of contralateral nasal/medial visual field may be preserved, owing to undecussated (those not crossed over) lateral optic nerve fibers.
    - Menace response absent in both eyes in bilateral/diffuse optic tract, lateral geniculate nucleus, optic radiation, or visual cortical lesions
    - Pupil size and PLRs normal unless certain portions of optic tract(s) affected that are common to both the PLR and visual pathways and/or unrelated, concurrent iris condition (see p. 944)
    - Dazzle reflex(es) normal (like the PLR, the dazzle reflex does not involve the visual cortex.)

ETIOLOGY AND PATHOPHYSIOLOGY

- "Red eye" blindness: the lesion is ocular or intraocular:
  - Opacity of the ocular media (e.g., cornea, aqueous humor, lens, vitreous) in cases of corneal edema/ulceration /pigmentation, uveitis, cataract and vitreal debris or hemorrhage
  - Retinal degeneration with or without detachment and optic nerve atrophy in glaucoma (see p. 448)
  - Retinal detachment in cases of chorioretinitis (see p. 985)
- Non-red, quiet eye blindness:
  - Prechiasmal/chiasmal: the lesion lies along the retinaoptic nerveoptic chiasm pathway
    - Retinal diseases (see p. 983 and p. 985)
    - Optic nerve lesions (e.g., congenital optic nerve hypoplasia, inflammation [see p. 784]), neoplasia (e.g., meningioma), or atrophy (e.g., glaucoma, trauma)
    - Optic chiasmal lesions (e.g., neoplasia, abscess)
  - Postchiasmal/cortical: the lesion affects the optic tract and/or radiations to and including the visual (occipital) cerebral cortex
    - Encephalitis (extension to bilateral optic tracts via cerebrospinal fluid)
    - Cerebral edema
    - Cerebral infectious, inflammatory, neoplastic or traumatic disease

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Lesion localization is the cornerstone of accurate diagnosis and treatment of causes of blindness. A complete cranial nerve and general neurologic examination () are an essential first diagnostic step. If the cause of blindness is not readily apparent, prompt referral of affected patients to a veterinary ophthalmologist is advised. Early diagnosis is key to determining whether or not return of vision with therapy is possible.

DIFFERENTIAL DIAGNOSIS

- "Red eye" blindness:
  - May be confused with disorientation due to causes other than blindness (see p. 314) and concurrent non–vision-threatening cause(s) of "red eye," including: conjunctivitis (see p. 237 and p. 239), episcleritis (see p. 356), and corneal disease (see p. 250)
- Non-red, noninflamed eye ("quiet eye") blindness:
  - May be confused with disorientation due to causes other than blindness
- Blindness may also be characterized as unilateral or bilateral. Note: unilateral processes listed more commonly affect only one eye but can affect both eyes in some cases; disorders that affect one or both eyes with equal frequency are listed in both categories.
  - Unilateral: corneal trauma, complex corneal ulceration, lens luxation, cataract, severe uveitis, retinal detachment, subretinal hemorrhage, glaucoma, cerebral lesions (optic radiation/visual occipital cortex)
  - Bilateral: cataracts, retinal detachment, subretinal hemorrhage, severe uveitis, glaucoma, optic neuritis, optic chiasm lesions, sudden ac quired retinal degeneration, progressive retinal degeneration/atrophy, diffuse cerebral/visual cortex disease

INITIAL DATABASE

- In order to accurately diagnose and treat causes of blindness, it is imperative to first localize the lesion causing the blindness. A thorough cranial nerve and general neurologic examination must be performed. Additional diagnostic tests may be indicated based on the site of the lesion.
- Cranial nerve (CN) examination:
  - Menace response (CN II & VII), assessment of pupil symmetry and size and direct and consensual PLRs (CN II & sympathetic and parasympathetic innervation), dazzle reflex (blinking in response to bright light; CN II & VII), palpebral (CN V & VII) and corneal (CN V & VII) reflexes, assessment of physiologic nystagmus (i.e., vestibuloocular reflex or "Doll's eye;" CN III, IV, VI & VIII), evaluation of facial sensation (CN V) and motor function (CN VII)
    - Normal PLRs: lesion usually postchiasmal/cortical (with a "non-red, noninflamed eye" ["quiet eye"] blindness) or due to opacity of ocular media
    - Sluggish, incomplete/absent PLR and dilated pupil: lesion involves retina, optic nerve, optic chiasm (causes bilateral blindness), or optic tract; or a separate, primary lesion of the pupil is present
- General neurologic examination (see p. 1311)
- Complete ophthalmic examination including:
  - Intraocular pressure assessment

- Examination of anterior segment
  - Evaluate for opacity of the cornea, aqueous humor, lens, or vitreous
- Posterior segment/fundic examination after pharmacologic pupil dilation (1% tropicamide)
  - Pharmacologic pupil dilation is contraindicated with glaucoma
  - Evaluate optic nerve (size, shape, color; see p. 448and p. 784)
  - Evaluate tapetum (dorsal reflective structure) for brightness and/or color changes
    - Appears hyperreflective/bright with retinal degeneration and/or certain forms of retinal detachment
    - Appears hyporeflective/dull grey to pigmented with subretinal inflammation and/or certain forms of retinal detachment
  - Evaluate nontapetal fundus (located ventrally and typically pigmented) for whitish or grey discoloration (e.g., edema, inflammatory exudate or depigmentation from active or past inflammation or retinal detachment) or hemorrhages
  - Evaluate vasculature of retina (should see small arteries and larger veins coming from the optic disk and coursing peripherally), and look for changes in vessel direction to indicate detachment or attenuation (thinning) to indicate degeneration.
- CBC, serum chemistry profile, urinalysis to assess systemic status
- +/− Blood pressure (see p. 985 , p. 1068, and p. 1209) if retinal hemorrhage and/or detachment is/are noted

ADVANCED OR CONFIRMATORY TESTING

- Thoracic radiographs (screen for neoplasia or systemic infectious disease if intraocular mass or uveitis, chorioretinitis are noted and/or if optic neuritis is suspected)
- Serologic titers for infectious diseases unique to geographic area:
  - Rickettsial diseases (particularly if intraocular hemorrhage is noted)
  - Blastomycosis, cryptococcosis, histoplasmosis, coccidioidomycosis (particularly if chorioretinal lesions with uveitis and/or optic neuritis are detected)
  - Lyme disease (if history of tick exposure + uveitis)
  - Bartonellosis (if history of flea exposure + uveitis)
  - Toxoplasmosis (if history of rodent exposure + chorioretinal lesions)
- Aspiration of enlarged lymph nodes for cytologic evaluation
- Ocular ultrasonography if opacity of ocular media precludes fundic examination
- Histopathologic study in cases when eye is blind and painful and enucleation is advised
- Referral is advisable for all cases of blindness of undetermined cause for additional workup, including one or more of the following:
  - Electroretinography to assess retinal function
  - Visual-evoked potentials
  - Cerebrospinal fluid tap
  - MRI or CT
  - Vitreous centesis with cytologic study, culture, titers

TREATMENT

TREATMENT OVERVIEW

- Treatment is directed at addressing any underlying cause of blindness such as hypertensive retinopathy, uveitis, cataracts, and so forth
- In general, administration of empirical therapy is not recommended until a tentative or final diagnosis has been reached.
  - Administration of systemic corticosteroids prematurely may preclude diagnosis of neoplasia and some inflammatory disorders and may exacerbate systemic infectious diseases.

ACUTE GENERAL TREATMENT

Depends on underlying etiology

CHRONIC TREATMENT

- Manage any underlying conditions such as chronic renal failure, systemic hypertension, systemic infectious disease.
- Systemic mycoses and immune-mediated disorders typically require long-term therapy.
- Treat primary cause of blindness when possible (e.g., refer for surgery of mature cataracts).

RECOMMENDED MONITORING

- Monitor for return of vision, PLR, dazzle reflex after commencing therapy.
- Serial fundic examinations

PROGNOSIS AND OUTCOME

- Variable depending on underlying cause
- Restoration of vision after acute vision loss may be possible after rapid diagnosis of underlying condition and intensive appropriate therapy.
- In many cases, however, blindness is irreversible, and long-term management aims to provide comfort if pain is likely (e.g., glaucoma).

PEARLS & CONSIDERATIONS

- Assessment of the direct and consensual PLRs and dazzle reflexes is imperative in evaluation of blindness.
    - Absence of the PLR and/or dazzle reflex is a poor prognostic indicator, because minimal retinal function is required to retain these reflexes.
- The PLR and dazzle reflexes are subcortical pathways (do not involve the cerebral cortex) and therefore are normal with blindness caused by optic radiation and cortical lesions.
- A PLR is dependent only on *quantity* of light; vision is dependent on *quality* of light; therefore, the PLR should remain intact despite opacity of the ocular media (such as nuclear sclerosis) if there is no concurrent retinal or optic nerve damage.

AUTHOR: ANNE J. GEMENSKY-METZLER

EDITOR: CHERYL L. CULLEN

Blastomycosis

BASIC INFORMATION

DEFINITION

Systemic mycotic infection affecting many mammalian species. Animals usually have lung, skin, eye, and bone lesions.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Occurs most often in people and dogs. Has been reported in domestic cats, lions, tigers, sea lions, wolves, ferrets, and a polar bear.
- Usually seen in 1- to 5-year-old large-breed male dogs

GENETICS & BREED PREDISPOSITION

Doberman pinschers may be at increased risk.

RISK FACTORS

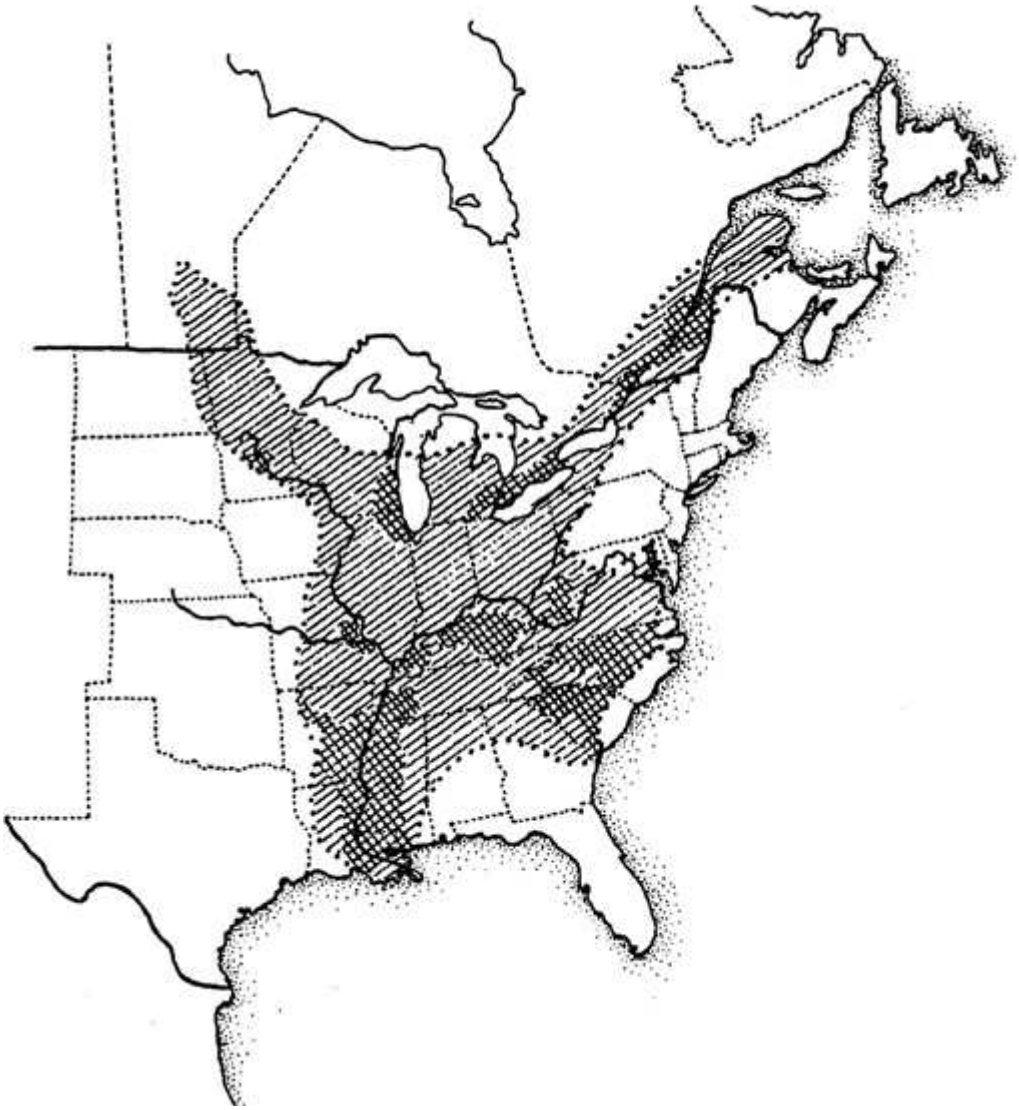
- Outdoor, roaming dogs in endemic areas living near a waterway are at increased risk.
- Exposure to sandy, acidic soil disrupted by construction involving earthmoving or excavation

CONTAGION & ZOONOSIS

- Bites, needlesticks while doing aspirates, and cuts during necropsies of infected dogs have caused infection in people.
- Organisms can be transmitted when cultured (aerosol) if plates are opened outside a hood.
- Direct airborne animal-human or human-animal transmission does not occur, because the yeast phase in the infected patient is too large to be transmitted by aerosol.
- Dogs and people may become infected from the same environmental source, but illness usually occurs first in the dog. The dog can serve as a sentinel for human disease.

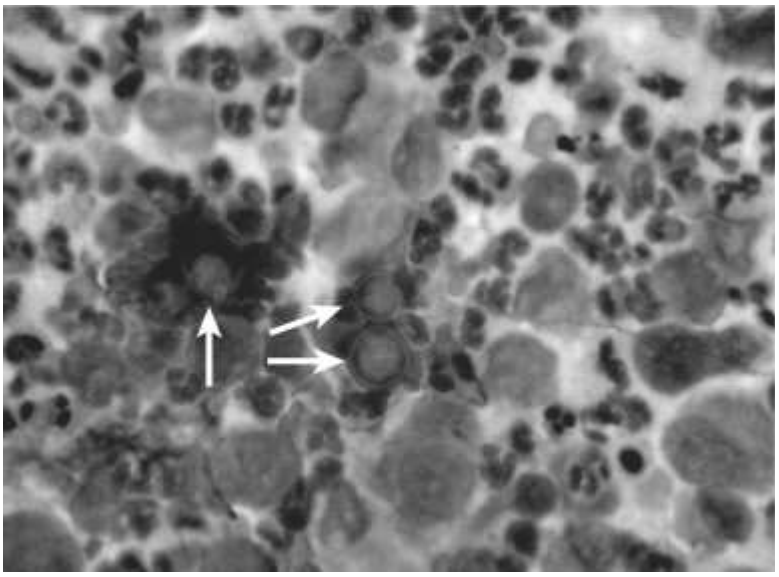
GEOGRAPHY AND SEASONALITY

- *Blastomyces dermatitidis* is present in North America, Africa, and Central America. Endemic areas include the Mississippi, Missouri, and Ohio River valleys; mid-Atlantic states; and the Canadian provinces of Alberta, Manitoba, Ontario, and Quebec.
- No seasonal distribution in the southeastern United States
- May be seasonally distributed in the U.S. Midwest, with more cases seen during late spring through late fall in Wisconsin
- The specific location of the fungus in soil is unknown; the fungal colonies are not grossly visible and are difficult to isolate from the environment.
- A "microfocus" model for the ecology of *B. dermatitidis* suggests that environmental pockets of fungal growth occur when a suitable combination of soil type and moisture is present. Rain, physical disruption of soil, or both, may promote release of spores.
- Proximity of the face to soil increases likelihood of inhalation/infection.



BLASTOMYCOSIS Geographic area in which blastomycosis is endemic. Areas of highest prevalence are cross-hatched.

(From Rippon JW: Medical mycology, ed 3. Philadelphia, 1988, Saunders, pp 474–505. Reprinted with permission.)



BLASTOMYCOSIS Cytologic evaluation of a fine-needle aspiration from a patient with blastomycosis. The cytologic diagnosis is

made based on the thick-walled, basophilic, spherical *B. dermatitidis (arrows)*. The intense inflammatory infiltrate surrounding the yeasts is typical.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Cutaneous, pulmonary, ocular, and osseous forms.

HISTORY, CHIEF COMPLAINT

Any combination of anorexia, weight loss, cough, dyspnea, exercise intolerance, ocular changes, lameness, skin lesions, and neurologic signs is possible.

PHYSICAL EXAM FINDINGS

- Fever, lethargy, emaciation, lymphadenomegaly
- Pulmonary involvement:
  - Harsh, dry lung sounds; cough; dyspnea at rest
- Ocular changes: signs of uveitis (see p. 1151), endophthalmitis, corneal edema, glaucoma
- Skin lesions (nasal planum, face, nail beds): subcutaneous abscesses, ulcerated draining lesions, or granulomatous proliferative lesions
- Bone involvement: lameness due to fungal osteomyelitis, toe involvement

ETIOLOGY AND PATHOPHYSIOLOGY

- *Blastomyces dermatitidis* is a dimorphic fungus that exists in the mycelial form in the soil and as a yeast in the tissues.
  - The mycelial form grows in soil, especially in manure-enriched soil, and produces infective spores which are released into the air. Soil disruption exposes organisms from deep within the soil.
  - The yeast phase grows at body temperature and is too large for aerosol transmission/contagion
- The route of infection is by inhalation of mycelial spores that enter the terminal airways from the environment.
- At body temperature, the spores become yeasts and establish an infection in the lungs which disseminates throughout the body via blood and lymphatics.
- Organisms cause a pyogranulomatous inflammation with a predilection for the skin, eyes, bones, lymph nodes, subcutaneous tissues, mouth, nares, brain, mammary tissues, prostate and testes.
- Cats are less commonly infected but develop a similar spectrum of lesions as dogs, and may also have pharyngeal lesions.
- Direct inoculation into a wound from soil is uncommon.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Characteristic lesions on chest films of a patient having been in an endemic area alert the clinician to the possibility of fungal infection. Identification of organisms by cytology, culture, or histopathology is best. A urine antigen test for blastomycosis is more sensitive than serologic testing.

DIFFERENTIAL DIAGNOSIS

- Pulmonary form: metastatic tumors, especially hemangiosarcomas; bacterial or viral pneumonia.
- Bone form: bacterial osteomyelitis, primary or metastatic bone tumors
- Cutaneous form: bacterial, fungal, parasitic, autoimmune dermatitis
- Other systemic mycoses

INITIAL DATABASE

- CBC:
  - Mild normocytic normochromic anemia
  - Moderate leukocytosis (17,000 to 30,000 white blood cell/µL), left shift, lymphopenia
- Serum biochemistry panel:
  - Hyperglobulinemia
  - Hypoalbuminemia
  - Hypercalcemia (occasionally)

- Thoracic radiographs:
  - Diffuse, nodular interstitial and bronchointerstitial lung patterns common
  - Solitary to multiple nodules may be seen
  - Tracheobronchial lymphadenomegaly
  - Less commonly: pleural effusion, pneumomediastinum
- Radiographs of bones: osteolytic or periosteal proliferation with soft-tissues welling

ADVANCED OR CONFIRMATORY TESTING

- Identification of the organism in more than half the cases by cytologic examination of lymph node aspirates, draining exudates, skin impression smears, or vitreous aspirates
  - A thick-walled, broad-based budding yeast is characteristic of *Blastomyces* (see figure).
- Lung aspirates (see p. 1275) often identify the organism but pneumothorax may occur. Tracheal wash (see p. 1350) is less sensitive than a lung aspirate.
- Urine *Blastomyces* antigen test has >90% sensitivity and is the preferred approach when organisms are not found. The *Blastomyces* urine antigen test is done by Mira Vista Labs in Indianapolis, IN (http://www.miravistalabs.com/services.aspx?o=veterinary).
- Agar-gel immunodiffusion test: a positive test result is very specific, but the test is not sensitive early in the disease process.

TREATMENT

TREATMENT OVERVIEW

Itraconazole is the treatment of choice because of efficacy, low toxicity, and ease of treatment. Dogs with neurologic disease need to be treated with amphotericin B. Corticosteroids may be indicated in dogs with dyspnea.

ACUTE AND CHRONIC TREATMENT

- General supportive care to include supplemental oxygen to dyspneic patients. Dogs with dyspnea at rest or dogs that become dyspneic after starting antifungal treatment require corticosteroid therapy (prednisone/prednisolone 0.5 mg/kg q 12 h × 5-7 days) to reduce pulmonary inflammation. Corticosteroids should not be used before antifungal therapy is started.
- Antifungal drugs:
  - Itraconazole is considered the drug of choice in most cases.
  - Amphotericin B may be superior in severe disease and in dogs with neurologic involvement.
- Itraconazole:
  - Dogs: 5 mg/kg q 12 h PO for 3 days, then 5 mg/kg PO q 24 h for at least 60 days and for 30 days after all signs of disease have resolved. The capsules should be given with canned food for maximal absorption. Brand-name itraconazole is preferred; poor absorption can occur with compounded itraconazole. Itraconazole is expensive in large dogs.
  - Cats: 5 mg/kg PO q 12 h
    - The pellets from the capsules can be mixed with palatable food for ease of administration.
    - Oral liquid formulation available (10 mg/mL)
- Amphotericin B (IV):
  - Dogs: 0.5 mg/kg IV in 5% dextrose 3 times a week at evenly spaced intervals. A cumulative dose of amphotericin B of 9 mg/kg is usually required. Amphotericin B should be temporarily discontinued when the blood urea nitrogen concentration (BUN) reaches 40 mg/dL (metric: 14 mmol/L). Therapy is continued until signs have resolved. When acute signs of blastomycosis have resolved, the treatment can be changed to itraconazole.
  - Cats: 0.25 mg/kg IV 3 times weekly. Monitor closely for nephrotoxicosis.
  - Animals must be adequately hydrated before receiving amphotericin B. The amphotericin B is usually given over a 30-minute period if there are no problems with nephrotoxicosis. Administration times of 3 hours will reduce the likelihood of nephrotoxicosis. Amphotericin B is light sensitive; therefore, the fluid bag containing the drug should be covered.
- Lipid-soluble amphotericin B:
  - Dogs, cats: 1 mg/kg IV 3 times weekly at evenly spaced intervals. The lipid formulations are costly and usually not required for blastomycosis unless there is preexisting renal disease.

DRUG INTERACTIONS

Itraconazole and ketoconazole should not be administered with drugs that inhibit cytochrome P450, such as some anticoagulants.

POSSIBLE COMPLICATIONS

- Itraconazole may cause hepatotoxicity and anorexia in dogs and cats but has fewer adverse effects than amphotericin B. Itraconazole at doses of 10 mg/kg/d may produce vasculitis, with ulcerative skin lesions that may resemble lesions of blastomycosis.
- BUN concentrations need to be monitored before every dose of amphotericin B, because the degree of nephrotoxicity varies greatly from dog to dog.
- Lung disease often worsens initially with treatment, owing to inflammation secondary to dying organisms. Corticosteroid therapy can be life saving in dyspneic dogs but should be given only after starting antifungal drugs.

RECOMMENDED MONITORING

- Liver enzymes should be monitored every 2-4 weeks during treatment in animals treated with itraconazole and measured if the patient develops anorexia.
- Assess BUN before each amphotericin B treatment. When BUN concentrations reach 40 mg/dL (metric: 14 mmol/L), treatment needs to be discontinued until BUN returns to normal.
- Thoracic radiographs should be done monthly to assess response to treatment in dogs with respiratory involvement.

PROGNOSIS AND OUTCOME

- Animals with severe lung involvement (dyspnea) or CNS involvement have a guarded prognosis. Most deaths occur in the first week of treatment.
- About 60% of dogs can be cured with the initial course of treatment.
- The mortality rate is about 20%.
- Recurrence of blastomycosis occurs in 20%-25% of treated dogs within a few months to a year after completion of treatment. Most dogs with recurrence are cured when given another course of treatment.
- Eyes that have anterior uveitis usually become glaucomatous and blind. Retinal lesions are more likely to be cured. Blind eyes should be enucleated because they can harbor organisms.
- The value of repeated urinary antigen testing in monitoring response to treatment and assessing duration of treatment is unclear but appears to be helpful.

PEARLS & CONSIDERATIONS

COMMENTS

- Early recognition is critical for successful treatment. Comprehensive diagnostic testing should be done initially in suspect cases.
- Obtaining a travel history when dogs have signs suspicious of blastomycosis is an important step for raising or lowering the disease on the differential diagnosis.

PREVENTION

- No vaccine exists
- Restrict activity in endemic areas, particularly lakes, creeks, and heavily shaded areas with moist soil in endemic areas.

TECHNICIAN TIP

- Although the disease is infectious (acquired by inhalation in the wild), it is not transmitted by inhalation from an infected patient to other animals or humans.
- Never culture a lesion or exudate in-house if it could harbor *Blastomyces;* the spores aerosolize from culture medium and are highly infectious in this context.
- Bandages contaminated with exudates should be disposed of as infectious waste, but the likelihood of aerosolization is low, owing to the specific conditions *Blastomyces* organisms require to grow.

CLIENT EDUCATION

- Long-term treatment is necessary.
- Can be fatal despite treatment
- Yeast form found in animal tissues is not directly transmissible.
- Can be transmitted via penetrating wounds

1ST EDITION AUTHOR: LISA TIEBER NIELSON

Bilious Vomiting Syndrome

BASIC INFORMATION

DEFINITION

A disorder resulting in vomiting of a bile-stained fluid, most likely due to gastric hypomotility or gastroduodenal reflux

SYNONYMS

Gastroduodenal reflux, idiopathic gastric hypomotility

EPIDEMIOLOGY

SPECIES, AGE, SEX

Only reported in dogs, but likely occurs in cats

RISK FACTORS

Concurrent gastric, pancreatic, or intestinal disease (i.e., outflow obstruction) possible, but usually affects otherwise normal dogs.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Gastric hypomotility causing vomiting when stomach is empty, otherwise healthy
- Gastric hypomotility causing chronic-vomiting and weight loss

HISTORY, CHIEF COMPLAINT

- Vomiting, typically in the morning (especially in animals fed once daily)
- Abdominal discomfort or increased “stomach noises” (borborygmi)
- Nausea
- Anorexia
- Weight loss
- Some or all of these may be present

PHYSICAL EXAM FINDINGS

- Typically normal; abdominal palpation is unremarkable
- Dehydration and lethargy (chronic vomiting)

ETIOLOGY AND PATHOPHYSIOLOGY

- Presumed to be caused by gastroduodenal reflux that occurs when the dog's stomach is empty for long periods or due to abnormal gastroduodenal motility
- Classically, the pet vomits bile-stained fluid, usually late at night or in the morning just before eating, but otherwise feels well.
- Anatomic abnormalities or pyloric obstruction are not present, and there are no inflammatory changes in the gastrointestinal mucosa.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A working diagnosis is made based on presenting signs (vomiting when the stomach is likely empty in an otherwise well dog) and response to treatment. Diagnostic testing is warranted if features of the case suggest other disorders.

DIFFERENTIAL DIAGNOSIS

- Outflow obstruction (e.g., pyloric stenosis, foreign bodies, polyps, neoplasia)
- Dietary intolerance or hypersensitivity
- Defective propulsion
- Gastric disorders (gastritis, gastroenteritis)
- Metabolic (hypokalemia, hypocalcemia, hypoadrenocorticism)
- Nervous inhibition (trauma, stress)
- Drugs (anticholinergics, others)

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis usually unremarkable. Hypokalemia, hypochloremia, and metabolic alkalosis possible with voluminous or chronic vomiting.
- Abdominal radiographs:
  - Normal
- Retention of food or fluid in the stomach longer than 8 hours, and often 12-16 hours after a meal, is suggestive of outflow obstruction or a motility disturbance.

ADVANCED OR CONFIRMATORY TESTING

- Motility studies are frequently difficult to perform, are not routinely available outside referral centers, and the repeatability and sensitivity of these studies are often questioned.
- Positive contrast radiography:
  - Typically normal
  - Incomplete gastric emptying following 4 hours (wide variability)
- Fluoroscopy:
  - Often normal
- Decreased frequency of gastric contractions and incoordination of antropyloric movement (objective criteria are lacking)
- Abdominal ultrasound:
  - Normal
  - Abnormal contractile activity (subjective)
- Scintigraphy:
  - Handling of radioisotopes limits the availability of scintigraphy to referral institutions.
- Gastroduodenoscopy is suggested to help rule out inflammatory, infectious, or structural causes of vomiting. The presence of an open pylorus with large amounts of bile reflux present in the stomach can be suggestive, but it is important to remember that certain anesthetic drugs can alter GI motility, creating the impression of reflux.

TREATMENT

TREATMENT OVERVIEW

Treatment goals consist of increasing gastric peristalsis and promoting gastric emptying. Nutrition and medical management using prokinetic therapy are important components of therapy.

ACUTE GENERAL TREATMENT

Management/resolution of systemic disorder if present, including fluid and electrolyte disturbances or acid-base abnormalities

CHRONIC TREATMENT

- Medical management: structural disease first must be ruled out.
  - Metoclopramide (0.2-0.4 mg/kg PO or SQ q 8 h); increases gastric peristalsis in some but not all affected dogs, *or*
  - Cisapride (0.5-1 mg/kg PO q 24 h); accelerates gastric emptying in dogs by stimulating pyloric motor activity
  - Erythromycin (1 mg/kg PO q 8-12 h); accelerates gastric emptying by inducing antral contractions, *or*
  - Ranitidine (1-2 mg/kg PO or SQ q 12 h) or nizatidine (2-5 mg/kg PO q 12 h); stimulate gastric antral contractions

NUTRITION/DIET

- Feeding small, frequent meals (especially late at night) to prevent the stomach from being empty for long periods and to encourage normal gastric motility
- Diets low in fat and fiber promote gastric emptying and may be helpful to reduce gastric retention.

- Canned or liquefied diets (solids are retained in the stomach longer) are also beneficial in animals with abnormal gastric retention of foods.

POSSIBLE COMPLICATIONS

- Acid-base or electrolyte disorders may occur secondary to chronic vomiting.
- Weight loss

PROGNOSIS AND OUTCOME

Prognosis is typically excellent; most dogs respond well to dietary and/or prokinetic therapy.

PEARLS & CONSIDERATIONS

COMMENTS

- Differential diagnoses for bilious vomiting syndrome include primary and secondary disorders of gastric emptying.
  - Primary disorders of gastric emptying may arise from mechanical obstruction or defective propulsion.
  - Secondary disorders of gastric emptying include metabolic and electrolyte disturbances.
- Weight loss should prompt a complete diagnostic evaluation, because it is not a common feature of uncomplicated bilious vomiting syndrome.

AUTHOR: BRANDY PORTERPAN

EDITOR: DEBRA L. ZORAN

Bile Duct Obstruction, Extrahepatic

BASIC INFORMATION

DEFINITION

Pathologic obstruction of the extrahepatic bile duct system

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dependent on the underlying cause. Dogs (middle-aged to older adults): pancreatitis; less commonly, neoplasia. Cats (middle-aged to older adults): neoplasia

RISK FACTORS:

Dogs:

- Pancreatitis

Cats:

- Pancreatitis
- Cholangitis/cholangiohepatitis
- Inflammatory bowel disease
- Neoplasia

ASSOCIATED CONDITIONS & DISORDERS

Dogs:

- Cholecystitis
- Gallbladder mucocele

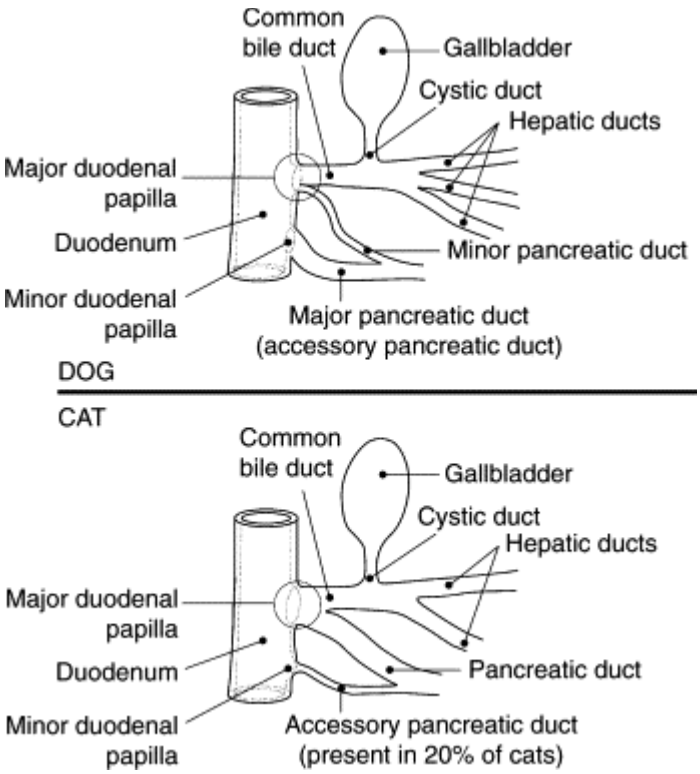
Dogs and cats:

- Coagulopathy possible due to lack of absorption of fat-soluble vitamin K
- Cholelithiasis
- Bile peritonitis
- Neoplasia

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Dogs: anorexia, lethargy, vomiting, diarrhea. *Cats:* anorexia, lethargy, weight loss, vomiting



BILE DUCT OBSTRUCTION Comparative anatomy of the canine and feline biliary systems.

(Courtesy Glenda Clements-Smith.)

PHYSICAL EXAM FINDINGS

Dogs: icterus, fever, tachycardia.

Cats: icterus, dehydration, fever or hypothermia

ETIOLOGY AND PATHOPHYSIOLOGY

Dogs:

- See Pancreatitis, Dog, p. 820
- Cholelithiasis: etiology poorly understood

Cats:

- Extrahepatic biliary obstruction often associated with a “triad” of diseases: cholangitis, pancreatitis, and inflammatory bowel disease
- Common opening of the pancreatic and common bile ducts into the duodenum and the increased duodenal bacterial content may predispose cats to ascending cholangitis and pancreatitis after vomiting associated with inflammatory bowel disease.

Dogs and Cats:

- Lack of bile entering intestinal tract:
  - Decreases absorption of fat and fat soluble vitamins, notably vitamin K: potential coagulopathy. May also result in increased absorption of endotoxin from the gut.
- Other possible etiologies include neoplasia, stricture in biliary system, duodenal obstruction by a foreign body, diaphragmatic hernia, and parasitic infection.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on presenting history and physical examination findings. Confirmation requires demonstration that the icterus is caused by an obstructed common bile duct rather than inherent liver disease, typically involving abdominal ultrasound exam.

DIFFERENTIAL DIAGNOSIS

- Hyperbilirubinemia:
  - Rule out hemolysis:
    - Immune-mediated hemolytic anemia, toxicity (zinc, onions, etc.) and other diseases causing hemolytic anemia
  - Rule out hepatic disease:
    - Hepatitis: acute, chronic
    - Cirrhotic/fibrosing liver disease
    - Neoplasia
    - Copper and other toxins in dogs, acetaminophen toxicosis in cats

INITIAL DATABASE

- CBC:
  - Possible anemia; generally very mild if any (unless concurrent gastrointestinal ulceration). By contrast, hyperbilirubinemia/icterus caused by hemolysis generally produces moderate to marked anemia
  - Inflammatory leukogram
- Serum biochemistry profile:
  - Elevated bilirubin concentration
  - Elevated liver enzyme concentrations
  - Possible elevated amylase and lipase concentrations
  - Hypokalemia
- Urinalysis: bilirubinuria is common in both species (but mild bilirubinuria is also normal in healthy dogs)
- Survey abdominal radiographs:
  - Cranial abdominal detail may be decreased in cases with biliary leakage and peritonitis.
  - May delineate radiopaque choleliths
- Survey thoracic radiographs:
  - Rule out metastatic disease if neoplasia is suspected.

ADVANCED OR CONFIRMATORY TESTING

- Abdominal ultrasound examination:
  - Common bile duct dilation
    - >5 mm diameter: diagnostic of bile duct obstruction in the cat
  - Visible contraction of the gallbladder is not expected in either healthy or diseased states.
- Peritoneal fluid analysis (obtained during abdominal ultrasound examination):
  - Elevated bilirubin concentration: bile peritonitis
  - Cytologic analysis and microbiologic (aerobic and anaerobic) culture and sensitivity testing: septic peritonitis
- Coagulation profile

TREATMENT

TREATMENT OVERVIEW

Patients require surgical correction of the problem along with appropriate intensive and supportive care. A major exception is transient biliary obstruction caused by acute pancreatitis, provided the patient's clinical course is mild and improves rapidly (few days) with medical therapy alone.

ACUTE GENERAL TREATMENT

- Rehydration by intravenous administration of balanced electrolyte solution
- Parenteral antibiotics effective against gram-negative bacteria and anaerobes:
  - Empirical therapy:
    - Cefoxitin, 30 mg/kg IV q 2 h perioperatively, then q 6 h, *or*
    - Metronidazole, 7.5-15 mg/kg IV q 12 h with
    - Enrofloxacin, 2.5-5 mg/kg IV q 12 h (5 mg/kg q 24 h maximum in cats, owing to risk of retinal toxicity)
  - Specific long-term therapy based on culture and sensitivity test results
- Possible administration of fresh frozen plasma:

    - Hypoproteinemia
    - Possible coagulopathy
- Vitamin K administration: 2.5 mg/kg SQ q 12 h × 3-5 days, then once weekly
- Relief of extrahepatic biliary obstruction—surgical intervention:
    - Duodenotomy and retrograde and antegrade flushing of biliary system: all cases
    - Common bile duct stenting: if temporary or dynamic obstruction likely (i.e., pancreatitis) and severe persistent hyperbilirubinemia
    - Cholecystoduodenostomy/jejunostomy: if advanced or permanent obstruction
    - Tube cholecystostomy
    - Cholecystectomy: if gallbladder wall is devitalized
    - Gastrointestinal biopsies: association of biliary disease with inflammatory bowel disease in cats
- Relief of intragallbladder luminal hypertension has been achieved via ultrasound-guided centesis of the gallbladder in dogs with pancreatitis-associated biliary obstruction

CHRONIC TREATMENT

Maintenance of bile flow: Ursodeoxycholic acid, 10-15 mg/kg PO q 24 h. Contraindicated if biliary obstruction is still present.

NUTRITION/DIET

Provide enteral feeding (e.g., gastrostomy tube; see p. 1270 and p.1267) if patient is anorexic

POSSIBLE COMPLICATIONS

Ongoing pancreatitis, bile leakage, peritonitis, endotoxemia, sepsis, death

RECOMMENDED MONITORING

- Clinical and laboratory parameters assessing perfusion, including capillary refill time, pulse rate and quality, blood pressure, urine output, arterial pH, and lactate concentrations
- Respiratory function
- Serum liver enzyme and bilirubin concentrations
- Coagulation profile

PROGNOSIS AND OUTCOME

- Poor if biliary obstruction associated with neoplasia: 100% mortality in cats
- Guarded if biliary obstruction associated with nonneoplastic causes in cats
- Guarded to fair if biliary obstruction associated with nonneoplastic causes in dogs

PEARLS & CONSIDERATIONS

COMMENTS

- Given the association of biliary obstructive disease in cats with cholangitis/cholangiohepatitis and inflammatory bowel disease, a liver biopsy and culture, bile culture, and small-intestinal biopsies must be obtained at the time of surgery in this species. A convenient site for duodenal biopsy is the edge of the duodenotomy performed to cannulate the duodenal papilla(e) or to perform a cholecystoduodenostomy.
- In assessing hyperbilirubinemia, total bilirubin concentration is important. Conjugated versus unconjugated bilirubin is not linked to the source of hyperbilirubinemia in dogs and cats as it is in humans.

AUTHOR: DAVID HOLT

EDITOR: RICHARD WALSHAW

Bicipital Tenosynovitis

BASIC INFORMATION

DEFINITION

Inflammation of the biceps brachii tendon and surrounding synovial sheath

SYNONYM

Bicipital bursitis (inaccurate)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs
- Medium and large breeds
- Middle-aged to older

RISK FACTORS

Trauma, overuse of muscle, shoulder joint osteoarthritis

ASSOCIATED CONDITIONS & DISORDERS

Osteoarthritis or osteochondrosis of shoulder joint, supraspinatus tendonitis

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Forelimb lameness exacerbated by exercise and unresponsive to nonsteroidal antiinflammatory drugs (NSAIDs); caused by trauma to shoulder or insidious in onset

PHYSICAL EXAM FINDINGS

- Shortened forelimb stride, with head lifted as affected forelimb is advanced
- Pain on palpation of the bicipital tendon in the intertubercular groove
- Pain on flexion of shoulder and extension of the elbow while placing tendon and muscle under tension

ETIOLOGY AND PATHOPHYSIOLOGY

- Can be caused by blow to cranial aspect of shoulder during flexion
- Tendon may be strained or stretched with disruption of fibers
- In chronic conditions, dystrophic mineralization occurs in tendon
- Secondary to shoulder joint osteoarthritis or osteochondrosis if cartilage fragments collect within the communicating tendon sheath and cause inflammation
- Adhesions between tendon sheath and tendon can occur secondary to trauma.
- Tendon can also be avulsed from supraglenoid tubercle

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Forelimb lameness raises the possibility of this diagnosis; pain on deep palpation of the bicipital tendon is characteristic.

DIFFERENTIAL DIAGNOSIS

- Supraspinatus tendonitis
- Supraglenoid tubercle fracture
- Biceps muscle tearing at the distal musculotendinous junction
- Shoulder joint collateral ligament injury
- Shoulder joint osteoarthritis
- Cervical nerve root compression

INITIAL DATABASE

- Patient database as indicated by stability and American Society of Anesthesiologists classification (p.1372)
- Medial to lateral radiograph of the scapulohumeral joint
- Skyline radiographic view of the intertubercular groove

ADVANCED OR CONFIRMATORY TESTING

- Contrast arthrography may reveal irregularity of tendon surface or sheath.
- Arthrocentesis may be consistent with osteoarthritis (increase nucleated cell counts 1500-4800 cells/mcL, primarily mononuclear; aseptic).
- Ultrasonography of the biceps tendon will identify irregular fiber arrangement and increased synovial sheath fluid content.
- MRI may be considered to identify tendon and sheath lesions.
- Arthroscopy for direct visualization of tendon and sheath

TREATMENT

TREATMENT OVERVIEW

Relieve pain due to tenosynovitis.

ACUTE GENERAL TREATMENT

- Local injection with methylprednisolone acetate (10-40 mg) followed by 2 weeks of rest. Repeat at 2-week intervals for 3 treatments; if no improvement, surgery is considered.
- Surgical treatment:
  - Preserve tendon and release transverse humeral ligament if it is restricting biceps tendon excursion.
  - Tenotomy via arthrotomy or arthroscopy
  - Tenodesis to the proximal humerus by screw/washer or passing tendon through a bone tunnel and suturing to the periosteum

CHRONIC TREATMENT

Exercise restriction for 6-8 weeks

POSSIBLE COMPLICATIONS

- Poor response to steroid treatment
- Chondromalacia in shoulder joint or biceps tendon rupture secondary to steroid injection
- Persistent lameness due to inadequate tenodesis

RECOMMENDED MONITORING

- Short-term postoperatively for seroma
- Long-term for restoration of limb function

PROGNOSIS AND OUTCOME

- Fair to good after steroid injection and rest
- Good after tenodesis or tenotomy (arthroscopic)

PEARLS & CONSIDERATIONS

COMMENTS

- Establishing a diagnosis of bicipital tenosynovitis can be difficult.
- Disease of the supraspinatus tendon can be a conflicting cause of shoulder joint pain. This condition is best evaluated by MRI or arthroscopy to identify tendon impingement into the groove; splitting this tendon resolves pain and lameness.
- The synovial sheath of the biceps tendon is continuous with the shoulder joint capsule.
- Transverse humeral ligament thickening may constrict the tendon and cause pain.

SUGGESTED READING

Lafuente MP, Fransson BA, Lincoln JD, et al: Surgical treatment of mineralized and nonmineralized supraspinatus tendi nopathy in twenty-four dogs. Vet Surg 38:380–387, 2009

AUTHOR: JAMES D. LINCOLN

EDITOR: JOSEPH HARARI

Behavior Problems, Miscellaneous

BASIC INFORMATION

DEFINITION

Species-typical and normal behaviors that may inconvenience clients

Dogs:

- Coprophagy (see p. 244)
- Digging
- Mounting/humping
- Roaming
- Fence running/scratching

Cats:

- Scratching of furnishings
- Late night activity, climbing on counters

EPIDEMIOLOGY

SPECIES, AGE, SEX

Younger animals more likely to exhibit exploratory and play behaviors that may irritate clients. Intact males may roam more frequently and greater distances.

GENETICS & BREED PREDISPOSITION

- Hounds and northern dog breeds (e.g., husky, malamute, Samoyed) are anecdotally reported to look more readily for opportunities to roam.
- Highly active breeds or individuals with inadequate stimulation and exercise to satisfy their behavioral and cognitive needs may look for alternatives for behavioral expression, which may be intolerable to owners.

RISK FACTORS

Management practices that decrease enrichment (both mental and physical) or fail to establish a humane rule structure that meet a pet's physical, social, developmental, behavioral, and cognitive needs. Examples are lengthy confinement within a day for dogs (e.g., 8 of 24 hours), lack of interactive toys, lack of basic training, inadequate aerobic exercise, and inadequate social exposure.

CONTAGION & ZOONOSIS

Multiple-dog and multiple-cat households may experience social facilitation that fosters many of these behaviors. In social facilitation, the behaviors of one individual in a group stimulate others to do the same or similar behaviors.

GEOGRAPHY AND SEASONALITY

Access (e.g., digging in soil) and the level of provocative stimuli (e.g., other cats outside) may vary seasonally.

ASSOCIATED CONDITIONS & DISORDERS

Obsessive-compulsive disorders (see p. 775).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Bouts of behaviors that can be interrupted and that seem only to occur opportunistically may be normal but annoying behaviors or management-related behavior problems. If the behaviors cannot be easily interrupted, or if the animal is constantly seeking ways to get access to do them, a more serious disorder should be suspected (e.g., obsessive-

compulsive disorder, see p. 775)

HISTORY, CHIEF COMPLAINT

Behavior that is annoying (e.g., cat walking on counters) or disgusting (e.g., dog rolling in feces) to the client, but not threatening or dangerous. The first step in eliciting relevant information is to get a good and complete description of the behaviors and the context in which they occur. Context is critical for assessment of whether the behaviors are “normal” or species-typical ones that can be redirected or managed while still meeting the animal's needs. For example, a cat's scratching at an inanimate object (e.g., furniture) is part of normal behavior and can be redirected, but scratching at humans or other cats may represent aggression.

PHYSICAL EXAM FINDINGS

Usually unremarkable, although history or evidence of minor self-trauma acquired during exploratory or escape behaviors may be present.

ETIOLOGY AND PATHOPHYSIOLOGY

- Clients must understand that animals do not undertake these behaviors to “spite” them or out of “jealousy;” attention-seeking is commonly involved, but the key to managing these disorders is having clients understand the significance of the behaviors in terms of normal dog and cat behavior.
- Most of these behaviors are normal behaviors in context, intensity, and frequency, at least at first.
- With time, if behaviors become increasingly abnormal, the context, intensity, and frequency with which they are exhibited will change, as will the animal's focus, interactions with humans and other animals, and daily time budget.
- Effective behavior modification: positive behaviors are encouraged and repeated if they result in a pleasurable outcome. This repetition leads to learning at the neurochemical level where new proteins at synapses are made. These more efficient neuronal connections make it more likely that the dog or cat will continue with the behavior. This sequence explains the importance of early identification and intervention.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

Many “nuisance” behaviors are actually within the species repertoire of normal behaviors. A problem exists when their expression is undesirable to owners, but even then, they may not be a sign of abnormal behavior. Therefore, the history is diagnostic; the context in which the specific behavior occurs will determine whether the behavior is normal but inconvenient, or indicative of a true disorder.

DIFFERENTIAL DIAGNOSIS

- If any of the signs are excessive, repetitive, and performed to the exclusion of other comfort, social, and maintenance behaviors, an anxiety disorder such as obsessive-compulsive disorder (see p. 775) must be considered.
- Late-night activity in middle-aged to older cats that is new and uncharacteristic based on the pattern of previous nocturnal behavior could be a sign of feline cognitive dysfunction (see p. 225).
- Hyperthyroidism also should be ruled out whenever an adult cat's activity level increases uncharacteristically.

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis: generally unremarkable
- Ingestion of feces or other nonnutritive items: fecal flotation, trypsin-like immunoreactivity (see p. 372)

TREATMENT 

TREATMENT OVERVIEW

Provide an acceptable outlet for the unmet behavioral, cognitive, and species-typical needs that lead the pet to engage in the behavior the client finds objectionable.

ACUTE GENERAL TREATMENT

- Increase aerobic activity through exercise and interactive play with humans or fellow dogs/cats. Play with compatible conspecifics, particularly for dogs, usually provides more effective exercise with greater aerobic scope than does play with

humans.
- Environmental modification should be used for preventing access to or limiting the repetition of the undesirable behavior, and to foster alternative, acceptable behaviors.

CHRONIC TREATMENT

- Behavior modification can provide outlets or encourage substitute behaviors that allow acceptable expression of the individual's mental and social needs. Depending on the problem, this may consist of continued aerobic exercise, goal-oriented activities (obedience, agility, tracking, coursing training in dogs; interactive predatory play in cats). Rewards—verbal, physical (e.g., petting or stroking), food—should be given for all spontaneous and calm behaviors (e.g., chewing on chew-toys, clawing on provided surfaces, digging in a sandbox provided for this purpose, pouncing on cat toys).
- Attention-seeking behaviors such as jumping or “playful” whining or biting need to be ignored completely. Elimination of the reward (of attention) will extinguish the behavior if, and only if, the client is consistent in not responding.
- In mild cases, devices that interrupt the behavior with an aversive stimulus can be useful early in the course of the problem, only if the animal is not afraid of the stimulus, and only if appropriate outlets to which the behavior can be redirected are also provided.
- Examples of aversive but not harmful or fear-inducing disruptive stimuli include inverted plastic carpet runners (spike side up), static electricity mats for surfaces the client wants to be off-limits to the pet, and pressurized air blasts triggered by motion-detector sensors. Note that some animals will be afraid of these stimuli. If this is the case, the devices should not be used. The purpose of a disruptive stimulus is to stop the behavior in a way that encourages the animal to seek information and engage in an alternative behavior that can be rewarded. If the animal is afraid, it cannot do this.

POSSIBLE COMPLICATIONS

Poor client compliance can lead conversely to continued self-reinforcement and worsening of the problem, and deterioration of the pet-client relationship. Therefore a cornerstone of treatment is owner understanding of the basis for the behavior and the intention of the proposed treatment.

RECOMMENDED MONITORING

- Frequent follow-up will help many clients comply more reliably.
- Demonstrations that show clients new ways to interact with their pet are essential.
- By dedicating these tasks to one staff member, continuity and consistency in advice and follow-up are maintained. Clients also feel that their veterinarians care more about them under these conditions.

PROGNOSIS AND OUTCOME 

- Excellent if the clients understand the pets' needs and are willing and able to meet them
- Poor if clients have unrealistic expectations, consider pets recyclable, feel guilty about discussing the issue with their vet, or are unwilling or unable to meet their pets' needs

PEARLS & CONSIDERATIONS 

COMMENTS

- In extreme forms that interfere with normal physical and social functioning, most of these “annoyance” behaviors are also characteristic of obsessive-compulsive disorder and other anxiety-related conditions. This does not mean that exhibition of these miscellaneous concerns will lead to obsessive-compulsive disorders. It does mean that the nonspecific signs and complaints can be similar, and clients should be aware of this and not dismiss unusual behaviors out of hand as just “bratty” behaviors without having them evaluated first. Referral to a veterinary behaviorist may be very helpful in such situations.
- Relinquishment and euthanasia are frequent sequelae to behaviors clients find undesirable, whether or not the behaviors were the pet's “fault.” The effect of this pattern on veterinary economics and veterinary staff morale is huge and often preventable.
- This is a quality of life (QoL) issue for pets.

PREVENTION

Puppy and kitten classes, basic obedience and agility training, and understanding of basic behavioral, physical, and social needs of dogs and cats will help clients to intervene before behaviors become problems.

CLIENT EDUCATION

Veterinarians are encouraged to keep a loaning library of books, newsletters, videos covering basic behaviors of dog and cats, and a list of trainers and facilities that a staff member has verified use humane training techniques. This will provide the atmosphere of caring that will make it easier for clients to seek and get the help they need. A useful source of video and other training and behavioral material is http://abrionline.org/.

Behavior Problem Prevention, Puppies

BASIC INFORMATION

DEFINITION

The first few puppy visits set the stage for future veterinary visits. They educate the new puppy owner about normal canine behavior and social systems and help prevent problems with toilet training, digging, jumping up, barking, mouthing and chewing.

SYNONYMS

Puppy socialization; puppy training; Puppy Preschool

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs <6 months old, both sexes; consider as 2 age groups (£3 months; >3 months) and multiple activity appropriate groups.
- Problematic behavior often becomes more pronounced at social maturity (“18-24 months of age).

RISK FACTORS

Dogs not adequately exposed to varied stimuli, especially during the sensitive socialization period (3-12 weeks old; later for ongoing novel experiences), are at increased risk of neophobia (fear of humans, other dogs).

CONTAGION & ZOONOSIS

Dog bites are a public health risk.

ASSOCIATED CONDITIONS & DISORDERS

- Increased risk of abandonment and euthanasia if owners do not understand normal canine behaviors and social structure and use this understanding to meet the dog's needs.
    - Risk factors for surrender/abandonment include absence of castration, lack of housetraining, no veterinary attention, and no obedience/manners training.
    - The average client with a problem dog keeps the dog 3 months before relinquishment.
- Dogs with inherited neurologic disorders (e.g., lissencephaly) often present with abnormal puppy behavior as the nonspecific complaint.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

The owner may not report any difficulties with the puppy or may report some problems with toilet training, digging, jumping up, barking, mouthing, or chewing.

PHYSICAL EXAM FINDINGS

If there are no medical problems, it should be unremarkable.

ETIOLOGY AND PATHOPHYSIOLOGY

Certain behaviors are normal for the individual/species and misunderstood by, or out of context for, an uninformed owner. Other behaviors are truly abnormal and warrant intervention.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Detailed history, discussion of expectations, and observation of interaction between owner and puppy are usually sufficient to identify potential misunderstandings and anticipate problems, allowing early intervention.

DIFFERENTIAL DIAGNOSIS

Normal behavior that may not be acceptable to the owner versus behavioral disorder

INITIAL DATABASE

History and physical exam are usually sufficient.

TREATMENT

TREATMENT OVERVIEW

Cornerstones of treatment are to identify the exact features of behaviors the owner considers abnormal, annoying, or troublesome and determine whether these are normal or pathologic; to counsel owners on behaviors that are normal for dogs; and to increase positive interaction between owner and puppy. The goal is to maximize positive interaction between puppy and owner, and with perceived or real behavioral disorders, to reduce the risk of surrender.

ACUTE AND CHRONIC TREATMENT

- Preventive health care for dogs should always include information about canine behavior. Many issues that lead to abandonment may be preventable with client education.
- Every veterinary visit should include an assessment of a puppy's behavior, thus educating the client about age-specific normal behavior and allowing early intervention. Sample questions could include: Does your puppy urinate in the house? Does your puppy avoid other dogs or strangers and/or appear concerned about them? Does your puppy vocalize when left alone? Does your puppy have any behaviors that concern you or that you do not like?
- Rewards (e.g., treats, pats, verbal praise) should be given for appropriate behaviors, including during veterinary visits.
- Inappropriate behaviors should be redirected and more appropriate behaviors substituted consistently and long term (e.g., the dog grabs a toy at the door, not the human's hand)
- Dogs should not be verbally or physically punished for inappropriate behaviors.
- Dogs should be taught to sit and settle/relax on cue.
- Head collars can help owners manage their puppy better with less need for “corrections.”
- Choke chains, prong collars, and electronic collars have no place in modifying or preventing unacceptable behaviors.
- Many behaviors such as jumping up, digging, or mouthing are normal behaviors that owners dislike or do not understand. They are best resolved by ignoring the behavior and teaching the dog an alternative response instead (response substitution), such as sitting for petting rather than jumping up and being pushed down.
- Many of these problem behaviors may be addressed by referral to a good positive-reinforcement trainer.

NUTRITION/DIET

- Dogs eat during the day and would naturally eat three meals. Using foraging devices/food toys can be used as way of enriching the dog's environment.
- Advice on prevention of obesity is important; use of only small treats and accurate exercise requirements must be explained.

BEHAVIOR/EXERCISE

- Age-appropriate physical and mental stimulation is necessary. These can include walking, swimming, games, interactive toys, agility, and tracking.
- Jumping up (see p. 133):
    - May start inadvertently as the puppy seeks attention
    - Puppy should be taught to sit on cue and quietly praised.
    - The owner should not pay attention to the dog when he/she jumps up. Instead, the owner should stand still or turn his/her back on the dog and wait until all of the dog's four feet are firmly placed on the ground and the dog is quiet and attending to the owner. The dog should then be given quiet, calm praise immediately.
    - Interactions only occur when the dog is calm.
    - Making eye contact, pushing the dog down, kneeing, pinching the toes, or saying “no” will encourage jumping as the dog gains attention.
- Chewing objects (see also p. 654).

    - Dogs use the mouth to investigate their environment, so it is important owners recognize this is a normal behavior.
    - Dogs may also chew when they are anxious or distressed, and chewing may be a sign of such problems as separation anxiety (see and p. 654).
    - Puppies need to be given suitable, safe toys to chew. Rotating toys or odors associated with toys may increase interest for some dogs.
    - Foraging devices such as Kongs, Treat Balls, the Busy Buddy line of toys, and Buster Cubes are useful for puppies to chew. The toys should be as indestructible as possible and must be checked and cleaned regularly.
    - The puppy should not have access to potentially valuable or unacceptable items. Puppies should not be given old shoes or other belongings of the owner to chew, as dogs cannot always tell the difference between what is a new shoe and what is an old shoe.
- Digging
    - Many dogs dig, and this is a normal behavior. The dog may be given a digging pit (the size of a child's size sandpit) filled with loose sand or soil to encourage digging in this area.
    - Burying bones, toys, and other treats in this area “rewards” the dog for digging there.
- Mouthing (see also p. 654)
    - Puppies mouth to investigate their environment. They may also mouth in play. It is important for owners not to use hands to play with puppies, as that may encourage mouthing.
    - Appropriate toys should be available for the puppy to chew and can be offered to the puppy if it mouths or bites.
    - If a puppy uses its mouth excessively in play or bites, play should stop immediately and the person should walk away. Once the puppy is calm, play can resume.
    - If the puppy persists in play biting, the owner needs to entirely discontinue any interaction or play for that session.
    - Owners should not to use hands to hit the puppy or push him/her away, as this may encourage mouthing or biting. Puppies may perceive this as a game and will persist in biting.
- Barking: see p. 127

RECOMMENDED MONITORING

Weekly phone call to monitor progress and help with troubleshooting for the first months of intervention.

PROGNOSIS AND OUTCOME

New puppy owners often are very open to learning about their puppy's development. Encourage this by asking about behavior and viewing photos/videos with clients.

PEARLS & CONSIDERATIONS

COMMENTS

- Educate owners often that rewarding appropriate behaviors while ignoring or redirecting inappropriate behaviors is the best way to manage potential problem behaviors.
- If behavior problems persist, refer to a veterinary behaviorist early in their development. Most dogs do not “grow out of it,” but instead learn to become more distressed and problematic with time.

PREVENTION

- Offer pre-pet selection advice, especially pertaining to size and grooming and exercise needs.
- Attendance at puppy socialization and training classes (Puppy Preschool) or puppy manners classes helps puppies to behave politely in society. The classes also help owners understand their dog's behavior and to have realistic expectations of their dog.

TECHNICIAN TIPS

Regular contact with owners to educate them and assist them with any behavior modification advice will increase client compliance. Participation in Puppy Preschool and routine manners classes are great ways of building client trust and confidence.

CLIENT EDUCATION

Exposing puppies to many stimuli in a manner where they are not distressed, or can easily overcome their distress, maximizes their chances to grow into well-behaved and accepted members of their households and society.

Behavior Problem Prevention, Kittens

BASIC INFORMATION

DEFINITION

The first few kitten visits set the stage for future veterinary visits. They help the new kitten owner understand normal feline behavior and social systems and help prevent problems with litter box usage, scratching furniture, biting, and chewing.

SYNONYMS

Kitten kindergarten, Kitten Kindy, kitten socialization, kitten training

EPIDEMIOLOGY

SPECIES, AGE, SEX

Cats <3 months of age of both sexes

RISK FACTORS

Increased risk of abandonment and euthanasia if owners do not understand normal feline behaviors and social structure and meet the cat's needs.

CONTAGION & ZOONOSIS

Cat scratch fever (bartonellosis) is most commonly transmitted with fleas. Exposure of 2- to 8-week-old kittens to humans helps adaptation and reduces future risk of aggression.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

The owner may not report any difficulties with the kitten or may report some difficulties with litter box usage, chewing undesirable or inappropriate objects, or scratching and/or biting humans or other animals.

PHYSICAL EXAM FINDINGS

If there are no medical problems, it should be unremarkable.

ETIOLOGY AND PATHOPHYSIOLOGY

People keep cats approximately 2 years after they start to exhibit behavior problems, which often occurs at the onset of social maturity (2-4 years old).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- Preventive health care for cats should always include information about feline behavior so the cat's long-term health and welfare are maximized, and owners have realistic expectations of their cats. Many issues that lead to abandonment and euthanasia may be preventable with client education.
- Make veterinary visits as stress free as possible for the cat, owner, and veterinary staff.

DIFFERENTIAL DIAGNOSIS

Based on the presenting signs and complaints of the owner

INITIAL DATABASE

As appropriate; often, no evaluation is needed beyond history and physical exam

TREATMENT

TREATMENT OVERVIEW

Treatment goals are:

- To educate owners about normal feline behavior
- To advise clients how to prepare the home for their kitten, including bedding, feeding, exercise, and health care requirements
- To reduce the risk of surrender or euthanasia in the future
- To help veterinary visits to be as stress free as possible for the owner, the cat, and the veterinary staff
- Early recognition of behavior problems and referral to a veterinary behaviorist as soon as concern becomes apparent, to decrease risk of surrender or euthanasia

ACUTE AND CHRONIC TREATMENT

- Rewards (e.g., treats, pats, verbal praise) should be given for appropriate behaviors.
- Inappropriate behaviors should be redirected and more appropriate behaviors substituted (e.g., chase the toy, not the human's foot).
- Cats should not be verbally or physically punished for inappropriate behaviors.
- Cat “carry-basket” training so the cat associates the cat basket with pleasant experiences
- Feliway diffusers in the consulting room and spray applied to hands and consultation table surface may decrease anxiety.
- Appropriate behaviors must be reinforced long term in order for them to be maintained.
- All veterinary visits should be as pleasant as possible. Use rewards and low-stress handling techniques, with minimal restraint. If profound distress occurs, consider use of panicolytic medication early in its development.
- Many behaviors such as scratching furniture are not true behavior problems but normal behaviors that are viewed as a problem by the owners.

NUTRITION/DIET

- Cats eat during the day and night and often graze. Using foraging devices can be a way of enriching the cat's environment.
- Obesity prevention is important (only small treats).
- Place water bowls apart from food bowls to encourage water consumption.
- Newer food toys may encourage more species-typical eating patterns and exercise if used for meal feeding.

BEHAVIOR/EXERCISE

Age-appropriate physical and mental stimulation are necessary, especially for indoor cats. These can include:

- Scratching posts: stable/anchored; horizontal and vertical [individual cat preferences]; large to allow stretching; can be homemade.
- Indoor garden box: growing grass, catnip or catmint for cats to nibble on can provide enrichment for many cats.
- Tunnels, paper bags, and cardboard boxes provide good hiding places, especially if placed up high.
- Commercially available toys such as the Bizzy Kitty, Cat Track, Kitty Kong, and Cat Dancer can provide enrichment, both physically and mentally.
- Two kittens: in some cases this can be appropriate, as they may keep each other company and play together while the owners are at work.
- Hiding the cat's dry food around the house so the cat “hunts” for its dinner. Food toys can also play this role.
- Training behaviors on cue: example, cats can be trained to come on cue, sit, or roll over.
- Agility training: cats are taught similar techniques to dogs, such as negotiating various stimuli.

RECOMMENDED MONITORING

Weekly phone call for the first month to monitor progress and troubleshoot can help increase owner compliance.

PROGNOSIS AND OUTCOME

New kitten owners often are very open to learning about them, so the outcome should be favorable. Encouraging questions and sharing of photos/videos will help.

PEARLS & CONSIDERATIONS

COMMENTS

- Educate owners that rewarding appropriate behaviors and ignoring or redirecting inappropriate behaviors is the best way to manage potential behavioral problems.
- If behavior problems persist, referral to a veterinary behaviorist early is preferable to waiting to see if the cat "will grow out of it."

PREVENTION

- Offer pre-pet selection advice, including information on what grooming the adult cat will entail.
- Attendance at kitten socialization and training classes (Kitten Kindy) can help owners to have realistic expectations of their cat.

TECHNICIAN TIPS

Regular contact with owners to educate and assist them with any behavior modification advice increases client compliance. Kitten Kindy is a great way to get to know and earn the respect of clients.

CLIENT EDUCATION

It is just as important to socialize and train kittens as it is puppies so they to grow up into well-behaved and accepted members of society.

EDITOR: KAREN OVERALL

Bee and Other Insect Stings

BASIC INFORMATION

DEFINITION

Stings from insects such as bees, wasps, and hornets. Spider envenomation is discussed separately (see p. 1035).

SYNONYM

Insect bites

EPIDEMIOLOGY

SPECIES, AGE, SEX

Bites and stings are more likely to occur in young, inquisitive animals. Cats may be more tolerant than dogs to many insect toxins.

GENETICS & BREED PREDISPOSITION

Boxers seem especially prone to insect reactions.

GEOGRAPHY AND SEASONALITY

Bee stings are more common during warm weather when the insects are active.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Bees, wasps, hornets (order Hymenoptera): Animals frequently present with no known history of an insect sting. Instead, they present for clinical signs associated with allergic reaction (see p. 64). Severity of signs will depend on the type of venom, location of the sting, number of stings, and sensitivity of the animal receiving the sting.

PHYSICAL EXAM FINDINGS

- Bees, wasps, hornets:
  - Local reaction associated with an immunologic response is the most common finding. This may include a swollen head/face or diffuse urticaria. Cases with severe facial swelling can develop respiratory distress from upper airway obstruction and occlusion.
  - Less commonly, an animal may develop anaphylaxis (see p. 64). Signs of anaphylaxis may develop within 15 minutes of a sting. Anaphylaxis in dogs can manifest as vomiting, defecation, urination, muscular weakness, respiratory depression, or seizures. Cats most often show signs of pruritus, dyspnea, salivation, incoordination, and collapse. Animals with massive envenomation may show signs of acute respiratory distress syndrome or disseminated intravascular coagulation.

ETIOLOGY AND PATHOPHYSIOLOGY

- Most systemic signs result from an immunoglobulin E (IgE)-mediated allergic reaction (see p. 1399).
- A small number of dogs and cats may develop anaphylaxis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of insect envenomation is frequently presumptive and made based upon clinical signs and history of possible (but unwitnessed) exposure.

DIFFERENTIAL DIAGNOSIS

- Cellulitis
- Peripheral edema
- Acute abdomen (black widow spider)
- Nonhealing wound (brown recluse spider)

INITIAL DATABASE

- Packed cell volume
- Serum total protein
- Blood glucose
- Blood urea quick-assessment test (Azo stick)

TREATMENT

TREATMENT OVERVIEW

- Relief of discomfort
- Prevent further edema/urticaria formation

ACUTE GENERAL TREATMENT

- Facial edema/urticaria:
  - Remove stinger if present. Use fine forceps/tweezers or a flat object (e.g., dull side of a scalpel blade), taking care not to press on the stinger's sac (if present) to avoid injecting the remaining contents of the stinger into the patient
  - Diphenhydramine 1-2 mg/kg IM
  - Dexamethasone sodium phosphate 0.2 mg/kg IV slowly
- Anaphylaxis (see p. 64):
  - Epinephrine 0.01 mg/kg IV
  - Intravenous fluid support
  - Diphenhydramine 1-2 mg/kg IM
  - Dexamethasone SP 0.2 mg/kg IV slowly

RECOMMENDED MONITORING

Animals with facial swelling or urticaria should be monitored for 20-30 minutes after therapy to ensure clinical signs are not progressing.

PROGNOSIS AND OUTCOME

Most animals with insect bites and stings have an excellent prognosis. Animals with severe systemic signs have a more guarded short-term prognosis as dictated by the severity of signs.

PEARLS & CONSIDERATIONS

COMMENTS

Animals with facial edema of unknown origin should have the face and lips closely examined for the presence of a stinger.

PREVENTION

Avoid insects and spiders.

SUGGESTED READING

Cowell AK, Cowell RL: Management of bee and other Hymenoptera stings. In Bonagura JD, editor: Current veterinary therapy XII. Philadelphia, 1995, WB Saunders, pp 226–228.

AUTHOR: SCOTT P. SHAW

EDITOR: ELIZABETH ROZANSKI

Baylisascaris Infection

BASIC INFORMATION

DEFINITION

A rare but potentially devastating zoonosis involving parasitic infection with the raccoon roundworm, *Baylisascaris procyonis*

SYNONYMS

Ocular or neural larval migrans; raccoon roundworm, visceral

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Raccoons are the natural host for the mature enteric parasite. However, larval stages of *B. procyonis* can infect more than 90 species of birds and mammals, including dogs.
- Cats appear to be only marginally susceptible or even resistant to disease caused by *Baylisascaris* larva migrans.

RISK FACTORS

- Zoonosis occurs when humans acquire the parasite by the fecal-oral route. Therefore, exposure to “aged” raccoon feces harboring embryonated eggs (eggs which contain infective second-stage larvae) of *B. procyonis* is a major risk factor (e.g., in uncovered outdoor sandboxes or similar “latrines,” which are areas where raccoons specifically choose to defecate).
- Dog feces have also been shown to contain *Baylisascaris* eggs when the dog is infected with intestinal adult *B. procyonis*.
- The tissues of transport or paratenic hosts (e.g., small rodents) may contain encysted/arrested second-stage larvae. If a raccoon or other suitable mammalian host (e.g., the dog) ingests this infected transport or paratenic host, the ingested larvae will excyst and migrate, thus infecting the gut (or other host tissues) of the definitive host.

CONTAGION & ZOONOSIS

Infective eggs within the environment can cause an often fatal meningoencephalitis in humans. Children younger than 2 years are at highest risk.

GEOGRAPHY AND SEASONALITY

More common in the Midwestern and Northeastern United States and California. Infected raccoons have also been reported in Georgia.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Clinical illness due to *B. procyonis* is extremely uncommon in small animal medicine; neurologic and ocular signs are theoretically possible.
- Rather, the greatest concern is regarding the zoonotic potential of *B. procyonis* eggs passed in raccoon or (rarely) canine feces.
- In humans, visceral larval migrans (VLM), ocular larval migrans (OLM), and neural larval migrans (NLM) may be observed.

HISTORY, CHIEF COMPLAINT

- Dogs infected with *B. procyonis* generally show no clinical signs, harboring the parasite without outward evidence of infection. Rarely, dogs may sustain larva migrans that causes overt clinical signs as early as 9-10 days after ingestion of raccoon feces containing ova with infective larvae.
- Signs often progress rapidly over several days.

PHYSICAL EXAM FINDINGS

- NLM: Depression, ataxia, head tilt, circling, nystagmus, opisthotonos, recumbency, coma
- OLM: Blindness, signs of uveitis (red eye, photophobia, etc.), observable larvae within the eye/retina
- VLM: Usually an incidental finding without clinical signs

ETIOLOGY AND PATHOPHYSIOLOGY

- Eggs of *B. procyonis* become embryonated and infective (contain infective second-stage larvae) 24-48 hours after being passed by the raccoon. Infective eggs are highly stable and may remain viable within the environment for years; however, they can be destroyed by heat.
- All animals (including dogs and humans) are infected by ingesting the embryonated/larvated eggs of *Baylisascaris procyonis*. Raccoons originally become infected in the same manner or by ingesting transport or paratenic hosts (see Risk Factors).
- Once ingested, the larvae emerge from the eggs within the host's intestine and begin to migrate *(larva migrans)* through the liver, lungs, brain, and eyes as early as 3 days post-infection.
- Migration of only one or two larvae through the brain can cause destruction of the white matter (leukomalacia) and severe inflammation and necrosis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Infection of the definitive host with *B. procyonis* is of great public health significance. If humans become infected with neural larva migrans, the consequences can be fatal. *B. procyonis* rarely poses a significant threat to dogs.

DIFFERENTIAL DIAGNOSIS

In dogs and raccoons, signs of central nervous system dysfunction are very uncommonly due to *Baylisascaris* infection. Causes that are much more common include:

- Other infectious causes of encephalitis: toxoplasmosis, tickborne diseases, *Neospora*, canine distemper virus, rabies
- Granulomatous meningoencephalitis
- Toxin exposure
- Neoplasia
- Metabolic disease (e.g., hepatic encephalopathy, hypoglycemia)

INITIAL DATABASE

- CBC: possible eosinophilia
- Serum biochemistry profile, urinalysis: may rule out toxic or metabolic diseases
- Complete neurologic and ocular examination: asymmetry of deficits is expected if any deficits are present.
- Fecal flotation and examination: more than 20 dogs in the Midwest have been shown to have a mature intestinal infection of *Baylisascaris* with infective eggs shed in their feces
- Cerebrospinal fluid tap with cytology: meningoencephalitis with increased eosinophils

ADVANCED OR CONFIRMATORY TESTING

- Virtually never performed in small animal medicine, given the rarity of clinical disease in dogs and cats
- MRI (brain): preferential destruction of white matter
- Serologic testing is available for humans but is not commercially available for veterinary patients.
- Definitive diagnosis may not be possible until postmortem.

TREATMENT

TREATMENT OVERVIEW

It is critical to remove all adult stages of this parasite from the small intestine of the infected host (dog) with anthelminthic therapy prior to treating neurologic signs with corticosteroids. All feces should be removed promptly from the cage or kennel and properly disposed of. Gloves should be worn at all times when there is contact with infected feces. Handwashing is essential. The therapeutic goal is rapid identification and treatment to prevent progression of leukomalacia and neurologic signs

ACUTE GENERAL TREATMENT

- Anthelmintics: when *Baylisascaris* eggs are found incidentally on a fecal flotation
  - Albendazole (50 mg/kg PO q 24 h × 10 days or more): traditionally the anthelmintic of choice. Administration for >3 days may risk myelosuppression.
  - Milbemycin oxime (0.5-1 mg/kg PO): *B. ascaris* infection is a newer application of this treatment. About 75% effective at eliminating *Baylisascaris* infection in dogs with one dose.
- Neurologic larva migrans (rare in dogs and cats): Corticosteroids (e.g., dexamethasone 0.1-0.2 mg/kg IV q 8-24 h) are essential to stabilize the inflammatory component of the encephalitis.
- Ocular larvae within the retina may be killed using laser photocoagulation or removed via enucleation.

CHRONIC TREATMENT

- Patients surviving the initial neurologic disease may be permanently handicapped and require supportive and nursing care.
- A long course of corticosteroids may be necessary to control the necrosis and inflammation associated with larval migration and death.

PROGNOSIS AND OUTCOME

- Severity of signs and speed of progression are related to the egg burden ingested.
- Prognosis is poor if clinical signs are advanced at time of diagnosis or treatment. Fair to good if signs are mild and treated quickly.

PEARLS & CONSIDERATIONS

COMMENTS

- Consider larval migrans in an animal with acute onset of neurologic dysfunction consistent with encephalitis, especially if recent contact with raccoon environments is possible.
- *B. procyonis* does not usually cause any outwardly observable clinical signs in raccoons.

PREVENTION

- Prevention is the most effective therapy.
- Preventing exposure to raccoons and their feces is paramount. Covering sandboxes when unused and avoiding raccoon latrines are essential.

TECHNICIAN TIPS

- It is important for the technician to make clients aware that raccoons should never be considered to be family pets, indoors or outdoors. They should always be considered to be wild animals, and therefore unsuitable to be in or around human habitats, particularly those with small children.
- Technicians should always wash hands when handling feces of suspect animals.

CLIENT EDUCATION

- People and pets should avoid raccoon latrines (bases of trees, fallen logs or large rocks, forks of trees, and also attics, haylofts), which may contain raccoon feces with millions of infective eggs.
- Raccoons are attracted to sources of food. People should not attempt to feed them.
- Young children should be closely observed when outside to avoid ingestion of infective eggs.

Bartonellosis

BASIC INFORMATION

DEFINITION

An emerging vector-transmitted disease of humans and domestic and wild mammals caused by bacteria of the genus *Bartonella*. These organisms are fastidious, pleomorphic, aerobic, gram-negative rods. In vivo *Bartonella* spp. can cause intracellular infections and are known to infect erythrocytes and endothelial cells.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats: any age and either sex

GENETICS & BREED PREDISPOSITION

Dogs: herding dogs may be at increased risk, whereas toy breeds may have a decreased risk for infection (possibly owing to environment).

RISK FACTORS

Exposure to vectors such as sand flies, lice, keds, biting flies, fleas, and ticks. Immunocompromised individuals may also be at increased risk of infection.

CONTAGION & ZOONOSIS

Many *Bartonella* spp. or subspecies infect humans, including via cat scratches (e.g., cat scratch disease).

- *B. henselae:* cat scratch disease, endocarditis, bacillary angiomatosis
- *B. vinsonii* subsp. *berkhoffi:* endocarditis
- *B. vinsonii* subsp. *arupensis:* endocarditis
- *B. koehlerae:* endocarditis
- *B. alsatica:* endocarditis, granulomatous lymphadenitis
- *B. elizabethae:* endocarditis
- *B. washoensis:* myocarditis
- *B. quintana:* trench fever, endocarditis, bacillary angiomatosis
- *B. bacilliformis:* Carrion's disease, Oroya fever, verruca peruana

GEOGRAPHY AND SEASONALITY

Seroprevalence is increased in warm, humid climates, although *Bartonella* spp. are being identified worldwide. Seasonality of disease may be associated with vector exposure.

ASSOCIATED CONDITIONS & DISORDERS

Dogs: Endocarditis, myocarditis and arrhythmias, peliosis hepatis, granulomatous and lymphocytic hepatitis, granulomatous lymphadenitis, epistaxis, granulomatous rhinitis, polyarthritis. Evidence of *Bartonella* exposure has been identified in patients with the following disorders, but a cause/effect relationship has not been established: immune-mediated hemolytic anemia, cutaneous vasculitis, anterior uveitis and choroiditis, meningoencephalitis.

Cats: Endocarditis (rare), osteomyelitis (rare). The high prevalence of *Bartonella* infections in cats makes clinical associations with diseases difficult. A correlation with some conditions such as stomatitis and uveitis has been suggested but remains unproven.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Dogs: naturally infected with *B. vinsonii* subspecies *berkhoffi, B. henselae, B. clarridgeiae, B. elizabethae, B. washoensis, B. quintana, B. rochalimae*.

Cats: can become infected or serve as a reservoir for numerous *Bartonella* species such as *B. henselae, B. clarridgeiae, B. koehlerae, B. quintana*, and *B. bovis*. They can also become infected with *B. vinsonii* subspecies *berkhoffi*. Cats may be bacteremic for several weeks to more than a year.

HISTORY, CHIEF COMPLAINT

Dogs: Affected individuals may have one or more of the following presentations:

- Weakness, lethargy, anorexia
- Nasal discharge and/or epistaxis
- Lameness
- Other reported signs include vomiting, diarrhea, cough, and seizures
- Subclinical and nonspecific signs are also possible

Cats: Affected individuals may have one or more of the following presentations:

- Lethargy, anorexia
- Reproductive difficulty
- Subclinical infections are very common.

PHYSICAL EXAM FINDINGS

Dogs: Affected individuals may have one or more of the following findings:

- Fever
- Splenomegaly
- Lameness
- Evidence of vasculitis
- Heart murmur
- Lymphadenopathy
- Hepatomegaly
- Neurologic dysfunction
- Uveitis
- Nasal discharge/epistaxis
- Some affected dogs have no abnormal findings detected during physical examination.

Cats: Affected individuals may have one or more of the following findings:

- Many cats have no abnormal findings.
- Fever
- Lymphadenitis
- *Bartonella*-associated stomatitis, uveitis, and neurologic dysfunction have also been reported.
- Coinfection with feline immunodeficiency virus (FIV) may be associated with stomatitis and lymphadenopathy.

ETIOLOGY AND PATHOPHYSIOLOGY

Dogs: A tick vector (*Rhipicephalus sanguineus, Dermacentor* spp., or *Ixodes* spp.) is the likely source of *B. vinsonii* subspecies *berkhoffi* and possibly other *Bartonella* infections. *Bartonella* spp. infect endothelial cells and are periodically released into the circulation, resulting in a waxing and waning course of infection. Infections are associated with a cyclical CD8+ cell lymphopenia, modulation of adhesion molecules on CD4+ T cells, defective monocytic phagocytosis, and impaired B-cell antigen presentation within lymph nodes.

Cats: B. henselae is believed to be transmitted via the inoculation of infected flea *(Ctenocephalides felis)* feces rather than flea bites. Direct or vertical transmission from cat to cat has not been identified. The sources of other feline *Bartonella* infections are unknown.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Understanding the clinical picture is paramount. In dogs, serologic and PCR testing is insensitive. As reservoir hosts, healthy cats may be bacteremic. Diagnosis can only be made by matching a clinical picture with a battery of serologic and molecular testing combined with culture.

DIFFERENTIAL DIAGNOSIS

- Bacterial endocarditis
- Other vector-borne diseases, including *Rickettsia, Ehrlichia, Babesia*, and *Borrelia* infections
- Systemic fungal infections, including histoplasmosis, blastomycosis, and coccidioidomycosis
- Neoplasia
- Immune-mediated disease
- Feline leukemia virus and feline immunodeficiency virus (cats)
- Polyarthritis

INITIAL DATABASE

- CBC
  - *Dogs:* Thrombocytopenia, anemia, neutrophilic leukocytosis, monocytosis, and eosinophilia: most common with *B. vinsonii* subspecies *berkhoffi*.
  - *Cats:* transient anemia and persistent eosinophilia possible.
- Serum biochemistry panel
  - *Dogs:* Often unremarkable or indicative of end-organ damage. Increased liver enzymes and hypoalbuminemia: most common specific abnormality.
  - *Cats:* No consistent abnormalities
- Urinalysis: no consistent abnormalities
- Arthrocentesis
  - *Dogs:* neutrophilic, lymphocytic, or mononuclear polyarthritis.
- Cerebrospinal fluid: no consistent abnormalities (dogs)

ADVANCED OR CONFIRMATORY TESTING

Dogs:

- IFA for immunoglobulin G (IgG) antibodies widely used; confirm exposure; cross reactivity (particularly with *Rickettsia* species) or nonreactivity are pitfalls; titers ≥1:64 are considered seroreactive.
- PCR from blood and tissue samples: also effective; risk for false positive and false negative
- Routine microbiological techniques usually inadequate (30-60 days to note detectable growth).
- Liquid media preparation (*Bartonella*-alphaproteobacteria growth medium, [BAPGM]) followed by *Bartonella* identification via PCR has resulted in faster, more sensitive detection of *Bartonella* and is currently the standard recommended by the Vector Borne Disease Diagnostic Laboratory at North Carolina State University.

Cats:

- Definitive identification of *Bartonella* as a causative agent of disease is difficult, given the large number of chronically infected healthy cats. Pursuing diagnostic testing for bartonellosis is currently only recommended in cats presenting for unexplained or clinically consistent illness.
- Antibody testing is only recommended on adopting new cats, especially kittens that immunocompromised individuals wish to adopt. Seronegative antibody tests have a strong correlation with the lack of bacteremia.
- Serologic testing is otherwise of limited utility in cats.
- Both IFA and Western blot testing for anti-*B. henselae* antibodies are widely available.
- PCR can accurately identify *Bartonella* infections in cats but does not necessarily indicate that bartonellosis is the cause of disease.
- Definitive isolation via culture on agar plates is still considered the gold standard for confirming bacteremia.

TREATMENT

TREATMENT OVERVIEW

There is no current treatment consensus. Treatment should be considered in bacteremic individuals, particularly if clinical signs are apparent. A lack of resolution of disease after treatment should prompt clinicians to consider alternative diagnoses. Seroreactive patients (titers >1:64) should be treated only after first considering the *Bartonella* species identified and the antibody prevalence

within the population before instituting therapy.

ACUTE GENERAL TREATMENT

- By extrapolation from human medicine: prolonged use of tetracyclines, erythromycin, rifampin, azithromycin, doxycycline, or a combination of these antibiotics could be effective (but efficacy and safety unproven in dogs and cats).
- *Dogs:* Azithromycin has been used: small dogs, 10 mg/kg; medium dogs, 7 mg/kg; large dogs, 5 mg/kg. Give PO q 24 h × 7 days, then q 48 h × 5 weeks. Doxycycline (10 mg/kg PO q 24 h) or enrofloxacin could possibly be beneficial; unproven in clinical veterinary medicine. In principle, prolonged treatment for 4-6 weeks is recommended, but the high rate of incidentally discovered infections in otherwise normal animals indicates that treatment should be considered only if compatible clinical signs are present and other possible causes have been ruled out.
- In dogs suffering from a life threatening *Bartonella* infection such as endocarditis, the use of aminoglycosides in the initial phase of treatment may be warranted. This class of antibiotics should only be considered if renal function is stable and kidney perfusion is going to be supported with intravenous fluid therapy.
- *Cats:* Azithromycin has been used: 10 mg/kg PO q 24 h × 7 days, then q 48 h × 5 weeks. However, there is no antibiotic protocol that has been shown to clear cats of infection. At the present time, there are no definitive recommendations for treatment of cats.

CHRONIC TREATMENT

- There are no clear recommendations for chronic relapsing disease in dogs and cats. Alternative diagnoses should be strongly considered in patients that “fail” treatment.
- Dogs that remain bacteremic after an initial treatment course of azithromycin may respond to combination therapy of continued azithromycin with the addition of rifampin (5 mg/kg PO q 24 h) for an additional 6 weeks.
- Development of antibiotic resistance is a risk and should be considered before deciding to institute therapy.

POSSIBLE COMPLICATIONS

Recurrent/persistent infection

RECOMMENDED MONITORING

- Resolution of clinical signs after therapy
- Antibody titers can be followed during treatment (at 1 month) and post treatment (at 6 months) to follow antibody trends. A resolution of detectable antibodies is generally considered a positive outcome. Since persistently infected dogs may fail to have an increased antibody titer, serology in combination with BAPGM culture and PCR is recommended to ensure bacterial clearance. The significance of persistent antibody titers after treatment is unknown.

PROGNOSIS AND OUTCOME

Depending on the clinical presentation, the prognosis can vary widely.

PEARLS & CONSIDERATIONS

COMMENTS

- Coinfection with multiple *Bartonella* spp. and subtypes, as well as with other vector transmitted infections, is possible and should be considered.
- Defining bartonellosis as a clinical entity is still in its infancy.
- It remains unknown in many circumstances whether *Bartonella* is a primary pathogen, opportunistic invader, or incidental finding.
- It is well established that *B. vinsonii* subspecies *berkhoffi* is an important infective agent in dogs, but the clinical implications of *B. henselae* bacteremia in both dogs and cats remains to be elucidated.

PREVENTION

Consistent use of flea and tick preventatives is recommended.

CLIENT EDUCATION

- Monitor for recurrence of presenting signs.
- Since the current understanding of the pathology and treatment of bartonellosis is far from complete, clients should be cautioned that treatment may not eliminate clinical disease.
- Zoonosis is possible, and immunocompromised individuals should be particularly cautious when adopting new pets.

Barking, Excessive

BASIC INFORMATION

DEFINITION

Either a normal amount of barking that is deemed unacceptable to humans or a pathologic amount of barking as part of an anxiety or other behavioral disorder

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs of any age and either sex. Puppy vocalizations: more often associated with care-seeking behaviors. Adult vocalizations: more often associated with care-giving behaviors, social interaction, cohesion.

GENETICS & BREED PREDISPOSITION

None; body size may affect the pitch.

RISK FACTORS

In breeds that have been selected for specific vocalization behaviors, such vocalizations may become more annoying to the clients and/or their neighbors and still be normal.

CONTAGION & ZOONOSIS

Naïve/newly added puppies or adults may learn barking by observation.

GEOGRAPHY AND SEASONALITY

Dogs kept outdoors, especially if confined and not walked, are more likely to use barking to communicate with other dogs in the vicinity.

ASSOCIATED CONDITIONS & DISORDERS

Barking may be a nonspecific sign in any anxiety-based disorder, including separation anxiety, aggression, obsessive-compulsive disorder, and noise, storm, and social phobias.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Excessive barking is noted by client at home. In some cases, however, clients may not know about the barking unless neighbors complain.
- Barking can appear indiscriminate or as a response to external stimuli. For example, barking associated with an anxiety disorder may also be characterized by hypervigilant behavior (continuous monitoring of the social and physical environments). In these cases, dogs may scan at windows, along fences, and at doors. Clients may also describe the patient as unable to rest or settle down for any considerable amount of time.
- Important elements of the history that should be elicited include whether it occurs in the owner's real or virtual absence (e.g., associated with separation anxiety) and whether it ends with the owner's inadvertently rewarding the behavior, as with a treat to “silence” the dog (i.e., learned behavior).

PHYSICAL EXAM FINDINGS

- Generally unremarkable
- If barking represents a change in behavior, vocal cords and surrounding tissue may become edematous;
- A change in quality of bark may be associated with oropharyngeal lesions (laryngeal paralysis, mass, and so on).
- Rarely, a source of pain or other physical abnormality can be identified as a trigger for barking or whining.

ETIOLOGY AND PATHOPHYSIOLOGY

- Barking may be used for making contact with other individuals (including when reuniting after being apart), to signal alarm, to signal concern or distress, and to solicit information from other dogs (depending on pitch, tone, frequency, and pattern).
- Spectrographic analysis of canine barks has shown that their structure varies predictably according to context; barks can likely be divided into contextual subtypes and are thought to convey complex information to both canine and human listeners.
- Recent studies support the observation that people can distinguish between barks and can correctly identify the context in which a bark was given, even when the dogs are unfamiliar to the human listeners and the humans have never owned dogs.
- Barking can also be a sign of an anxiety disorder, including obsessive-compulsive disorder (see p. 1012 and 775).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is made based on history. The context in which the barking occurs will determine whether the behavior is normal but inconvenient, or indicative of a mood disorder.

DIFFERENTIAL DIAGNOSIS

- Normal barking, especially alarm barking by watch and guard dogs selected to alert by barking, reactive barking in terrier and hound breeds, and working barking in some herding breeds. These barking behaviors can be modified with humane training and are typically context-appropriate, although inconvenient or undesirable for some clients.
- Learned behavior: barking that elicits a response/reward from the client (e.g., the client lets the dog out when it barks, or pets it to “calm it down”)
- Separation anxiety
- Thunderstorm phobia
- Noise phobia
- Obsessive-compulsive disorder

Change in vocalization:

- Laryngeal paralysis, laryngeal masses, and thyroid neoplasia can result in changes in bark quality (see p. 1172), which must be differentiated from barking-induced hoarseness and from owner-induced trauma to the cervical region through leash, choke chain, or pinch collar “corrections.”

INITIAL DATABASE

Minimum database: complete blood count, serum chemistry profile, and urinalysis to rule out any underlying contraindications for psychotropic medication, if their use is warranted. Other laboratory or imaging procedures should address any other concurrent physical exam findings.

ADVANCED OR CONFIRMATORY TESTING

Learned behaviors are ruled out if they are extinguished by complete removal of the reward. Extinction is a gradual waning in occurrence of a behavior in the absence of a reward. The longer the behavior has been ongoing, reinforced, or rewarded, the longer eradication of the learned behavior will usually take.

TREATMENT

TREATMENT OVERVIEW

The goal is to treat the disorder or modify the behavior (if normal) based on accurate identification of cause.

ACUTE GENERAL TREATMENT

- If barking is within the normal behavioral repertoire, given triggers and context, the dog can be taught when and when not to bark by rewarding “good barking” and not “bad barking” and coupling both to words used only in those situations.
    - When the dog barks in a context that is unacceptable to the owner, redirecting the dog to an incompatible behavior (such as catching a toy with the mouth or playing tug) stops barking and rewards an alternative behavior. The offered alternative behavior must be of higher value to the dog.

- If barking is pathologic, the anxiety state that leads to the abnormal vocalization must be treated.
  - Identify triggers and limit exposure to them whenever possible.
  - When barking occurs, redirect the dog's attention and activity to alternative behaviors (play, relaxation) and reward for compliance; use a leash or head collar if necessary; reward all decreases in barking in response to triggers.
  - A neutral stimulus (noise, citronella spray burst) may be used for interrupting the behavior, followed by positive engagement in a different, non barking-related behavior that can be rewarded.
  - Treatment with psychotropic medication (amitriptyline, fluoxetine, or clomipramine) is only appropriate if barking is a manifestation of a behavioral disorder (e.g., anxiety); consider referral to a behaviorist.
  - Punishment, yelling, and use of shock collars should be avoided. Aversive responses serve only to increase, rather than decrease, arousal and may exacerbate the barking behavior.

CHRONIC TREATMENT

- Dogs should be taught to relax while making eye contact with the clients as a preferred default/substitute behavior when the dog encounters a situation about which it is anxious or unsure.
- Systematic desensitization can be used if the triggers can be identified and manipulated (e.g., Manners Minder [www.premier.com]).
- Alternate ways of alerting (sitting in a designated spot or in front of the clients) should be taught so the dog is still allowed to signal information.

DRUG INTERACTIONS

Amitriptyline, fluoxetine, and clomipramine should not be used with mono-amine oxidase inhibitors (e.g., some tick collars and flea, tick, and mite dips, and some medications used for treating cognitive dysfunction). Combinations of different classes of psychotropic medications at lowered doses are usually safe other than for the potential for sedation, in which case dosages can be adjusted downward.

- Fluoxetine, paroxetine, and possibly sertraline, if given with tramadol, which has a weak but similar effect, may increase the risk of serotonin syndrome. If coadministration is necessary, start both at reduced dosages, titrate each to effect, and monitor for serotonin syndrome.

POSSIBLE COMPLICATIONS

Clients who try to work with behavior modification too quickly (e.g., rewarding sitting even if the dog is distressed, instead of working to teach the dog to relax), with force, or inconsistently (in a multiperson household) may experience slow or no progress. Leash, choke chain, or pinch collar “corrections” can damage the esophagus, trachea, larynx, thyroid, and recurrent laryngeal nerves, altering quality of vocalization +/− swallowing and respiratory functions.

RECOMMENDED MONITORING

Frequent follow-up with the clients—at least weekly—is helpful. Medications should be monitored for cardiac, renal, or hepatic side effects (uncommon) or sedation (more common).

PROGNOSIS AND OUTCOME

- For species-appropriate but inconvenient barking, prognosis is very good to excellent when owners understand the diagnosis.
- For pathologic barking, prognosis ranges from fair to very good depending on severity and chronicity of disorder.
- Both are influenced by client compliance, environmental circumstances, and response to psychotropic medication in the case of pathologic barking.

PEARLS & CONSIDERATIONS

COMMENTS

Shock collars have no place in the treatment of any behavioral condition. They will always exacerbate anxiety, even if they may suppress some aspects of behavioral signs; the behavior of dogs trained with a shock collar changes even outside the context of the training environment (display of signs of anxiety). Assessment for the potential risk of physical abuse of pets, spouses, and children should be made in any case in which such techniques have been used or the clients wish to use them (see online chapter: Abuse).

TECHNICIAN TIP

Verbal reprimands serve no useful purpose. If a dog is barking excessively in the hospital, changing stimuli (e.g., moving the dog to an area with less/more activity or different animals in surroundings) is far better.

PREVENTION

Early intervention. When dogs are added to the home, education of the dog as to what level of barking is acceptable to the client should be instituted on the first episode of unwanted barking.

CLIENT EDUCATION

- Yelling at a dog to be quiet will increase arousal and is therefore counterproductive.
- Clients can teach their dog the level of alarm barking they will tolerate by calmly taking the barking dog away from the trigger (using a leash if necessary), asking for an alternative behavior (sitting while looking at the client in a relaxed fashion), and then rewarding the quiet response.
- Clients can also thank their dog for barking when the barking is appropriate (e.g., someone is in the driveway), and then reward them for stopping, which the dog will do when he or she looks at the client in response to the client's praise.

AUTHOR: SORAYA V. JUARBE-DIAZ

EDITOR: KAREN L. OVERALL

Barbiturates Toxicosis

BASIC INFORMATION

DEFINITION

Barbiturates are hypnotic, sedative, anticonvulsant drugs derived from barbituric acid (2,4,6-trioxohexahydropyrimidine). *Barbiturate toxicosis* refers to the onset of clinical signs caused by an acute, excessive exposure by ingestion or injection to this class of substances. The chronic effects of therapeutic phenobarbital use are discussed in greater detail elsewhere (see p. 871).

EPIDEMIOLOGY

SPECIES, AGE, SEX

All species, breeds, and both sexes of companion animals are susceptible; dogs are more likely to be involved.

GENETICS & BREED PREDISPOSITION

Greyhounds and other sight hounds: prolonged duration of action

RISK FACTORS

- Underlying liver disease (decreased metabolic capacity)
- Patients with kidney disease may accumulate parent drug (may require dose adjustment) or decompensate with barbiturate-induced hypotension.
- Cardiorespiratory disease (regarding arrhythmogenicity, potential hypoxemia)
- Puppies, kittens, starved animals (decreased metabolic capacity)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History/evidence of exposure
- Rapid onset of central nervous system (CNS), respiratory, and cardiovascular (CV) depression, ataxia, hyporeflexia

PHYSICAL EXAM FINDINGS

- Decreased response to stimuli, obtunded mentation/coma
- Slow, shallow respirations
- Hypotension: poor pulse quality, prolonged capillary refill time
- Bradycardia
- Hypothermia

ETIOLOGY AND PATHOPHYSIOLOGY

Source

- Based on their half-lives, barbiturates are divided into ultra-short-acting, short-acting, and long-acting drugs:
- Ultra-short-acting: methohexital (Brevital), thiamylal (Surital), thiopental (Pentothal)
- Short-acting: amobarbital, butabarbital (Buticaps, Butisol, Barbased, Butolan), butalbital (marketed in combinations with aspirin, acetaminophen, caffeine, codeine, and anticholinergic alkaloids), hexobarbital (Evipal), pentobarbital (Nembutal), secobarbital (Seconal)
- Long-acting: phenobarbital (Donnatal, in combination with anticholinergic alkaloids), primidone (metabolized to phenobarbital), metharbital (not available in United States)

Mechanism of Toxicosis

- Toxicosis occurs when animals accidentally eat large amounts of prescription medication (phenobarbital), from an overdose or accidental administration of injectable solution (pentobarbital, euthanasia solution), or from eating flesh of an animal that

had been euthanized with a barbiturate.
- Barbiturates cause nonselective depression of both presynaptic and postsynaptic excitability via several mechanisms (GABA and glutamate receptors, sodium channels).
- Toxicosis is characterized by hyporeflexia, ataxia, hypothermia, hypotension, coma, slow shallow respirations, and death.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Barbiturate toxicosis is suspected from a history of possible or confirmed exposure, and suspicion is heightened by the presence of one of more overt signs (ataxia, depression, coma, hypothermia, hyporeflexia, and CV and respiratory depression). In most instances, this is sufficient to proceed to treatment and monitoring. The diagnosis can be definitively confirmed by identification of drug in bodily fluids or tissues.

DIFFERENTIAL DIAGNOSIS

- Toxicologic: alpha-2 agonists (amitraz, detomidine, medetomidine, xylazine, etc.), benzodiazepines, cardiac drugs causing hypotension (calcium channel blockers, high doses of ACE inhibitors, and beta blockers), ethanol or other alcohols, essential oils, ethylene glycol, isoxazole mushrooms, ivermectin and other avermectins, marijuana, muscle relaxants (baclofen, methocarbamol, guaifenesin), opioids, phenothiazines, trazodone (tetracyclic antidepressant)
- Nontoxicologic disorders: hepatic encephalopathy, hypoglycemia, primary intracranial disorder (encephalitis, neoplasia, etc.), shock (septic, hypovolemic), trauma

INITIAL DATABASE

- CBC
- Serum chemistry profile
- Blood pressure
- Heart rate and rhythm
- Acid-base status: monitor for acidosis

ADVANCED OR CONFIRMATORY TESTING

Barbiturates can be analyzed antemortem in stomach contents/vomitus, urine, serum, or plasma. Postmortem, barbiturates can be detected in liver, heart, or kidney.

TREATMENT

TREATMENT OVERVIEW

Treatment is aimed at decontamination of the patient (emesis, activated charcoal) if no clinical signs are seen. Supportive care—intravenous fluids to maintain blood pressure, thermoregulation, oxygen supplementation/assisted ventilation, and enhanced elimination of barbiturates—is implemented according to anticipated (ingested dosage known to be large) or visible (marked clinical signs) severity of toxicosis.

ACUTE GENERAL TREATMENT

- Decontamination of patient:
  - Emesis (see p. 1364): Useful within 2 to 4 hours only in animals not showing clinical signs (3% hydrogen peroxide 2 mL/kg PO up to maximum of 45 mL/dose, may be repeated once if no results within 15 minutes)
  - Activated charcoal (1-2 g/kg PO once, with sorbitol or other cathartic); repeating charcoal (half of the original dose; omitting the cathartic) q 6 to 8 hours until improvement of depression will help decrease severity and duration of signs. May be ingested by patient if conscious and stable or given by stomach tube in a recumbent animal if the airway is protected (see p. 1281).
  - Gastric lavage: consider if large toxic doses have been ingested (see p. 1281) and the animal is not already comatose.
  - Enema (5 mL/lb, lukewarm water) may help promote gastrointestinal evacuation; administer 1-2 hours after administration of activated charcoal.
  - Peritoneal or hemodialysis may be considered if hemodynamic compromise occurs, but likely not any more helpful than fluids and repeated doses of activated charcoal.
  - Lipid emulsion therapy: Intravenous administration of lipid emulsion is a potential new method of enhanced elimination

of lipophilic barbiturates; efficacy/safety of this has not been established. Use when other measures fail. Risk of hyperlipidemia from therapy (see p. 127).

- Supportive care:
  - Intravenous administration of isotonic crystalloid fluids (warmed if animal is hypothermic), rate titrated to support blood pressure
  - If hypothermia: external warmth (see p. 587)
  - If hypoventilation or apnea:
    - Supplemental oxygen
    - Cuffed endotracheal tube to protect airway (always with mouth gag/speculum in place to avoid tube chewing). Monitoring of tube and airway care are essential (tube cleaning, deflating, and repositioning PRN; avoid pressure injury from overinflated cuff).
    - Positive-pressure ventilation (see p. 1362)

CHRONIC TREATMENT

(See p. 871)

DRUG INTERACTIONS

- Drugs that can increase barbiturate action: any CNS depressant, valproic acid, chloramphenicol
- Decreased efficacy of oral anticoagulants, chloramphenicol, corticosteroids, doxycycline, beta blockers, quinidine, theophylline, and metronidazole
- Rifampin may induce P450 enzymes and reduce the half-life of phenobarbital
- Increased risk of hypotension with concurrent furosemide

POSSIBLE COMPLICATIONS

- Aspiration pneumonia
- Renal impairment secondary to hypotension
- Cardiorespiratory arrest

RECOMMENDED MONITORING

- Oxygenation
- Blood pressure
- Body temperature
- Mentation

PROGNOSIS AND OUTCOME

With coma, prognosis is guarded to poor if intensive supportive care is not pursued.

PEARLS & CONSIDERATIONS

COMMENTS

- Induction of emesis at home should be considered only if no clinical signs are present, if an observed ingestion took place, or if the pet was found with the container.
- Boiling or freezing of meat does not destroy barbiturates. Barbiturate-contaminated meat is a high risk source of relay (secondary) toxicity for scavengers.
- Acute signs of toxicosis (depending on the dose and the type of agent involved) can last several days.
- Repeated doses of activated charcoal are useful even when overdose occurs from barbiturate injection, since plasma barbiturates diffuse into the acidic stomach environment. Be aware of possible hypernatremia from multiple doses of activated charcoal.

PREVENTION

- Keep medications out of animal's reach.
- Prevent unsupervised roaming of animals.
- To prevent secondary acute poisoning, animals euthanized with barbiturates should not be used for animal (or human)

consumption.
- Proper disposal of euthanized carcasses

CLIENT EDUCATION

- Control and monitor pet's environment.
- Do not feed barbiturate-contaminated meat/euthanized animal to pets.

Baclofen and Other Centrally Acting Muscle Relaxants Toxicosis

BASIC INFORMATION

DEFINITION

Syndrome developing following the ingestion of one of several centrally-acting skeletal muscle relaxants (SMR) and characterized mainly by central nervous system (CNS) depression.

SYNONYMS

Generic Name	Trade Name(s)
Baclofen	Lioresal, Kemstro
Carisoprodol	Soma
Chlorphenesin carbamate	Maolate
Chlorzoxazone	Parafon Forte
Cyclobenzaprine	Flexeril
Guaifenesin	Gecolate
Metaxalone	Skelaxin
Methocarbamol	Robaxin, Robaxin-V
Orphenadrine	Norflex
Tizanidine	Zanaflex

EPIDEMIOLOGY

SPECIES, AGE, SEX

All species susceptible; dogs more likely because of indiscriminate eating habits.

RISK FACTORS

- Availability of muscle relaxants in the animal's environment
- Many people taking skeletal muscle relaxants for diseases of spasticity (e.g., multiple sclerosis) take other medication as well, increasing the risk for accidental exposures to multiple drugs by pets (polypharmacy).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

History of exposure to muscle relaxants or presence of drugs in environment (see Table).

Drug	Chief Complaint
Baclofen	• Onset of signs within 15 minutes to 7 hours following ingestion • *Dogs:* vomiting, ataxia, hypersalivation, depression, vocalization, disorientation/agitation, recumbency, coma, seizure • *Cats:* vomiting, depression, ataxia, weakness, hypothermia, recumbency, coma, mydriasis, diarrhea

PHYSICAL EXAM FINDINGS

- Baclofen:
  - As above
  - Hypothermia (if recumbent), hyperthermia (if seizing)
  - Hypertension or hypotension
  - Tachycardia or bradycardia

    - Hypoventilation
    - Miosis (dogs) or mydriasis (cats)
    - Muscular hypotonia, weakness
- Cyclobenzaprine and orphenadrine
    - Depression or agitation, hyperesthesia (cats), vocalization
    - Miosis (dogs) or mydriasis (cats), nystagmus (occasional, dog and cat)
    - Muscle weakness, tremors, fasciculation
    - Panting
    - Tachycardia or bradycardia
    - Hyperthermia
- Tizanidine
    - Depression, weakness, ataxia
    - Hypotension, bradycardia
    - Pale mucous membranes, prolonged capillary refill time
    - Hypothermia
- Other SMR
    - Depression, somnolence, weakness
    - Hypoventilation, cyanosis
    - Tachycardia, hypotension
    - Hypothermia (if recumbent), hyperthermia (if seizuring)

ETIOLOGY AND PATHOPHYSIOLOGY

Source

- Most centrally acting SMRs are used for controlling spasticity in humans with neuromuscular disorders. May also be prescribed for relief of musculoskeletal pain.

Mechanism of Toxicosis

- Baclofen: Mimics gamma-aminobutyric acid (GABA) within the spinal cord, blocking excitatory responses to sensory input and causing flaccid paralysis. Baclofen-induced seizures may be due to interference with GABA release from presynaptic neurons, resulting in excessive postsynaptic nerve firing.
- Cyclobenzaprine: Structurally and functionally related to tricyclic antidepressants. Skeletal muscle relaxation may be related to sedative effects as well as inhibition of brainstem and spinal cord gamma and alpha motor neurons. In overdose situations, anticholinergic and antihistaminic effects become exaggerated.
- Tizanidine has a mechanism of action similar to that of xylazine and clonidine, in that it stimulates alpha-adrenoreceptors in the brainstem, causing decreased vascular resistance, heart rate, and blood pressure. At therapeutic levels, skeletal muscle effects predominate, but in overdose situations, pronounced cardiovascular effects occur.
- Orphenadrine has pronounced anticholinergic and antihistaminic effects.
- Chlorphenesin carbamate, guaifenesin, and methocarbamol may act by blocking nerve impulse transmission within the brainstem, spinal cord, and subcortical levels of the brain. Some of the skeletal muscle relaxant effect is due to sedation.
- Carisoprodol causes skeletal muscle relaxation via depression of postsynaptic spinal reflexes. Some of the skeletal muscle relaxant effect is due to sedation.
- Chlorzoxazone and metaxalone have no direct effect on skeletal muscles; muscle relaxant properties are likely due to sedative effects.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on history of exposure or presence of drugs in animal's environment along with appropriate clinical signs (ataxia, depression, coma, vocalization).

DIFFERENTIAL DIAGNOSIS

Toxicologic:

- Other CNS depressants: barbiturates, benzodiazepines, opioids, ivermectin, ethylene glycol, tick paralysis, botulinum toxin, ionophore ingestion (dogs).
- Other causes of seizures: amphetamines, ethylene glycol, metaldehyde, strychnine, methylxanthines, zinc phosphide, tricyclic

antidepressants, serotonergic drugs.

Nontoxicologic, Spontaneous:

- Spinal trauma
- Polyradiculoneuritis, tick paralysis
- Organic brain disease (neoplasia, inflammation, etc.)

INITIAL DATABASE

- CBC, serum biochemistry profile: minimal alterations expected from SMR (identify preexisting liver or kidney dysfunction that may interfere with drug elimination)
    - Orphenadrine overdose in humans has been associated with hypokalemia, hypoglycemia, liver enzyme elevations, and bleeding disorder.

ADVANCED OR CONFIRMATORY TESTING

- Baclofen, carisoprodol, chlorzoxazone, cyclobenzaprine, guaifenesin, and methocarbamol levels can be determined in urine and/or serum; presence will confirm exposure.
    - Turnaround time may limit usefulness in dealing with an acute intoxication.
    - Cyclobenzaprine will result in a positive serum or urine assay for amitriptyline.

TREATMENT

TREATMENT OVERVIEW

Treatment is aimed at early decontamination of the patient (emesis induction then administration of activated charcoal) when clinical signs are absent, and supportive care to address overt signs when they are present.

ACUTE GENERAL TREATMENT

- Stabilize patient
    - Maintain respiration: endotracheal intubation and positive-pressure mechanical ventilatory support may be required.
    - Control seizures: diazepam (0.5-1 mg/kg slow IV, to effect); propofol or isoflurane may be considered in cases refractory to diazepam (induce, keep anesthetized 5-10 minutes, then recover). Barbiturates should be considered a last resort, as their use may result in severe exacerbation of CNS depression; diazepam also generally useful for managing agitation.
- Manage cardiovascular abnormalities: most arrhythmias and blood pressure irregularities resolve during supportive care. Nitroprusside constant-rate IV infusion (1-2 mcg/kg/min [dogs] or 0.5 mcg/kg/min [cats], increased incrementally q 3-5 min until target BP is obtained) has been successfully used to manage baclofen-induced hypertension in dogs. Use of atropine to manage bradycardia is contraindicated in orphenadrine or cyclobenzaprine toxicosis, because it exacerbates anticholinergic effects.
- Supportive care:
    - Intravenous fluid therapy: as needed for hypotension/hypovolemia and to promote urine formation; may enhance excretion of baclofen
    - Atipamezole (50 mcg/kg, give ¼ to ⅓ of dose IV, remainder IM) or yohimbine (0.025 mg/kg slow IV) can be helpful to reverse hypotension from tizanidine.
    - Cyproheptadine (1.1 mg/kg PO or per rectum q 6 h) has been helpful in reducing vocalization in dogs.
    - Thermoregulation is essential, especially in comatose or recumbent animals.
- Decontamination of patient (no clinical signs):
    - Emesis (see p. 1364): Because of the potential for rapid onset of clinical signs, induction of emesis is best done under veterinary supervision (hydrogen peroxide 3%: 0.25-0.5 mL/kg PO once [dogs] or xylazine hydrochloride 0.44 mg/kg IM [cats]). Emesis is contraindicated in animals showing overt clinical signs.
    - Gastric lavage (see p. 1281): Consider for large ingestions (many tablets); protect airway with cuffed endotracheal tube.
    - Activated charcoal (see p. 1322): dose according to packaging label of product (e.g., 10 mL/kg of activated charcoal suspension PO made from 2 g activated charcoal suspended in 10 mL kg tap-water). Repeated doses of activated charcoal q 8 h × 24 h and a cathartic, given every 3rd charcoal dose, are recommended for cyclobenzaprine and orphenadrine; single doses are recommended for all other SMRs.

CHRONIC TREATMENT

Ventilatory support may be required for several days (particularly with baclofen)

NUTRITION/DIET

For animals requiring long-term ventilatory support, parenteral nutrition may be considered (see p. 1322).

DRUG INTERACTIONS

Use caution when administering drugs to sedated agitated animals.

RECOMMENDED MONITORING

Respiratory rate and rhythm, heart rate, blood pressure, body temperature, blood gases, electrolyte status, hydration status, fluid ins/outs

PROGNOSIS AND OUTCOME

- Signs can persist for hours to several days, depending on the SMR involved and the dose ingested.
- Most animals with mild to moderate signs and receiving prompt and appropriate veterinary attention have an excellent prognosis.
- Animals exhibiting respiratory depression requiring ventilatory support have a more guarded prognosis, depending on the availability of mechanical ventilators.
- Seizuring or comatose animals have a more guarded prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- Because the primary effect of these drugs is CNS depression, when treating animals showing paradoxical excitation, it is important to use the lowest sedative dose necessary to relieve the stimulation in order to avoid oversedation once the agitation has resolved.
- Baclofen, cyclobenzaprine, and tizanidine have narrow margins of safety, and significant (potentially life-threatening) signs can be seen at low doses.
    - Baclofen: doses >1 mg/kg can cause signs; doses 8-16 mg/kg can be fatal to dogs.
    - Cyclobenzaprine: doses as low as 0.07 mg/kg have resulted in clinical signs in dogs.
    - Tizanidine: doses as low as 0.05 mg/kg have been associated with clinical signs in dogs, with hypotension occurring at doses as low as 0.08 mg/kg.
- Methocarbamol, guaifenesin, and chlorphenesin carbamate have fairly wide margins of safety, and overdoses rarely cause life-threatening problems.
- Anecdotally, intravenous lipid solutions have hastened recovery of dogs with baclofen toxicosis. This treatment modality is new and considered experimental.
    - Use 20% intravenous lipid solution (normally used for parenteral nutrition, readily available from pharmacies, human hospitals)
    - Bolus 1.5 mL/kg, then constant rate infusion of 0.25 mL/kg/min for 30-60 minutes. Can repeat in 6-8 h if serum is not lipemic and animal is still showing clinical signs.
    - More information on this treatment method may be found at www.lipidrescue.org.

TECHNICIAN TIP

Be prepared for paradoxical excitement when a sedative is given to patients with this type of intoxication: be sure doors are closed to prevent escape, have the patient on a surface clear of sharp or breakable objects, and take precautions to avoid being injured.

PREVENTION

Keep medications out of reach of pets.

CLIENT EDUCATION

- When taking medication, do so in a room away from pets with the door closed to prevent pets from ingesting an accidentally dropped tablet.
- Never administer human medications to pets without first consulting a veterinarian.

Back Pain

BASIC INFORMATION

DEFINITION

Pain localized to the thoracolumbar spinal column

SYNONYMS

Spinal hyperesthesia, spinal hyperpathia

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dependent on the underlying cause
- Dogs: middle-aged (type I intervertebral disk disease), older adults (type II intervertebral disk disease, neoplasia)
- Cats: older adults (neoplasia), males more commonly represented (aortic thromboembolism)

GENETICS & BREED PREDISPOSITION

Dogs: chondrodystrophic breeds (type I intervertebral disk disease)

RISK FACTORS

Cats: thromboembolism associated with cardiomyopathy

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Vocalization, reluctance to movement or activity, pain elicited if patient touched or moved

PHYSICAL EXAM FINDINGS

- Hunched posture (kyphosis), pain elicited on epaxial palpation; ataxia, paresis, or paralysis; heat or swelling in epaxial region; splinting and pain on abdominal palpation
- Fever, if back pain is associated with infection (e.g., diskospondylitis)
- Heart murmur, diminished femoral pulses, cyanosis of toenails if back pain is associated with aortic thromboembolism

ETIOLOGY AND PATHOPHYSIOLOGY

- Neurogenic: compression, inflammation, or traumatic disruption of spinal cord, spinal roots, spinal nerves, dorsal root ganglia, or meninges
- Vertebral column: trauma, inflammation, or lysis of vertebral bone, intervertebral disks, or articular facets
- Epaxial muscle: inflammation, abscessation, ischemia, or trauma

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Back pain often presents nonspecific physical signs (or absence of any observable deficits) and gentle, thorough physical manipulations during the physical examination are used for eliciting signs of back pain. Diagnostic imaging and specific techniques then help to elucidate the source of the pain.

DIFFERENTIAL DIAGNOSIS

- Intervertebral disk disease (IVDD)

- Vertebral fracture or luxation
- Meningitis or meningomyelitis (granulomatous)
- Polyarthritis (immune-mediated or infectious)
- Diskospondylitis
- Vertebral osteomyelitis
- Spondylosis deformans/degenerative joint disease of articular facets
- Neoplasia (primary or metastatic)
- Polymyopathy (traumatic or inflammatory myositis)
- Fibrocartilaginous embolism (FCE; acute but transient pain, resolving within hours)
- Pain not localized to the spinal column: aortic thromboembolism, abdominal pain

INITIAL DATABASE

- Neurologic examination (see p. 1311)
- CBC, serum biochemistry, urinalysis: often unremarkable unless systemic disease or infection present
- Radiographs: bone lysis or proliferation (neoplasia, osteomyelitis), vertebral fracture or luxation (trauma), intervertebral disk mineralization, disk space narrowing, wedging or displacement (IVDD), vertebral endplate lysis or proliferation (diskospondylitis), articular facet sclerosis and malformation, spondylosis

ADVANCED OR CONFIRMATORY TESTING

Selection based on history, clinical signs, and results of initial database:

- Cerebrospinal fluid tap: cytologic evaluation, culture, serologic testing for immunoglobulin A (IgA) or infectious agents
- Myelogram: identify and discern between extradural compression (IVDD), intradural/extramedullary lesion (meningioma), or intramedullary lesion (other neoplasia or cord swelling [e.g., due to FCE])
- Urine culture (diskospondylitis)
- Blood culture and sensitivity (discospondylitis, osteomyelitis, bacterial meningitis)
- Needle aspirate of intervertebral disk (diskospondylitis)
- Serology: *Brucella canis* (discospondylitis), rickettsial diseases (polyarthritis, meningitis)
- Arthrocentesis: cytology (polyarthritis), culture (septic polyarthritis or meningitis)
- Advanced imaging: CT or MRI if lesion is suspected but not identified on myelogram
- Biopsy of vertebral bone (neoplasia, osteomyelitis)

TREATMENT

TREATMENT OVERVIEW

- Elimination of infectious or noninfectious paraspinal inflammatory causes
- Elimination of any compressive lesion on spinal cord or nerve roots
- Stabilization of vertebral column

ACUTE GENERAL TREATMENT

Address the underlying cause.

CHRONIC TREATMENT

- Degenerative joint disease may require persistent or recurrent nonsteroidal antiinflammatory drug (NSAID) administration.
- Chronic intervertebral disk disease or immune-mediated disease may require intermittent or persistent corticosteroid treatment.
- Antibiotic therapy for diskospondylitis (see p. 312) or vertebral osteomyelitis continued for 6 weeks beyond resolution of clinical signs.

DRUG INTERACTIONS

Corticosteroids and NSAIDs must not be administered concurrently, owing to the risk of severe gastrointestinal ulceration.

POSSIBLE COMPLICATIONS

- Worsening or recurrence of signs
- Progression of spinal cord lesions

- Myelomalacia
- Valvular endocarditis, for infectious conditions

RECOMMENDED MONITORING

- Repeat physical and neurologic examination within 12 to 24 hours of treatment
- Follow-up examination and radiographs as needed

PROGNOSIS AND OUTCOME

Variable, depending on underlying cause

PEARLS & CONSIDERATIONS

COMMENTS

- Localization of pain requires thorough physical and neurologic examination.
- Acute back pain with neurologic deficits may represent a surgical emergency and should be evaluated immediately.

CLIENT EDUCATION

- Owner should monitor for recurrence of signs.
- Acute worsening of signs warrants emergency evaluation and treatment.

EDITOR: ETIENNE CÔTÉ

Babesiosis

BASIC INFORMATION

DEFINITION

Canine babesiosis is a tickborne disease caused by a hemoprotozoan parasite that infects red blood cells of dogs causing hemolytic anemia and thrombocytopenia. Two primary species have been identified: *Babesia canis* (large *Babesia*) and *Babesia gibsoni* (small *Babesia*).

SYNONYMS

- Babesiosis: piroplasmosis
- *Babesia annae: B. microti*-like parasite
- *Babesia gibsoni: B. gibsoni* (Asian genotype)
- *Babesia conradae:* Referred to in some literature as *B. gibsoni* (USA genotype)

EPIDEMIOLOGY

GENETICS & BREED PREDISPOSITION

- American pit bull terriers (APBT) and Tosa Inus at risk for *B. gibsoni*
- Greyhounds at risk for *B. canis vogeli*

RISK FACTORS

- Dog fights (particularly bites by an APBT)
- Tick infestation
- Blood transfusion
- Shared needles or surgical instruments
- Vertical transmission in affected breeds

CONTAGION & ZOONOSIS

- Transmission is through blood contamination or arthropod infestation (*Rhipicephalus, Haemaphysalis*, or *Dermacentor* spp.).
- Canine babesiosis is not a documented zoonotic disease; *B. microti* is a small *Babesia* infecting human red blood cells. Canine species of *Babesia* causing infections in humans have not been well documented.

GEOGRAPHY AND SEASONALITY

- Since babesiosis can be either acute or chronic, it can be diagnosed at any time of year.
- Small babesias:
  - *B. gibsoni* was once limited to Asia but now has a worldwide distribution.
  - *B. annae:* Spain
  - *B. conradae:* southern California
- Large babesias:
  - B. canis vogeli: worldwide
  - B. canis canis: Europe
  - B. canis rossi: southern Africa

One of the novel large *Babesia* sp. has been diagnosed in the United States and the other in the United Kingdom.

ASSOCIATED CONDITIONS & DISORDERS:

- Some patients with babesiosis have been concurrently diagnosed with other tickborne diseases.
- The novel large *Babesia* sp. identified in United States has been primarily diagnosed in dogs that have previously undergone splenectomy or are undergoing chemotherapy.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Babesiosis can cause severe, life-threatening disease in some dogs; others show few or no outward clinical signs. *B. annae* is commonly associated with azotemia and proteinuria.

HISTORY, CHIEF COMPLAINT

Owners may observe weakness, lethargy, anorexia, pallor, icterus, or discolored urine (bilirubinuria or hemoglobinuria). Other historic findings may include tick exposure, recent blood transfusion, or recent dog fight (especially with an APBT).

PHYSICAL EXAM FINDINGS

Pallor and splenomegaly, +/− lymphadenopathy, fever or icterus.

ETIOLOGY AND PATHOPHYSIOLOGY

- Sporozoites in tick salivary glands transmitted to dog during feeding (requires 2-3 days)
- Sporozoites enter red blood cells (RBCs), where they become merozoites and undergo asexual reproduction.
- Intravascular and extravascular hemolysis occur.
- Secondary immune-mediated destruction of RBCs and platelets may occur.
- Azotemia and proteinuria are presumed to be secondary to glomerulonephritis and are most commonly seen with *B. annae* infections.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

Most dogs with babesiosis have one or more of the following abnormalities: thrombocytopenia, anemia, hyperglobu linemia or splenomegaly. PCR assays have become the primary means of accurately diagnosing *Babesia* infections.

DIFFERENTIAL DIAGNOSIS

- Immune-mediated hemolytic anemia
- Immune-mediated thrombocytopenia
- Zinc toxicity
- Splenic torsion
- Ehrlichiosis
- Leptospirosis
- Dirofilariasis with caval syndrome
- Neoplasia: lymphoma or hemangiosarcoma

INITIAL DATABASE

One or more of the following may be identified in dogs with babesiosis:

- Regenerative anemia: It is important to note that not all dogs with *Babesia* infections have anemia.
- Thrombocytopenia: This is the most common hematologic abnormality in dogs with babesiosis; platelet counts can be as low as <5000 platelets/µL.
- Blood smear: identification of *Babesia* organisms
    - Small babesiosis: 1-3 mcm signet ring forms.
    - Large babesiosis: 3-6 mcm single or paired tear drop forms, but other more ameboid forms can predominate.
- Serum bilirubin: may be increased.
- Hyperglobulinemia: a polyclonal gammopathy is frequently detected.
- Urinalysis: +/− bilirubinuria or hemoglobinuria
- Coombs' test: positive in up to 85% of cases

ADVANCED OR CONFIRMATORY TESTING

- PCR test: only way to determine species or subspecies. More sensitive than blood smear

- False-positive, false-negative results recognized
- Tests vary between laboratories.
- Not always able to detect all species (check with laboratory about sensitivity and specificity)
- IFA test >1 : 64 is considered positive.
    - Cannot differentiate species
    - False-negative results can occur with acute or peracute disease or severe immunosuppression.

TREATMENT

TREATMENT OVERVIEW

It may not be possible to completely eradicate the parasite in all cases, but clinical signs usually improve with supportive care and antiparasitic therapy. The treatment of choice is dependent upon which *Babesia* species is identified. Currently, most data are available for treatment of *B. canis* and *B. gibsoni*.

ACUTE GENERAL TREATMENT

Supportive treatment may require blood transfusion or hemoglobin polymer (e.g., Oxyglobin) for animals that are anemic:

- IV fluids may be required in animals that are febrile and dehydrated.
- Imidocarb diproprionate (6.6 mg/kg IM once, repeat in 7-14 days). Pretreatment with atropine (0.04 mg/kg IM or SQ 30 minutes before imidocarb injection) may reduce cholinergic side effects. This drug appears to reduce morbidity and mortality for nearly all *Babesia* spp. but is not effective for the clearance of *B. gibsoni*. It is the treatment of choice for *B. canis vogeli*.
- Atovaquone (13.5 mg/kg PO q 8 h with fatty meal for 10 days) plus azithromycin (10 mg/kg PO q 24 h for 10 days) is the treatment of choice for *B. gibsoni*. Results in elimination or reduction of the parasite below the limit of detection of PCR testing in ≈82% of cases. Resistance to atovaquone has been identified.
- Clindamycin (25 mg/kg PO BID for 14 days) has been associated with clinical improvement but not clearance of *B. gibsoni*.
- A combination of clindamycin (25 mg/kg PO BID), metronidazole (15 mg/kg PO BID), and doxycycline (5 mg/kg PO BID) had been associated with elimination or reduction of the parasite below the limit of detection of PCR testing. Unfortunately, a well-defined treatment course has not been established, with treatment times ranging from 24-92 days.
- Concurrent immune suppression should be avoided whenever possible, as it may reduce the ability to clear the infection with antiprotozoal drugs.

CHRONIC TREATMENT

- Vector control: topical acaricide (e.g., fipronil) plus flea/tick collar
- Dogs with positive *Babesia* titers or PCR should not be used as blood donors.

POSSIBLE COMPLICATIONS

Prolonged immunosuppressive therapy before specific antibabesial treatment can worsen outcome and should not be used in sick, hospitalized dogs.

RECOMMENDED MONITORING

- Monitor hematocrit and platelet count daily until improvement is seen and then every 1-3 weeks until anemia and thrombocytopenia resolve.
- PCR should be negative 60 and 90 days post treatment if the parasite has been successfully eradicated.

PROGNOSIS AND OUTCOME

- Good prognosis with early diagnosis and treatment
- Animals may remain subclinically infected for life
- Severely anemic animals may die without supportive care such as blood transfusions or hemoglobin based oxygen carrying solutions.

PEARLS & CONSIDERATIONS

COMMENTS

B. gibsoni is an emerging infectious disease in North America. New species are being identified through molecular techniques.

TECHNICIAN TIP

The characteristic features of *Babesia* make them identifiable on a blood smear with little practice.

PREVENTION

- Effective tick control, particularly topical acaricides, are likely to reduce the risk of infection.
- Screening blood donors for *Babesia* infections will reduce the chances of iatrogenic infections.

CLIENT EDUCATION

- In endemic areas, use both a topical acaricide and a repellent tick collar. Avoid blood transmission (shared needles, vaccines, etc.).
- *Babesia* spp. can be transmitted vertically and should be considered in puppies with weakness and pallor.

Cytauxzoonosis

BASIC INFORMATION

DEFINITION

Cytauxzoon felis is a protozoal organism transmitted by ticks that causes potentially fatal illness in domestic cats.

EPIDEMIOLOGY

SPECIES, AGE, SEX

C. felis infects only domestic and wild cats. There is no age or sex predilection.

RISK FACTORS

Outdoor cats with tick exposure in endemic areas are at risk. Specific risk factors include urban-edge habitats and close proximity to wooded or unmanaged areas. It is common for multiple cats from the same household to become infected.

CONTAGION & ZOONOSIS

Extensive investigation of *C. felis* has shown that many nonfelidae species cannot be infected. There is no evidence of human infections.

GEOGRAPHY AND SEASONALITY

C. felis infection has been reported in the south central and southeastern United States, but its range appears to be expanding north and east, corresponding to changes in distribution of the tick, *Amblyomma americanum*. Nearly all cases occur between April and September. The majority of cases are diagnosed between March and June, with a second wave of infections occurring in August and September.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Historically, almost all reported cases of *C. felis* in domestic cats were fatal, but many cats are now surviving infection. Some cats are even incidentally diagnosed with *C. felis* erythroparasitemia.

HISTORY, CHIEF COMPLAINT

Clinical signs are acute and nonspecific and include anorexia, lethargy, dyspnea, icterus, and pallor.

PHYSICAL EXAM FINDINGS

Affected cats are usually febrile (103°F-107°F [39.4°C-41.7°C]), but hypothermia is seen in moribund cats. Abdominal palpation reveals splenomegaly and hepatomegaly. Tachypnea, tachycardia, altered mentation, vocalization, seizures, and coma can be seen in the later stages of disease. Most cases exhibit a rapid course, with death occurring within 1 week of onset of signs if left untreated.

ETIOLOGY AND PATHOPHYSIOLOGY

- The natural host is thought to be the eastern bobcat *(Lynx rufus rufus),* which develops a mild or subclinical infection compared to the rapidly progressive and usually fatal disease seen in domestic cats.
- The organism is transmitted by the *Dermacentor variabilis* or *Amblyomma americanum* ticks during feeding.
- Sporozoites released from the tick salivary glands infect macrophages.
- Asexual reproduction occurs within the host macrophage during the schizont phase, causing infected cells to grow to enormous size (=250 m in diameter). These schizont-laden macrophages then occlude arterioles, venules, and capillaries, causing organ failure and clinical illness.
- When the schizonts rupture, merozoites are released to infect erythrocytes. Merozoites are minimally pathogenic.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Early diagnosis through aspiration of lymph nodes, spleen, or bone marrow is indicated when a clinical suspicion exists (via history and physical exam); earlier diagnosis is associated with better response to treatment. Identification of the organism on a blood smear is a relatively late finding.

DIFFERENTIAL DIAGNOSIS

- Toxoplasmosis
- Cholangitis/cholangiohepatitis
- Pancreatitis
- Hemotropic *Mycoplasma* infection
- Feline infectious peritonitis
- Immune-mediated hemolytic anemia
- Feline leukemia virus infection
- Feline immunodeficiency virus

INITIAL DATABASE

- Blood smear: pleomorphic (round, oval, anaplasmoid, bipolar [binucleated], or rod-shaped) organism; the round and oval piroplasm forms are most common (0.8-2.2 m in diameter). Infected macrophages may also be seen on the feathered edge and may be mistaken for platelet clumps at low power.
- If cytauxzoonosis is suspected but not immediately detected by examination of a blood smear, tissue aspirates of lymph node, liver, and spleen are indicated to identify infected macrophages. These cells range in size from 15-250 m in diameter, typically have a large distinct nucleolus, and their cytoplasm is filled with numerous small (1-2 m) basophilic particles (i.e., developing merozoites).
- CBC: pancytopenia (normocytic, normochromic, nonregenerative anemia, leukopenia, and thrombocytopenia) is the classic finding, but mono- or bicytopenias may occur.
- Serum biochemistry profile: elevated liver enzymes (frequently lower than expected for the degree of hyperbilirubinemia), hyperbilirubinemia (mild to moderate), and hyperglycemia are the most common findings.
- Abdominal radiographs or ultrasound reveal splenomegaly and hepatomegaly but do not contribute directly to the diagnosis.
- Urinalysis reveals bilirubinuria.
- Coagulation testing may be consistent with disseminated intravascular coagulation (DIC).

ADVANCED OR CONFIRMATORY TESTING

- PCR testing can be used for confirming infection.
- Necropsy of cats presented with consistent signs should be performed. This is usually the first method of identification of cytauxzoonosis in regions that were previously considered non-endemic.

TREATMENT

TREATMENT OVERVIEW

New treatments with antiprotozoal therapy have proven effective along with supportive care in this disease that was previously considered universally fatal. Since the disease progression can be very rapid, specific treatment should be instituted immediately in cases suspected of having cytauxzoonosis.

ACUTE GENERAL TREATMENT

- Crystalloid fluids: to correct dehydration, restore intravascular volume, and maintain perfusion
- In anemic animals, oxygen delivery to tissues must be restored with a transfusion of whole blood (20 mL/kg IV administered over 4 hours), packed red blood cells (20 mL/kg IV administered over 4 hours), or polymerized hemoglobin (e.g., Oxyglobin; 5 mL/kg IV administered over 4 hours).
- Some clinicians treat/prevent DIC with heparin (100-300 IU/kg SQ q 8 h or 18 IU/kg/h IV CRI [constant rate infusion]).
- Animals with respiratory compromise may require supplemental oxygen.
- Minimal stress and handling is recommended.
- Antiprotozoal therapy should be started immediately.

- Atovaquone (15 mg/kg PO q 8 h administered with a fatty meal for 10 days) and azithromycin (10 mg/kg PO q 24 h for 10 days) associated with survival rates of approximately 65%.
- Imidocarb dipropionate (Imizol [Schering-Plough, Kenilworth, N.J.]): 2-5 mg/kg IM repeated in 7-14 days after pretreatment with atropine (0.04 mg/kg SQ) to minimize cholinergic side effects. Survival estimates with imidocarb range from 0%-50%. In the author's hospital, survival with imidocarb therapy is approximately 25%.
- Diminazene aceturate (Ganaseg [ER Squibb, Princeton, NJ]) 2 mg/kg IM repeated in 7 days. A small case series showed this to be a promising treatment, but it is not FDA approved or currently available in the United States.
- Doxycycline (5 mg/kg PO q 12-24 h × 14 days) is recommended as treatment for coinfection with other tick-borne pathogens.
- Antiinflammatory medications may be helpful in reducing fever: meloxicam (only given after rehydration in nonazotemic patients), 0.1 mg/kg PO q 24 h; or prednisolone, 1 mg/kg PO q 24 h

CHRONIC TREATMENT

- Some cats that survive infection remain chronically infected but do not exhibit clinical signs of illness.
- No treatments have been demonstrated to consistently clear the carrier phase.

PROGNOSIS AND OUTCOME

- With early diagnosis and treatment (atovaquone and azithromycin), survival rates are approximately 65%.
- It is important to note that even with early diagnosis and treatment, some cats that survive infection develop severe clinical disease that lasts for 5–7 days.
- Progressive hemolysis (presumably associated with antibody production against parasite antigens) is frequently detected during the second or third week of treatment and may require treatment with blood products, but immune suppression has not been required in the author's hospital.
- All clinical, hematologic, and biochemical abnormalities resolve within 4–6 weeks.
- Chronic infection does not appear to be associated with decreased lifespan.
- Recurrent severe infections appear extremely rare in surviving animals, suggesting some degree of protective immunity.
- Without treatment, death usually occurs within 1–3 weeks after infection or within 1 week of developing clinical signs.
- Hypothermia, icterus, severe anemia, and collapse warrant a poor prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

Clinical suspicion and early diagnosis through tissue aspiration and cytology have resulted in successful response to treatment.

PREVENTION

In endemic areas, an effective acaricide and tick repellent should be used to prevent exposure to ticks. Since infections have occurred despite acaricide treatment, keeping cats indoors is also recommended.

CLIENT EDUCATION

Outdoor cats in areas where bobcats roam are at risk for this deadly disease.

1ST EDITION AUTHOR: DOUGLASS K. MACINTIRE

Cystitis, Fungal/Algal

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Rare infection of the urinary tract caused by fungal or algal organisms (most often *Candida* sp.). Infections can be primary (confined to the urinary tract) or secondary (systemic or disseminated infection with secondary shedding of organisms into the urine).

SYNONYMS

Candiduria, fungal urinary tract infection (UTI), funguria

EPIDEMIOLOGY

SPECIES, AGE, SEX

Reported in dogs and cats. Secondary algal infections only reported in dogs. No age predilection, but associated risk factors more common in older animals. Females possibly at increased risk.

RISK FACTORS

Diabetes mellitus, urinary tract stoma formation (e.g., perineal urethrostomy), urinary tract catheterization, concurrent lower urinary tract disease (e.g., neoplasia, recurrent bacterial cystitis), prolonged antibiotic administration, immunosuppressive drug administration (e.g., glucocorticoids, chemotherapeutics)

CONTAGION & ZOONOSIS

No zoonotic risk because organisms are ubiquitous in the environment.

ASSOCIATED CONDITIONS & DISORDERS

Fungal pyelonephritis, fungal septicemia, disseminated/systemic fungal or algal infection

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Primary fungal cystitis: infection confined to bladder/lower urinary tract
- Fungal pyelonephritis: infection of renal pelvis and parenchyma, usually due to ascending lower UTI
- Secondary fungal/algal cystitis: urinary shedding of fungal or algal organisms due to systemic/disseminated infection with renal involvement

HISTORY, CHIEF COMPLAINT

- Primary fungal cystitis may be asymptomatic.
- Lower urinary tract disease signs (dysuria, pollakiuria, stranguria) possible.
- Clinical signs associated with renal failure (see pp. 205 and 207) may accompany fungal pyelonephritis or secondary fungal cystitis.
- Signs of other organ system disease may occur with secondary fungal/algal cystitis.

PHYSICAL EXAM FINDINGS

- Primary fungal cystitis or pyelonephritis: usually unremarkable
- Secondary fungal/algal cystitis: depends on organism and distribution (see Aspergillosis, p. 96; Blastomycosis, p. 138; Cryptococcosis, p. 266; Protothecosis, p. 926)

ETIOLOGY AND PATHOPHYSIOLOGY

- Primary fungal cystitis: disruption of urinary tract defense mechanisms allows ascending infection from genital mucosa and environment.
  - Pyelonephritis results when organisms ascend from the bladder to renal pelvis.
  - Reported primary fungal infections include those caused by *Aspergillus* spp., *Candida* spp., *Cryptococcus neoformans*, *Trichosporon* sp., *Rhodotorula* sp.
- Secondary fungal/algal cystitis: disseminated/systemic infection that includes colonization of the kidneys results in urinary shedding of organisms.
  - Fungal organisms isolated from urine in dogs or cats with disseminated infections: *Acremonium* sp., *Aspergillus* spp., *Blastomyces dermatitidis*, *Candida* spp., *Cryptococcus neoformans*, *Paecilomyces* sp., *Penicillium* sp., *Phialemonium obovatum*, *Trichosporon* sp.
  - Algal organisms isolated from urine in dogs with disseminated infections: *Prototheca wickerhamii*, *Prototheca zopfii*.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Identification of fungal organisms on urine sediment examination allows presumptive diagnosis of fungal cystitis, but definitive diagnosis and identification of the infective organism requires fungal urine culture. Identification of the infecting species is required for determining whether primary or secondary infection is more likely, and for determining the most effective antifungal therapy.

DIFFERENTIAL DIAGNOSIS

Differentials for fungal elements in urine: contamination from genital mucosa, contamination from skin, primary or secondary fungal infection

INITIAL DATABASE

- CBC and chemistry profile:
  - Primary fungal cystitis: unremarkable
  - Fungal pyelonephritis: +/- azotemia
  - Disseminated infection: variable; depends on extent and location of infection
- Urinalysis:
  - Organisms often seen on urine sediment examination or urine cystospin preparations
  - Often lack pyuria, hematuria despite active infection

ADVANCED OR CONFIRMATORY TESTING

- Urine culture:
  - Identification of fungal or algal organisms in urine sediment should be followed by urine culture (cystocentesis).
  - Most fungal and algal organisms grow readily on standard culture media.
    - *Candida* sp. (most commonly isolated agent) grows on blood agar within 2-3 days.
    - Other fungal organisms may require culture for longer periods.
  - Speciation requires culture on specific media (e.g., Sabouraud's).
- Antifungal drug susceptibility testing
  - Recommended for *Candida albicans* infections that do not respond to standard therapy
  - Recommended for all non –*C. albicans* fungal infections (including non –*C. albicans* candidal infections) because of increased likelihood of resistance
  - Recommended for *Prototheca zopfii* infections, because reported cases have had widely varying susceptibility patterns

TREATMENT

TREATMENT OVERVIEW

- Successful resolution of primary fungal cystitis requires identification and elimination or control of any predisposing conditions. Fluconazole is the recommend first-line antifungal drug, but many infections recur.

ACUTE GENERAL TREATMENT

- Primary *C. albicans* infections: fluconazole 5-10 mg/kg PO q 12 h for 4-6 weeks

- Primary non –*C. albicans* candidal infections, other fungal agents, and secondary/systemic fungal and algal infections: therapy based on susceptibility testing
    - Primary infections: start fluconazole while waiting for susceptibility results.
    - Secondary/systemic infections: start itraconazole while waiting for susceptibility.

CHRONIC TREATMENT

- Primary fungal infections should always be treated as "complicated" UTIs:
    - To assess efficacy, reculture urine 1-2 weeks after starting therapy.
    - Continue treatment until two successive negative urine cultures 2 weeks apart.
- If infection does not respond or recurs, repeat susceptibility testing.
- Intravesicular clotrimazole infusion may be attempted:
    - Comparative trials are lacking.
    - Can be performed in dogs (easy) or cats.
        - Place Foley catheter, empty bladder.
        - Infuse 7.5-10 mL/kg 1% clotrimazole solution.
        - Solution should be retained for a minimum of 30 minutes if possible.
        - Repeat q 1 wk for 3-4 weeks.
        - Continue oral antifungal therapy during infusions.
- Other treatment options (e.g., systemic or intravesicular amphotericin B, fluconazole, and terbinafine cotherapy) or benign neglect (absent clinical signs) have not been evaluated in pet animals.

POSSIBLE COMPLICATIONS

Primary infections may progress to pyelonephritis or disseminated/systemic infection.

RECOMMENDED MONITORING

Culture urine regularly (q 2-4 mon) after resolution to monitor for recurrence.

PROGNOSIS AND OUTCOME

- Primary fungal infections may be very difficult to treat; prognosis is fair.
    - Intravesicular clotrimazole infusion protocol may improve treatment success.
- Prognosis for secondary fungal or algal cystitis due to disseminated/systemic infections is poor.

PEARLS & CONSIDERATIONS

COMMENTS

- Control or elimination of predisposing factors is critical for resolution of fungal infections.
- Patients with primary fungal cystitis should be screened for diabetes mellitus and concurrent lower urinary tract diseases.
- Urine culture in animals suspected of having disseminated or systemic fungal or algal disease, even when organisms are not identified on urine sediment examination, may be a noninvasive method of diagnosis.

Cystitis, Bacterial

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Bacterial infection of the urinary bladder occurs very commonly in dogs and less commonly in cats.

SYNONYM

Lower urinary tract infection (UTI)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs affected more often than cats.
- Females affected more often than males.

RISK FACTORS

- Bladder disease, including cystic calculi and neoplasia
- Congenital or acquired structural defects of the lower urinary tract
- Conditions causing formation of dilute urine, including diabetes mellitus and hyperadrenocorticism
- Immunosuppressive drug therapy, including glucocorticoids
- Disorders of micturition, including urine retention (physical or functional causes), urinary incontinence, and vulvar (or, rarely, preputial) conformational abnormalities
- Bacteremia
- Prostatitis, vaginitis, pyometra, pyelonephritis
- Urinary catheterization, especially indwelling catheters
- Perineal urethrostomy

CONTAGION & ZOONOSIS

Occasionally, clonally identical strains of uropathogenic *Escherichia coli* are transmitted between human and animal members of a household.

ASSOCIATED CONDITIONS & DISORDERS

Struvite urolithiasis, pyelonephritis, emphysematous cystitis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Uncomplicated: infection in the absence of structural or functional host defects
- Complicated: infection in a host with structural or functional defects (see Risk Factors)
- Recurrent: repeated infections with the same or different species of bacteria
- Persistent: continued infection with the same bacteria despite antibiotic treatment

HISTORY, CHIEF COMPLAINT

- Clinical signs may be absent.
- When present, the signs encountered most commonly include:
  - Pollakiuria
  - Stranguria/dysuria
  - Hematuria
  - Inappropriate elimination
  - Malodorous urine

- Perivulvar dermatitis

PHYSICAL EXAM FINDINGS

- Usually unremarkable
- Occasionally: findings related to associated illness or condition (e.g., findings suggestive of endocrine disorder, urolithiasis, prostatitis)
- Rarely:
  - Painful bladder
  - Palpably thickened urethra on rectal exam (if concurrent urethritis)

ETIOLOGY AND PATHOPHYSIOLOGY

- Infecting bacteria usually ascend through the urethra to the bladder, but hematogenous infection or infection from pyelonephritis is possible.
- Bacterial virulence factors influence likelihood of infection. Flora adapted for preputial and vaginal environments are protective from uropathogenic infection.
- Multiple physical (e.g., intact uroepithelium, voiding action of urination, urethral pressure and length), chemical (e.g., urine osmolality, urea content, pH), and immunologic host defenses protect from infection. Disruption or defects in these defenses predispose to infection.
- The most common pathogens are *E. coli, Staphylococcus, Proteus, Enterococcus, Klebsiella, Streptococcus, Enterobacter, and Pseudomonas.* Only ~20% of infections involve more than one species.
- Bacterial resistance to antibiotics can be problematic. Resistance may be inherent or may result from genetic transfer of resistance factors or from mutation and selection pressures.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

UTI is often recognized on routine urinalysis as bacteriuria and pyuria; results should be confirmed on a "clean" sample (cystocentesis, catheter, or midstream catch). Urine culture and susceptibility are indicated for all complicated, recurrent, or persistent UTIs. Absence of bacteriuria cannot rule out UTI, especially when urine is poorly concentrated.

DIFFERENTIAL DIAGNOSIS

- Urolithiasis
- Prostatitis
- Lower urinary tract neoplasia
- Feline lower urinary tract signs/disease; interstitial cystitis
- Obstructive uropathy

INITIAL DATABASE

- CBC: unnecessary for uncomplicated UTI; may reflect predisposing illness or condition in complicated infections
- Serum biochemistry profile: unnecessary for uncomplicated UTI; may reflect predisposing illness or condition in complicated infections
- Urinalysis: bacteriuria, pyuria, hematuria, proteinuria. Sample should be obtained via midstream catch, clean catheterization, or cystocentesis (ideal).
  - May reflect predisposing illness or condition (e.g., crystals, glucosuria)
  - Sediment exam may be inactive despite infection, especially with diabetes mellitus, hyperadrenocorticism, or other conditions producing dilute urine.
  - "Leukocyte" squares on urine dipstick are notoriously inaccurate
- Gram stain of urine sediment
- Urine culture/sensitivity:
  - Samples should be collected via clean catheterization or cystocentesis (ideal). If urine is collected via catheter, bacterial number should be quantified to distinguish contamination ($<10^3$ bacteria/mL) from infection.
  - Although preferred, culture is not necessary for first occurrence of uncomplicated infection.
  - Culture/sensitivity should always be obtained from complicated, recurrent, or persistent infection.
  - An inactive sediment does not eliminate the need for culture and sensitivity when UTI is suspected, because many concurrent disorders produce dilute urine, limit leukocyte responses in the urine, or both, producing a negative microscopic sediment exam despite active cystitis.

ADVANCED OR CONFIRMATORY TESTING

Reserved for complicated, recurrent, or resistant infection, primarily with the intention of identifying risk factors for UTI

- Abdominal radiographs: radiopaque uroliths, prostatomegaly, rarely emphysematous cystitis
- Abdominal ultrasound: identify radiolucent uroliths, thickened bladder wall or mass, evidence of pyelonephritis or prostatic disease
- Urinary contrast studies: identify radiolucent uroliths, bladder mass, evidence of pyelonephritis, urethral abnormalities

TREATMENT

TREATMENT OVERVIEW

Most uncomplicated UTIs respond readily to a short course of antimicrobial drugs. Complicated, recurrent, and persistent UTI may be very difficult to cure. In such cases, the primary goal is resolution of clinical signs and prevention of complications of infection rather than elimination of all urinary microbes.

ACUTE GENERAL TREATMENT

Several antibiotic choices are appropriate for empirical treatment of uncomplicated infection, or pending culture/sensitivity results in complicated infection:

- Gram-positive infections: amoxicillin (15-20 mg/kg PO q 8-12 h) or amoxicillin-clavulanic acid (10 mg/kg PO q 12 h).
- Gram-negative infections: trimethoprim/sulfadiazine ([TMS]; 15-30 mg/kg q 12 h) or enrofloxacin (5-10 mg/kg q 12 h).
    - In cats, a maximum enrofloxacin dosage of 5 mg/kg/day is recommended to reduce the risk of ocular toxicity (permanent retinal degeneration).
    - Cefovecin (8 mg/kg SQ once) has been used off-label with good success (*Enterococcus* spp. and *Pseudomonas* spp. will be resistant).

CHRONIC TREATMENT

- Predisposing illnesses or conditions should be addressed.
- Duration of antibiotic therapy:
    - Uncomplicated: 7-14 days
    - Complicated: 4 weeks or more
- Antibiotic therapy is adjusted based on in vitro susceptibility results while considering cost-effectiveness, potential adverse reactions, and the likelihood of developing resistance.
- Multidrug resistant *E. coli* infections may be encountered in complicated or persistent infections. Susceptibility may be limited to expensive, potentially toxic, or parenterally administered antibiotics:
    - Amikacin (5-10 mg/kg SQ [or IV, IM] q 24 h) or gentamicin (2-6 mg/kg SQ [or IV, IM] q 24 h):
        - Nephrotoxic
        - Avoid use in dehydrated animals or those with compromised renal function.
    - Meropenem (8.5 mg/kg SQ [or IV] q 12 h) or imipenem-cilastatin (2-5 mg/kg SQ [or IV,IM] q 8 h)
        - Although not an approved route of administration, the 250- or 500-mg imipenem-cilastatin powder for injection may be diluted in 10 mL of saline and the appropriate dose of the resultant solution given SQ. The vial may be kept refrigerated for up to 24 hours.
- Fosfomycin tromethamine may be useful for *E. coli* UTI (3-g packet divided into 3 equal oral daily doses, repeated in 1 week).
- Other therapies may be used to reduce recurrence (see Prevention).

POSSIBLE COMPLICATIONS

- Emphysematous cystitis: rare complication resulting in gas formation in bladder wall; most often identified in diabetic animals.
- Pyelonephritis: vesicoureteral junction usually prevents bacterial ascension to kidneys.
- Urolithiasis: especially struvite
- Adverse reactions to antibiotics are possible (e.g., TMS may cause ker-atoconjunctivitis sicca, gentamicin is nephrotoxic, enrofloxacin is detrimental to cartilage in growing dogs and, in high doses, may irreversibly damage the feline retina).

RECOMMENDED MONITORING

- For uncomplicated infection, urinalysis should be repeated just before discontinuing antibiotic. If sediment is inactive, antibiotic may be stopped, and analysis should again be evaluated 2-3 weeks later.
- For recurrent or relapsing infection, urine culture is repeated 3-5 days after initiation of appropriate antibiotic and again 2-3

weeks after completion of course. Urine sediment should be inactive just before discontinuing antibiotic. If it is not, culture is repeated.
- For animals with continuing predisposing illness or conditions, periodic urine culture may be warranted even without signs of lower urinary tract disease. Inactive sediment exam cannot be substituted for urine culture in animals with diabetes mellitus, hyperadrenocorticism, or dilute urine from any cause.

PROGNOSIS AND OUTCOME

- Prognosis of uncomplicated infection is excellent.
- Prognosis of complicated infection depends on ability to correct predisposing illness or condition.

PEARLS & CONSIDERATIONS

COMMENTS

- Any bacterial cystitis in a male dog should be viewed as a complicated infection.
- Struvite crystalluria in dogs is most commonly due to bacterial UTI or delayed microscopic examination of the sediment, and virtually never is related to diet.
- Lower urinary tract signs in cats are seldom caused by bacterial cystitis (<5% of cats age 10 years or younger with lower urinary tract signs have bacterial cystitis), making empirical antibiotic therapy inappropriate in cats. Therefore, urine from such cats should first be cultured to rule out an infectious contribution.
- Concurrent pyelonephritis commonly occurs in the absence of "classic" signs such as lumbar pain, intermittent fever, or neutrophilia. The absence of these signs in a patient with recurrent bacterial cystitis should not defer an evaluation for pyelonephritis (e.g., abdominal ultrasound) when pyelonephritis is otherwise suspected (e.g., azotemia).
- Many antibiotics are present in high concentration in the urine as a result of renal excretion:
    - Disk diffusion assays of sensitivity evaluate expected serum drug concentration, so sensitivity of a uropathogen in vivo may be greater than that predicted in vitro.
    - If expected urine concentration of antibiotic exceeds minimum inhibitory concentration by four times, the antibiotic should be effective.
- Persistent bacterial cystitis usually results from either inappropriate choice of antibiotic or inadequate dose/duration of administration, emergence of bacterial resistance to the chosen antibiotic, or failure to correct underlying illness or condition allowing infection to occur.

PREVENTION

- Correction of predisposing illness or conditions is the most effective strategy to prevent infection.
- For animals in which predisposing factors cannot be corrected and recurrent infections are problematic, prophylactic antibiotic use or urinary antiseptics may be warranted:
    - Antibiotics:
        - One-third to half of usual daily dose of amoxicillin, TMS, or fluoroquinolone, administered once daily before bed
        - Fosfomycin tromethamine (⅓ packet orally once weekly)
    - Antiseptics (dogs):
        - Methenamine mandelate (10 mg/kg PO q 6-8 h) or methenamine hippurate (500 mg PO q 12 h)
            - Both effective in acidic urine; may require addition of ammonium chloride as acidifying agent (60-100 mg/kg q 12 h). Caution: urinary acidification may precipitate formation of certain uroliths.
    - Alternative (unproven) therapies
        - Cranberry juice concentrate, D-mannose, *Coleus forskohlii* (an herb)

CLIENT EDUCATION

Antibiotics should be given as prescribed to completion even if clinical signs resolve quickly.

AUTHOR & EDITOR: LEAH A. COHN

Cystadenoma, Hepatobiliary

BASIC INFORMATION

DEFINITION

Benign hepatic tumor primarily seen in older cats; may occur as focal or multifocal cystic lesions of the liver. The cysts are lined by cuboidal, occasionally vacuolated, epithelium. Histogenesis remains uncertain.

SYNONYM

Bile duct adenoma

EPIDEMIOLOGY

SPECIES, AGE, SEX

Primarily cats older than 10 years. No sex predisposition. Rare in dogs.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Focal or multifocal hepatic lesions are most common.
- Solitary masses are far less common.

HISTORY, CHIEF COMPLAINT

Abdominal enlargement, lethargy, vomiting, and polydipsia. Patients may show no overt clinical signs, with cystadenomas identified as incidental findings on abdominal palpation, radiographs, abdominal ultrasound, or necropsy.

PHYSICAL EXAM FINDINGS

Generally unremarkable. Cranial abdominal organomegaly may be noted with very large cystadenomas.

ETIOLOGY AND PATHOPHYSIOLOGY

Etiopathogenesis remains unknown.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A tentative diagnosis can be made by a skilled ultrasonographer; histopathologic evaluation of a biopsy is required for a definitive diagnosis.

DIFFERENTIAL DIAGNOSIS

Congenital or acquired hepatic cysts, hepatic abscess, malignant hepatobiliary tumors (e.g., cystadenocarcinoma), metastatic hepatic neoplasia

INITIAL DATABASE

- Serum biochemical profile, CBC, and urinalysis are generally unremarkable.
- Abdominal radiographs may prove useful with large cysts that displace surrounding structures.
- Ultrasonography is the diagnostic test of choice. It reveals fluid-filled mass(es) with internal septae, with a variable tissue component. The mass can appear hypoechoic or anechoic due to the cystic nature of the lesion.
- Aspiration of the cystic fluid yields an acellular fluid with a low total protein concentration (<2.0 g/dL).

ADVANCED OR CONFIRMATORY TESTING

- Advanced imaging is generally not indicated.
- Histopathologic evaluation is required for a definitive diagnosis; a presumptive diagnosis may be made by a skilled ultrasonographer.

TREATMENT

TREATMENT OVERVIEW

Surgical excision is advised if possible, as complete excision can be curative. Many cases do not require therapy (small lesions not causing clinical signs). These patients should then be monitored by ultrasonography.

ACUTE GENERAL TREATMENT

- Surgical removal to prevent progressive enlargement and associated clinical signs
  - The decision to excise the mass must be weighed against the condition of the patient (e.g., patients with comorbid conditions in which cystadenoma is an incidental finding).
- Enteral feeding should be considered postoperatively in patients that are anorectic (esophagostomy or gastrostomy tubes).

POSSIBLE COMPLICATIONS

Hemorrhage and bile leakage and resultant bile peritonitis are potential postoperative complications.

RECOMMENDED MONITORING

Follow-up hepatic ultrasound may be considered to monitor for recurrence in cases with incomplete excision or in patients that do not undergo surgery.

PROGNOSIS AND OUTCOME

- Complete tumor excision warrants an excellent prognosis.
- Given the slow-growing nature of the tumor, surgical debulking of nonresectable lesions may provide long-term palliation.
- Hepatobiliary cystadenomas are not known to have malignant potential in veterinary medicine.

PEARLS & CONSIDERATIONS

COMMENTS

- Given the potential for malignancy, histopathologic evaluation should be advised for all cystic hepatic lesions in general.
- Malignant transformation has been reported in humans with hepatobiliary cystadenoma.

TECHNICIAN TIPS

The most common perioperative complication associated with liver surgery is hemorrhage. Increasing heart rate, decreasing blood pressure, decreasing pack cell volume/total solids and decreasing body temperature can be suggestive of hemorrhage in the immediate postoperative period.

CLIENT EDUCATION

Percutaneous cyst drainage may be palliative in select cases; however, given the excellent prognosis associated with complete excision, surgical intervention is advised.

AUTHOR: FRED S. PIKE

EDITOR: KEITH P. RICHTER

Cyclic Thrombocytopenia

BASIC INFORMATION

DEFINITION

A tickborne disease characterized by periodic parasitemia of platelets, leading to intermittent episodes of thrombocytopenia.

SYNONYM

Anaplasma platys (formerly *Ehrlichia platys*) infection

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs; no sex or age predilection

RISK FACTORS

Increased tick exposure

CONTAGION & ZOONOSIS

Transmitted by tick vectors, primarily *Rhipicephalus sanguineus* (brown dog tick); possible transmission via other arthropods. Not reported in humans.

GEOGRAPHY AND SEASONALITY

Reported worldwide. United States strains typically less pathogenic.

ASSOCIATED CONDITIONS & DISORDERS

Concurrent or previous infection with other tickborne organisms (e.g., *Babesia*, *Borrelia*, *Ehrlichia* spp.) is common and can potentiate severity of both diseases.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

The organism found in the United States rarely causes any clinical signs or hematologic abnormalities other than thrombocytopenia itself. A more virulent strain causing overt clinical disease exists outside the United States. For less pathogenic strains, history and physical exam are often unremarkable. Thrombocytopenia may be an incidental finding on workup for other disease.

HISTORY, CHIEF COMPLAINT

- Commonly none
- Otherwise, presenting complaint may include lethargy, anorexia, ocular changes, epistaxis, petechiae/ecchymoses.

PHYSICAL EXAM FINDINGS

- Commonly none (e.g., organism may be incidental hematologic finding)
- When present, may include pallor, fever, petechiae/ecchymoses, postoperative hemorrhage, uveitis/hyphema, lymphadenopathy, mucopurulent nasal discharge

ETIOLOGY AND PATHOPHYSIOLOGY

- Ribosomal RNA sequencing has led to reclassification of causative organism. Formerly *Ehrlichia platys* (family

Rickettsiaceae). Renamed *Anaplasma platys* (family Anaplasmataceae).
- Two mechanisms of platelet destruction:
  - Direct injury from replicating organisms
  - Immune-mediated destruction and clearance
- Incubation period is 8-15 days after tick bite, followed by a rapid decline and rebound in platelet numbers.
- Cycles occur every 1-2 weeks, lessening in severity with each recurrence.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Definitive diagnosis requires verification of *A. platys* exposure via serologic titer or genetic isolation in an animal with proven thrombocytopenia.

DIFFERENTIAL DIAGNOSIS

- Other tickborne diseases:
  - *Ehrlichia canis*
  - *Rickettsia rickettsii* (Rocky Mountain spotted fever)
- Immune-mediated thrombocytopenia
- Toxin- or drug-induced thrombocytopenia (cisplatin, cyclophosphamide, chlorambucil, doxorubicin, hydroxyurea)
- Bone marrow suppression
- Disseminated intravascular coagulation (DIC)
- Platelet consumption due to internal or external hemorrhage or vasculitis
- Modified live canine distemper vaccine can rarely cause a transient, nonclinical thrombocytopenia.
- Canine cyclic hematopoiesis of gray collie dogs (see Color Disorders of the Skin and Haircoat, p. 233)

INITIAL DATABASE

- CBC:
  - Thrombocytopenia of varying severity (as little as <10,000 to near-normal >100,000 platelets/mcL)
  - Giant platelets often noted
  - ± Regenerative anemia if extensive hemorrhage
  - Mild nonregenerative anemia with repeated disease cycles
  - Mild leukopenia (occasional)
- Serum biochemistry panel: often unremarkable
- Activated clotting time and buccal mucosal bleeding time will be prolonged with severe thrombocytopenia; other coagulation tests normal.
- Bone marrow exam: megakaryocytes normal or increased in number
- Diagnostic imaging of thorax and abdomen is often unremarkable but should be performed to rule out other causes of thrombocytopenia such as internal hemorrhage or neoplasia.

ADVANCED OR CONFIRMATORY TESTING

- Giemsa-stained blood smear may show dark-staining morulae, representing organisms within platelets, but these are found in fewer than 10% of affected animals.
- Serology: indirect immunofluorescent antibody test is available. Monitor convalescent titers every 2-3 weeks.
- An in-house ELISA (Idexx Snap 4DX) that tests for exposure to heartworms, *E. canis*, *B. burgdorferi*, and *Anaplasma phagocytophilum* is now available, but cross-reaction with *A. platys* occurs. A positive result should be followed up with PCR testing for speciation.
- PCR has become the diagnostic test of choice. PCR is highly specific (false positives rare). Sensitivity is also good, but a negative result does not rule out *A. platys* infection.

TREATMENT

TREATMENT OVERVIEW

Treatment should focus on elimination of organisms and providing supportive care for complications of thrombocytopenia.

ACUTE GENERAL TREATMENT

- Drugs of choice: doxycycline (5-10 mg/kg PO or IV q 12 h) or tetracycline (20-30 mg/kg PO q 8 h) for 21 days
- Administration of blood or oxygen-carrying solutions, intravenous crystalloids/colloids as indicated for acute hemorrhage
- Platelet-rich plasma may be administered for severe thrombocytopenia. Expensive, poorly available (refrigerated shelf life = 2-3 days), and often unsuccessful.
- Vincristine: induces thrombocytosis via an unknown mechanism. Give 0.02 mg/kg IV once, maximum once weekly.

CHRONIC TREATMENT

Tick control is imperative to prevent reinfection.

DRUG INTERACTIONS

- Many oral drugs and foods can decrease absorption of oral tetracyclines: aluminum- or calcium-containing antacids, iron, kaolin-pectin, bismuth salicylate, milk products. Theophylline may enhance adverse gastrointestinal side effects.
- Doxycycline has fewer issues with the listed drug interactions than tetracycline.

POSSIBLE COMPLICATIONS

- Common side effects of tetracyclines are anorexia, vomiting, and diarrhea.
- Doxycycline is caustic to the esophageal mucosa and can cause esophageal strictures. Ensure the pill reaches the stomach by following with water or a small food bolus after administration.
- Vincristine can cause sloughing of soft tissues if extravasation occurs during intravenous injection. CBC is indicated 5-7 days after administration to monitor for a neutrophil nadir. If neutrophils are less than 1500/mcL, prescribe broad-spectrum antibiotics.

RECOMMENDED MONITORING

Serial CBCs q 1-2 weeks posttreatment to monitor recurrence

PROGNOSIS AND OUTCOME

- Good with effective treatment and less pathogenic strains
- Guarded if severe hemorrhage, DIC

PEARLS & CONSIDERATIONS

COMMENTS

Since coinfection with other tickborne diseases is common, diagnostics should include workup for multiple causative agents.

TECHNICIAN TIP

Depending on prevalence, this disease may be first identified during examination of a blood smear; examination of platelet morphology (looking for the organism) is important, especially in thrombocytopenic patients.

PREVENTION

Tick control is most important.

CLIENT EDUCATION

Has not been reported to affect humans

Cyanosis

BASIC INFORMATION

DEFINITION

A bluish or grayish discoloration of the mucous membranes or skin due to hypoxemia.

SYNONYMS

Oxidized hemoglobin: oxygenated hemoglobin. Reduced hemoglobin: deoxygenated hemoglobin.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dog or cat of any age and either sex

GENETICS & BREED PREDISPOSITION

Predispositions for underlying causes

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Generalized cyanosis: all mucous membranes have a bluish tinge.
- Regional cyanosis: due to localized hypoxia. Not discussed further.

HISTORY, CHIEF COMPLAINT

- Dyspnea
- Exercise intolerance
- Collapse; hind limb collapse (described by owners as unexplained periods of sitting during walks) in cases of cyanosis affecting only the caudal half of the body (differential cyanosis)
- Syncope
- Visible cyanosis noted by owner

PHYSICAL EXAM FINDINGS

- Dyspnea may range in severity from mild to severe, in positive correlation to the severity of the underlying problem.
    - An exception is right-to-left shunting heart disease, which may cause pronounced cyanosis even in a patient with minimal dyspnea.
- Heart murmur possible with some right-to-left shunts (e.g., tetralogy of Fallot)
- Stunted growth if congenital right-to-left cardiac shunts

ETIOLOGY AND PATHOPHYSIOLOGY

ETIOLOGY

- Severe pulmonary disease (e.g., pneumonia, pulmonary edema, hemorrhage):
    - Ventilation/perfusion (V/Q) mismatch
    - Pulmonary diffusion disorder
- Severe bronchial disease (e.g., asthma)
- Airway obstruction (laryngeal paralysis, elongated soft palate/brachycephalic airway syndrome, foreign body, mass)
- Hypoventilation
- Pulmonary arterial disease (pulmonary hypertension, pulmonary thromboembolism)
- Diminished lung capacity (severe pleural effusion, pneumothorax, intrathoracic mass, obesity)
- Right-to-left shunting heart disease:

- Cyanosis is usually generalized (tetralogy of Fallot, Eisenmenger's complex, others).
- Differential cyanosis, with pink oral and conjunctival mucous membranes and cyanotic vulvar/preputial mucosa, is characteristic of right-to-left shunting patent ductus arteriosus.

PATHOPHYSIOLOGY

- Reduced (deoxygenated) hemoglobin is blue, whereas oxidized (oxygenated) hemoglobin is red.
- Cyanosis appears when there is a substantial quantity of reduced hemoglobin in the blood:
  - The deep blue color of a reduced hemoglobin molecule overwhelms the red color of an oxidized hemoglobin molecule.
  - Therefore, when cyanosis first appears, there is less reduced hemoglobin than oxidized hemoglobin.
  - Typically, in a patient with a normal hematocrit, the presence of cyanosis indicates a blood concentration of reduced hemoglobin of >5 g/dL (normal total blood hemoglobin concentration: 12.4–19.1 g/dL [dog], 8.5–14.4 g/dL [cat]).
- When cyanosis is observed, severe hypoxemia is present. In a patient with a normal hematocrit, cyanosis begins to appear when Pao2 < 50 mm Hg, which corresponds to SaO2 < 80%, (normal Pao2 = 90-100 mm Hg when breathing room air; normal SaO2 > 95%).
- It is the *absolute* amount of reduced hemoglobin that determines the presence of cyanosis, not the proportion of total hemoglobin that is reduced. Therefore, anemic animals are cyanotic only when they have a very severe degree of hypoxemia, whereas polycythemic animals can be cyanotic with proportionally less oxidized hemoglobin, or even under normal conditions.
- Carboxyhemoglobin, which is elevated in carbon monoxide poisoning, confers a “cherry-colored flush” to the skin and mucous membranes, and this may mask cyanosis in a severely hypoxemic, carbon monoxide–intoxicated patient.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Cyanosis is recognized on physical exam. Beyond a history to suggest recent causes (e.g., smoke inhalation), a CBC (including examination of whole blood for methemoglobinemia, if relevant) and thoracic radiographs are usually the most important initial diagnostic tests.

DIFFERENTIAL DIAGNOSIS

- Methemoglobinemia from oxidative injury to red blood cells (e.g., acetaminophen toxicosis in cats):
  - Methemoglobin gives a “muddy” color to the mucous membranes, which may be indistinguishable from cyanosis.
  - Differentiation is possible based on the gross appearance of the blood. A drop of blood is applied to a white paper towel. With cyanosis, the blood is dark blue, whereas with methemoglobinemia, it is chocolate-brown.
- Normal pigmentation/melanin. Differentiation involves evaluation of other, nonpigmented mucous membranes or measurement of an arterial blood gas sample for oxygen content.
- Normal pink mucous membranes observed in certain lighting conditions (e.g., fluorescent lights) may falsely appear cyanotic.

INITIAL DATABASE

- Thoracic and lateral cervical radiographs: identify airway or lung structural lesions
- CBC: identify clues indicating cause (e.g., polycythemia with right-to-left shunts or chronic lung disease)
- Arterial blood gas: confirm hypoxemia
- Echocardiography: identify cardiac shunts
- Oral and pharyngeal exam if upper airway dyspnea or apnea: identify and correct obstruction

TREATMENT

TREATMENT OVERVIEW

Correct critical hypoxemia.

ACUTE GENERAL TREATMENT

Oxygen supplementation (see p. 1318). Beneficial effect expected in most cases, although right-to-left shunts are minimally to poorly responsive to oxygen supplementation.

CHRONIC TREATMENT

Management or correction of the underlying cause

POSSIBLE COMPLICATIONS

Worsening hypoxemia leading to respiratory arrest

RECOMMENDED MONITORING

- Observation of respiratory effort
- Mucous membrane color
- Pulse oximetry and/or arterial blood gas measurements help quantify response to treatment but are not a replacement for careful observation of respiratory effort and monitoring of underlying cause.

PROGNOSIS AND OUTCOME

- Short term: always guarded, because severe hypoxemia is present.
- Long term: varies widely, depending on underlying cause. Ranges from excellent (e.g., with good response to treatment for lung disease) to poor (e.g., with end-stage heart disease).

PEARLS & CONSIDERATIONS

COMMENTS

- Cyanosis depends on the absolute amount of reduced, or deoxygenated, hemoglobin in the circulation. Therefore, anemic animals or animals with hypoperfusion (e.g., shock) are less cyanotic despite severe hypoxemia, whereas polycythemic animals may show cyanosis with minimal hypoxemia.
- A patient with marked cyanosis and minimal dyspnea should be suspected of having right-to-left shunting or a hematologic problem (e.g., methemoglobinemia from oxidative red blood cell injury).

AUTHOR & EDITOR: ETIENNE CÔTÉ

Cutaneous Neoplasia

BASIC INFORMATION

DEFINITION

Benign or malignant tumor arising from cells within the skin and adnexa. The most common cutaneous neoplasms in dogs are, in descending order of frequency, lipoma, sebaceous gland hyperplasia/adenoma, mast cell tumor, histiocytoma, and papilloma. In cats, basal cell tumors are the most common, followed by squamous cell carcinoma and fibrosarcoma. Squamous cell carcinoma (p. 1045) and mast cell tumor (canine, ; feline,) are discussed separately.

SYNONYMS

Basal cell tumor: basal cell epithelioma Infundibular keratinizing acanthoma: keratoacanthoma, intracutaneous cornifying epithelioma

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: 30% of all tumors arise within the skin
- Cats: 20% of all tumors arise within the skin
- Median age for cutaneous neoplasia is 10.5 years for dogs and 12 years for cats
- Predilection for histiocytoma in young dogs

GENETICS & BREED PREDISPOSITION

- Canine breeds with highest incidence of skin tumors include the boxer, Scottish terrier, bull mastiff, basset hound, Kerry blue terrier, and Norwegian elkhound.
- Shar-peis tend to develop mast cell tumors at a younger age (mean 4 years).
- Feline breeds with highest incidence are the Siamese and Persian.
- Infundibular keratinizing acanthoma: generalized form may have a hereditary basis in Norwegian elkhound and keeshond.

RISK FACTORS

- Basal cell carcinoma: a strong correlation in humans exists with exposure to ultraviolet light and development. This association has not been established in dogs and cats.
- Cutaneous hemangioma/hemangiosarcoma: short-coated dogs with nonpigmented skin in sun-exposed areas such as the glabrous (hairless) skin of the ventral abdomen and white cats are at higher risk.

CUTANEOUS NEOPLASIA Histiocytoma on the pinna of a 1-year-old beagle.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Basal cell tumors: benign or malignant (basal cell carcinoma) tumors arising from the pluripotential basal epithelial cells in the epidermis and adnexa
- Hemangioma/hemangiosarcoma: benign or malignant neoplasms arising from endothelial cells of blood vessels
- Histiocytoma: benign neoplasm that arises from epidermal Langerhans cells
- Infundibular keratinizing acanthoma: benign neoplasms of hair follicle origin
- Trichoepithelioma: benign neoplasms that arise from keratinocytes that differentiate toward all three segments of the hair follicle
- Sebaceous gland hyperplasia/adenoma: epithelial growths arising from sebocytes

HISTORY, CHIEF COMPLAINT

Solitary to multiple cutaneous masses

PHYSICAL EXAM FINDINGS

- Basal cell tumor: solitary, well-circumscribed, firm to cystic, alopecic, commonly ulcerated, often pigmented mass, typically located on the head, neck, shoulders, or thorax. In cats, malignant lesions also can occur on the nasal planum and eyelids.
- Cutaneous hemangioma/hemangiosarcoma: dermal or subcutaneous, solitary or multiple, oval masses or red to dark red plaques, usually located along the limbs and ventral abdomen. In cats: bluish to reddish-black nodules to plaques.
- Histiocytoma: solitary, well-circumscribed, firm, erythematous, intradermal nodule found most frequently on the head, limbs, and thorax. Fast growing but benign. Occasionally observed as multiple cutaneous nodules or plaques.
- Infundibular keratinizing acanthoma: most commonly found on the back, neck, thorax, and limbs. Well-circumscribed dermal or subcutaneous masses with a pore opening to the skin surface; pore usually consists of a keratin plug. Not metastatic.
- Trichoepithelioma: usually solitary, solid or cystic, elevated, round, and well circumscribed; frequently become ulcerated and alopecic.
- Sebaceous gland tumors: solitary or multiple, raised, wartlike to smooth, may ulcerate; most commonly found on limbs, trunk, eyelids, head.

ETIOLOGY AND PATHOPHYSIOLOGY

- Neoplastic transformation relies on changes within specific growth-regulating genes
- Principal growth-regulating genes include:
  - Oncogenes that code for proteins that increase growth
  - Tumor-suppressor genes that decrease proliferation and differentiation

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The only way to distinguish benign neoplasms from malignant neoplasms and nonneoplastic proliferative skin disease is histopathologic examination of biopsied tissue. Malignant lesions show rapid invasive growth, infiltration, and metastasis.

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis (if indicated): assess systemic abnormalities if any
- Cytologic exam (fine-needle aspirate):
  - Basal cell tumor: small, round to cuboidal epithelial cells arranged in groups or ribbons. Basal cell carcinomas are difficult to differentiate cytologically from benign lesions.
  - Histiocytoma: sheets of round cells with a pale blue cytoplasm and variable size and shape to the nuclei; variable numbers of neutrophils and lymphocytes, depending on stage of growth and involution
  - Sebaceous gland hyperplasia: clusters of lipid sebocytes
- Histopathologic exam (biopsy):
  - Basal cell tumor: well-circumscribed, symmetric proliferation of basal epithelial cells that has a broad zone of connection to the overlying epidermis
  - Basal cell carcinoma: circumscribed, irregular dermal mass comprising multiple epithelial cell aggregates embedded in a fibrous stroma that may extend into the underlying subcutis
  - Hemangioma: proliferation of blood-filled vascular spaces lined by single layers of well-differentiated endothelial cells
  - Hemangiosarcoma: invasive proliferation of atypical endothelial cells with areas of vascular space formation
  - Histiocytoma: uniform sheets and cords of histiocytes infiltrating the dermis and subcutis; characteristic high mitotic index
  - Infundibular keratinizing acanthoma: keratin-filled crypt in the dermis that has an opening to the skin surface

ADVANCED OR CONFIRMATORY TESTING

Abdominal and cardiac ultrasonography to determine whether hemangiosarcoma lesions are primary or metastatic

TREATMENT

TREATMENT OVERVIEW

Treatment typically should be localized for local disease. Systemic attack on cancer should be reserved for generalized disease or disease in which local therapy alone is not likely to be curative. Treatment options include surgery, chemotherapy, radiation, cryosurgery, electrosurgery, immunotherapy, combinations thereof, or observation.

ACUTE GENERAL TREATMENT

- Basal cell tumor: surgical excision is curative.
- Hemangioma: surgical excision, cryotherapy, or electrosurgery usually curative
- Hemangiosarcoma: aggressive surgical excision is treatment of choice; complete excision of subcutaneous tumor is difficult.
- Histiocytoma: spontaneous remission may occur within 3 months. Surgical excision is curative for lesions that do not regress.
- Infundibular keratinizing acanthoma: may resolve spontaneously. Surgical excision, cryosurgery, or observation without treatment are also options.
- Trichoepithelioma: surgical excision, cryosurgery, electrosurgery, or observation without treatment
- Sebaceous gland hyperplasia/adenoma: surgical excision, cryotherapy, or observation without treatment. May recur after surgery. Sebaceous gland carcinomas rarely metastasize.

CHRONIC TREATMENT

Hemangiosarcoma: chemotherapy can be used before surgery to reduce tumor size; median postsurgical survival of 425 days with the use of a regimen including doxorubicin, cyclophosphamide, and vincristine (study of six dogs). See p. 483.

POSSIBLE COMPLICATIONS

Hemangiosarcoma: local recurrence and metastasis are common in dogs; metastasis is rare in cats.

PROGNOSIS AND OUTCOME

- Excised basal cell tumor and trichoepithelioma: generally very good
- Intradermal hemangiosarcoma: excellent
- Subcutaneous hemangiosarcoma: poor
- Excised solitary histiocytoma: excellent

PEARLS & CONSIDERATIONS

COMMENTS

- The most effective way to separate benign neoplasms from malignant neoplasms and nonneoplastic proliferative skin disease is histopathologic examination of biopsied tissue.
- The key to successful management is an accurate diagnosis.
- Cytologic evaluation of smears may provide valuable information about the cell type.
- Immunohistochemistry has markedly improved our ability to determine progenitor cells for many skin neoplasms, with a positive impact on treatment selection and in some cases on prognostication.

TECHNICIAN TIP

Fine-needle aspirates of subcutaneous masses cannot reliably be interpreted without a microscope. The water-droplet appearance on a glass slide of “classic adipose tissue” is also observed with mast cell tumors and other malignant tissues, not just lipomas; routine staining and microscopic assessment are essential.

SUGGESTED READING

Gross TL: Skin diseases of the dog and cat— clinical and histopathological diagnosis, ed 2, Ames, 2005, Blackwell Science, pp 645–646, 853–859.

AUTHOR: EDWARD JAZIC

EDITOR: MANON PARADIS

Cutaneous Lymphoma

BASIC INFORMATION

DEFINITION

A malignant neoplasm of lymphoid origin involving the skin or oral cavity. It may be primary or secondary to other forms of lymphoma.

SYNONYMS

Epitheliotropic lymphoma, mycosis fungoides

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Uncommon in dogs and rare in cats
- Usually affects older animals
- No gender predisposition

ASSOCIATED CONDITIONS & DISORDERS: Sézary syndrome, a concurrent tumor cell population in peripheral blood

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Epitheliotropic lymphoma: the more common form; lesions most commonly involve epidermis, superficial dermis, and periadnexa; oral mucosal form also described; T-cell origin; characteristic histologic feature is Pautrier's microabscesses (small aggregates of epitheliotropic lymphoid tumor cells in epidermis); protracted clinical course.
- Nonepitheliotropic lymphoma: uncommon; subcutaneous nodules; B-cell origin; more rapid onset and progression

HISTORY, CHIEF COMPLAINT

- Epitheliotropic lymphoma may be divided into three stages:
  - Premycotic stage: erythematous lesions with varying degrees of depigmentation and alopecia over the trunk and neck which may progress to other body locations
  - Mycotic stage: erythematous, raised, firm plaques which may be ulcerated and exudative
  - Tumor stage: progressive thickening and proliferation of plaque lesions with ulceration; lymph node and/or other organ involvement possible
- Nonepitheliotropic lymphoma in dogs presents as rapidly progressing and frequently multiple subcutaneous nodules.
- Cutaneous lymphoma in cats presents as progressive solitary or disseminated ulcerated plaques or nodules.

PHYSICAL EXAM FINDINGS

- Typical presentation of epitheliotropic lymphoma involves chronic, progressive, generalized exfoliative dermatitis with crusting, ulceration, and alopecia.
- Epitheliotropic lymphoma may present as solitary or multiple ulcerated plaques or nodules involving oral mucosa.
- Variably sized subcutaneous nodules are characteristic of nonepitheliotropic lymphoma.
- In cats, plaquelike lesions are most common; nodules and erythroderma are also possible; solitary lesions may be present initially, with additional lesions developing as the disease progresses.

ETIOLOGY AND PATHOPHYSIOLOGY

Neoplastic lymphocytes in epitheliotropic lymphoma are T cells; CD3 and CD8 phenotype most common in dogs.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Immune-mediated disease (e.g., pemphigus vulgaris, bullous pemphigoid, discoid lupus erythematosus)
- Allergic skin disease with pyoderma
- Infectious disease (e.g., dermatophytosis)

INITIAL DATABASE

- CBC, serum biochemistry panel, urinalysis: typically unremarkable. Occasionally, circulating lymphoblasts may be present, consistent with Sézary syndrome.
- Skin biopsy: test of choice for establishing the definitive diagnosis of cutaneous lymphoma

ADVANCED OR CONFIRMATORY TESTING

- Lymph node aspirate cytologic evaluation: to assess enlarged lymph nodes for lymphoma infiltration versus inflammation/reaction if severe dermatopathy
- Thoracic radiographs: to assess for pulmonary infiltration, intrathoracic lymph node enlargement
- Abdominal ultrasound: to identify changes consistent with hepatic or splenic involvement, lymphadenopathy, or other sites of lymphoma
- Bone marrow aspirate cytologic evaluation: to identify bone marrow involvement, particularly in cases with suspected Sézary syndrome (prognostic value)
- Phenotyping (flow cytometry, immunocytochemistry, immunohistochemistry): if uncertainty exists regarding the histologic diagnosis

TREATMENT

TREATMENT OVERVIEW

Treatment goal: complete remission with resolution of lesions

ACUTE GENERAL TREATMENT

Canine epitheliotropic lymphoma:

- Oral differentiating agents:
  - Vitamin A analogs (isotretinoin, 1-3 mg/kg PO q 24 h): 45% response rate for 5 to 15 months
- Topical agents:
  - Nitrogen mustard (25% solution applied once daily): anecdotal response reported; use is *not recommended* because of concern over human contact dermatitis and carcinogen exposure.
- Radiation therapy:
  - Total skin electron beam therapy may prove beneficial; however, current limited availability precludes wide application.
  - Other forms of radiation therapy may benefit patients with localized oral lesions or those with more generalized disease needing palliation of specific discrete skin lesions.
- Chemotherapy: special handling requirements and potentially severe or life-threatening adverse patient effects exist with many of these chemotherapeutic drugs; such concerns and rapid evolution of protocols warrant consultation with/referral to an oncologist. Chemotherapeutic drug options may include:
  - Chloroethyl-cyclohexyl-nitrosurea (CCNU [lomustine]), 60-70 mg/m^2 PO q 21 days: 15%-30% CR rate and 50%-60% PR rate for median duration of 3-4 months; *or*
  - Prednisone alone, 20-40 mg/m^2 PO q 24-48 h: 25%-35% response rate
  - Combination chemotherapy (see Lymphoma, Dog [Multicentric], p. 675) has limited activity; response durations range from 2-16 weeks.
- Surgery:
  - May be beneficial for patients with solitary resectable oral lesions

Canine nonepitheliotropic lymphoma:

- Treat as for other forms of canine multicentric lymphoma.

Feline cutaneous lymphoma:

- Consider treatment as for canine epitheliotropic lymphoma.

POSSIBLE COMPLICATIONS

See Lymphoma, Dog (Multicentric), p. 675.

RECOMMENDED MONITORING

Regular monitoring of remission status (see Lymphoma, Dog [Multicentric], p. 675).

PROGNOSIS AND OUTCOME

Biological behavior and response to treatment vary widely. Solitary epitheliotropic lymphoma oral lesions may respond well to local therapy (surgery, radiation therapy). Generalized epitheliotropic lymphoma may benefit from chemotherapy, and early results from the administration of oral CCNU are promising.

PEARLS & CONSIDERATIONS

COMMENTS

- Although rapid complete responses to treatment are uncommon, and standard therapy in human medicine (topical chemotherapy or total skin electron-beam therapy) is not currently feasible in veterinary medicine, CCNU alone or in combination with prednisone may be considered a reasonable option for veterinary patients with epitheliotropic lymphoma.
- Most cases of cutaneous lymphoma are epitheliotropic, such that the terms *cutaneous lymphoma* and *epitheliotropic lymphoma* are often used interchangeably.
- Mycosis fungoides is cutaneous lymphoma, not a fungal disease.

AUTHOR: LAUREL E. WILLIAMS

EDITOR: KENNETH M. RASSNICK

Cutaneous Lupus Erythematosus

BASIC INFORMATION

DEFINITION

Cutaneous lupus erythematosus (CLE) is a chronic inflammatory autoimmune disease with a broad spectrum of clinical manifestations and a variable course. Discoid lupus erythematosus (DLE) is a relatively benign skin disease with no systemic involvement. Two other forms, exfoliative cutaneous lupus erythematosus (ECLE) and vesicular cutaneous lupus erythematosus (VCLE), can be debilitating and potentially fatal.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Uncommon in dogs; very rare in cats
- No age or clear sex predilection

GENETICS & BREED PREDISPOSITION

Breed predispositions include German shepherd, Siberian husky, Brittany spaniel, collies, and Australian herding breeds (DLE). German shepherds may have been excessively represented, as many alleged cases were probably affected with mucocutaneous pyoderma instead. German short-haired pointer (ECLE); rough collie and Shetland sheepdog (VCLE).

RISK FACTORS

Breed, exposure to ultraviolet light.

GEOGRAPHY AND SEASONALITY

More common in summer months and sunny climates.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Lesions on the nasal planum +/− bridge of the nose (DLE), generalized scaling (ECLE), or ulcerative skin lesions of the axillae and groin (VCLE).

PHYSICAL EXAM FINDINGS

- DLE: Usually localized to the nasal planum (unhaired, rostral surface of the nose). Less commonly, lesions affect other sites, including lip folds, oral cavity, periocular area, pinnae, genitalia and rarely distal limbs.
  - Erythema, depigmentation, and scaling of the nasal planum with or without involvement of the bridge of the nose. Early depigmentation manifests as a change in color from normal black to gray/white; there is also a change in surface texture of the nasal planum from the normal rough “cobblestone”-like appearance to a smooth, shiny surface.
  - Scaling and crusting may be present at the junction between nasal planum and haired skin. When other sites are affected; crusting, erosions, and ulceration may be noted. Dogs with DLE are otherwise healthy.
- ECLE: Initially there is scaling on the face, pinnae, and dorsum, progressing to a more generalized distribution. Peripheral lymphadenopathy and fever may be present.
- VCLE: Characteristic lesions include annular, polycyclic, and serpiginous ulcerations distributed over sparsely haired areas of the body, specifically the ventral abdomen, axilla, groin, and concave aspects of the pinna.

CUTANEOUS LUPUS ERYTHEMATOSUS Discoid lupus erythematosus in a collie. Note the depigmentation, erosion, and crusting of the nasal planum.

(Copyright Dr. Manon Paradis.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Pathogenesis is thought to involve autoreactive T cells that stimulate B cells to produce antibodies to a number of different nuclear proteins.
- Ultraviolet light may initiate the process of expression in photosensitive individuals (50% of cases).
- Antibodies are deposited in the basement membrane, and subsequently, epidermal basal layer cells are damaged. This results in subepidermal vesicle formation and immune complex deposition in the basement membrane zone.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A strong suspicion exists on physical examination alone. The differential diagnosis varies according to the type of CLE. Biopsy for histopathologic evaluation is the confirmatory test of choice.

DIFFERENTIAL DIAGNOSIS

- Bacterial infection: mucocutaneous pyoderma (DLE), staphylococcal folliculitis
- Immune-mediated diseases: systemic lupus erythematosus, pemphigus foliaceus and erythematosus
- Drug reaction, uveodermatologic syndrome
- Vitiligo
- Neoplasia: squamous cell carcinoma, epitheliotrophic lymphoma (DLE)
- Trauma
- Dermatophytosis
- Demodicosis
- Dermatomyositis (collie and Shetland sheepdog)
- Nasal parakeratosis in Labrador retriever (DLE)

INITIAL DATABASE

- Deep skin scrapings

- Skin cytology (impression smear)
- Dermatophyte culture
- Routine hematology, chemistry profile, and urinalysis: generally unremarkable
- Serum antinuclear antibody test: usually negative (helps rule out SLE)

ADVANCED OR CONFIRMATORY TESTING

- Biopsy (under general anesthesia for DLE) for histopathologic evaluation, which is the gold standard for diagnosis. The typical lesional patterns are a lymphocyte-rich interface dermatitis along the dermoepidermal junction, hair follicles, and adnexal glands in conjunction with hydropic degeneration and apoptosis in the basal cell layer in DLE; hyperkeratosis and lymphocytic interface dermatitis in ECLE; and a lymphocyte-rich interface dermatitis and folliculitis with vesiculation at the dermal-epidermal junction in VCLE.
- Immunohistochemistry may be required.
- Biopsy for fungal and bacterial culture (DLE)

TREATMENT

TREATMENT OVERVIEW

Control and resolution of existing lesions are the goals of treatment. More than one therapeutic modality may be necessary. Typically, secondary/concurrent infections are treated first if present, and topical immunosuppression is the cornerstone of treatment.

ACUTE GENERAL TREATMENT

DLE:

- Routine antibiotic therapy: cephalexin, 22–30 mg/kg PO q 12 h for 30 days to rule out mucocutaneous pyoderma.
- If no or only partial improvement is noticed, a potent topical glucocorticoid (e.g., betamethasone, 0.1% amcinonide, or fluocinolone in dimethyl sulfoxide [Synotic]) can be used. Switch to a low-potency product (e.g., 1% hydrocortisone cream) once a favorable response is noted. If long-term topical glucocorticoid is not an option, the following treatment can be attempted:
- Topical tacrolimus, 0.1% ointment (ProTopic) q 12 h initially, wean based on a favorable response.
- Vitamin E 400-800 IU/d
- Essential fatty acids (n3 EFA, eicosapentaenoic acid) 30 mg/kg PO q 24 h
- Tetracycline and niacinamide: dogs >10 kg, 500 mg (<10 kg, 250 mg) of each drug PO q 8 h. May take 6–8 weeks to produce improvement. If good response, wean gradually (several weeks). Doxycycline, as an alternative to tetracycline: 5–10 mg/kg PO q 24 h.
- In refractory cases, systemic corticosteroids: prednisone, 1.7–2 mg/kg/d PO initially, then wean based on a favorable response. Concomitant azathioprine, 1–2 mg/kg PO q 24–48 h while administering prednisone.

ECLE and VCLE:

- Oral immunosuppressive doses of prednisone (1.7–2 mg/kg) are the first choice, with appropriate antibiotic therapy (see Canine Pyoderma, p. 951).
- Azathioprine (1–2 mg/kg, q 24-48 h) or cyclosporine (5 mg/kg PO q 12 h) may be added if lesions persist. Some form of combination therapy will likely be required in most cases. In ECLE, pentoxifylline and topical keratolytic/keratoplastic therapy (e.g., salicylic acid/sulfur shampoo) may be added, but in general, therapeutic response is poor.

CHRONIC TREATMENT

- Avoid intense sunlight (e.g., 8 am- 5 pm)
- Topical sunscreens if sunlight exposure is unavoidable
- Bilateral rotational nasal flaps for refractory cases (DLE)

POSSIBLE COMPLICATIONS

- Nasal cartilage erosion and arteriole hemorrhage (DLE)
- Squamous cell carcinoma (DLE)
- Septicemia (VCLE)
- Iatrogenic hyperadrenocorticism with chronic glucocorticoid use

RECOMMENDED MONITORING

- Routine CBC and serum biochemistry profiles if using azathioprine. Initially assessed q 14 days, reducing to q 3 months when condition is stable.
- High-dose corticosteroids are rarely required, but appropriate serum biochemistry profiles and urinalysis should be used in such cases.
- With chronic use of intermediate-or long-acting topical corticosteroid application, adrenal function should be monitored.

PROGNOSIS AND OUTCOME

- DLE: Good, but may require chronic therapy
- VCLE: Guarded
- ECLE: Poor

PEARLS & CONSIDERATIONS

COMMENTS

- Dogs with DLE typically feel and act well; the disorder is usually confined to the nasal planum.
- Depigmentation on the inner surfaces of the nostrils accompanied by nasal discharge suggests an intranasal problem (e.g., nasal aspergillosis) rather than DLE.
- In the past, many cases of mucocutaneous pyoderma and nasal parakeratosis have been wrongly diagnosed as DLE.
- Oral antibiotic trial is required prior to skin biopsies of the nasal planum, particularly in German shepherd dogs.

TECHNICIAN TIP

Dogs may quickly lick topical medications applied to the rostral nose, reducing their efficacy (and causing systemic absorption). Application of a thin film of topical creams or liquids to the nasal planum (using gloves with immunosuppressant drugs like tacrolimus) should be followed by distraction of the patient, feeding of a small treat, or other measures to reduce the likelihood of immediate licking away of the medication.

CLIENT EDUCATION

- Avoid intense ultraviolet light.
- Sunscreen use

AUTHOR: MICHAEL HANNIGAN

EDITOR: MANON PARADIS

Cutaneous Cysts

BASIC INFORMATION

DEFINITION

Variably sized nonneoplastic masses within the skin, forming saclike structures with an epithelial lining. Identification of cyst origin depends on epithelial lining or the structure from which the cyst developed. Most common are follicular cysts. Dermoid cysts are congenital and hereditary (see online chapter: Pilonidal Cyst).

SYNONYMS

Infundibular cyst (epidermal inclusion cyst, epidermoid cyst, sebaceous cyst)

EPIDEMIOLOGY

SPECIES, AGE, SEX

Common in dogs, rare in cats. Multiple follicular cysts may be noted in young dogs (congenital). Solitary follicular cysts may occur at any age.

GENETICS & BREED PREDISPOSITION

Follicular cysts: most commonly noted in boxers, Doberman pinschers, shih tzus, and miniature schnauzers

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Follicular cysts, infundibular cysts

HISTORY, CHIEF COMPLAINT

- Patients often present for evaluation of a fluctuant to solid, nonpainful, freely movable mass anywhere within the skin, although may be painful if ruptured or infected.
- Cysts may drain a yellow to brown liquid with caseous material. May refill over time.

PHYSICAL EXAM FINDINGS

- Majority of dogs do not show clinical signs.
- Multiple follicular cysts may be noted over the dorsal midline or pressure points (associated with trauma).
- Solitary follicular cysts are firm to fluctuant dermal or subcutaneous masses, 0.5-5 cm in diameter; often found on the head, neck, sacral area (dogs and cats), and proximal limbs (dogs).
- Ruptured cysts may be painful and pruritic with evidence of inflammation, infection, and self-trauma, especially if cellulitis is present.

ETIOLOGY AND PATHOPHYSIOLOGY

- Majority of cysts are follicular and classified as infundibular, matricial, or of hybrid type, based on whether the cyst develops from the infundibulum of the hair follicle, hair follicle matrix, or a combination of the two, respectively.
- Multiple follicular cysts are thought to be congenital, as are dermoid cysts.
- Solitary follicular cysts may develop secondary to dermal fibrosis, microtrauma, or blockage of follicular ostia.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Chief complaint and physical exam revealing a single or multiple nonpainful cutaneous masses with central fluctuation and/or draining are evocative of cutaneous cysts. Confirmation comes with treatment (excisional biopsy).

DIFFERENTIAL DIAGNOSIS

- Keratoacanthoma (intracutaneous cornifying epithelioma): benign skin tumors, thought to be of follicular origin, that superficially appear very similar to follicular cysts. Usually have a pore with a keratinous plug. May be multiple and generalized.
- Papilloma
- Trichofolliculoma
- Cutaneous horn
- Caseous abscess

INITIAL DATABASE AND ADVANCED OR CONFIRMATORY TESTING

- Excisional biopsy and histopathologic examination to determine specific cyst origin and rule out skin neoplasia
- Fine-needle aspirate with impression smears demonstrates sebaceous or keratinous debris.

TREATMENT

TREATMENT OVERVIEW

Surgical excision is chosen over conservative management (observation) if signs of pain, infection, or rupture are present (or recurrent); if masses are of concern to the owner or interfere with the patient's well-being; or if any uncertainty exists regarding the true nature of the mass. The latter situation is common, such that cutaneous cysts often are only suspected at first, and then are diagnosed postoperatively when histopathologic analysis is complete.

ACUTE GENERAL TREATMENT

Options are:

- Surgical excision
- Observation without treatment

CHRONIC TREATMENT

Retinoids such as isotretinoin (Accutane), 1-2 mg/kg q 12 h PO, or acitretin (Soriatane), 0.5-1 mg/kg PO q 12 h may be helpful as prophylactic therapy for multiple follicular cysts.

POSSIBLE COMPLICATIONS

- Cysts may rupture, leading to inflammation, secondary infection, and a foreign-body reaction.
- Retinoid therapy: keratoconjunctivitis sicca, conjunctivitis, pruritus, hyperactivity, stiffness, mucocutaneous junction, erythema, vomiting, diarrhea, teratogenicity, elevated liver enzymes are possible risks.

RECOMMENDED MONITORING

Retinoids: monitor liver enzymes, tear production.

PROGNOSIS AND OUTCOME

Good to excellent

PEARLS & CONSIDERATIONS

COMMENTS

- Never squeeze a cyst firmly to evacuate it, because this will increase the risk of inward cyst rupture, leading to a foreign-body reaction and secondary infection.

- If the client is concerned enough to present the patient for examination of a skin mass, benign neglect should not be encouraged.

EDITOR: MANON PARADIS

[+]Deceased

Cryptosporidiosis

BASIC INFORMATION

DEFINITION

A sporadic gastroenterocolitis caused by *Cryptosporidium* sp., a ubiquitous coccidian parasite.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Cats of any age and gender can be affected. Canine cryptosporidiosis is almost entirely seen in puppies <6 months old.

RISK FACTORS

- Immunosuppression due to concurrent viral (feline leukemia virus [FeLV], feline immunodeficiency virus [FIV], canine distemper virus [CDV]) infection
- Overcrowded conditions (humane shelters, catteries, etc.) raises prevalence of infection, since oocysts shed in feces are highly infective.
- Presence of other gastrointestinal parasites (*Giardia* sp., *Toxocara cati*) or in adult cats with severe intestinal disease (e.g., inflammatory bowel disease, lymphoma)
- Feeding home-cooked diets

CONTAGION & ZOONOSIS: Exposure and transmission are from fecally contaminated water or food sources. Zoonosis risk with immunocompromised humans warrants screening of cats/puppies to ensure they are not shedding oocysts.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Chronic small–bowel diarrhea (see p. 305) is the main clinical sign initially. Vomiting is less likely. Tenesmus, hematochezia, and weight loss may occur in long-standing infections.

PHYSICAL EXAM FINDINGS: Many *Cryptosporidium*-infected cats have subclinical infection. In cats with overt clinical signs, gas- and fluid-filled intestinal loops can be identified on abdominal palpation; cats may appear thin, unthrifty, and undernourished with chronic disease. Fever usually does not occur.

ETIOLOGY AND PATHOPHYSIOLOGY

- *Cryptosporidium parvum* and/or *C. felis* (in cats) or *C. canis* (in dogs) are transmitted by the fecal-oral route.
- Oocysts are found in feces. They may be shed at any time—during diarrhea, or in the absence of clinical signs—but the incidence of shedding from carriers (not showing signs) is low.
- Infection occurs without invasion into intestinal epithelium.
- The mechanism of clinical disease is postulated to be an interruption of normal flora by the parasite and later influx of inflammatory cells into the intestinal epithelium, leading to villous atrophy, secretory diarrhea, and malabsorption.
- The terminal ileum usually has the highest parasite load.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Routine screening specifically for *Cryptosporidium* is a low-yield procedure, given current techniques and the low prevalence of shedding, but testing should be considered in animals with compatible clinical signs and/or for immunocompromised pets or owners. More than one method of parasite identification may be necessary to rule out infection in highly suspect animals with clinical disease.

DIFFERENTIAL DIAGNOSIS

- Causes of gastroenterocolitis that prevail in overcrowded conditions: *Giardia* spp., *Cystoisospora* spp., *Tritrichomonas foetus, Toxoplasma gondii, Entamoeba histolytica*
- Other causes of diarrhea and weight loss: inflammatory bowel disease, gastrointestinal lymphoma, hyperthyroidism

INITIAL DATABASE

- Complete fecal examination consisting of direct smear, Sheather's solution flotation, and ZnSO4 analysis (any cat with diarrhea)
  - *Cryptosporidium* oocysts (4 mm; about half the diameter of an erythrocyte) may be identified by light microscopy at 100× power using any of these techniques.
  - Multiple fecal samplings improve the likelihood of finding oocysts.
  - Direct fecal smear stained with crystal violet makes oocysts more visible.
  - Phase microscopy is usually required on unstained preparations from a Sheather's fecal float.
  - In general, microscopic identification of oocysts requires expertise, is challenging even with fluorescent antibody staining and analysis with fluorescent microscopic and direct immunofluorescence, and is inferior to ELISA.
- CBC, serum biochemistry profile, urinalysis, total T4 analysis, abdominal imaging: if diarrhea and weight loss are present (rule out other disorders)
- FeLV and FIV ELISA

ADVANCED OR CONFIRMATORY TESTING

- Specimens shipped to commercial laboratories should be sent in a 38% formaldehyde (100% formalin) solution added to feces in a 1:10 dilution to kill oocysts but still allow detection. The oocysts can be detected using direct immunofluorescence antibody (DFA) staining after centrifugation.
- Feline serum cryptosporidial IgG ELISA: highly correlates with exposure to parasite but not necessarily active infection
- ELISA tests for cryptosporidial antigen in feces of humans and rodents are available. Diagnostic efficacy is unproven in cats and dogs.
- PCR tests for detecting cryptosporidial antigen in feces are available, more sensitive than DFA, and used for molecular typing of species in cats and dogs.
- Intestinal biopsy can differentiate from other intestinal disease but is costly, time consuming, and less effective than fecal examination.
- If necropsy is used for primary diagnosis, intestinal samples should be taken within hours after death; otherwise postmortem autolysis will prevent confirmation.

TREATMENT

TREATMENT OVERVIEW

The overall goals of treatment are to cure the infection, resolve clinical signs, and prevent further oocyst shedding. High numbers of oocysts may still be shed after completion of a course of therapy with resolution of clinical signs. Treatment should persist in an attempt to stop fecal shedding of oocysts.

ACUTE GENERAL TREATMENT

- Parenteral fluid therapy to correct hypovolemia, electrolyte imbalances, and acid-base disturbances if present.
- Antiprotozoal and antibiotic agents have been shown to be effective:
  - Azithromycin, 7-15 mg/kg PO q 12 h for 5-7 days. Current drug of choice for human cryptosporidiosis. Studies in cats have not been performed, but efficacy would be expected.
  - Paromomycin, 125-165 mg/kg PO q 12 h for 5 days, was the traditional drug of choice, but because of side effects, it has fallen from favor.
  - Tylosin, 11 mg/kg PO q 12 h for 28 days, helpful in treatment of diarrhea only
  - Nitazoxanide successfully used in human infections but dose for cats and dogs still under research

CHRONIC TREATMENT

Treatment of concurrent antibiotic-responsive enteritis/small-intestinal bacterial overgrowth (metronidazole, 10-15 mg/kg PO q 12-24 h for 5-7 days) may be beneficial in addition to treatment for *Cryptosporidium*.

NUTRITION/DIET

Feeding of a highly digestible diet is recommended in addition to pharmacotherapy in cats with severe clinical signs of chronic infection.

POSSIBLE COMPLICATIONS

Chronic infection: intestinal intussusception or lymphangiectasia are possible.

RECOMMENDED MONITORING

- Fecal analysis is recommended after treatment to determine if oocyst shedding is still occurring.
- Another fecal analysis may be required if diarrhea persists and/or recurs after treatment.
- Animals with chronic infection should be reevaluated at frequent intervals to assess progress.

PROGNOSIS AND OUTCOME

Prognosis is good with treatment in cats that do not have FeLV/FIV infection.

PEARLS & CONSIDERATIONS

COMMENTS

- This disease occurs in immunocompromised cats.
- Glucocorticoids and other immunosuppressive agents should be avoided until the infection is resolved.

PREVENTION

- This is a disease that is prevalent in overcrowded and unsanitary conditions.
- Reducing environmental contamination with improved sanitation is an important aspect of prevention.
- Although 5% ammonia will kill parasites, it requires 18 hours of contact for effect. Therefore, higher concentrations of ammonia are required if contact time is shortened. Dilute sodium hypochlorite (bleach diluted 1 part bleach to 32 parts water) kills *Cryptosporidium*.

CLIENT EDUCATION

- Potential for zoonosis
- Caution with immunosuppressed individuals and young children (greatest potential for infection)

AUTHOR: SARALYN SMITH-CARR

EDITOR: DEBRA L. ZORAN

Cryptorchidism

BASIC INFORMATION

DEFINITION

Failure of one or both testicles to descend into the scrotum. Literally, “hidden testicle.”

SYNONYM

Retained testicle(s)

EPIDEMIOLOGY

SPECIES, AGE, SEX: Intact males, canine and feline. A presumptive diagnosis can be made at 8 weeks, and a definitive diagnosis can be made by 6 months.

GENETICS & BREED PREDISPOSITION

- Considered to be a simple autosomal recessive trait. Incomplete penetrance and failure of Mendelian probability suggest a multifactorial or polygenic mode of inheritance.
- Mixed-breed dogs ~3.9%
- Purebred dogs ~8.7% (toy and miniature breeds show a significantly higher rate of occurrence).
- Cats (mixed and purebred) ~1.3%

RISK FACTORS

- Familial
- Drugs used during pregnancy with antiandrogen effects: diethylstilbestrol, estradiol cypionate, progestagens, cimetidine, flutamide, finasteride

ASSOCIATED CONDITIONS & DISORDERS

- Testicular neoplasia (see p. 1081): a cryptorchid testicle has a 10-fold greater risk of tumorigenesis.
- Intersex: male pseudo-hermaphrodite, Klinefelter's syndrome
- Infertility (see p. 603): only if bilaterally cryptorchid
- Benign prostatic hyperplasia (see p. 919): if left intact, cryptorchid males are as likely to develop prostatic disease as normal intact males.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Unilateral: one testicle retained (the right testicle is twice as likely to be retained as the left).
- Bilateral: both testicles retained (less common than unilateral cryptorchidism)
- Abdominal: testicle(s) retained within the abdomen (usually near the internal inguinal ring; rarely at the caudal pole of the kidney)
- Inguinal: testicle(s) retained within the inguinal canal (most common, ~75%)

HISTORY, CHIEF COMPLAINT

- Absence of one or both testicles in scrotum
- Male breeding behavior in a “neutered” animal

PHYSICAL EXAM FINDINGS

- Only one or no testes are palpable within the scrotum. Testes should be easily palpable and normally descended by 8 weeks of age.
- Penile examination: in cats, presence of penile spines indicates circulating androgens, most likely of testicular origin.

ETIOLOGY AND PATHOPHYSIOLOGY

- Testosterone is responsible for testicular descent in three stages of migration—abdominal, inguinal, and scrotal—through the dissolution of the cranial suspensory ligament and contraction of the gubernaculum.
- Testicular descent in cats is complete at birth, but the testicles can move freely into the inguinal canal for up to 6 months.
- Testicular descent in dogs is not completed until approximately 40 days after birth.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis of cryptorchidism can usually be made by palpation. Under unique circumstances, hormone testing or exploratory surgery may be required to make a definitive diagnosis.

DIFFERENTIAL DIAGNOSIS

- Monorchidism (unilateral testicular aplasia)
- Anorchidism (bilateral testicular aplasia)
- Intersex: male pseudohermaphrodite, Klinefelter's syndrome

INITIAL DATABASE

- Palpation. In tense or nervous animals, the testicle(s) may be drawn proximally toward the inguinal canal and may be palpable under sedation or general anesthesia.
- Examine the feline penis for spines.
- Ultrasonography may be useful in evaluating testicles retained in the abdomen.

ADVANCED OR CONFIRMATORY TESTING

- In animals where it is suspected but castration history is unknown:
  - Exploratory surgery
  - Human chorionic gonadotropin (hCG) stimulation test: measure blood testosterone concentrations before and 24 hours after 750 IU hCG given IV to dogs or cats, regardless of body weight. Presence of testicular tissue should yield a twofold increase in testosterone concentration (>0.1 ng/mL)

TREATMENT

TREATMENT OVERVIEW

- Prevent development of testicular tumors.
- Render the animal sterile to prevent propagation of heritable abnormalities.
- Remove testosterone-producing tissues to eliminate undesirable male behavior.

ACUTE GENERAL TREATMENT

- Castration:
  - Parainguinal approach for inguinally retained testicle(s)
  - Abdominal approach for abdominally retained testicle(s)

CHRONIC TREATMENT

GnRH vaccination: there is a commercially-available canine gonadotropin releasing hormone (GnRH) vaccine (Pfizer Animal Health) labeled for the nonsurgical management of benign prostatic hyperplasia in dogs. Immunization against GnRH elicits a reduction in gonadotropin (follicle-stimulating hormone and luteinizing hormone) and androgen concentrations via the production of serum neutralizing antibodies against GnRH. This immunocastration vaccine has been used by the section editor (Kutzler) for the nonsurgical management of cryptorchid cats and dogs to lower serum testosterone concentrations. The vaccination should be repeated at 6-month intervals to provide continued gonadotropin and androgen suppression. Administration of a nonsteroidal antiinflammatory drug (NSAID) at the time of vaccination will eliminate/minimize temporary injection site tenderness and pyrexia that can occur. The risk of tumorigenesis in the cryptorchid testicle is unknown but likely unchanged.

BEHAVIOR/EXERCISE

Where castration is not an option, cryptorchid males should be isolated from receptive females to prevent unwanted pregnancy. Cryptorchid males have serum testosterone concentrations equivalent to normal intact males, and the propensity to transmit the heritable trait to their offspring.

DRUG INTERACTIONS

Androgen or progestogen administration to pregnant dogs and cats prior to the time of fetal sexual determination may result in masculinization of female fetuses or increased incidence of cryptorchidism in male fetuses. Masculinized female offspring are genetically female with ovaries (no testicular tissue) but possess external genitalia similar to males.

POSSIBLE COMPLICATIONS

- If left untreated, it is considered a matter of time before neoplasia develops in the retained testicle.
- If left untreated, BPH and prostatitis (see p. 919) are potential secondary disease processes that commonly affect intact males.

RECOMMENDED MONITORING

If bilateral testicles cannot be palpated at 8 weeks, it is recommended to recheck the animal at 6 months before definitively diagnosing it as cryptorchid.

PROGNOSIS AND OUTCOME

Prognosis for life is excellent. Surgical castration eliminates the risk of testicular cancer and greatly reduces the risk of prostatic disease.

PEARLS & CONSIDERATIONS

COMMENTS

- Surgical correction or medical treatment (using gonadotropin-releasing hormone [GnRH] or hCG) to induce descent of the aberrant testicle into the scrotum have been reported in dogs (GnRH: two injections 50-100 mcg given SQ or IV with a 7-day interval; hCG: four injections of 100-1000 IU given IM with a 3- to 4-day interval between injections), but efficacy and ethics of such protocols are suspect. In addition, artificially corrected, cryptorchid testicles have the same 10-fold increased potential for neoplasia as retained testicles.
- A luteinizing hormone (LH) test is commercially available and commonly used to diagnose the presence or absence of ovarian tissue in bitches and queens. In spayed females, LH concentrations remain persistently elevated due to the lack of negative feedback from the gonads. This has also been found to be true in castrated male dogs. A positive LH test result (LH level > control [1 ng/mL]) is consistent with a castrated dog and rules out cryptorchidism.

PREVENTION

- Removal of affected animals from the breeding population results in reduced incidence within the breed.
- The dam and female siblings of affected males may be homozygous or heterozygous carriers but will not demonstrate phenotypic signs.
- The sire and some male siblings will be heterozygous carriers not showing any manifestations of cryptorchidism.

CLIENT EDUCATION

Do not breed animals that are cryptorchid or have sired cryptorchid offspring.

SUGGESTED READING

Klonisch T, et al: Molecular and genetic regulation of testis descent and external genita-lia development. Develop Biol 270:1–18, 2004.

AUTHOR: RICHARD WHEELER

EDITOR: MICHELLE A. KUTZLER

Cryptococcosis

BASIC INFORMATION

DEFINITION

A systemic mycosis caused by a dimorphic fungus with the yeast phase being infective, unlike other mycoses. Clinically, there is a predilection for the upper respiratory tract, central nervous system (CNS), skin, and eyes. The organisms are called the *Cryptococcus neoformans/Cryptococcus gatti* species complex.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- This is the most common systemic fungal disease in cats.
- Domestic and wild animals and humans may be infected.
- Cats may be more susceptible than dogs.
- No age or sex predilection in cats
- Young adult dogs are more commonly affected.

RISK FACTORS

- Exposure to pigeon droppings and soil in warm, humid climates
- Immunosuppressed states (glucocorticoids) and diseases (feline immunodeficiency virus [FIV] or feline leukemia virus [FeLV] infections in cats, ehrlichiosis/anaplasmosis in dogs) may be risk factors.

CONTAGION & ZOONOSIS

Zoonosis is unlikely, but caution is warranted. The yeast form is infective, and this does not aerosolize from infected tissues or body fluid.

GEOGRAPHY AND SEASONALITY

Worldwide distribution

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Respiratory, cutaneous, CNS, and ocular forms

HISTORY, CHIEF COMPLAINT

- Cats typically present with upper respiratory tract signs (sneezing, nasal discharge), swelling of the nose, skin lesions. Neurologic or ophthalmic signs may also be present.
- Dogs may present with weight loss, anorexia, lethargy, and neurologic or ophthalmic signs.

PHYSICAL EXAM FINDINGS

- Cats: unilateral or bilateral nasal discharge, sneezing, firm swelling over bridge of nose. Submandibular lymphadenomegaly.
- Dogs and cats: Multifocal neurologic signs with cranial nerve involvement. Ocular abnormalities including retinal detachment, chorioretinitis, panophthalmitis, optic neuritis. Cutaneous lesions including papules, nodules, or ulcerated draining lesions. Fever possible.

ETIOLOGY AND PATHOPHYSIOLOGY

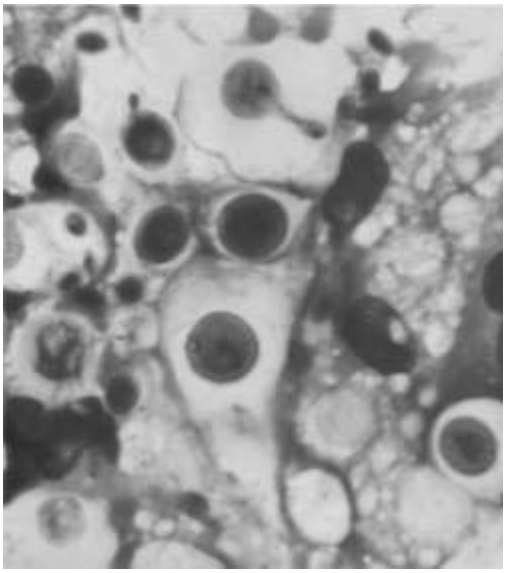
- *Cryptococcus* spp. are a saprophytic, round, yeastlike dimorphic fungus with a large heteropolysaccharide capsule
- Inhalation of yeastlike, nonencapsulated, airborne organisms is the most likely route of infection.
- The organism may then establish itself in the upper respiratory tract or in the alveoli, forming granulomas.

- In tissues, the organism forms a polysaccharide capsule that interferes with the immune response, preventing clearance of the organism.
- Hematogenous dissemination and invasion into the CNS and eyes may follow.
- Establishment of the organism in tissues and dissemination will occur if there is a poor cell-mediated immune response.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Characteristic physical findings raise the suspicion of the diagnosis; confirmation is achieved via serologic titers (most often) or fine-needle aspiration and cytology (less common now).



CRYPTOCOCCOSIS Cytology shows capsulate yeasts with narrow-neck budding and prominent unstained region surrounding each yeast (corresponding to capsule). Diff-Quik-stained smear.

(Courtesy R. Malik, University of Sydney, Sydney, Australia. In Greene CE: Infectious diseases of the dog and cat, ed 3, St Louis, 2006, Saunders, 2006, p 587, with permission.)

DIFFERENTIAL DIAGNOSIS

- Lymphosarcoma
- Respiratory: chronic rhinitis (bacterial or viral), nasal tumors, other systemic fungal diseases, toxoplasmosis, nasal polyps
- CNS:
  - Feline infectious diseases (FeLV, FIV, feline coronavirus/feline infectious peritonitis, toxoplasmosis, rabies)
  - Canine infectious diseases (canine distemper, rabies, ehrlichiosis, Rocky Mountain spotted fever, toxoplasmosis)
  - Noninfectious: granulomatous meningoencephalitis, neoplasia
- Cutaneous: bacterial pyoderma, abscesses, autoimmune skin disease
- Other systemic fungal disease (dogs)

INITIAL DATABASE

- CBC, serum chemistry panel, and urinalysis can be within normal limits.
- May find *Cryptococcus* spp. organisms in urine sediment (uncommon)
  - Stain to help differentiate organisms from fat droplets
- Thoracic radiographs may show an interstitial nodular pattern.
- Nasal radiographs may show bony lysis or proliferative lesions.

ADVANCED OR CONFIRMATORY TESTING

- Cytologic examination of nasal exudates, skin exudates, lymph node aspirate, cerebrospinal fluid (CSF), ocular fluid, tissue biopsy may reveal organisms.
- Latex agglutination test for capsular antigen in serum, urine, or CSF:
  - Diagnostic test of choice: positive test result indicates infection.

- False-negative results possible with localized infection
- Fungal culture from exudates, CSF, urine, ocular or joint fluid, and tissue samples
  - Represent a possible zoonotic hazard (aerosol) and should be performed in a specialized laboratory only. Not clinically recommended.

TREATMENT

TREATMENT OVERVIEW

Most cats can be treated with oral antifungal drugs only. Some cats/dogs may require additional treatment in severe cases. Treatment typically is given for months and can be expensive.

ACUTE AND CHRONIC TREATMENT

- Treatment of choice is fluconazole, 5-15 mg/kg PO q 12-24 h (dogs and cats); should continue at least 1 month past resolution of clinical signs.
- Amphotericin B if oral drugs are impossible or cost of fluconazole is prohibitive (dogs); ensure adequate hydration and renal function.
  - SQ: 0.5-0.8 mg/kg diluted with 400-500 mL 0.45% saline/2.5% dextrose and given 2-3 times weekly to a cumulative dose of 8-26 mg/kg (dogs; caution with fluid overload in small dogs)
  - IV: 0.25 (cats) or 0.5 (dogs) mg/kg IV q 48-72 h; total cumulative target dose of 4-8 mg/kg or 4-10 mg/kg for cats and dogs, respectively
- Lipid-soluble amphotericin B (less nephrotoxic, more expensive): 1 mg/kg IV q 48-72 h for 60 days (target for dogs, cats)
- Itraconazole (less expensive than fluconazole), 5 mg/kg PO with food q 12 h (cats). Formulation may make dosing difficult (100-mg capsules), but oral liquid (10 mg/mL) available.
- Ketoconazole, 5-15 mg/kg PO q 12 h (dogs). Least effective but least expensive.
- Terbinafine, 10 mg/kg PO q 24 h (cats that show resistance to azoles)
- Voriconazole is also effective (and crosses blood-brain barrier) but very expensive.
- CNS infections: fluconazole is preferable (crosses the blood-brain barrier) over amphotericin B or ketoconazole.

DRUG INTERACTIONS

- Itraconazole and ketoconazole should not be administered with other hepatically metabolized drugs.
- Amphotericin B should not be administered with other renally excreted drugs.
- Fluconazole is eliminated through the kidneys, and dose must be decreased in patients with renal failure.

POSSIBLE COMPLICATIONS

- Itraconazole may result in gastrointestinal signs and hepatotoxicity (initially manifested with elevated serum alanine aminotransferase). Rare side effects include vasculitis and cutaneous ulcerations.
- Ketoconazole may cause gastrointestinal signs and elevated serum liver enzymes. Cats have an increased risk for hepatotoxicity, and use of this drug is controversial in this species.
- Amphotericin B is potentially nephrotoxic and can cause phlebitis.

RECOMMENDED MONITORING

- Monitoring of serial titers may help assess response to therapy:
  - A decrease in serum antigen titer implies a favorable prognosis (specifically, better prognosis if titer decreases 10-fold or more after 2 months of treatment).
  - Use of antigen titers to guide duration of treatment: treatment should be continued for 1 month after complete resolution of clinical signs and a decrease in titer by at least two orders of magnitude (e.g., if 1:512 at diagnosis, then 1:128, 1:64, or lower) but ideally when there is an undetectable titer.
  - In some cats it may take 3-5 years to reach a negative titer, if ever, irrespective of treatment.
- Liver enzymes and renal values should be routinely monitored while animal is treated with antifungals.
- Animals treated with amphotericin B should have blood urea nitrogen (BUN), creatinine, urine GGT if possible, and urine sediment examinations performed routinely. A rising BUN and/or casts in the urine sediment may necessitate discontinuing or lowering the dose of amphotericin B.

PROGNOSIS AND OUTCOME

- Infection may be cleared in cats; however, maintenance antifungal therapy may be necessary, especially in FeLV/FIV-positive cats.
- FeLV/FIV seronegative status is significantly associated with treatment success (data for itraconazole) in cats with nasal cryptococcosis. FeLV/FIV-positive cases are associated with severe signs involving the CNS and eyes.
- CNS infections and disseminated infections are more likely to exist in cats with FeLV or FIV and may be more difficult to clear.
- Magnitude of pretreatment antigen titers has no significant effect on prognosis using itraconazole.
- More cats with the cutaneous forms of cryptococcosis (82%) were treated successfully than cats with intranasal (53%) cryptococcosis or cryptococcal infection of other sites (43%).
- Guarded prognosis in dogs

PEARLS & CONSIDERATIONS

TECHNICIAN TIP

The subtle deformation of the muzzle or face of an early lesion of cryptococcosis may first be noticed by a member of the technical staff and is an important observation to bring to the attention of the attending veterinarian.

PREVENTION

- No vaccine available
- Avoid pigeon droppings and damp, shaded soil.

Cricopharyngeal Achalasia/Dysphagia

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Cricopharyngeal achalasia is a rarely diagnosed condition representing the failure of upper esophageal sphincter (the cricopharyngeus muscle) relaxation and lack of synchrony with pharyngeal muscular activity.

SYNONYMS

Cricopharyngeal dysphagia, cricopharyngeal asynchrony

EPIDEMIOLOGY

SPECIES, AGE, SEX

Spaniel dogs overrepresented (springer, cocker). Often congenital; most cases present at a young age upon weaning. Rarely is diagnosed in older animals or in conjunction with other conditions. Predominantly recognized in the puppy/young dog.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Signs include gagging, retching, regurgitating food, coughing, and nasal reflux, typically beginning with the introduction of solid food (time of weaning). Repeated attempts to swallow may be seen upon careful evaluation during eating. Dogs are often thin and in poor body condition because of ineffective food intake and may lose weight despite an increased appetite.

PHYSICAL EXAM FINDINGS

- Patients are usually thin and may be smaller in stature compared to littermates.
- Observation of respiratory effort and thoracic auscultation may offer clues of underlying aspiration pneumonia. The dog should be observed while eating; repeated, ineffective attempts to swallow are suggestive of cricopharyngeal achalasia.

ETIOLOGY AND PATHOPHYSIOLOGY

- Cricopharyngeal achalasia results from asynchrony of relaxation of the cricopharyngeus muscle in relation to pharyngeal activity that forms and directs a bolus caudally.
- The cricopharyngeus muscle contracts during normal activity. When a bolus formed by pharyngeal muscular activity is pushed caudally by the base of the tongue, the cricopharyngeus muscle relaxes, allowing passage of the bolus into the upper esophagus.
- Asynchronous cricopharyngeal relaxation results in repeated caudal movement of a bolus against persistent cricopharyngeal contraction. Boluses may eventually reach the upper esophagus, may be regurgitated, or may be aspirated into the trachea.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Characteristic history of prehension of food but inability to swallow is highly suggestive of the diagnosis. Confirmation is obtained with fluoroscopic evaluation of the oropharyngeal and esophageal processing of liquids and solids. Clinical signs and static imaging (even with contrast) may not differentiate oral, pharyngeal, and cricopharyngeal disorders. However, a correct diagnosis is imperative prior to surgical treatment to avoid worsening clinical signs and aspiration pneumonia.

DIFFERENTIAL DIAGNOSIS

- Pharyngeal dysfunction (usually results in the inability to form a bolus)
- Oral dysfunction (interferes with prehension)

- Oropharyngeal/proximal esophageal obstruction (foreign body, mass): apparent radiographically, on sedated pharyngeal exam, or endoscopically

INITIAL DATABASE

- Clinical pathologic abnormalities result from severe malnutrition or aspiration pneumonia.
- Thoracic radiographs should be made to rule out megaesophagus and aspiration pneumonia.

ADVANCED OR CONFIRMATORY TESTING

A definitive diagnosis is made with fluoroscopy of the pharynx and esophagus when the patient is offered food mixed with barium.

- A bolus is formed, but repeated attempts at caudal movement of the bolus beyond the upper esophageal sphincter result in little or no entry of barium into the esophagus. Barium may enter the nasopharynx or the trachea.
- When barium does enter the esophagus, esophageal motility must be evaluated prior to considering surgical correction of the condition. Decreased esophageal motility or megaesophagus are contraindications to surgical therapy.

TREATMENT

TREATMENT OVERVIEW

- The definitive treatment approach of choice is surgical; medical management of complications (e.g., aspiration pneumonia) is imperative for preoperative stabilization.
- The goal of surgical treatment is to allow unimpaired passage of boluses from the pharynx into the esophagus, without tracheal contamination.

ACUTE AND CHRONIC TREATMENT

- Treatment of complications prior to anesthesia (e.g., aspiration pneumonia (p. 885), undernourishment)
- Partial cricopharyngeal myectomy: most common. Partial thyropharyngeal myectomy in conjunction with cricopharyngeal myectomy has also been reported. Referral to a veterinary soft-tissue surgeon is recommended.

NUTRITION/DIET

- Preoperatively, esophagostomy tube (see p. 1267) or gastrostomy tube (see p. 1270) placement may be required to meet nutritional requirements and normalize body condition.
- Postoperatively, the patient is fed canned food in the form of easily swallowed round portions. The diet may be returned to normal over a period of 1 month.

POSSIBLE COMPLICATIONS

Clinical signs can recur due to inadequate muscular excision or fibrosis of the myectomy site. Reoperation may be performed on the contralateral side of the cricopharyngeus muscle if necessary. Surgery with concurrent esophageal dysfunction is relatively contraindicated because it results in recurrent reflux of esophageal contents in the caudal pharynx, and endotracheal aspiration.

PROGNOSIS AND OUTCOME

- The prognosis for cricopharyngeal achalasia is generally good, but poor in cases of concurrent pharyngeal or esophageal dysfunction.
- Recurrence of clinical signs or aspiration pneumonia has been reported in 0 of 6 and 8 of 14 patients in two different studies.

PEARLS & CONSIDERATIONS

- To decrease the risks of anesthesia and surgery, intensively treat undernourishment and/or aspiration pneumonia prior to surgical intervention.
- Seriously consider whether cricopharyngeal myectomy should be done in patients with esophageal motility disorders, as aspiration pneumonia is likely after surgery.
- Closely monitor patients after surgery, and consider reoperation if clinical signs recur.

Cranial Vena Cava Syndrome

BASIC INFORMATION

DEFINITION

Cranial vena cava syndrome is an uncommon sequela to extraluminal compression, invasion, or intraluminal obstruction of the cranial vena cava (CrVC). Obstruction of the CrVC results in pitting edema of the head, neck, and forelimbs.

SYNONYMS

Caval syndrome, precaval syndrome, superior vena caval syndrome

EPIDEMIOLOGY

SPECIES, AGE, SEX

Depends on underlying cause

RISK FACTORS

- Jugular catheters
- Cranial mediastinal neoplasia (e.g., thymoma, lymphoma, carcinoma, aortic body tumors)
- Hypercoagulable conditions (e.g., sepsis, immune-mediated hemolytic anemia, protein-losing nephropathies, corticosteroid excess, neoplasia, pancreatitis)
- Mycoses leading to the formation of granulomas (e.g., blastomycosis, cryptococcosis)
- Transvenous pacemaker implantation

CONTAGION & ZOONOSIS

Fungal granulomas causing CrVC syndrome may be caused by organisms that can also infect humans (*Blastomyces dermatitidis, Cryptococcus neoformans*), but these would be common-source infections, not zoonoses.

GEOGRAPHY AND SEASONALITY

Infectious causes (e.g., blastomycosis) are more prevalent in certain geographic areas.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Head, neck, and forelimb swelling
- Additional clinical signs depend on underlying cause

PHYSICAL EXAM FINDINGS

- Symmetric, nonpainful pitting edema of head, neck, and forelimbs
- Dyspnea, tachypnea, muffled heart/lung sounds (if pleural effusion present)
- Weakness, tachycardia, arrhythmias, muffled heart sounds (if pericardial effusion present)
- ± Jugular venous distension
- ± Engorgement of conjunctival and scleral vessels
- Additional physical exam findings depend on underlying cause.

ETIOLOGY AND PATHOPHYSIOLOGY

- Extraluminal compression, invasion, or intraluminal obstruction of the CrVC causes impaired venous return from the cranial portion of the body. This leads to interstitial fluid accumulation, resulting in edema of the head, neck, and forelimbs.
- The most common causes include mediastinal neoplasia, fungal granulomas, cranial vena caval thrombosis (e.g., secondary to hypercoagulable states, tumor emboli, jugular catheters), and transvenous pacemaker implantation.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The physical exam findings (notably pitting edema of the head and forelimbs) are highly suggestive of the diagnosis. Diagnostic tests such as thoracic radiographs, advanced imaging, cytologic evaluation of masses and effusions, and histopathologic examination of tissue specimens are used in sequential steps to confirm the diagnosis and identify the underlying etiology.

DIFFERENTIAL DIAGNOSIS

For head and neck swelling:

- Angioedema (e.g., vaccine reaction, insect-bite hypersensitivity)
- Generalized peripheral edema (e.g., secondary to hypoalbuminemia, vasculitis, right-sided congestive heart failure)
- Acute blunt trauma to head/neck
- Subcutaneous emphysema
- Lymphangiosarcoma of the head and neck
- Myxedema (e.g., secondary to hypothyroidism)
- Foreign body around neck (e.g., elastic band)
- Salivary mucocele (cervical)
- Jugular vein thrombosis or mass
- Abscessation or cellulitis
- Rattlesnake bite

INITIAL DATABASE

- To help determine underlying cause:
- CBC
- Serum biochemistry profile
- Urinalysis
- Feline leukemia and feline immunodeficiency tests (to help evaluate for the presence of lymphoma in cats)
- Thoracic radiographs (to identify cranial mediastinal masses, pleural and/or pericardial effusion)

ADVANCED OR CONFIRMATORY TESTING

- Thoracic ultrasonography (to visualize emboli or tumor compression/invasion of cranial vena cava)
- Nonselective angiography, venography (to identify CrVC filling defects, localize site of obstruction, highlight collateral circulation)
- CT or MRI
- Echocardiography (to identify pericardial effusion or masses at the level of the terminal CrVC)
- Fine-needle aspiration or biopsy of thoracic masses
- Blastomycosis urine antigen test (for detection and potential monitoring of blastomycosis infections)

TREATMENT

TREATMENT OVERVIEW

Treatment is directed toward removing obstructive lesion from CrVC and treating inciting cause.

ACUTE GENERAL TREATMENT

- Mediastinal masses: depending on tumor type, treatment may include surgery, chemotherapy, or radiation (alone or in combination).
- Fungal granulomas: systemic antifungal drugs (e.g., itraconazole, fluconazole, depending on extent and type of mycosis)
- CrVC thrombosis:
  - Treat underlying cause
  - Remove jugular catheters if present
  - ± Anticoagulants (e.g., heparin): efficacy unproven
  - ± Thrombolytic agents (e.g., streptokinase, tissue plasminogen activator): efficacy controversial; may result in life-threatening hemorrhage
- ± Diuretics (to minimize edema formation): efficacy limited

CHRONIC TREATMENT

Depends on underlying disease

POSSIBLE COMPLICATIONS

Thrombolytic agents may result in life-threatening hemorrhage.

PROGNOSIS AND OUTCOME

- Prognosis depends on severity of underlying illness; presence of CrVC syndrome does not appear to confer a worse prognosis than that of the underlying disorder alone.
- Head, neck, and forelimb edema may abate if CrVC obstruction removed and/or if adequate collateral circulation develops.

PEARLS & CONSIDERATIONS

COMMENTS

- Although the name is similar, heartworm caval syndrome is an entirely different clinical entity involving right-sided heart failure, hemolysis, and hemoglobinuria as a consequence of severe heartworm disease.
- Human medicine offers promising alternatives to the current therapies available in veterinary medicine:
    - Surgical bypass of the CrVC obstruction
    - Endovascular therapy—a combination of:
        - Thrombolytic agents
        - Angioplasty (balloon dilation of obstructed vessel)
        - Stent placement at the level of vascular obstruction
        - ± Anticoagulants

PREVENTION

- Avoid jugular catheters in hypercoagulable patients.
- Consider prophylactic anticoagulant therapy in patients with hypercoagulable disorders.
- If thrombolysis successful, the use of antiplatelet therapy to reduce vascular reocclusion of residual thrombus or endothelial injury is recommended.

Cranial Cruciate Ligament Injury

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Partial or complete tearing of the cranial cruciate ligament (CrCL), causing stifle instability; a very common condition in dogs and an uncommon condition in cats.

SYNONYM

Anterior cruciate ligament (ACL) rupture

EPIDEMIOLOGY

SPECIES, AGE, SEX

Seen in dogs, and less frequently in cats, of all ages

GENETICS & BREED PREDISPOSITION

- Dogs: more common in large breeds, especially rottweilers, Labrador retrievers, Newfoundlands, Staffordshire terriers. Genetic predisposition has been demonstrated in Newfoundlands and boxers (so far)
- Cats: not known to be a heritable problem

RISK FACTORS

- Underlying systemic disease: hyperadrenocorticism, autoimmune disease, cutaneous asthenia
- Overweight condition

ASSOCIATED CONDITIONS & DISORDERS

- Patellar instability
- Intercondylar notch stenosis
- Meniscal injury
- Osteoarthritis
- Immune-mediated arthritis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Partial CrCL rupture
- Complete CrCL rupture
- Avulsion of the insertion of the CrCL: usually occurs in immature dogs
- Injury to the medial meniscus often accompanies CrCL rupture

HISTORY, CHIEF COMPLAINT

- Variable lameness of one or both hind limbs; onset acute or progressive
- Affected hind limb may be held up or off-weighted when animal is standing.
- Lameness may worsen with exercise and improve with rest.

PHYSICAL EXAM FINDINGS

- Unilateral or bilateral hind limb lameness; affected limb may be held up in acute injuries, will be weightbearing with more chronic affliction
- Affected stifles are externally rotated and more flexed than normal when walking.
- Stifle joint effusion and thickening of joint capsule, often most pronounced over medial aspect of proximal tibia (medial

buttress formation)
- Asymmetric sitting position with one stifle abducted
- Cranial drawer sign, cranial tibial thrust (see Initial Database) may or may not be elicited.
- Meniscal clicking may be present during joint manipulation.

ETIOLOGY AND PATHOPHYSIOLOGY

- Biomechanical instability of the stifle joint results from an imbalance of muscular and weight-bearing forces necessary to control the cranial tibial thrust, excessive internal rotation, and hyper-extension of the stifle usually limited by an intact cranial cruciate ligament.
- In dogs, CrCL rupture is usually due to degeneration rather than direct trauma. The cause of this degeneration is unknown: conformation problems, collagen abnormalities, immune disease and low-grade bacterial infection may play a role.
- In cats, direct trauma is usually the cause.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

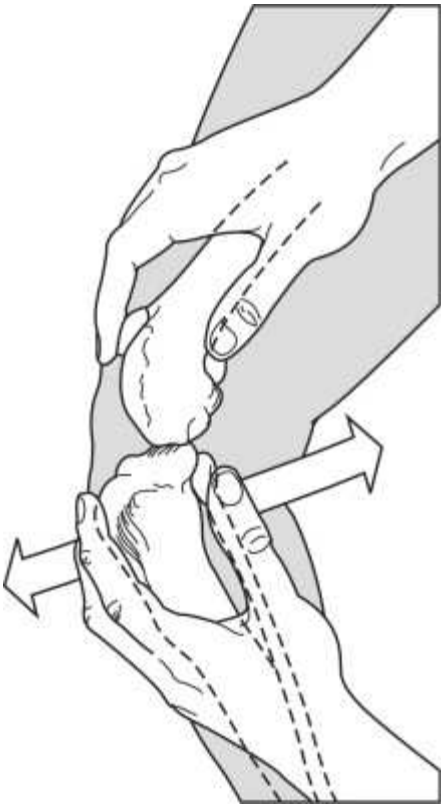
Diagnosis is usually based on presence of the characteristic hindlimb lameness combined with evidence of stifle effusion on physical examination and radiographs. Absence of pain on manipulation, cranial drawer sign, or cranial tibial thrust does *not* rule out cranial cruciate rupture as the source of the lameness.

DIFFERENTIAL DIAGNOSIS

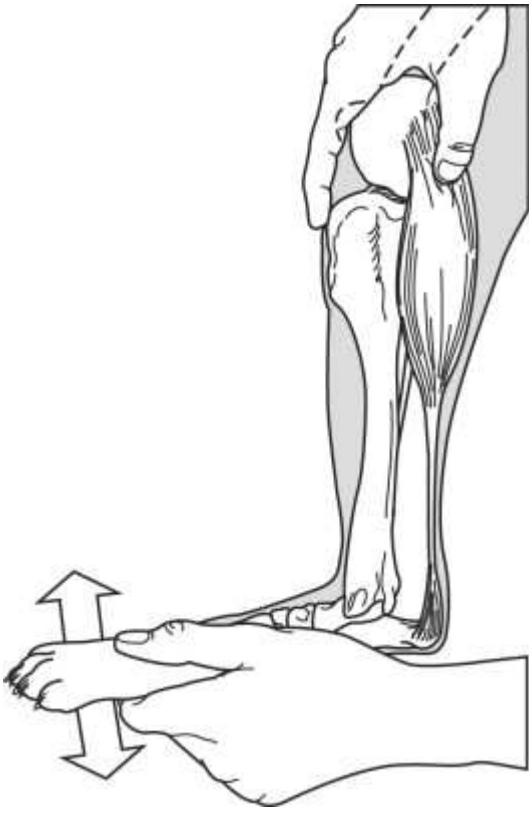
- Patellar luxation
- Lumbosacral disease
- Hip dysplasia or osteoarthritis
- Iliopsoas strain
- Bone/joint neoplasia
- Osteochondrosis of the lateral femoral condyle
- Bacterial, rickettsial, or fungal infection
- Immune-mediated arthritis
- Caudal cruciate or collateral ligament injury (uncommon)
- Long digital extensor tendon avulsion (uncommon)
- Isolated meniscal injury (boxers almost exclusively)

INITIAL DATABASE

- Rickettsial and/or fungal titers (based on geography)
- Palpation of stifle joints for instability; this may require sedation:
    - Cranial drawer sign: manual cranial displacement of tibia relative to femur
    - Cranial tibial translation or thrust: cranial movement of tibial tuberosity as hock is flexed and gastrocnemius muscle contracts.
- Lateral and craniocaudal stifle radiographs
    - Effusion will be evident in almost all patients (except for some small dogs). Degenerative changes are present in cases more chronic than a few weeks. Some animals (especially small dogs and cats) will show cranial displacement of the tibia relative to the femur (static drawer).
    - Measurements such as tibial plateau slope angle are made for planning when an osteotomy technique is chosen for repair.



CRANIAL CRUCIATE LIGAMENT INJURY Palpation of the stifle joint for cranial drawer motion of the tibia relative to the femur with cranial cruciate ligament insufficiency.



CRANIAL CRUCIATE LIGAMENT INJURY Palpation of the stifle joint using tibial compression test for cranial cruciate ligament injury. With cranial cruciate ligament injury, flexion of the hock will cause cranial displacement of the tibia.

ADVANCED OR CONFIRMATORY TESTING

- Arthrocentesis (to eliminate infection, immune-mediated arthropathy as causes)

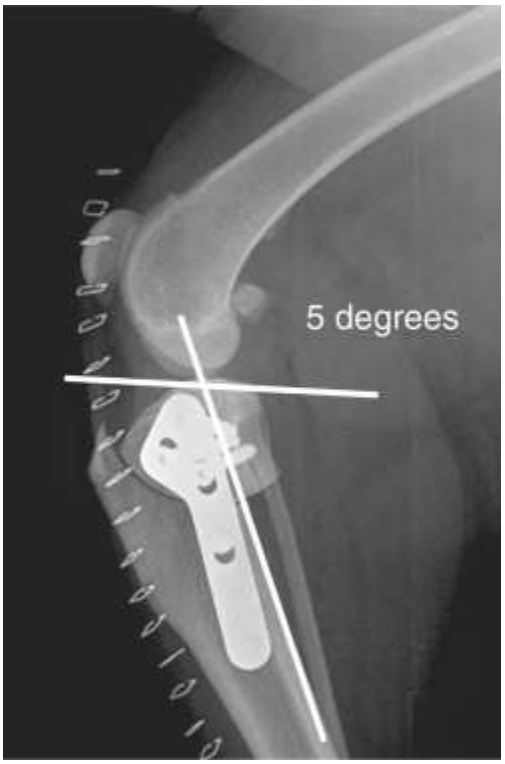
- Arthroscopy or arthrotomy (the most common way to confirm diagnosis)
- MRI

TREATMENT

TREATMENT OVERVIEW

- About 50% of small (<15 kg) dogs and most cats do well with conservative therapy. Only about 20% of larger dogs return to good function with conservative management. By contrast, all of the surgical treatments listed below have a reported success rate of 85% or more for patients of all sizes.
- Surgical management usually involves inspection (and débridement or release if necessary) of menisci, combined with a stabilization technique. Stabilization techniques involve either creation of a structure ("prosthetic ligament") to mimic the function of the CrCL, or osteotomy to change the geometry of the stifle so there is minimal cranial tibial translation when the limb is bearing weight.
- Success rates are similar for prosthetic ligament and osteotomy (TPLO, TTA) repairs. After osteotomy techniques, return to full weightbearing is usually faster and progression of osteoarthritis may be somewhat slower (controversial), however. Cats and small dogs are most commonly treated with prosthetic ligament techniques.

CRANIAL CRUCIATE LIGAMENT INJURY Preoperative radiograph of the stifle of a dog with cranial cruciate ligament rupture. The tibial plateau angle is 30°.



CRANIAL CRUCIATE LIGAMENT INJURY Photograph of the same stifle after tibial plateau leveling osteotomy (TPLO). The tibial plateau angle is satisfactory at 5°.

ACUTE GENERAL TREATMENT

- Medical management:
  - Physical rehabilitation (see Physical Rehabilitation section p. 1329 for details)
    - Controlled leash walks
    - Sit-to-stand exercises
    - Swimming, water treadmill work
  - Nonsteroidal antiinflammatory drugs (NSAIDs):
    - Carprofen, 2 mg/kg PO q 12 h; *or*
    - Etodolac, 10-15 mg/kg PO q 24 h; *or*
    - Deracoxib, 1-2 mg/kg PO q 24 h (may use 3-4 mg/kg PO q 24 h for first 7 days only); *or*
    - Meloxicam, 0.1 mg/kg PO q 24 h; *or*
    - Meclofenamic acid, 1.1 mg/kg PO q 24 h after eating for 5 days maximum; *or*
    - Tepoxalin, 10 mg/kg PO q 24 h (new product, objective data pending)
- Surgical stabilization of the stifle:
  - Intraarticular fascia lata or patellar tendon autogenous graft: limits cranial motion and internal rotation of the tibia.
  - Extracapsular suture stabilization (femoral condyle or fabella to tibia): limits drawer motion and rotation. There are a number of variations on this theme.
  - Fibular head transposition: advances the insertion of the lateral collateral ligament so it can limit cranial drawer and internal rotation.
  - Tibial plateau leveling osteotomy (TPLO): neutralizes cranial tibial thrust by chancing tibial plateau angle from a normal of 20○-26○ to between 5○ and 10○ postoperatively.
  - Tibial tuberocity advancement (TTA): neutralizes cranial tibial thrust by making the pull of the patellar tendon perpendicular to the tibial plateau when the knee is bearing weight.
  - Triple tibial osteotomy (TTO) simultaneously reduces tibial plateau slope and slightly advances the tibial tuberosity, making it something like a hybrid of TPLO and TTA.
  - Pinning or wiring of avulsion injuries to reattach ligament origin or insertion can be done in young dogs with large avulsion fragments.
- Treatment of meniscal injury:
  - Medial meniscectomy (partial or complete)
  - Medial meniscal release (has an effect similar to meniscectomy, sometimes done prophylactically)

CHRONIC TREATMENT

- Management includes the same treatments as in acute cases, but more long-term medical management of osteoarthritis may

be required. Success rates are similar for surgical treatment of acute and chronic cranial cruciate injuries.
    - NSAIDs as listed previously
    - Physical rehabilitation
    - Disease-modifying osteoarthritis agents may be helpful, including:
        - Polysulfated glycosaminoglycan, 5 mg/kg IM once weekly × 4-6 weeks; *or*
        - Pentosan polysulfate, 3 mg/kg SQ once weekly; *or*
        - Oral formulations (glucosamine, chondroitin sulfate, avocado soy unsaponifiables): according to formulation/labeled instructions

NUTRITION/DIET

- Weight control helps alleviate lameness due to osteoarthritis.

POSSIBLE COMPLICATIONS

- Medical management:
    - Gastrointestinal, hepatic, renal, or other systemic reactions from NSAID therapy
    - Continued progression of degenerative joint disease
    - Failure of medical management to control pain
- Surgical management:
    - Failure to stabilize the stifle joint
    - Progression of degenerative joint disease
    - Postoperative meniscal injury:
        - Damage not recognized at surgery
        - Shear forces not neutralized
    - Fracture or implant failure
    - Infection (soft tissue or bone)

RECOMMENDED MONITORING

- Basic laboratory monitoring of patients on NSAID therapy
- Weight loss, exercise levels (rehabilitation), and clinical signs as dictated by the patient
- Radiographic monitoring of healing of osteotomies (usually at 6 and 10 weeks after surgery), and of any repair if clinical signs worsen

PROGNOSIS AND OUTCOME

- Long-term function for patients that have undergone a reconstructive procedure is good. Published assessments of most techniques in the past 25 years describe improvement in 80%-90% of dogs after surgery, regardless of the methodology.
- Postoperative rehabilitation is critical for clinical recovery (see p. 1329).

PEARLS & CONSIDERATIONS

COMMENTS

- Bilateral lameness may be difficult to recognize and is often confused with neurologic disease.
    - A careful orthopedic examination is essential.
- Injury of the contralateral cranial cruciate ligament occurs in 40%-50% of canine patients. No measures have yet been identified to prevent this from occurring.
- Some surgeons recommend surgery for patients (including cats) of any size to ensure optimum function.
- In one arthroscopic study of partial CrCL injury, TPLO stopped the progression of further ligament rupture in six of seven dogs.
- *Editor's note*: Practitioners should consider consultation and referral with an orthopedic surgeon; selection of the “best” procedure continues to be controversial among specialists.

AUTHOR: KATHLEEN LINN

EDITOR: JOSEPH HARARI

1ST EDITION AUTHORS: JAMES P. BOULET, BARBARA R. GORES

Cough

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A reflexive, forceful expulsion of air from the lungs and airways

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats of any age and either sex

RISK FACTORS

- Exposure to airborne irritants or allergens
- Contact with other animals (infectious causes)

CONTAGION & ZOONOSIS

- Dogs: infectious tracheobronchitis ("kennel cough"); canine distemper
- Cats: viral rhinotracheitis

ASSOCIATED CONDITIONS & DISORDERS

Vomiting: the "terminal retch" that occurs at the end of a paroxysm of coughing may be misinterpreted as vomiting by clients.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

A useful way to consider the causes of cough, and the way to manage a coughing patient, involves the following categories:

- Purposeful cough. The cough is beneficial in expelling foreign material (e.g., inhaled foreign body) or substances (e.g., pus in pneumonia patients).
- Warning cough. The cough is a respiratory manifestation of a systemic disturbance that may become life threatening (e.g., pulmonary edema from congestive heart failure, pulmonary hemorrhage from anticoagulant rodenticide toxicosis).
- Nuisance cough. The cough is disturbing or distressing to the patient and/or the owner but is not immediately life threatening (e.g., infectious tracheobronchitis/"kennel cough," chronic sterile bronchitis).

HISTORY, CHIEF COMPLAINT

- Character (moist versus dry, soft versus hacking, nocturnal versus diurnal): may offer some insight regarding cause, but much overlap exists between different diseases.
- Dyspnea concurrently: generally indicates a more pressing need for diagnosis and treatment (purposeful and warning categories).
- Exposure to detrimental environment: contagion, inhalation of irritant substances
- Duration of the cough: coughs that have maintained an equal intensity for months or more are commonly associated with disorders in the "nuisance cough" category.

PHYSICAL EXAM FINDINGS

- Dyspnea. See History, Chief Complaint above.
- Inducible cough. A cough that is elicited with application of tracheal pressure may occur with tracheobronchial diseases, with pulmonary parenchymal disease, or in unaffected animals. It does not indicate the anatomic location of the underlying problem. Tracheal pressure may be useful for confirmatory purposes if the owner is unsure whether the clinical sign observed at home is a cough.
- Pulmonary auscultation. Possible abnormalities include crackles/rales (interstitial fibrosing lung disease, pulmonary edema,

others), loud bronchovesicular sounds (pulmonary edema, airway disease, others), wheezes (airway disease), and decreased lung sounds (pleural effusion, pneumothorax, intrathoracic mass).
- Cardiac auscultation. The presence of a heart murmur in a coughing dog raises the possibility of pulmonary edema (see p. 468). However, unrelated cardiac and respiratory diseases often coexist.
- A complete physical examination is indicated because many disorders produce cough as only one manifestation of the underlying disease.

ETIOLOGY AND PATHOPHYSIOLOGY

- Abnormal presence of gases, substances, or material on the respiratory epithelium triggers afferent vagal impulses to the brainstem.
- Efferent impulses cause a sequence of glottis closure, abdominal and thoracic muscle contraction, and sudden glottis opening, causing the burst of air flow that is the cough.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The first step is to confirm if the chief complaint is indeed coughing if the owner is unsure; tracheal pressure to elicit a cough or videotaping at home can help. With a confirmed cough, history, physical exam, and thoracic radiographs are the cornerstones of first-line diagnostic evaluation.

DIFFERENTIAL DIAGNOSIS

Causes of cough:

- Tracheobronchitis
- Collapsing trachea (dogs only)
- Chronic sterile bronchitis
- Asthma/allergic airway disease (cats)
- Bronchiectasis
- Allergic bronchitis
- Tracheal neoplasia
- Tracheal/bronchial foreign body
- Pneumonia (aspiration, bacterial, fungal, protozoal)
- Cardiogenic pulmonary edema (dogs only)
- Noncardiogenic pulmonary edema/acute respiratory distress syndrome
- Eosinophilic bronchopneumopathy
- Pulmonary hemorrhage
- Heartworm disease
- Pulmonary thromboembolism
- Pulmonary neoplasia
- Lungworms
- Tracheobronchial lymphadenopathy
- Left atrial enlargement
- Mediastinal mass

INITIAL DATABASE

- Thoracic radiographs and lateral cervical radiograph:
  - Radiographs are the initial diagnostic test of choice for coughing patients.
  - Indicated in any patient with signs of systemic illness, any patient with a cough of >10 days' duration, and any patient whose owner is concerned and wishes more than an exam-room evaluation
- Fecal analysis (Baermann) if lung-worms are locally endemic
- Heartworm antigen test in endemic areas
- Routine medical evaluation, including CBC, serum biochemistry profile, and urinalysis if patient shows systemic signs
- Prothrombin time, partial thromboplastin time, platelet count if the patient roams outdoors or could otherwise have been exposed to anticoagulant rodenticide

ADVANCED OR CONFIRMATORY TESTING

Based on specifics of case as assessed with history, presenting signs, physical exam findings, and initial database results

TREATMENT

TREATMENT OVERVIEW

- Correction/cure of inciting disorder when possible
- Palliation of cough if underlying cause cannot be eliminated

ACUTE AND CHRONIC TREATMENT

- Dependent on underlying cause:
  - Purposeful cough: primary respiratory lesion requires correction (e.g., pneumonia treatment, foreign body removal, lung lobectomy) and treatments that increase the efficacy of the cough (e.g., nebulization and coupage). Cough suppression is contraindicated.
  - Warning cough: systemic disorder must be identified and addressed promptly. (Cardiogenic pulmonary edema: diuretics. Pulmonary hemorrhage from anticoagulant toxicity: plasma transfusion, vitamin K1 replacement.) Treatments to increase the efficacy of the cough, such as nebulization and coupage, or treatments aimed at decreasing the cough (cough suppressants) are contraindicated.
  - Nuisance cough: avoidance of triggers (e.g., allergens, dusts) and cough suppression. Treatment of complicating factors if they occur (e.g., infection).
- Cough suppressants (e.g., butorphanol, 0.25-1 mg/kg PO q 8-24 has needed; or hydrocodone, 0.25 mg/kg PO q 6-24 h as needed; or codeine 0.5-2 mg/kg PO q 6-12 h as needed):
  - Only used when a sterile, uncomplicated process is responsible for the cough and the patient is systemically well. Examples: collapsing trachea, chronic sterile bronchitis, uncomplicated allergic airway disease.
- Empirical antibiotics or corticosteroids are not recommended in the absence of a diagnosis for the cause of the cough (minimum: completion of the initial database).

RECOMMENDED MONITORING

- Respiratory effort
- Resolution of cough is expected in 7-10 days, with no worsening or new clinical signs of illness, in cases of benign, self-contained processes such as infectious tracheobronchitis. Failure to self-resolve may indicate a more complex cause and warrants further evaluation.

PROGNOSIS AND OUTCOME

Based on cause:

- Purposeful cough: prognosis fair to good if underlying cause can be controlled (eradication of pneumonia, removal of foreign body)
- Warning cough: short-term prognosis guarded. Long-term prognosis variable, based on response to acute treatment and underlying cause.
- Nuisance cough: short-term prognosis generally good, long-term prognosis fair (e.g., with collapsing trachea patients responding well to treatment) to good (e.g., patients with infectious tracheobronchitis)

PEARLS & CONSIDERATIONS

COMMENTS

- Cough is a clinical sign, not a disease. Optimal management must involve an accurate diagnosis of the underlying cause.
- Cigarette smoke inhalation and obesity are common but reversible complicating factors in patients with chronic cough.

SUGGESTED READING

Anderson-Wessberg K: Coughing. In Ettinger SJ, Feldman EC, editors: Textbook of veterinary internal medicine, ed 7, St Louis, 2010, Saunders Elsevier, pp 250–253.

AUTHOR & EDITOR: ETIENNE CÔTÉ

Coronaviral Enteritis

BASIC INFORMATION

DEFINITION

Infectious intestinal disease that causes a generally mild diarrhea in dogs and cats. Coronaviral infections causing feline infectious peritonitis are discussed in greater detail on .

SYNONYMS

CCV (canine coronavirus), FECV (feline enteric coronavirus)

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs: neonatal puppies are more severely affected. Cats: virus virtually ubiquitous in the cat population; however, clinical disease is more common in young kittens in catteries and shelters.

RISK FACTORS

Dogs: infection is prevalent in animal shelters and breeding farms (dense populations and concurrent infections). Cats: multicat households (more than five cats) or catteries.

CONTAGION & ZOONOSIS

Dogs: CCV is highly contagious and spreads rapidly through groups of susceptible dogs (dog to dog). Cats: FECV is highly contagious and spreads rapidly through multicat households (cat to cat). Transmission is by the fecal-oral route. CCV and FECV are not known to infect people.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Dogs:

- Subclinical in adult dogs
- Diarrhea and vomiting (neonatal puppies)

Cats:

- Subclinical in adult cats
- Mild to moderately severe diarrhea in kittens
- Mutation to feline infectious peritonitis virus resulting in multisystemic disease (see p. 383)

HISTORY, CHIEF COMPLAINT

Some or all may be present:

- Mild to moderately severe diarrhea
- Blood in feces (infrequent)
- Vomiting is more common in dogs.
- Lethargy and inappetence
- Weight loss

PHYSICAL EXAM FINDINGS

- Dehydration; degree depends on severity of the diarrhea

- Occasionally concurrent ocular and nasal discharge, or weight loss in chronically infected kittens

ETIOLOGY AND PATHOPHYSIOLOGY

- Member of the virus family Coronaviridae; single-stranded RNA virus
- Dogs and cats: virus infects epithelial cells in the tips of small-intestine villi, causing a malabsorptive diarrhea. The virus remains infective for 2-3 days at room temperature (several days longer at temperatures just above freezing) and may be transmitted to other animals via infected litterboxes or fomites.
- Cats only: RNA mutations of FECV result in the formation of a new virus (feline infectious peritonitis [FIP] variant) that is able to enter and replicate within feline macrophages (see p. 383).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in dogs or cats with generally mild, self-limiting diarrhea. Most cases require little if any treatment, so diagnostic testing is not necessary for confirming the diagnosis. Rather, tests are indicated to rule out other more serious disorders that initially mimic (or coexist with) coronavirus infection.

DIFFERENTIAL DIAGNOSIS

- Intestinal disease caused by enteric bacteria (*Campylobacter*, salmonellosis), protozoa (coccidiosis), or other viruses (i.e., canine parvoviral enteritis, feline panleukopenia-associated enteritis)
- Dietary indiscretion (dogs)
- Parasites (both dogs and cats)
- Dietary intolerance (cats)

INITIAL DATABASE

- CBC, biochemistry panel, urinalysis: nonspecific changes
  - Severe diarrhea can result in marked dehydration and electrolyte abnormalities.
- Fecal testing for parasites and protozoa

ADVANCED OR CONFIRMATORY TESTING

Generally not performed, since corona-viral enteritis is usually self-limiting (exception: FIP) and even in severe cases, responsive to supportive care. *Dogs:*

- Detection of CCV in fresh feces by electron microscopy (false-negative findings possible)
- Virus isolation (however, CCV does not grow well).
- Reverse transcriptase PCR has been developed to detect CCV in fecal specimens (not commercially available).
- Serologic evaluation: positive titers only confirm exposure to CCV, not necessarily active infection.

Cats:

- Serologic evaluation (indirect immunofluorescent antibody, ELISA)
  - Does not differentiate FECV that causes isolated enteritis from FECV that causes FIP
  - Does not correlate with severity of disease
  - Positive titers only confirm exposure to FECV, not necessarily active infection.
  - In multicat (more than six cats) households, virtually all cats are seropositive.
- Reverse transcriptase PCR has been developed to detect FECV in fecal specimens.
  - Does not reliably differentiate FECV that causes isolated enteritis from FECV that causes FIP

TREATMENT

TREATMENT OVERVIEW

Treatment, if any is required, is primarily supportive during the time needed for the disease to run its natural course.

ACUTE GENERAL TREATMENT

- Parenteral fluids to maintain fluid and electrolyte balance
- Broad-spectrum antimicrobial agents to treat secondary bacterial infections are rarely indicated.
- Good nursing care and hygiene

POSSIBLE COMPLICATIONS

Dogs:

- Clinical course (typically 7-10 days) may be longer and more severe in dogs that develop secondary complications or infection.
- Dehydration, acidosis, shock
- Concurrent canine parvovirus or parasitic infections

Cats:

- In immunocompromised kittens or cats, the virus may persist, resulting in chronic diarrhea or vomiting (months).
- Enteric coronavirus can mutate into feline infectious peritonitis virus. Monitor the affected cat and others in contact with it for signs of FIP (e.g., abdominal distension, fever, weight loss, neurologic signs, and icterus). However, the occurrence of coronaviral enteritis in an individual cat is not predictive of FIP.

RECOMMENDED MONITORING

Response to therapy

PROGNOSIS AND OUTCOME

- Dogs: good; neonatal puppies with concurrent parvovirus and coronavirus infections have a more guarded prognosis.
- Cats: generally good; guarded to poor in cats in whom FECV mutates and causes FIP

PEARLS & CONSIDERATIONS

COMMENTS

- Clinical disease is considered infrequent compared with other viral enteropathies.
- Dogs: CCV vaccines are not considered core vaccines but should be reserved for animals in which the risk of exposure may be higher (dense, stressful environments).
- Cats:
    - Inapparent infection is common in normal cats.
    - FECV-associated enteritis does not predispose a cat to development of FIP.

CLIENT EDUCATION

Reducing the number of cats per household (especially kittens less than 12 months old) and keeping potentially FECV-contaminated surfaces clean (e.g., litterboxes) can reduce population loads of FECV and thus also reduce the risk of FIP.

Cornification Disorders

Additional Images Available on Website

BASIC INFORMATION

DEFINITION

A well-recognized class of scaling or greasy skin disorders resulting from primary (usually hereditary) or secondary (acquired) defects in epidermal maturation, desquamation, or sebum production. Many disorders were formerly grouped under the heading *seborrhea*, but this term was nonspecific and inaccurate and is now obsolete.

SYNONYMS

- Keratinization defects/disorders
- Keratoseborrheic disorders

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Primary (hereditary) causes: early in life for many conditions
- Secondary (acquired): any age; usually adult animals

GENETICS & BREED PREDISPOSITION

- Primary idiopathic seborrhea: cocker spaniel, West Highland white terrier, basset hound, shar-pei, dachshund, Doberman pinscher, English springer spaniel, German shepherd, Irish setter, Labrador retriever
- Primary hereditary seborrhea oleosa: Persian, Himalayan, and exotic short hair cats
- Vitamin A–responsive dermatosis: cocker spaniel, Labrador retriever, miniature schnauzer
- Zinc-responsive dermatosis: Alaskan malamute, Siberian husky, Samoyed
- Lethal acrodermatitis: bull terrier
- Epidermal dysplasia: West Highland white terrier
- Sebaceous adenitis (see p. 1007): Akita, Samoyed, standard poodle, and many other breeds have been reported to have this condition.
- Ichthyosis: golden retriever, Norfolk terrier

CONTAGION & ZOONOSIS

Most are not contagious, but parasitic and fungal etiologies have contagious and zoonotic potential.

GEOGRAPHY AND SEASONALITY

Scaling (formerly called seborrhea sicca) is more common in the winter (low environmental humidity).

ASSOCIATED CONDITIONS & DISORDERS

Primary cornification disorders may be associated with ceruminous otitis externa.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Primary cornification disorders (usually hereditary and incurable) or secondary (acquired, usually curable)
- Generalized or localized

HISTORY, CHIEF COMPLAINT

Owners generally present pets for evaluation of an unpleasant-appearing hair coat or coat with a foul odor. Specific complaints may include a generalized waxy or scaly coat condition, often associated with a rancid odor. Pruritus is of variable intensity, depending on presence of parasites, dry skin, or secondary bacterial or yeast infection; however, scaling may be an incidental finding in some

animals.

PHYSICAL EXAM FINDINGS

- Primary cornification disorders: varying degrees of alopecia and dry scale that may be focal, multifocal, or generalized over the trunk. Animals may present with large hyperkeratotic patches of adherent scale. Follicular casts (waxy debris surrounding hair shafts), fronds (clumps of hairs stuck together like a paint brush), or severe “dandruff” with large flakes may be noted.
- Localized cornification disorders:
  - Nasal hyperkeratosis of the Labrador retriever: restricted to the nasal planum
  - Nasodigital hyperkeratosis: restricted to nasal planum and digital pads
  - Ear margin dermatosis: alopecia and scaling of distal pinnal margins, possibly associated with fissures
  - Feline acne: comedones on the chin +/− lips; papules, pustules, erosion, crust and pruritus if secondarily infected
- Secondary cornification disorders: general physical findings depend on underlying etiology or vary with underlying etiology. Cutaneous findings include a dull (or waxy) coat with various combinations of alopecia, scaling, crusting, collarettes, and excoriations secondary to self-trauma and pyoderma.

ETIOLOGY AND PATHOPHYSIOLOGY

- Cornification encompasses all the processes that lead to the formation of the stratum corneum. This includes keratinization and formation of the lipid-rich intercellular domain that binds corneocytes to maintain a relatively impermeable barrier.
- Disorders of cornification are due to a defective cornification process or excessive proliferation and/or defective desquamation (retention hyperkeratosis). Therefore, any alteration in epidermal turnover times, maturation processes, and/or desquamation or trans epidermal water loss lead to scaling.
- Other considerations include abnormal apocrine or sebaceous glandular secretions (either in volume or quality).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Scale formation is a common response of the skin to any insult. It is critical to evaluate the patient for underlying causes—in particular, the roles parasite and microbial dermatitis may be playing if any—before pursuing other etiologies.

DIFFERENTIAL DIAGNOSIS

- Secondary cornification disorders; underlying causes include:
  - Microbial: pyoderma, *Malassezia*, dermatophytosis, leishmaniasis
  - Parasitic: flea infestation, cheyletiellosis, sarcoptic mange, pediculosis, and demodicosis (including *Demodex injai*, the long-bodied *Demodex* mite that has been associated with a greasy seborrheic dermatosis, especially in adult terriers)
  - Endocrinopathy: hypothyroidism, hyperadrenocorticism, sex hormone imbalance (e.g., Sertoli cell tumor)
  - Allergic: dermatologic adverse food reaction (food allergy), atopic dermatitis
  - Management deficiencies: low environmental humidity, inappropriate topical therapy or frequency, nutritionally inadequate diet (especially if high in phytates and fiber, low in fatty acids)
  - Metabolic disease (especially liver disease)
  - Immune-mediated disease: pemphigus foliaceus, systemic lupus erythematosus, adverse drug reaction
  - Neoplasia: Cutaneous epitheliotropic lymphoma, exfoliative dermatitis associated with thymoma in cats
- Primary cornification disorders: usually genetically determined; may be multi-focal and generalized or localized:
  - Multifocal and generalized:
    - Idiopathic primary seborrhea (dogs)
    - Hereditary seborrhea oleosa (cats)
    - Vitamin A–responsive dermatosis
    - Zinc-responsive dermatosis
    - Sebaceous adenitis
    - Epidermal dysplasia
    - Schnauzer comedo syndrome
    - Canine ichthyosis
  - Localized:
    - Nasal parakeratosis of the Labrador retriever (autosomal recessive)
    - Footpad hyperkeratosis in dogues de Bordeaux and Irish terrier
    - Feline acne
    - Stud tail
    - Ear margin dermatosis

INITIAL DATABASE

- Comprehensive evaluation for ectoparasites (skin scrapings, flea combing, acetate tape preparations, fecal evaluation, ectoparasiticide response trial)
- Skin cytologic examination (to rule out bacterial and yeast involvement)
- Fungal culture (dermatophytosis)
- CBC, serum biochemical profile, urinalysis (as appropriate, to look for evidence of underlying disease)

ADVANCED OR CONFIRMATORY TESTING

- Skin biopsy: useful for many disorders once infectious and parasitic causes have been ruled out
- Elimination diet trial to rule out food allergy (if pruritic)
- Intradermal and serum allergy testing for atopic dermatitis (if pruritic)
- Response to dietary management (if poor-quality diet)
- Thyroid function testing
- Adrenal function testing

TREATMENT

TREATMENT OVERVIEW

- The goal of treatment is to address the underlying etiology specifically if possible. In primary conditions, it is important to control secondary microbial dermatitis while controlling the amount of scale produced.

ACUTE GENERAL TREATMENT

- Systemic antibiotics, such as cephalexin, 22-30 mg/kg PO q 12 h for at least 2 weeks past resolution of clinical signs or until improvement plateaus (minimum of 4 weeks), if a bacterial component is suspected. Some animals require chronic treatment.
- Essential fatty acid (EFA) oral supplementation (omega-3 and omega-6); rarely provides complete control of scaling but may be beneficial as adjunctive therapy
- Systemic and topical antifungal treatment as needed (see *Malassezia* dermatitis, p. 682; Dermatophytosis,)
- Topical therapy: clipping of hair coat may benefit topical therapy:
    - Antiseborrheic shampoos contain keratolytic and/or keratoplastic compounds and are used initially twice weekly. Good choices of ingredients for dry, scaly coats include sulfur and salicylic acid; decrease frequency as needed.
    - Topical antiseborrheic products containing phytosphingosine may be of benefit.
    - Greasy, scaly skin in dogs can be degreased using products containing benzoyl peroxide, or selenium sulfide. These products should always be followed with a conditioner. Note: Shampoos containing benzoyl peroxide are drying and will bleach fabric.
    - Mild dry scaling may respond to moisturizing or hypoallergenic shampoos. Conditioners containing lipids or humectants (agents that help the skin to retain moisture) are beneficial.

CORNIFICATION DISORDERS Extensive erythroderma and scaling (exfoliative erythroderma) in a dog with epitheliotropic lymphoma.

(Copyright Dr. Manon Paradis.)

CORNIFICATION DISORDERS Primary seborrhea oleosa in a Himalayan cat. Note the greasy haircoat especially apparent across the ventrum.

(Copyright Dr. Manon Paradis.)

CHRONIC TREATMENT

- Generalized disease
  - Primary idiopathic seborrhea: topical therapy as already described; EFA supplementation; antibiotics administered as already described. Consider retinoids; acitretin (Soriatane), 0.5-1 mg/kg PO q 24 h; or cyclosporine, 5-10 mg/kg PO q 12-24 h.
  - Vitamin A–responsive dermatosis: topical therapy and antibiotics as already described; vitamin A 625-800 IU/kg PO q 24 h; usually 10,000 IU PO daily, lifelong, for the average cocker spaniel. Improvement is noted by 3 weeks, with remission in 8-10 weeks.
  - Zinc-responsive dermatosis: zinc supplementation is recommended at 1-3 mg/kg elemental zinc PO q 24 h (see p. 1189).
  - Epidermal dysplasia: address any bacterial, yeast, parasitic, atopic, and hypersensitivity disorders. Bathe the animal frequently with keratolytic and keratoplastic shampoos.

- Schnauzer comedo syndrome: benzoyl peroxide shampoos help the condition via follicular flushing. Systemic antibiotics (as already described) to control bacterial folliculitis. In some cases, retinoids such as isotretinoin (Accutane), 1-2 mg/kg PO q 24 h, may be helpful but can be costly. Wean to alternate day therapy after 4 weeks if a favorable response is noted.
- Canine ichthyosis: Antiseborrheic shampoos and a topical spray conditioner containing propylene glycol and humectants can be useful. Try isotretinoin (Accutane), 1-2 mg/kg PO q 24 h for 8-12 weeks, decreasing to alternate-day therapy if effective) in more severe cases
- Sebaceous adenitis (see p. 1007):

- Localized disease
  - Feline acne (see p. 20)
  - Ear margin dermatosis: local use of an antiseborrheic shampoo. If inflammation is severe, topical glucocorticoid such as 0.5%-1% hydrocortisone may reduce inflammation.
  - Nasal and digital hyperkeratosis: moisturize affected area with water or wet dressings, and then apply petrolatum jelly. More severely affected animals may benefit from topical application of an ointment containing salicylic acid and urea, or 50%-75% propylene glycol, or 0.025 or 0.01% tretinoin gel (Retin-A).

DRUG INTERACTIONS

Cyclosporine: Concurrent use of cyclosporine with other *P*-glycoprotein inhibitors or substrates can increase blood cyclosporine levels. This may be beneficial (e.g., lowers the dose of cyclosporine required by half when administered with standard doses of ketoconazole) but can also increase the potential toxicity.

POSSIBLE COMPLICATIONS

- High fatty acid treatment may increase the potential for gastrointestinal (GI) disturbance or pancreatitis.
- Retinoids: keratoconjunctivitis sicca, conjunctivitis, pruritus, hyperactivity, stiffness, mucocutaneous junction erythema, vomiting, diarrhea, teratogenicity, elevated liver enzymes
- Cyclosporine: diarrhea, vomiting, anorexia, gingival hyperplasia, gingivitis, renal effects, hypertension; monitor animals for tumors.

RECOMMENDED MONITORING

- Vitamin A, retinoids: monitor liver enzymes and tear production.
- Cyclosporine: physical examination (tumor, infection, gingival hyperplasia), urea, creatinine, urinalysis, and liver enzymes; blood pressure. Check trough serum cyclosporine levels if adverse reactions are noted or if there is a poor clinical response (see p. 1471).

PROGNOSIS AND OUTCOME

Primary causes often require lifelong therapy; secondary syndromes usually recover with correction or control of underlying etiology.

PEARLS & CONSIDERATIONS

COMMENTS

- Control secondary microbial dermatitis, and evaluate thoroughly for other underlying secondary etiologies before diagnosing a primary seborrheic syndrome.
- The term *seborrhea* as a diagnosis should be limited to the breed-specific diseases (e.g., idiopathic primary seborrhea of cocker spaniel, primary hereditary seborrhea oleosa of Persian cats). Use other descriptive terms such as *scaling, exfoliation, crusting, greasiness, malodor* to characterize skin changes, rather than the nonspecific term, *seborrhea*.

PREVENTION

Animals affected with primary (genetically determined) cornification disorders should not be used for breeding.

CLIENT EDUCATION

Concept of control versus cure

Corneal/Scleral Trauma

BASIC INFORMATION

DEFINITION

Ocular injury secondary to blunt or sharp trauma. *Penetrating* infers partial-thickness injury; *perforating* infers full-thickness injury. *Simple* wounds involve only cornea or sclera; *complicated* wounds involve multiple ocular structures.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Any species, age, or sex

RISK FACTORS

- Young, active animals
- Hunting animals
- Interanimal fighting
- Dog's head out the window while car is in motion
- Existing visual impairment may predispose

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Running through dense or dry vegetation just before onset of clinical signs
- Owner may or may not observe trauma or causal event.
- Acute onset of any or all of the following:
  - Blepharospasm
  - Ocular discharge
  - Blood or fluid coming from eye
  - Swelling around the eye (e.g., eyelids; conjunctiva)
  - Cloudy eye

PHYSICAL EXAM FINDINGS

- Signs of pain on ophthalmic examination (see p. 1313) manifested by blepharospasm and resistance to ophthalmic examination.
- Linear, V-shaped, or stellate corneal lesion of acute onset accompanied by any or all of the following:
  - Hyphema (see p. 571) and/or sub-conjunctival hemorrhage
  - Corneal edema with or without cellular infiltrate
  - Uveal prolapse: appears as pigmented structure in damaged cornea or sclera; associated with:
    - Dyscoric/misshapen pupil
    - Hyphema (see p. 571)
  - Foreign body embedded in cornea or perforating cornea
  - Signs of uveitis, particularly with perforating trauma (see p. 1151)
  - Fibrin in cornea may fill perforation; light brown in color, may be associated with blood.
  - Yellowish/whitish lens material in anterior chamber and cataract (see p. 181) if lens involved
  - Shallow anterior chamber if wound actively leaking
- Thorough examination of the entire conjunctival sac is necessary to identify any retained foreign material. Sedation, general anesthesia, or referral may be required in difficult cases or if this procedure is unfamiliar to the practitioner.
- Subconjunctival hemorrhage and hyphema should alert clinician to possibility of posterior scleral rupture if no anterior segment lesions are present, particularly if accompanied by very low intraocular pressure (i.e., <10 mm Hg).

ETIOLOGY AND PATHOPHYSIOLOGY

- Variable; usually traumatic (sharp or blunt) in origin

- Foreign body may be retained in laceration.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

History and preliminary examination suggest the diagnosis; an ophthalmic exam helps define whether the cornea and/or sclera has/have been damaged. If so, the exam should also determine whether lesion is partial or full thickness (affects prognosis).

DIFFERENTIAL DIAGNOSIS

If traumatic event not witnessed, consider other causes:

- Corneal ulceration
- Uveitis
- Hyphema

INITIAL DATABASE

- Assess vision: menace response, dazzle reflex, direct and consensual pupillary light reflexes (if deficient, see Blindness, p. 141)
- Cytologic study and aerobic culture and sensitivity of wound
- CBC, serum biochemistry profile, urinalysis for preanesthetic purposes if surgery necessary

ADVANCED OR CONFIRMATORY TESTING

- Consider ocular ultrasound exam to determine extent of intraocular involvement, presence of intraocular foreign body, or posterior globe rupture.
- Orbital radiographs or CT to determine presence or path of foreign body if suspected
- Seidel test to determine if cornea or scleral wound is sealed: apply dry fluorescein strip carefully to surface of wound to cover surface with stain; leaking aqueous will appear as a green rivulet.

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are to:

- Remove foreign bodies if present.
- Repair lacerations that penetrate >50% of the thickness of the corneal stroma or perforate the cornea or sclera.
- Eliminate infection.
- Control intraocular inflammation.

ACUTE GENERAL TREATMENT

- Do not put pressure on the globe until the possibility of rupture is eliminated.
- Elizabethan collar placement to prevent self-trauma
- Small, nonperforating or very small sealed perforating wounds without uveal prolapse, consider conservative therapy:
  - Topical antibiotic solution (e.g., neomycin/polymyxin/gramicidin, gentamicin, or ciprofloxacin) q 6 h
  - Add broad-spectrum systemic antibiotics if perforating (e.g., amoxicillinclavulanate, 13.75 mg/kg PO q 12 h; base long-term choice on culture and sensitivity).
  - Systemic antiinflammatory therapy with either nonsteroidal antiinflammatories (e.g., meloxicam, 0.1 mg/kg PO q 24 h; or carprofen, 2 mg/kg PO q 12 h) or antiinflammatory doses of prednisone (e.g., 0.5-1 mg/kg PO q 24 h)
  - Topical atropine 1% solution q 6-24 h if significant uveitis present (see p. 1151).
- Perforating or deep, large, or gaping penetrating wounds and wounds with uveal prolapse require primary surgical repair (referable procedure) involving:
  - Replacement of viable uveal tissue or resection of nonviable uveal tissue
  - Irrigation and reinflation of anterior chamber
  - Repair of cornea with appropriate-size suture material (8-0 to 10-0)
  - Careful inspection of lens; if lens rupture noted, lens should be removed by phacoemulsification.

CHRONIC TREATMENT

- Monitor and treat for uveitis and wound dehiscence.
- Consider changing antibiotics if indicated by culture and sensitivity results.

DRUG INTERACTIONS

Do not use topical ophthalmic ointments if globe rupture is suspected.

POSSIBLE COMPLICATIONS

- Retinal Detachment, p. 985
- Cataracts, p. 181
- Chronic Uveitis, p. 1151
- Glaucoma, p. 448
- Endophthalmitis (inflammation of the uveal tract and anterior and posterior compartments of the eye)
- Loss of vision and eye
- Cats may develop posttraumatic ocular sarcomas years after original injury, particularly if lens involved (see p. 620).

RECOMMENDED MONITORING

- Reevaluate in 24-48 hours to ensure wounds are sealed, inflammation is improving, and there are no signs of infection.
- Frequency of examination then depends on response to therapy.

PROGNOSIS AND OUTCOME

- Intuitively, small, shallow penetrating wounds of the cornea or lacerations involving only the cornea have a good prognosis, whereas complicated, perforating wounds with uveal and/or lens involvement have a poorer prognosis for vision.
- Posterior wounds involving sclera or sclera and uvea have a grave prognosis for vision.
- Blunt trauma usually has a grave prognosis for vision, particularly if extensive hyphema is present.
- Negative menace response and negative dazzle and pupillary light reflexes at initial examination of a patient with corneal or scleral trauma indicate grave prognosis for vision.

PEARLS & CONSIDERATIONS

COMMENTS

- Consider sedation to keep patient calm and prevent self-trauma.
- Elizabethan collar to prevent self-trauma

PREVENTION

Animals should be monitored when introduced to new environment with other animals.

CLIENT EDUCATION

Discuss the possibility of long-term complications that could lead to loss of vision and loss of an eye.

AUTHOR: ELLISON BENTLEY

EDITOR: CHERYL L. CULLEN

Corneal Vascularization

BASIC INFORMATION

DEFINITION

The presence of blood vessels in or on the cornea

SYNONYMS

Corneal neovascularization, vascularized keratitis

EPIDEMIOLOGY

SPECIES, AGE, SEX

Varies depending on underlying cause

ASSOCIATED CONDITIONS & DISORDERS

Corneal ulceration, irritation, desiccation, uveitis, episcleritis, or scleritis

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Some or all may be present:

- History:
  - Ocular trauma
  - Chronic ophthalmic disorder (e.g., keratoconjunctivitis sicca, indolent corneal ulcer, others)
- Chief complaint:
  - Red discoloration of the eye
  - Ocular discharge
  - Signs of ocular pain, manifesting as behavior change, blepharospasm

PHYSICAL EXAM FINDINGS

- Focal to diffuse red discoloration of the corneal surface or stroma
- New corneal vessels enter stroma at the limbus and may be small:
  - May give the affected cornea a reddish haze
  - Are leaky and cause surrounding corneal edema (bluish haze)
  - May be missed altogether owing to a cursory exam
- Other findings will vary depending on the cause.

ETIOLOGY AND PATHOPHYSIOLOGY

Blood vessel ingrowth occurs:

- As a response to injury of the corneal epithelium or stroma as a normal component of healing
  - Neutrophils, which enter the cornea from the tear film and the limbus, are important sources for angioblast and fibroblast growth factors.
  - There is a 3- to 4-day delay before the ingrowth of corneal blood vessels.
  - Ingrowth then occurs at a rate of approximately 1 mm/d.
- As part of an immune-mediated inflammatory response
- Secondary to disease of adjacent ocular tissues, including uveitis, episcleritis, scleritis, glaucoma, and orbital disease

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- The diagnosis is made on careful visual inspection of the corneal surface. Important features for pinpointing the underlying cause and treatment approach include the location and pattern of vascularization, and evaluation for other concurrent ocular disease.

DIFFERENTIAL DIAGNOSIS

- Corneal injury or inflammation:
  - Corneal ulceration
  - Chemical irritation
  - Mechanical irritation:
    - Distichiasis/ectopic cilia/trichiasis
    - Entropion
  - Exposure:
    - Large palpebral fissure
    - Lagophthalmos (incomplete closure of the eyelids)
    - Ectropion
    - Buphthalmos (chronic glaucoma)
    - Exophthalmos
  - Neuroparalytic keratitis (cranial nerve VII lesion)
  - Neurotrophic keratitis (cranial nerve V lesion)
  - Keratoconjunctivitis sicca
  - Qualitative tear film abnormalities
  - Chronic superficial keratitis (CSK/pannus) (dogs)
  - Proliferative keratoconjunctivitis (cats)
  - Corneal degeneration
- Adjacent ocular disease:
  - Uveitis
  - Episcleritis/scleritis
  - Orbital disease
  - Glaucoma

INITIAL DATABASE

- Neuroophthalmic examination, : evaluate palpebral reflexes (cranial nerves V and VII) and completeness of eyelid closure.
- Schirmer tear test: values <10 mm/min and clinical signs consistent with keratoconjunctivitis (KCS)
- Tear film break-up time: values <10 seconds are suggestive of qualitative tear film abnormalities.
- Fluorescein staining: positive in corneal ulceration
- Tonometry: elevated intraocular pressure (>30 mm Hg) in glaucoma, or reduced (<10 mm Hg) in cases of uveitis
- Ophthalmic examination, : evaluate for abnormalities of eyelids and aberrant cilia, sclera, and intraocular structures.

TREATMENT

TREATMENT OVERVIEW

- The goals of treatment are to address the underlying cause, halt progression, and reduce ocular discomfort.

ACUTE GENERAL TREATMENT

Treatment will vary depending on underlying cause.

POSSIBLE COMPLICATIONS

- Corneal vascularization may lead to pigmentation and scarring.
- Vascularization is often part of normal healing and should not be inappropriately suppressed.

PROGNOSIS AND OUTCOME

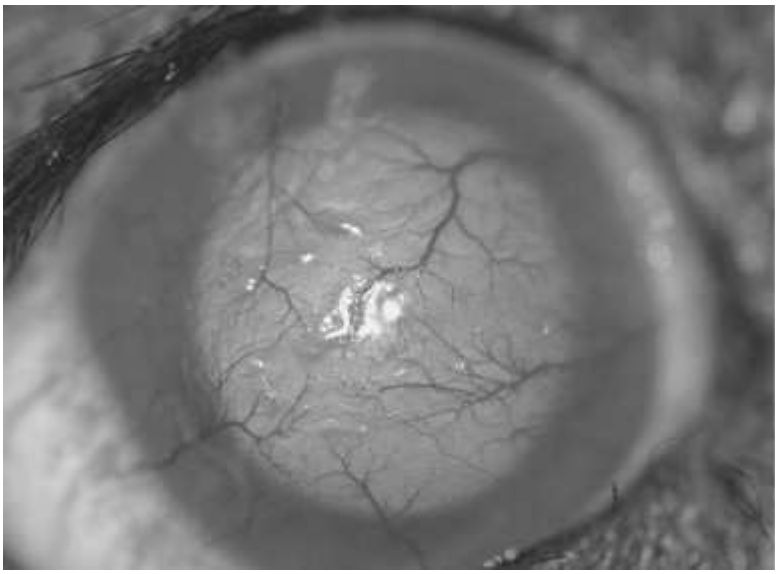
- Prognosis and outcome will vary depending on the underlying cause.
- In corneal injury, corneal vascularization denotes progression toward healing and is therefore a positive sign, provided the underlying problem can be controlled or eliminated.

PEARLS & CONSIDERATIONS

COMMENTS

It may be useful to distinguish between superficial and deep vascularization:

- Superficial vascularization occurs in response to superficial corneal or external ocular disease.
    - Superficial blood vessels arise from the conjunctiva, cross the limbus, are bright red, and branch frequently.
- Deep vascularization occurs in response to deep corneal or intraocular disease.
    - Deep blood vessels arise from the ciliary circulation, disappear at the limbus, and appear darker red and straight.



CORNEAL VASCULARIZATION Superficial corneal vascularization secondary to keratoconjunctivitis sicca in a dog. Note the numerous branching blood vessels located diffusely throughout the cornea.

Corneal Ulceration

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A common condition of loss of superficial corneal epithelium with or without loss of varying amounts of the underlying corneal stroma. There are three main categories of corneal ulceration:

- *Simple* corneal ulcer: an acute loss of epithelial layers of the cornea due to trauma; usually noninfected
- *Complex* corneal ulcer: an acute or chronic loss of epithelial and stromal layers of the cornea due to trauma and/or infection
- *Indolent/refractory* corneal ulcer: a superficial ulcer resulting from failure of epithelial adhesion to the corneal basement membrane and stroma

SYNONYMS

Corneal abrasion, corneal erosion, keratomalacia, ulcerative keratitis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Simple/complex ulcers: dogs and cats of any age or sex
- Indolent/refractory ulcers: middle-aged to older dogs

GENETICS & BREED PREDISPOSITION

- Simple/complex ulcers: brachycephalic breeds (dogs and cats) predisposed, but any breed may be affected
- Indolent/refractory ulcers: dogs: boxers predisposed, but any breed may be affected

RISK FACTORS

- Keratoconjunctivitis sicca (KCS, dry eye; see p. 628)
- Brachycephalic conformation
- Eyelid conformational abnormalities (see Entropion/Ectropion, ; Distichiasis/Ectopic Cilia/Trichiasis, p. 319)
- Feline herpesvirus 1 (FHV-1), feline viral rhinotracheitis infection (see p. 524)

CONTAGION & ZOONOSIS

FHV-1 keratoconjunctivitis is contagious among cats.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Three main categories of corneal ulceration:

- Simple corneal ulcer
- Complex corneal ulcer:
  - Stromal ulcer (ulcer with loss of varying amounts of the corneal stroma)
  - Keratomalacia/melting ulcer (softening and necrosis of the cornea, often associated with infection)
  - Descemetocele (loss of all stromal layers down to Descemet's membrane [basement membrane of the corneal endothelium] and endothelium)
  - Ruptured ulcer (perforation of the cornea)
- Indolent/refractory corneal ulcer

HISTORY, CHIEF COMPLAINT

- Variable onset from acute to insidious or chronic

- +/− History of trauma
- Ocular pain (squinting and/or rubbing at eye)
- Cloudiness to surface of eye
- "Red" eye
- Ocular discharge (watery, mucoid or mucopurulent)
- Occasionally, upper respiratory signs in cats (see p. 524)

PHYSICAL EXAM FINDINGS

- Simple and indolent corneal ulcers—any or all of the following may be present:
  - Blepharospasm (squinting)
  - Conjunctival hyperemia (enlarged vessels) +/− swelling
  - Third eyelid elevation
  - Ocular discharge: often serous
  - Corneal edema, usually focal
  - Obvious defect in corneal epithelium
  - Fluorescein dye retention in corneal stroma
  - Miotic (small) pupil (reflex uveitis; see p. 1151)
  - Aqueous flare (see p. 1151)
- Complex corneal ulcer—any or all of the above *and* one or more of the following:
  - Mucopurulent ocular discharge
  - Diffuse corneal edema
  - Corneal blood vessels (see p. 254)
    - Corneal vessels indicate chronicity (vessels migrate at a maximum of 1 mm/d)
  - Corneal white-yellow cellular infiltrate (inflammatory cells +/− microorganisms)
  - Corneal stromal defect (i.e., crater appearance to affected cornea)
  - Keratomalacia/melting (softening and necrosis of the cornea as evidenced by edema, a gelatinous appearance to the affected tissues, and/or stromal loss)
  - Hypopyon (white blood cells in anterior chamber; see p. 583)
- Descemetocele—any or all of the above *and* the following:
  - Fluorescein-negative clear center of a stromal ulcer (Descemet's membrane is hydrophobic and does not retain fluid or fluorescein stain)
- Ruptured corneal ulcer—any or all of the above *and* one or more of the following:
  - Copious ocular discharge with fibrin and/or blood (see Hyphema, p. 571) in the anterior chamber
  - Visible tan-brown-black iris prolapse (iris filling the corneal defect) and/or tan-yellow fibrin clot within ulcer
  - Shallow anterior chamber
  - Dyscoria (abnormal pupil shape)
  - Visible anterior synechia (iris adhesion) to the ulcerated area
- Indolent ulcer—in addition to any or all of the findings of a *simple ulcer*, indolent ulcers are characterized by the following clinical findings:
  - Rim of loose epithelium
  - Halo of fainter fluorescein uptake around stained ulcer
  - Minimal to moderate pain
  - +/− Corneal vascularization (slow to vascularize)
  - Noninfected

ETIOLOGY AND PATHOPHYSIOLOGY

- Trauma
- Ocular foreign body
- Tear film abnormalities:
  - Keratoconjunctivitis sicca (i.e., quantitative tear film deficiency [see p. 628])
  - Mucin and/or lipid deficiency (i.e., qualitative tear film deficiency [see p. 1076])
- Eyelid conformational abnormalities:
  - Entropion/ectropion
  - Distichiasis/ectopic cilia/trichiasis
  - Lagophthalmos (incomplete closure of the eyelids, usually in brachycephalics)
- Neurologic disorders (e.g., facial nerve paralysis [cranial nerve VII lesion]; corneal denervation [cranial nerve V lesion])
- FHV-1 infection
- Corneal sequestration (cats)
- Simple corneal ulcers may progress to complex or ruptured corneal ulcers secondary to bacterial infection or sterile inflammation.
- Indolent ulcers result from a primary defect of corneal epithelial adhesion to the underlying corneal basement membrane and stroma:

- Look for and address any other underlying cause(s) listed previously to promote healing of these refractory corneal ulcers.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Corneal ulceration is suspected based on history and physical exam findings. The cornerstone of diagnosis is a complete ophthalmic examination, including tear testing and fluorescein staining, and assessment of the cornea for edema, vessels, pigment, cellular infiltrate, fibrosis, and defects in the stroma. The goals of the ophthalmic exam are (1) confirm that an ulcer is present (versus healed defects), (2) determine whether the ulcer is acute or chronic (consider history and presence/length of corneal vessels), (3) determine the depth of the ulcer (and thus the risk of perforation), and (4) determine whether the ulcer may be infected (presence of cellular infiltrate, marked pain, uveitis, stromal loss, etc). When infection is suspected, corneal culture and susceptibility and cytologic examination should also be performed to direct appropriate antimicrobial therapy.

DIFFERENTIAL DIAGNOSIS

- Corneal dystrophy or degeneration
- Proliferative/eosinophilic keratoconjunctivitis (cats)
- Anterior uveitis
- Glaucoma
- Horner's syndrome

INITIAL DATABASE

- Cranial nerve examination (see pp. 1311 and p. 1313): menace response, pupillary light reflexes, palpebral and corneal reflexes
- Schirmer tear test (STT): Normal >15 mm/min in dogs, variable in cats
- Fluorescein dye application: Stains exposed stroma to confirm and demarcate ulcer
- Tear film break-up time (TFBUT): see p. 1076
- Corneal culture and sensitivity: ideally performed before STT and topical anesthesia
- Corneal cytologic study: assess for evidence of infection, such as neutrophils, bacteria (gram-positive cocci, gram-negative rods) and/or fungal hyphae. Identification of microorganisms can direct initial choice of therapy.
- Intraocular pressure to rule out glaucoma (recommended for any “red eye”)

ADVANCED OR CONFIRMATORY TESTING

- Keratectomy sample for corneal histopathologic evaluation
- Corneal swab and/or keratectomy sample for PCR (FHV-1, bacterial, fungal)

TREATMENT

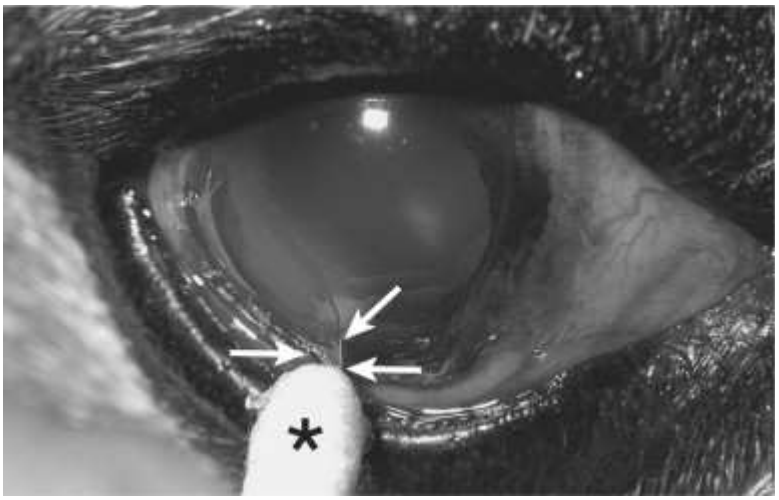
TREATMENT OVERVIEW

- Prevent progressive loss of corneal stroma and corneal rupture.
- Eliminate ocular pain.
- Prevent or eliminate corneal infection.
- Promote corneal epithelialization.
- Minimize corneal scarring.
- Standard treatment of a corneal ulcer consists of topical application of abroad-spectrum antimicrobial agent q4-6 h and atropine q 12-48 hours, +/− systemic administration of a nonsteroidal antiinflammatory medication (NSAID).

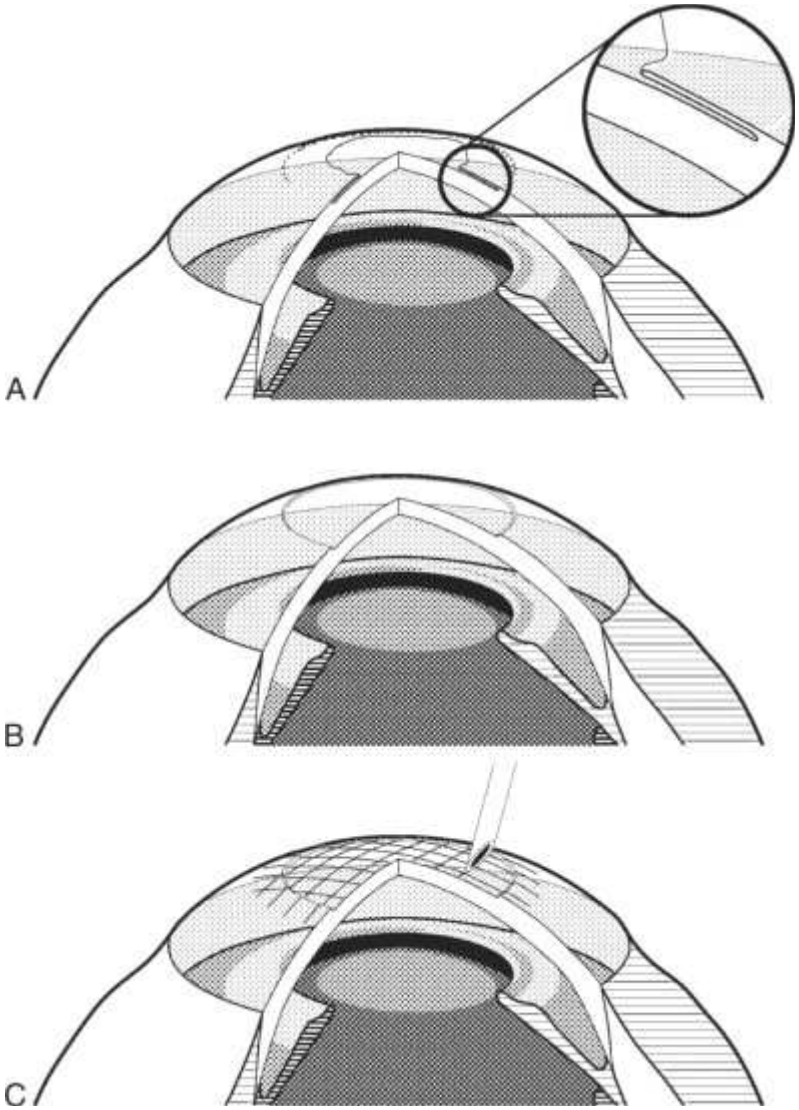
ACUTE GENERAL TREATMENT

- Simple corneal ulcer:
  - Broad-spectrum topical antibiotic solution or ointment (e.g., triple antibiotic or oxytetracycline/polymyxin B) q 6 h
    - Gentamicin is a poor first choice because of its narrow spectrum for only gram-negative bacteria (ocular flora is primarily gram-positive bacteria).
  - Topical atropine 1% ophthalmic solution or ointment q 12-48 h
  - ± Systemic NSAID

- Complex corneal ulcer—any or all of the above *and* one or more of the following:
  - Anticollagenase therapy is indicated if keratomalacia/melting/stromal ulcer detected:
    - Oxytetracycline/polymyxin B ointment topically q 4-6 h *and/or*
    - Autogenous serum q 1-4 h (prepared by obtaining a sample of the patient's own blood, anticoagulating and centrifuging, and using the supernatant [serum] topically for its antiprotease, anticollagenase properties)
  - Topical fluoroquinolone antibiotic (e.g., ciprofloxacin or levofloxacin; q 2-4 h for 24 h, then q 4-6 h) for improved corneal penetration and spectrum of activity. Use at increased frequency (q 2-4 h) for keratomalacia/melting/stromal ulcer.
  - +/− Topical antifungal agent q 4-6 h (e.g., natamycin or those derived from systemically administered agents such as voriconazole or miconazole) if fungal keratitis is implicated by corneal cytologic evaluation and/or culture (fungal keratitis is *rare* in cats and dogs)
  - Hospitalization of animals with deep or rapidly progressive ulcers for frequent medical treatments and monitoring
  - +/− Structural surgical repair (i.e., keratectomy to remove the diseased cornea with placement of a graft: conjunctival, corneal); referral procedure is advisable if:
    - Stromal loss continues despite aggressive appropriate medical management
    - Ulcer exceeds 50% stromal depth or is ruptured
- Indolent/refractory ulcer:
  - Application of topical ophthalmic anesthetic (e.g., proparacaine 0.5% solution) with or without sedation or general anesthesia (depending on the animal)
  - Débridement of all loose corneal epithelium with dry, sterile, cotton-tipped applicators
  - Perform multiple grid keratotomy with the beveled edge of a 25-gauge needle held at a 45-degree angle to the cornea:
    - Gentle vertical and horizontal scratches every 0.5 mm over ulcerated area just through basement membrane into superficial stroma (grid lines should be barely visible)
    - Contraindicated in cats (may predispose to sequestrum formation [see p. 248])
  - Oxytetracycline/polymyxin B ointment (promotes corneal epithelialization) q 6-8 h
- Atropine 1% ophthalmic solution or ointment q 24-72 h
- ± Systemic NSAID (e.g., carprofen)
- ± Application of a bandage soft contact lens to improve comfort and minimize mechanical forces of eyelids on migrating corneal epithelium
- Placement of an Elizabethan collar to prevent dog from rubbing eye



CORNEAL ULCERATION Débridement of an indolent corneal ulcer of the right eye in a dog. Note the lip of nonadherent corneal epithelium *(arrows)* attached to the sterile cotton-tipped applicator *(asterisk).*



CORNEAL ULCERATION Grid keratotomy. **A,** Indolent ulcer with corneal epithelial flaps (at time of presentation). **B,** After topical anesthesia and débridement. **C,** Performing the grid keratotomy.

CHRONIC TREATMENT

- Adjust antimicrobial therapy as directed by culture and susceptibility results and/or lack of improvement.
- Change to a topical antibiotic with expanded spectrum and/or improved corneal penetration (e.g., fluoroquinolone).
- FHV-1 ulcer (see p. 524 for details):
    - Topical antiviral ointment or solution (idoxuridine, vidarabine, trifluridine) q 4-6 h.
    - +/− Famciclovir (systemic antiviral)
    - Oxytetracycline/polymyxin B ointment q 6-8 h (to prevent secondary bacterial infection)
    - Chronic ulceration may lead to formation of corneal sequestrum

POSSIBLE COMPLICATIONS

- Corneal perforation, corneal scarring, corneal pigmentation, corneal stromal permanent defect (i.e., facet), corneal sequestration (cats), vision impairment/loss are possible.

RECOMMENDED MONITORING

- Evaluate for epithelialization (healing) or progressive loss of corneal stromal layers.
- Repeat corneal cytology and/or culture to monitor response to antimicrobial therapy, especially if progressive stromal loss occurs despite current therapies.
- STT: repeat after ulcer is healed to rule out KCS as initiating cause.

PROGNOSIS AND OUTCOME

- Simple/indolent: most heal with minimal scarring within 5-10 days with appropriate treatment.
- Complex: healing may take 2-8 weeks, and substantial corneal scarring is expected.

PEARLS & CONSIDERATIONS

COMMENTS

- Topical corticosteroids are contraindicated with corneal ulceration; they delay healing and promote keratomalacia/melting.
- Referral to a veterinary ophthalmologist is recommended if ulcer progresses despite appropriate medical management and/or if ulcer exceeds 50% stromal depth or is ruptured, because surgical repair is usually required.
- Any simple corneal ulcer that does not heal within 5-10 days should be considered a complex or indolent/refractory ulcer, and underlying causes such as infection, foreign body, ectopic cilia, distichia, and the like must be ruled out.
- Gentamicin is a poor first choice for the treatment of simple corneal ulcers because of its limited spectrum of activity (gram-negative only).

PREVENTION

Avoid or treat underlying cause(s).

CLIENT EDUCATION

- Simple corneal ulcers may become complex; therefore, topical antibiotic treatment and regular follow-up to assess ulcer healing are crucial.
- Indolent corneal ulcers may recur in the same eye or occur in the opposite eye.
- The patient's eye is frequently more uncomfortable for 24-48 hours after epithelial débridement and multiple grid keratotomy have been performed to treat an indolent corneal ulcer.

TECHNICIAN TIPS

- To prevent rupture or expulsion of aqueous humor due to increased intraocular pressure, avoid excessive restraint or jugular pressure in patients diagnosed with a descemetocele or corneal rupture.

Corneal Sequestration, Cat

BASIC INFORMATION

DEFINITION

Corneal sequestration is a disease unique to cats, characterized by an area of necrotic cornea that is variably pigmented.

SYNONYMS

Corneal mummification, corneal necrosis, corneal sequestrum, corneal nigrum, necrotizing keratitis

EPIDEMIOLOGY

SPECIES, AGE, SEX

Cats of any age; average age of 5 years in retrospective studies

GENETICS & BREED PREDISPOSITION

All breeds, but Persian, Himalayan, Burmese appear predisposed.

RISK FACTORS

- Feline herpesvirus type 1 (FHV-1; see p. 524), particularly in domestic short-hairs and longhairs
- Any corneal insult, particularly chronic
- Brachycephalic cats are predisposed.
- Grid keratotomy performed for non-healing/indolent corneal ulcers (see p. 250) in cats may predispose to sequestrum formation.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- “Black spot on eye”
- Blepharospasm
- Ocular discharge
- “Red” eye

PHYSICAL EXAM FINDINGS

- Circular to oval pigmented lesion in central to paracentral cornea is pathognomonic.
- Pigmentation varies from subtle tan discoloration of cornea to a dense black, opaque lesion.
- Lesion may form a slightly raised, irregular corneal plaque.
- Corneal neovascularization with chronicity
- Variable corneal edema and inflammation surrounding sequestrum
- A rim of loose, edematous corneal epithelium may develop around the sequestrum.
- Depth of corneal involvement (i.e., extent of lesion) difficult to ascertain because sequestrum often opaque

ETIOLOGY AND PATHOPHYSIOLOGY

- The fundamental problems generated by corneal sequestration are (1) pain, (2) obstruction of vision, and (3) cosmetic appearance.
- Chronic corneal irritation, such as that found in brachycephalic cats with entropion (see p. 348) and/or lagophthalmos (incomplete closure of the eyelids), is a common feature.
- FHV-1 is linked to sequestrum formation, particularly in nonbrachycephalic cats (see p. 524).
- Tear film deficiencies (e.g., keratoconjunctivitis sicca [see p. 628], qualitative tear film abnormality [e.g., mucin deficiency; see p. 1076]) have been reported in cats with sequestra.
- Source of pigment unknown; cats with sequestra noted to have pigmented tears. Contact lenses placed in cats with

sequestra (see Acute General Treatment below) often become discolored.

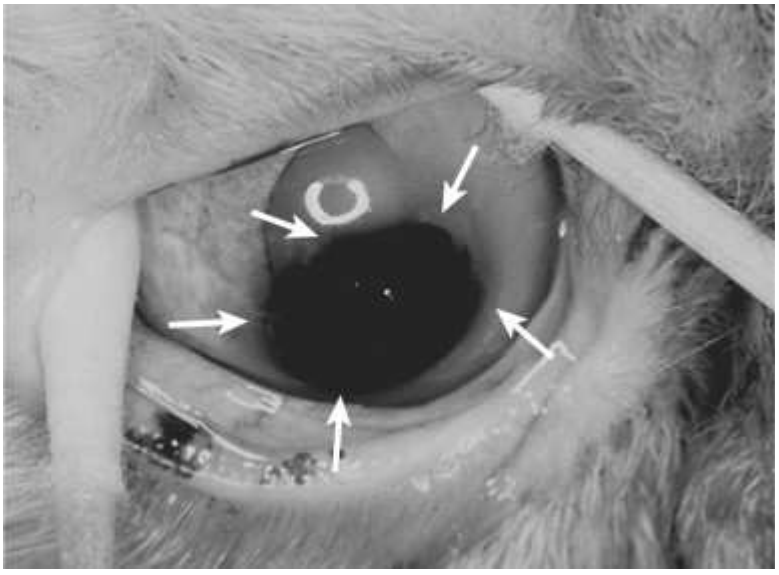
DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is generally based on signalment (species) and physical appearance of the lesion.

DIFFERENTIAL DIAGNOSIS

Corneal rupture with iris prolapse (should have dyscoric/misshapen pupil and uveitis if this has occurred; see p. 249)



CORNEAL SEQUESTRATION Corneal sequestrum in a cat *(arrows).* Note its dark appearance and paracentral location.

INITIAL DATABASE

Complete ophthalmic examination to assess for underlying causes of corneal irritation:

- Schirmer tear test (if <5 mm/min, see Keratoconjunctivitis Sicca,)
- Fluorescein dye application (sequestrum itself often does not retain fluorescein dye; there may be positive fluorescein dye retention around sequestrum).

ADVANCED OR CONFIRMATORY TESTING

- Consider testing for FHV-1 (see p. 524).
- Tear film break-up time (see Corneal Ulceration, p. 250, Tear Film Abnormalities, p. 1076)

TREATMENT

TREATMENT OVERVIEW

Treatment goals are to:

- Completely remove the sequestrum and prevent recurrence.
- Eliminate ocular pain.
- Minimize corneal scarring.

ACUTE GENERAL TREATMENT

- Prophylactic topical antibiotic therapy (can be ointment or solution formulation) such as ciprofloxacin or neomycin/polymyxin /gramicidin q 6-8 h, particularly if fluorescein positive

- If sequestrum appears small and superficial and affected eye is comfortable, observation is a treatment option:
  - Sequestrum may spontaneously slough, resulting in minimal scarring; however, sequestra can take months to years to slough. Rupture of the eye may occur if sequestrum is deep.
- If sequestrum is long-standing, large, or eye is painful, surgical removal is indicated through keratectomy (sequestrum excision using a corneal dissector; generally a referable procedure)
  - No postoperative pigmented corneal tissue should remain; a contact lens may be placed for protection for 2 weeks.
  - Very deep sequestra may require conjunctival or frozen donor corneal grafting.

CHRONIC TREATMENT

Treat underlying contributing factors/causes, such as entropion or lagophthalmos (see p. 348) and FHV-1 (see p. 524)

POSSIBLE COMPLICATIONS

- Recurrence of the sequestrum in the surgical site
- If the sequestrum is allowed to slough, descemetocele (see Corneal Ulceration, p. 250) formation or corneal rupture is a possibility.

RECOMMENDED MONITORING

- If the lesion is not treated surgically, owners should monitor carefully for sequestrum sloughing and return to the veterinarian immediately after the sequestrum sloughs to avoid complications from deep corneal defects. At the time of sequestrum sloughing, initiation of prophylactic topical antibiotic treatment (e.g., neomycin/polymyxin/gramicidin or ciprofloxacin) q 6-8 h is indicated, and referral for further evaluation (with or without surgical treatment) should again be considered.
- Surgical treatment: usually several rechecks at 1- to 2-week intervals until defect is epithelialized.

PROGNOSIS AND OUTCOME

Good, but recurrence is possible

PEARLS & CONSIDERATIONS

COMMENTS

Avoid topical corticosteroid use, because this may induce herpetic stromal keratitis if FHV-1 is an underlying cause.

CLIENT EDUCATION

Recurrence possible, as is involvement of contralateral eye

AUTHOR: ELLISON BENTLEY

EDITOR: CHERYL L. CULLEN

Corneal Pigmentation

BASIC INFORMATION

DEFINITION

Brown to black discoloration of the cornea, usually due to the presence of melanin

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: pigmentary keratitis: brachycephalic breeds; no age or sex predilection; chronic superficial keratitis (CSK; see p. 825)
- Cats: corneal sequestrum (see p. 248)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Brown discoloration of cornea
- Concurrently: redness of the conjunctiva, ocular discharge, ocular pain, reduced vision

PHYSICAL EXAM FINDINGS

- Brown or black discoloration of the corneal epithelium, stroma, or endothelium
- Extensive pigmentation may cause reduced or absent menace response.
- Other findings will vary depending on underlying cause.

ETIOLOGY AND PATHOPHYSIOLOGY

- Epithelial and stromal pigmentation:
  - Melanin is produced by melanocytes in the epithelium and superficial stroma in response to chronic corneal irritation from desiccation or mechanical trauma.
  - Proliferation and migration of limbal melanocytes into the stroma may also occur secondary to chronic inflammation in response to corneal ulceration, degeneration, or an immune response to corneal antigen.
- Endothelial pigmentation:
  - Adherence of melanin or melanin-containing cells, usually arising from the anterior uvea, to the endothelium.
- Stromal infiltration at the limbus as extension of a melanin-containing neoplasm.
- Protrusion of pigmented tissue through a corneal defect (see Corneal/Scleral Trauma, p. 249).
- Corneal sequestrum (cats; see p. 248):
  - Associated with chronic irritation
  - The central/paracentral corneal stroma becomes necrotic, stained, and the overlying epithelium is usually disrupted.
  - Cause of stromal discoloration is unresolved.

DIAGNOSIS

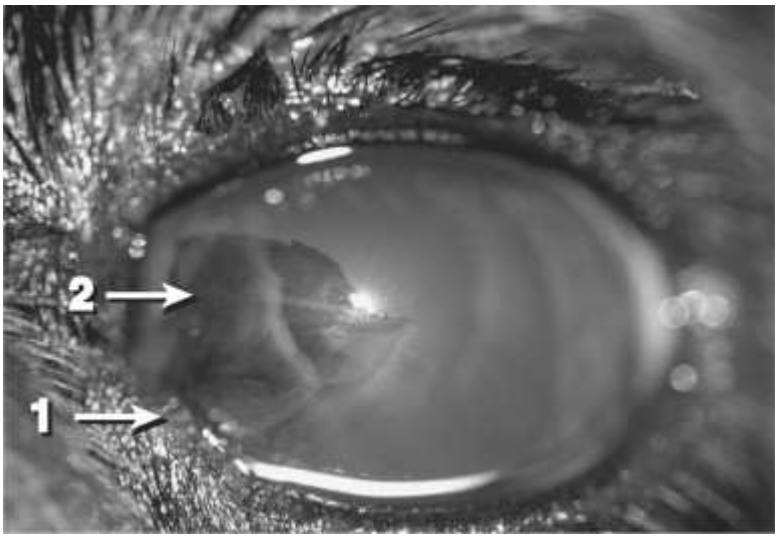
DIAGNOSTIC OVERVIEW

The diagnosis is apparent on physical examination, assisted by determining the location and pattern of the pigmentation as well as evaluating for other concurrent ocular disease. Species and breed are also important considerations.

DIFFERENTIAL DIAGNOSIS

- Epithelial and stromal pigmentation:
  - Pigmentary keratitis: large palpebral fissure, lagophthalmos (incomplete closure of the eyelids), distichiasis/ectopic cilia, trichiasis (entropion, nasal folds, aberrant dermis at medial canthus)
  - Exposure keratitis: buphthalmos (chronic glaucoma), neuroparalytic keratitis (cranial nerve VII lesion)

    - Keratoconjunctivitis sicca
    - Chronic superficial keratitis (CSK/pannus): dogs
    - Limbal melanocytoma (Note: melanomas of the limbus in dogs and cats are almost always benign and therefore are appropriately called melanocytomas, benign tumors of melanocyte origin.)
    - Invasive anterior uveal melanoma/melanocytoma
    - Protrusion of iris tissue through corneal defect (i.e., iris prolapse)
    - Corneal sequestrum (cats)
    - Brown foreign material
- Endothelial pigmentation: persistent pupillary membrane (iris to cornea), anterior synechia, uveal melanoma/melanocytoma, rupture of pigmented uveal cyst



CORNEAL PIGMENTATION Pigmentary keratitis of the left eye in a brachycephalic dog. There is medial entropion *(1)* and a triangular area of corneal pigmentation *(2)* overlying the medial cornea, secondary in part to the entropion.

(Courtesy Dr. Bruce Grahn.)

INITIAL DATABASE

- Neuroophthalmic examination (): evaluate palpebral reflexes and completeness of eyelid closure
- Schirmer tear test (STT): values <10 mm/min and clinical signs consistent with keratoconjunctivitis = KCS
- Fluorescein staining: positive if corneal ulceration is present. Fluorescein uptake usually occurs only around the edge of a corneal sequestrum
- Tonometry: elevated intraocular pressure (>30 mm Hg) in glaucoma (can arise with uveal melanoma/melanocytoma and uveal cysts) and reduced (<10 mm Hg) in cases of uveitis (can cause anterior synechia)
- Ophthalmic examination (see p. 1313): evaluate for abnormalities of eyelids and aberrant cilia

TREATMENT

TREATMENT OVERVIEW

The goals of treatment are to address the underlying cause, halt progression, reduce pigmentation, and reduce ocular discomfort.

ACUTE GENERAL TREATMENT

Treatment will vary depending on underlying cause.

RECOMMENDED MONITORING

- Recheck at regular intervals (every 4-6 months or more frequently depending on the cause).
- Photographs help monitor progression of lesions.

PROGNOSIS AND OUTCOME

Prognosis and outcome will vary depending on the underlying cause.

PEARLS & CONSIDERATIONS

COMMENTS

Ocular examination is an essential part of the routine physical examination, because corneal pigmentation may go unnoticed by owners until it is so extensive it compromises vision.

Corneal Lipid Infiltrates

BASIC INFORMATION

DEFINITION

- *Corneal dystrophy* is a hereditary, noninflammatory, often bilateral infiltration of lipid not associated with systemic disease.
- *Corneal degeneration* is stromal lipid and/or mineral deposition secondary to previous or concurrent corneal disease.
- *Lipid keratopathy* is a typically bilateral, predominantly peripheral corneal stromal lipid infiltrate secondary to dyslipoproteinemias of systemic disease origin.

SYNONYMS

- Arcus lipoides corneae; corneal arcus; corneal limbal lipid infiltrates
- Calcareous (calcium) degeneration; lipid (fatty) degeneration
- Corneal epithelial dystrophy; corneal stromal dystrophy

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs; rare in cats
- Corneal dystrophy: usually develops between 2 and 4 years of age

GENETICS & BREED PREDISPOSITION

Corneal dystrophy: any breed of dog, rare in cats; most commonly diagnosed breeds include the beagle, Cavalier King Charles spaniel, Siberian husky, Alaskan malamute, Samoyed, American cocker spaniel, and Labrador retriever.

ASSOCIATED CONDITIONS & DISORDERS

- Corneal degeneration: ulcerative and nonulcerative keratitides including:
  - Chronic superficial keratitis (see p. 825)
  - Limbal melanocytoma
  - Nodular granulomatous episclero-keratitis (see p. 356)
  - Keratoconjunctivitis sicca,
  - Ocular trauma (see p. 249)
  - Lipid keratopathy: hyperlipoproteinemias/systemic diseases including:
    - Hypothyroidism, p. 562
    - Hyperadrenocorticism, p. 548
    - Diabetes Mellitus,
    - Pancreatitis Dog, p. 820; Pancreatitis, Cat, p. 817
    - Primary hyperlipidemia (see p. 558)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Corneal dystrophy: well-demarcated, oval to round, grey-white or silver opacities in the central or paracentral cornea, often ringlike with a clear central zone
- Corneal degeneration: highly variable appearance, dense white to grayish stromal scars, irregular shape and distribution, often with ulceration and stromal vascularization
- Lipid keratopathy: dense, often arc-shaped, white to yellow crystalline opacities in the peripheral cornea, often separated from the limbus by a clear zone; additional opacity centrally if the cornea is vascularized

HISTORY, CHIEF COMPLAINT

- Corneal opacity
- Visual behavior change (uncommon in corneal dystrophy)

- Blepharospasm, serous ocular discharge/tearing (with ulceration in corneal degeneration)

PHYSICAL EXAM FINDINGS

- See Disease Forms/Subtypes, above
- Corneal abnormalities (corneal dystrophy, corneal degeneration)
- Variable, dependent on systemic disorder involved (lipid keratopathy)

ETIOLOGY AND PATHOPHYSIOLOGY

- Heritable genetic mutation (corneal dystrophy)
- Secondary pathologic changes, including altered lipid metabolism and dystrophic calcification (corneal degeneration)
- Deposition of lipid-laden serum across the limbus from hyperlipidemia (lipid keratopathy)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Ophthalmic exam is an important first step to differentiate corneal lipid infiltrates from other types of grey to white corneal opacities (see Differential Diagnosis below). Corneal lipid infiltrates tend to be crystalline white in appearance. It is important to then determine the type of corneal lipid deposits (i.e., corneal dystrophy versus corneal degeneration versus lipid keratopathy) to address the underlying cause when possible (e.g., corneal disease with corneal degeneration; systemic disease with lipid keratopathy) and to aid in prognostication.

DIFFERENTIAL DIAGNOSIS

Other types of grey to white corneal opacities (see p. 245) including:

- Scar: dull grey to white; does not retain fluorescein stain
- Edema: bluish to grey; indistinct borders
- Ulcer: retains fluorescein stain (see p. 250)
- Inflammatory cell infiltrate: grey to yellow; indistinct borders and varying degrees of uveitis (see p. 1151)

INITIAL DATABASE

- Complete ophthalmic examination (see p. 1313) including:
  - Assessing corneal appearance (see Disease Forms/Subtypes above)
  - Schirmer tear test (may be low in cases of corneal degeneration, which can occur as a result of keratoconjunctivitis sicca [see p. 628]). Normal >15 mm in 1 minute in dogs, variable in cats.
  - Fluorescein dye application (positive staining of cornea most common with corneal degeneration)
- CBC, serum biochemistry panel (including fasting cholesterol, triglycerides, blood glucose, calcium, phosphorus) to screen for underlying disorders, and urinalysis (typically unremarkable except for systemic disorders)

ADVANCED OR CONFIRMATORY TESTING

- Referral to a veterinary ophthalmologist to confirm/document crystalline nature and depth/distribution (often breed-specific) of presumed lipid infiltrate via slit-lamp biomicroscopic examination (corneal dystrophy)
- Evaluation of thyroid and adrenal function (see pp. 588 and p. 548); serum lipid electrophoresis (lipid keratopathy)

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are to:

- Minimize further deposition of lipid infiltrate if possible
- Surgically remove infiltrate if significant visual impairment and/or chronic corneal ulceration (referral to veterinary ophthalmologist)
- Manage any underlying systemic disease

ACUTE GENERAL TREATMENT

- Corneal dystrophy:
  - Treatment typically not required
  - Poor response to medical management
  - If advanced epithelial or stromal disease with vision impairment and/or corneal ulceration, may require surgical removal (lamellar keratectomy); may or may not recur
- Corneal degeneration:
  - Therapy aimed at underlying corneal disease
  - Lamellar keratectomy if degeneration is progressive and interfering with functional vision or creating ocular discomfort (chronic ulceration)
  - Topical application of disodium EDTA in an ophthalmic preparation (0.4%-1.38% q 6-8 h) if calcium component suspected.
- Lipid keratopathy:
  - Therapy aimed at underlying systemic disease (dogs); treat anterior segment inflammation/uveitis (often seen concurrently in cats; see p. 1151).

CHRONIC TREATMENT

Management/resolution of systemic disorder if present

NUTRITION/DIET

Corneal degeneration: anecdotal evidence of improvement subsequent to dietary restriction of lipid/cholesterol or following use of dietary additives to reduce cholesterol (flaxseed oil, oat bran, niacin)

RECOMMENDED MONITORING

Dictated by concurrent corneal disease management (corneal degeneration) or systemic disease management (lipid keratopathy)

PROGNOSIS AND OUTCOME

- Corneal dystrophy: favorable prognosis because opacities are focal and lesion typically nonprogressive; may resolve spontaneously
- Corneal degeneration: prognosis dependent on underlying corneal disease; may progress with chronic inflammatory or neoplastic disease; typically static after trauma
- Lipid keratopathy: may improve post resolution or control of underlying systemic abnormality

PEARLS & CONSIDERATIONS

COMMENTS

- The most common cause of corneal lipid infiltrate is corneal dystrophy; it is often discovered as an incidental finding and rarely causes appreciable vision impairment.
- At this time, there are serious questions about the safety and efficacy of systemically administered “lipid-lowering” medications for small-animal ocular disease.

CLIENT EDUCATION

Corneal dystrophy: suspected cases should be evaluated by a veterinary ophthalmologist, because the disease has genetic implications.

AUTHOR: RICHARD F. QUINN

EDITOR: CHERYL L. CULLEN

Corneal Discoloration

BASIC INFORMATION

DEFINITION

Any alteration of corneal clarity

SYNONYMS

Corneal opacification, corneal opacity

EPIDEMIOLOGY

SPECIES, AGE, SEX

Varies depending on the underlying cause

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Brown, white, white/yellow, white/pink, blue/grey, or red spot(s) on or within the cornea
- Vision may be reduced, depending on the location and size of discoloration.
- Discomfort and ocular discharge may be present, depending on the cause.

PHYSICAL EXAM FINDINGS

- Focal to diffuse brown, white, white/yellow, white/pink, blue/grey, or red discoloration of the corneal surface, stroma, or endothelium
- Reduced or absent menace response if lesion covers significant portion of axial cornea

ETIOLOGY AND PATHOPHYSIOLOGY

- Brown discolorations:
  - Epithelial and stromal pigmentation occurs secondary to chronic irritation or inflammation:
    - Melanin is produced by melanocytes in the epithelium and superficial stroma in response to chronic corneal irritation from desiccation or mechanical trauma.
    - Proliferation and migration of limbal melanocytes into the stroma may also occur secondary to chronic inflammation in response to ulceration, degeneration, or an immune response to corneal antigen.
  - Endothelial pigmentation:
    - Adherence of melanin or melanin-containing cells, usually arising from the anterior uvea, to the endothelium
    - Stromal infiltration at the limbus as extension of a melanin-containing neoplasm
    - Protrusion of pigmented tissue through a corneal defect (i.e., iris prolapse)
  - Corneal sequestrum (cats):
    - Associated with chronic irritation: the central/paracentral stroma becomes necrotic, stained, and overlying epithelium is usually disrupted.
    - Cause of stromal discoloration is unresolved.
    - See p. 248.
- White discolorations:
  - Fibrosis/scarring:
    - During the healing of stromal injury, such as ulceration, trauma, or inflammation, fibroplasia occurs, and newly produced collagen is laid down in a disorganized fashion.
  - Lipid (see p. 245):
    - Lipid deposition is associated with a primary defect of corneal lipid metabolism in inherited corneal dystrophy in some breeds.
    - Lipid deposition may be associated with a secondary defect of corneal metabolism such as in corneal degeneration caused by trauma, ulceration, chronic irritation, uveitis, or glaucoma.
    - Lipid infiltration in the cornea may occur in systemic disorders of lipid metabolism as a result of leakage of

lipid-laden serum at the limbus (arc-shaped) or in association with corneal vascularization.
    - Calcium:
        - Calcium deposition may be associated with a secondary defect of corneal metabolism such as in corneal degeneration caused by trauma, ulceration, chronic irritation, uveitis, or glaucoma.
        - Calcium deposition in the cornea may occur secondary to derangements in systemic calcium and phosphorus metabolism.
- White/yellow or white/pink discolorations:
    - Epithelial or stromal infiltration of inflammatory cells occurs in association with sterile inflammation or secondary to infection.
    - Endothelial deposition of inflammatory cells occurs in association with chronic uveitis (keratic precipitates).
    - Epithelial inclusion cysts usually form when mitotically active basal epithelial cells become displaced into the corneal stroma as a result of trauma or surgery and continue to grow.
- Grey/blue discolorations:
    - Corneal edema:
        - Fluid from the tear film may enter the corneal stroma secondary to loss of corneal epithelium (i.e., corneal erosion, ulcer, or other trauma).
        - Aqueous humor may enter corneal stroma owing to loss or damage of corneal endothelium or endothelial pump function.
        - Fluid from vascular leakage secondary to newly formed blood vessels may enter the cornea.
    - Florida spots:
        - Slowly to nonprogressive corneal disease that does not cause other overt clinical signs
        - Typically characterized by bilateral multifocal, grey-white opacities within the cornea
        - Recognized in dogs and cats in the southeastern United States
        - Etiology unknown, possibly mycobacterial organism
- Red discolorations:
    - Corneal vascularization:
        - Vascularization occurs as a response to injury of the corneal epithelium or stroma as a normal component of healing.
        - Vascularization may occur as part of an immune-mediated inflammatory response.
        - Vascularization may occur secondary to disease of adjacent ocular tissues including episcleritis, uveitis, and glaucoma.
    - Hemorrhage into the cornea may be due to trauma to blood vessels invading the cornea or as an extension of conjunctival hemorrhage.

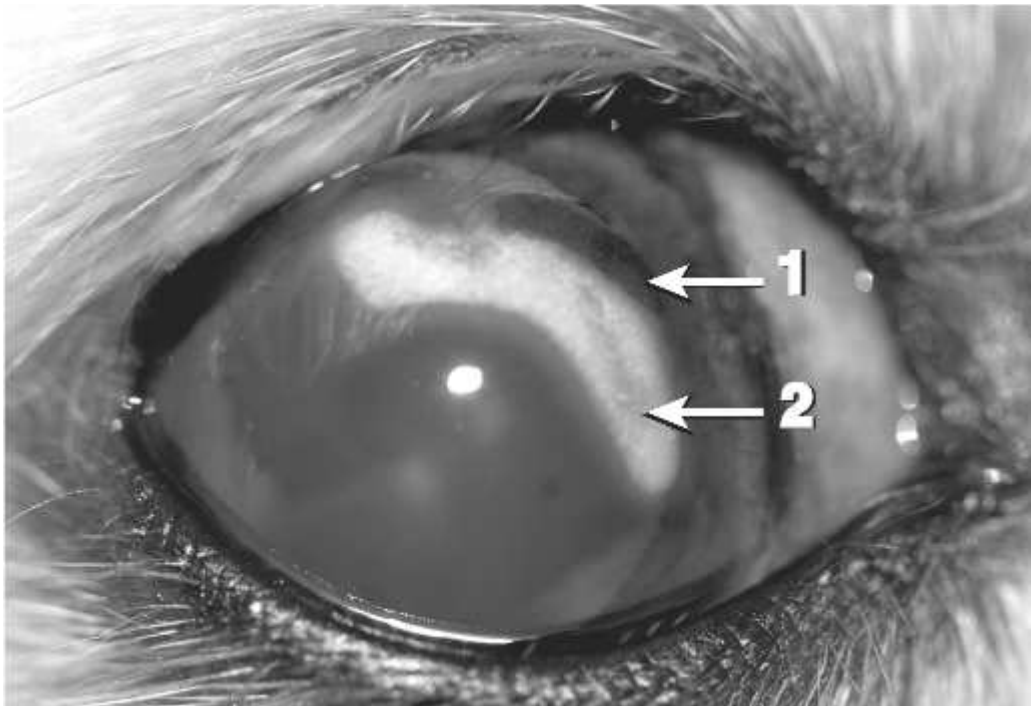
DIAGNOSIS

DIAGNOSTIC OVERVIEW

- The diagnosis is broad, and evaluation should begin with determining qualities such as color, location, pattern, and size of discoloration as well as evaluation for other concurrent ocular disease.

DIFFERENTIAL DIAGNOSIS

- Brown discolorations:
    - Corneal Pigmentation, p. 246:
        - Chronic irritation/inflammation:
            - Pigmentary keratitis (in brachycephalic dogs primarily): large palpebral fissure, lagophthalmos (incomplete closure of the eyelids), ectopic cilia, trichiasis (entropion, nasal folds, aberrant dermis at medial canthus)
            - Exposure keratitis: buphthalmos (chronic glaucoma), neuroparalytic keratitis (cranial nerve VII lesion)



CORNEAL DISCOLORATION Corneal degeneration in a dog. There is a horizontally ovoid area of corneal pigmentation *(1)* and a white arc of corneal lipid deposit *(2)*.

- Keratoconjunctivitis sicca (KCS)
- Chronic superficial keratitis (CSK/pannus): dogs
- Protrusion of iris tissue through corneal defect
- Persistent pupillary membrane (iris to cornea)
- Anterior synechia
- Rupture of pigmented uveal cyst
- Neoplasia (see p. 620): limbal melanocytoma, invasive anterior uveal melanoma
- Corneal sequestrum: cats (see p. 248)
- Brown foreign material

- White discolorations:
  - Corneal fibrosis/scarring (hazy grey-white) (see p. 249)
  - Corneal lipid infiltrate or deposition (bright white, crystalline; see p. 245):
    - Corneal dystrophy
    - Corneal degeneration
    - Lipid keratopathy (systemic lipid abnormalities): diabetes mellitus, pancreatitis, hypothyroidism, hyperadrenocorticism, thyroid carcinoma, hepatic disease, primary hyperlipoproteinemia, postprandial hyperlipoproteinemia
  - Corneal calcium deposition (dense, chalky-white)
    - Corneal degeneration
    - Systemic disease: hypercalcemia, hyperphosphatemia, hyperadrenocorticism, renal disease, hyperparathyroidism, hypervitaminosis D
- White/yellow or white/pink discolorations:
  - Inflammatory cell infiltration:
    - Infected corneal ulcer
    - Corneal abscess (infectious or sterile)
  - Feline proliferative keratoconjunctivitis (plaques and infiltrates)
  - Corneal epithelial inclusion cyst
- Grey-blue discolorations:
  - Corneal edema:
    - Corneal endothelial loss or damage: endothelial dystrophy, uveitis, glaucoma, trauma (anterior lens luxation with endothelial contact, intraocular surgery)
    - Corneal edema due to epithelial loss: corneal ulceration
    - Corneal edema associated with corneal vascularization
  - Florida spots (see Etiology and Pathophysiology above)
- Red/pink discolorations:
  - Corneal vascularization
    - Corneal injury or inflammation:

- Corneal ulceration
- Chemical irritation
- Mechanical irritation: (trichiasis, ectopic cilia, entropion)
- Exposure: large palpebral fissure, lagophthalmos (incomplete closure of the eyelids), ectropion, buphthalmos (chronic glaucoma), exophthalmos, neuroparalytic keratitis (cranial nerve VII lesion)
- Neurotrophic keratitis (cranial nerve V lesion)
- Keratoconjunctivitis sicca
- Qualitative tear film abnormalities (see p. 1076)
- Chronic superficial keratitis (CSK/pannus): dogs
- Proliferative keratoconjunctivitis: cats
- Corneal degeneration (see figure)

- Adjacent ocular disease: uveitis, episcleritis, scleritis, orbital disease, glaucoma

INITIAL DATABASE

Complete ophthalmic examination (see p. 1313) is essential, including the following:

- Schirmer tear test: values <10 mm/min are consistent with KCS; values of 10 to 15 mm/min suggestive of KCS and should be interpreted in light of other clinical signs
- Tear film break-up time: values <10 seconds are suggestive of a qualitative tear film abnormality (see p. 1076)
- Fluorescein staining: positive in corneal ulceration
- Tonometry: elevated intraocular pressure (>30 mm Hg) in glaucoma, and reduced (<10 mm Hg) in cases of uveitis

ADVANCED OR CONFIRMATORY TESTING

- CBC, serum biochemistry profile, urinalysis, serum lipid profile (total serum lipids, cholesterol, triglycerides, lipoprotein electrophoresis, ± cholesterol esters and phospholipids), thyroid ± adrenal gland testing are recommended if lipid or calcium infiltration is suspected in association with systemic disease.
- Cytologic evaluation of conjunctival scraping or conjunctival biopsy is useful in diseases associated with conjunctival inflammation or proliferation.
- Cytologic evaluation of corneal scrapings is useful in proliferative disease of the cornea or inflammatory cell infiltration of a corneal ulcer.

TREATMENT

TREATMENT OVERVIEW

- The goals of treatment are to halt progression of the lesion, treat the underlying cause, and reduce ocular discomfort.

ACUTE AND CHRONIC TREATMENT

Treatment will vary depending on the underlying cause.

PROGNOSIS AND OUTCOME

Prognosis and outcome vary depending on the underlying cause.

PEARLS & CONSIDERATIONS

COMMENTS

In determining the underlying cause, documentation of location, color, shape, and pattern of corneal discoloration and presence of other concurrent ocular disease are extremely helpful.

Cor Triatriatum Sinister and Supravalvular Mitral Stenosis

BASIC INFORMATION

DEFINITION

- Congenital cardiac malformations involving membranous division of the left atrium into a proximal high-pressure chamber and a distal low-pressure chamber
- Cor triatriatum sinister (CTS) can be distinguished from supravalvular mitral stenosis (SVMS) by the location of the membrane relative to the left auricle.
    - Cor triatriatum ("three atria") sinister ("left"): the auricle is distal to the dividing membrane and connected with the distal low-pressure left atrial chamber.
    - Supravalvular mitral stenosis: the left auricle is proximal to the dividing membrane and is connected with the proximal high-pressure left atrial chamber.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Feline; most often diagnosed in cats younger than 1 year of age but has been reported in older cats; males reported more frequently
- Canine: no cases reported (see cor triatriatum dexter)

GENETICS & BREED PREDISPOSITION

Uncommon; no known breed predisposition or genetic defect defined

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Respiratory distress
- Anorexia
- Lethargy

PHYSICAL EXAM FINDINGS

Not all signs will be present in every patient:

- Tachypnea
- Dyspnea
- Tachycardia
- Gallop
- Diastolic murmur
- Arrhythmias with pulse deficits
- Crackles and/or wheezes
- Muffled lung sounds (pleural effusion)

ETIOLOGY AND PATHOPHYSIOLOGY

- CTS results from incomplete incorporation of the embryologic pulmonary venous chamber into the developing left atrium.
- SVMS results from embryologic malformation of the mitral valve apparatus.
- Both CTS and SVMS cause left atrial inflow obstruction, which may result in signs of left-sided congestive heart failure, including pulmonary edema, pleural effusion, and pericardial effusion. Therefore, clinical signs of CTS and SVMS are identical.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Clinical presentation of left-sided congestive heart failure should generally lead to the suspicion of other, more common cardiac disorders. However, the diagnosis is established during the echocardiographic examination (generally an unexpected finding).

DIFFERENTIAL DIAGNOSIS

- Mitral valve stenosis
- Hypertrophic cardiomyopathy
- Dilated cardiomyopathy
- Thyrotoxic heart disease
- Left atrial tumor

INITIAL DATABASE

- Thoracic radiographs demonstrate marked left atrial enlargement, ± left ventricular enlargement. Signs of congestive heart failure may also be present: pulmonary venous distension, interstitial to alveolar infiltrate, and/or pleural effusion.
- Electrocardiogram may show wide P waves consistent with left atrial enlargement, and tall R waves consistent with left ventricular enlargement.
- CBC may show a stress leukogram. Biochemistry panel and urinalysis are likely to be unremarkable.

ADVANCED OR CONFIRMATORY TESTING

- Echocardiography:
  - Two-dimensional echocardiography will display a membrane dividing the atrium and indicating the position of the membrane relative to the auricle.
  - Doppler echocardiography can be used for determining the degree of obstruction by measuring the velocity of blood flow across orifice.
    - The modified Bernoulli equation can be used for calculating the pressure gradient across the membrane (Pressure change = 4 × velocity^2).
- Angiography is an alternate imaging technique to define the location of the obstruction and determine if other concurrent cardiac defects are present, but invasiveness of angiography makes echocardiography a superior first choice.

TREATMENT

TREATMENT OVERVIEW

Alleviate clinical signs of left heart failure. The lesion does not lend itself to catheter-based correction; open-heart surgery is the definitive method of correction of the defect.

ACUTE GENERAL TREATMENT

If patient is in acute heart failure, then treat with furosemide, oxygen, and nitroglycerin (see p. 468).

CHRONIC TREATMENT

- Furosemide and an angiotensin-converting enzyme inhibitor to control fluid accumulation (see p. 470)
- Periodic thoracocenteses may be necessary to treat pleural effusion (see p. 1338).
- Successful surgical correction of CTS has been reported.

DRUG INTERACTIONS

Electrolyte depletion and dehydration may result from overzealous diuretic administration.

POSSIBLE COMPLICATIONS

Surgery is highly invasive, and therefore the risk of mortality is increased with an inexperienced surgeon.

RECOMMENDED MONITORING

- Pulmonary edema/pleural effusion should resolve with successful reduction/removal of the membranous obstruction.

- Renal function should be periodically monitored if medical therapy is chosen.

PROGNOSIS AND OUTCOME

- Excellent with successful reduction/removal of the obstruction
- Medical management alone is unlikely to be satisfactory on a long-term basis if signs of congestive heart failure have already occurred, but the small number of recorded veterinary cases of CTS/SVMS limits the extent of this conclusion.

PEARLS & CONSIDERATIONS

COMMENTS

These defects are rare but represent potentially curable abnormalities. Any cat presenting with signs of heart failure should have an echocardiogram performed to rule out CTS or SVMS.

CLIENT EDUCATION

Owner should monitor for recurrence of heart failure: increased respiratory rate or effort, lethargy, or anorexia. Owner should monitor patient's resting respiratory rate and call clinician if rate exceeds 40 breaths/min when the patient is asleep.

Coprophagia

BASIC INFORMATION

DEFINITION

Ingestion of feces, common in dogs

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Common and generally normal behavior in all types of dogs
- Normal expression of maternal behavior during pregnancy and nursing in both cats and dogs; very rare in cats

RISK FACTORS

- Dietary preference
- Access to feces
- Lack of other outlets for exploratory behavior
- Inadequate diet, hunger
- Inadequate utilization of food (e.g., severe intestinal malabsorption, exocrine pancreatic insufficiency [EPI], severe parasitism)

GEOGRAPHY AND SEASONALITY

- Ubiquitous behavior of domestic dogs
- May increase in winter when feces are frozen or when less access to organic material in environment

ASSOCIATED CONDITIONS & DISORDERS

- Polyphagia
- Poor body condition associated with malnutrition
- Anxiety
- Compulsive behavior which may include pica (ingestion of nonfood items other than feces)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Acute or chronic behavior, often an incidental finding
- Ingestion of own feces, those of other dogs, or of any other herbivore or carnivore species, especially of cats
- May occur daily or intermittently
- With EPI, owners may report weight loss, ravenous appetite, steatorrhea, borborygmus, flatulence, and diarrhea with voluminous stools

PHYSICAL EXAM FINDINGS

- Typically no abnormal findings on physical exam
- In an older dog may indicate abnormality in endocrine function (e.g., hyperadrenocorticism, hypothyroidism) or cognitive dysfunction

ETIOLOGY AND PATHOPHYSIOLOGY

- Typically normal behavior in domestic dogs, likely evolved from scavenging and nest-cleaning behaviors
- Onset may be associated with change in diet or environment, but behavior will often persist after return to previous management

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A common and normal behavior in many dogs, coprophagia alone should not ordinarily arouse suspicion of a dietary, physical, or behavioral abnormality.

DIFFERENTIAL DIAGNOSIS

- Hunger
- Separation anxiety
- Compulsive disorder
- Pica
- Polyphagia (e.g., diabetes mellitus, hyperadrenocorticism, drug-induced)
- EPI
- Thiamine deficiency (rare)

INITIAL DATABASE

- Generally no additional diagnostic testing required beyond regular wellness recommendations
- If abnormality suspected based on history and physical exam, basic laboratory diagnostic tests may be indicated, including CBC, serum chemistry, urinalysis, and fecal analysis for parasites.

ADVANCED OR CONFIRMATORY TESTING

Thyroid profile, trypsin-like immunore-activity, serum cobalamin, serum folate, fecal fat, and fecal trypsin may be considered for cases where a primary medical disturbance is suspected (rarely the case).

TREATMENT

TREATMENT OVERVIEW

Many dogs are highly motivated to engage in this self-rewarding behavior, and it should therefore be expected that behavior modification will be difficult and not completely successful in the long term.

ACUTE AND CHRONIC TREATMENT

- No additives to the dog's food or products applied to the feces have been consistently effective in preventing coprophagia.
- The most effective methods for prevention include:
    - Attention to yard hygiene
    - Removing access to cat litterboxes
    - Training the dog to defecate on command and then return immediately to the owner
    - Use of a remote-activated spray collar to interrupt the behavior
    - Use of a head collar on walks to redirect the behavior
    - Addressing any issues related to separation anxiety and poor environments
    - Client education

NUTRITION/DIET

In dogs already receiving a nutritionally adequate diet, a change in diet is unlikely to influence the frequency of this behavior.

PROGNOSIS AND OUTCOME

Prognosis is guarded for complete cessation of this unwanted behavior, although it is possible to reduce the frequency of coprophagia through behavior modification and environmental management.

PEARLS & CONSIDERATIONS

COMMENTS

- Coprophagia and pica (ingestion of nonfood items) may both be found in patients with polyphagia. Therapeutic success depends on properly identifying the primary disorder.
- Many owners find coprophagia by dogs to be extremely offensive and are not aware that it is normal for the species.
- Owner counseling is important to reduce the likelihood of inhumane treatment or abandonment of dogs due to coprophagia.

PREVENTION

- Reducing access to feces by young dogs may prevent the initial ingestion of feces as part of exploratory behavior.
- Providing dogs with an adequate diet, exercise, and socialization may reduce the likelihood of coprophagia but is unlikely to completely prevent it from occurring.

CLIENT EDUCATION

Clients should be reassured that coprophagia is normal and generally harmless to their dog, and be provided with strategies to reduce the likelihood of it occurring if it adversely affects the way they interact with their dog.

EDITOR: ETIENNE CÔTÉ

Contact Dermatitis

BASIC INFORMATION

DEFINITION

Cutaneous inflammation which occurs after contact with an irritant or antigenic substance

SYNONYMS

Allergic contact dermatitis, contact hypersensitivity, irritant contact dermatitis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Uncommon in dogs and rare in cats
- Allergic contact dermatitis typically occurs in animals older than 1 year; irritant contact dermatitis may occur at any age.

GENETICS & BREED PREDISPOSITION

Terrier breeds, French poodles, and golden retrievers may be at increased risk.

RISK FACTORS

Concurrent inflammatory dermatoses

ASSOCIATED CONDITIONS & DISORDERS

- Atopic dermatitis
- Secondary bacterial or *Malassezia* dermatitis is common.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Allergic contact dermatitis
- Irritant contact dermatitis

HISTORY, CHIEF COMPLAINT

- Allergic contact dermatitis:
  - The chief complaint is typically chronic pruritus that may be seasonal or nonseasonal, depending on the allergen.
  - A recent change in environment or housing is typically not noted, because signs may take longer than 2 years to develop from the time of initial exposure.
  - The animal is typically the only one in the household affected.
- Irritant contact dermatitis:
  - The chief complaint may be acute cutaneous pain rather than pruritus.
  - Onset of the condition often correlates with the introduction of a new substance.
  - There may be more than one individual affected (including the owner).

PHYSICAL EXAM FINDINGS

Lesion distribution reflects the area of the body in contact with the offending substance.

- Sparsely haired areas and those areas in contact with the environment are more frequently affected (ventral surfaces of the feet, chest, and abdomen, perineum, and scrotum).
- Regional dermatitis of the muzzle and chin may occur with reactions to substances such as rubber chew toys or plastic food dishes (rare).

- A generalized distribution may be present with contact reactions to shampoos.
- The ears may be the only area affected if the offending substance is a topical otic medication
- The primary lesion is an erythematous papular and macular eruption.
- Vesicles are occasionally present.
- With chronic exposure, alopecia, lichenification, and hyperpigmentation develop.

ETIOLOGY AND PATHOPHYSIOLOGY

- Allergic contact dermatitis is a type IV hypersensitivity disorder. The development of clinical disease requires two stages: induction and elicitation. The induction phase is the time from allergen exposure until the time lymphocytes become programmed to recognize the allergen (lasts months to years; no evidence of clinical disease). Elicitation is the time from reexposure to the allergen to the development of cutaneous inflammation. This phase may take several days. Reported causes include shampoos, insecticides, topical/otic medications, plastic, detergents, wool, synthetic rugs, fertilizers, cement, perfumed cat litter, and several species of plants.
- Irritant contact dermatitis is an antigen-independent process that is the result of direct keratinocyte damage by the offending compound. No induction phase is necessary. Acids, alkalis, surfactants, solvents, enzymes, and oxidants may cause irritant contact dermatitis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Contact dermatitis is difficult to definitively diagnose with commonly available clinical tools. Its diagnosis often relies upon ruling out other potential causes of inflammation in conjunction with a suggestive history. More common causes of the apparent clinical signs need to be ruled out first.

DIFFERENTIAL DIAGNOSIS

- Parasitic: fleas, contagious acarioses *(Sarcoptes, Cheyletiella, Otodectes, Notoedres), Demodex, Pelodera,* chiggers, and hookworm dermatitis
- Allergic: flea-bite hypersensitivity, atopic dermatitis, food hypersensitivity
- Bacterial pyoderma
- Fungal: dermatophytosis, *Malassezia* dermatitis
- Erythema multiforme
- Drug eruptions
- Lupus erythematosus

INITIAL DATABASE

- Skin scrapings and cytologic examination should be performed to detect microbial or parasitic infections.
- A fungal culture should be considered, especially in cats, to detect dermatophytosis.
- An elimination food trial may be performed to rule out dermatologic adverse food reactions/food allergy.
- Intradermal skin testing or in vitro serum allergy testing may be performed to investigate atopic dermatitis.

ADVANCED OR CONFIRMATORY TESTING

- Histopathologic evaluation may provide supportive evidence and help differentiate between allergic and irritant contact dermatitis if biopsies are taken early in the disease process. Results from biopsies of chronically diseased skin are usually nonspecific.
- Patch testing is a specific test for investigating allergic contact dermatitis. A series of compounds is applied to the skin for 48 hours, and the degree of erythema, induration, and papular eruptions caused by each agent is evaluated. Standardized kits for veterinary medicine are not available, but human standardized kits have been used successfully in dogs.
- Restriction and provocative exposure is the most reliable test. Ideally the animal should be bathed to remove all possible allergens and removed completely from the home environment for 2 to 4 weeks. After resolution, the animal is reintroduced to the environment. A return of clinical signs will typically occur within 24 to 72 hours in cases of contact dermatitis.

TREATMENT

TREATMENT OVERVIEW

The ideal treatment involves identification and removal of the offending substance. Unfortunately, patch testing and restriction/provocation testing are either not widely available are logistically difficult to perform, often leaving history as the only clue to the potential contact allergen/irritant. In cases where the offending substance cannot be identified, nonspecific palliative therapy may be necessary.

ACUTE GENERAL TREATMENT

- Treat any secondary microbial infections.
- Identify and remove the offending substance.
- Palliative therapy with glucocorticoids (prednisone, 0.5-1 mg/kg PO q 24 h initially, before weaning down based on response), pentoxifylline (15-20 mg/kg PO q 8-12 h), or topical tacrolimus (0.1% ointment) may provide relief in cases of allergic contact dermatitis.

CHRONIC TREATMENT

- Long-term palliative therapy may be necessary if clinical signs persist and the offending substance cannot be identified and removed. The treatment plan for each patient should be chosen based upon efficacy in that patient as well as long-term safety. For example, pentoxifylline is typically well tolerated and should be chosen over glucocorticoids for long-term treatment if effective.

PROGNOSIS AND OUTCOME

Excellent if the offending substance is identified and removed

PEARLS & CONSIDERATIONS

COMMENTS

Some substances may cause both irritation and allergic contact dermatitis.

AUTHOR: ANDREW LOWE

EDITOR: MANON PARADIS

Constipation/Obstipation and Megacolon

BASIC INFORMATION

DEFINITION

- Constipation: infrequent or difficult evacuation of feces; does not imply loss of function
- Obstipation: intractable constipation
- Megacolon: persistent dilation of the large intestine associated with chronic constipation or obstipation, or occurring secondary to idiopathic loss of colon function. Dilated megacolon implies permanent loss of colonic structure and function.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Constipation: both dogs and cats. Megacolon is rarely reported in dogs. Obstipation/megacolon is reported to be more common in middle-aged, male cats of the domestic shorthair, domestic long hair, or Siamese breeds.

GENETICS & BREED PREDISPOSITION

Manx cats may be predisposed to neurogenic megacolon.

RISK FACTORS

- Intrinsic dysfunction preventing passage of feces: spinal cord/spinal nerve disease or trauma, dysautonomia
- Mechanical obstruction preventing passage of feces: pelvic fracture, colonic stricture or neoplasia, extraluminal mass or stricture compressing colon, anal stricture, colonic foreign body
- A predominantly bony diet and low levels of exercise may predispose dogs to megacolon.

ASSOCIATED CONDITIONS & DISORDERS

Perineal hernia may be either the cause or result of constipation and megacolon.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Hypertrophic megacolon: develops as a consequence of obstructive lesions and thus may be reversible with early therapy,
- Dilated megacolon: end stage of colonic dysfunction (both idiopathic or untreated hypertrophic megacolon); may be poorly responsive to treatment

HISTORY, CHIEF COMPLAINT

- Reduced, absent, or painful defecation is typical presentation.
- Fecal balls are often very hard if passed, and occasionally watery diarrhea may be passed around fecal concretion.
- Prolonged constipation will result in anorexia, lethargy, weight loss, or vomiting (may be projectile).

PHYSICAL EXAM FINDINGS

- Poor body condition
- Dehydration
- Colon distended with hard feces on abdominal palpation; signs of abdominal pain may be present.
- Perineal irritation/ulceration
- Rectal exam (usually requires sedation in cats): hard feces, possible pelvic narrowing, stricture or mass palpated, perineal hernia

ETIOLOGY AND PATHOPHYSIOLOGY

- Prolonged retention of feces in colon due to functional (neurogenic) or mechanical obstruction (e.g., pelvic fractures, intraluminal or extraluminal masses)
- Inflammation can also be associated with constipation (perianal fistula, proctitis, anal sac abscess, or perianal bite wounds).
- Water absorption from feces in colon results in concretion that is difficult or impossible to pass (common in cats with chronic progressive renal disease or diabetes mellitus).
- Neurogenic dysfunction from dysautonomia (autonomic system failure), trauma to pelvic or hypogastric nerves (pelvic fracture), neoplasia of spinal cord, or caudal spinal cord diseases (e.g., lumbosacral disease, lumbosacral stenosis/cauda equina syndrome, Manx cat sacral deformities)
- Prolonged distension of colon causes irreversible changes in colonic smooth muscles and nerves.
- Retained bacterial toxins may be absorbed, resulting in endotoxemia and signs of illness (anorexia, lethargy, vomiting).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of constipation is based on a history of difficult, reduced, or absent defecation and finding firm feces in the colon on abdominal palpation. The underlying cause can usually be determined by physical examination and abdominal radiography.

DIFFERENTIAL DIAGNOSIS

- Reversible causes of constipation:
  - Dehydration, electrolyte disorders, inflammatory diseases of the anorectum
  - Drug administration (opioids, anticholinergics)
  - Environmental changes (inactivity, litter box changes)
- Any of the risk factors causing mechanical obstruction

INITIAL DATABASE

- CBC: leukocytosis (mature neutrophilia/stress leukogram), occasionally anemia
- Serum biochemistry profile: azotemia (associated with dehydration or concurrent chronic renal failure), hypokalemia, hypercalcemia
- Urinalysis: no specific changes. Isosthenuria in azotemic patients if chronic kidney disease.
- Abdominal radiographs: feces-distended colon. Underlying cause of initial colonic distension/fecal retention may be evident: pelvic fractures, evidence of spinal trauma (vertebral fracture/luxation), extraluminal compressive masses, foreign material in colon.

ADVANCED OR CONFIRMATORY TESTING

- Ultrasonography: identifies suspected extraluminal masses. Poor utility for intraluminal visualization because even minute amounts of colonic gas block ultrasound waves.
- Barium enema: defines strictures or intraluminal masses (see p. 1204)
- Endoscopy: identifies colorectal neoplasia, stricture, inflammatory lesions, sacculations and diverticula, etc.
- Evaluation of animals with suspected neurologic impairment may include cerebrospinal fluid analysis, CT/MRI scanning of distal spinal cord and cauda equina region, myelogram, and electrophysiologic studies (electromyography).
- Diagnosis of dysautonomia is based on finding other systemic evidence of the disease (megaesophagus, mydriasis, decreased lacrimation, prolapsed nictitans, and bradycardia) but is considered a rare cause of megacolon (see).

TREATMENT

TREATMENT OVERVIEW

Mild to moderate constipation is usually successfully treated with a combination of enemas, laxatives, colonic prokinetic agents, and diet modification. Patients with severe constipation often also require intravenous fluid therapy and manual extraction of feces under anesthesia. Subtotal colectomy is necessary for patients with end-stage megacolon.

ACUTE GENERAL TREATMENT

- Fluid therapy for dehydration, with supplementation to correct hypokalemia if present. Intravenous fluid therapy (60-90 mL/kg/d) is often needed for most severely affected cats. Correction of dehydration assists in constipation relief through rehydration of the colonic mucosa.

- Enemas and careful manual extraction of feces if obstipated. In most cats, sedation or anesthesia will be required. Multiple procedures over a day or two may be needed in the most severely obstipated/impacted cats to prevent additional injury or rupture of the diseased colon.
- Warm water enemas (5-10 mL/kg water) using a 12-14 Fr, well-lubricated, red rubber catheter for insertion are well tolerated. See for procedure description. Higher volumes of water must be used with caution because they may cause vomiting (and aspiration). If multiple enemas are administered in a short period of time, saline is preferred instead of tap water to avoid an excessive osmotic shift of sodium and other electrolytes into the colon, and resultant hyponatremia.
- Enemas should not contain soaps or other irritants; lactulose or mineral oil can be used.
- Enemas containing sodium phosphate (e.g., Fleet) are contraindicated in cats and small dogs because of the severe hyperphosphatemia and subsequent hypocalcemia they can cause.
- Broad-spectrum antibiotics (e.g., ampicillin, 22 mg/kg IV q 8 h, and enrofloxacin, 5 mg/kg diluted 1:1 in saline and given slowly IV q 12 h [q 24 h in cats]) are indicated if signs of endotoxemia or fever are noted.

CHRONIC TREATMENT

- Medical therapy includes stool softeners or laxatives (e.g., lactulose, 0.25-0.5 mL/kg PO q 8-12 h; or docusate sodium/dioctyl sulfosuccinate, 50 mg/cat PO q 12-24 h; or mineral oil) and prokinetics (cisapride, 0.1-1 mg/kg POq 8-12 h or 2.5-5 mg/cat PO q 8-12 h). Lactulose is the most effective stool softener and is given to effect daily to maintain a soft to semiformed stool (usual dose after titration: 1-4 mL/cat PO q 8-12 h).
- Bulk-forming laxatives (cellulose, psyllium) will not be effective in cats prone to dehydration or in cats with poor colonic muscle function, because their mechanism of action is similar to high-fiber diets.
- Stimulant laxatives (e.g., bisacodyl, castor oil, cascara) should not be used for relieving constipation but are best used as a preventive in cats that still have normal colonic function.
- Prokinetic therapy may assist smooth-muscle function in cats with recurrent constipation or obstipation. The most effective drugs are the serotonergic agonists (cisapride, prucalamide) and histamine H2 receptor antagonists (ranitidine, 1-2 mg/kg PO q 8-12 h, or nizatidine [dogs only] 5 mg/kg PO q 24 h; famotidine does not have this effect).
- Correct underlying cause: remove masses or strictures causing obstruction to outflow, or correct pelvic fractures obstructing outflow with pelvic osteotomy.
- Subtotal colectomy (with or without preservation of the ileocolic valve) may be indicated if lack of response to medical treatment or pelvic fracture malunion >6 months from onset of obstipation.

NUTRITION/DIET

- Control recurrent constipation with high-fiber or low-residue diet.
- High-fiber diets induce colonic contraction and are useful in management of constipation when the patient still has a functional colon and is well hydrated. Avoid high-fiber diets in patients that are prone to dehydration (can exacerbate it).
- Low-residue diets are often best inpatients with chronic recurrent episodes of obstipation or true megacolon, because they reduce the amount of material reaching the colon and make it easier to keep a soft stool.

POSSIBLE COMPLICATIONS

- Medical treatment: perforation secondary to trauma from enemas and evacuation of feces; gentle manipulation and being patient (don't be in a hurry to remove the concretion) are essential.
- Subtotal colectomy: leakage, dehiscence, and peritonitis; chronic diarrhea (may be associated with bacterial overgrowth from loss of ileocolic sphincter); recurrent constipation; stricture.

RECOMMENDED MONITORING

- For cats undergoing medical management, close observation of fecal passage by the owner is essential for prevention of severe recurrent constipation.
- After subtotal colectomy, monitor:
    - Hydration
    - Appetite
    - Temperature, blood glucose, abdominal pain (signs of leakage or dehiscence of anastomosis)

PROGNOSIS AND OUTCOME 

- Fair prognosis with medical management. Recurrent constipation requiring repeated enemas and manual evacuation is common.
- Good to excellent prognosis with subtotal colectomy. Owner needs to be aware that stools are usually soft, and the frequency of defecation is increased, for 2 to 3 months after surgery. Occasionally diarrhea is a persistent long-term problem.
- Guarded prognosis with pelvic osteotomy for pelvic fracture malunion. Correction of obstruction may not resolve megacolon

and constipation.

PEARLS & CONSIDERATIONS

COMMENTS

- Do not attempt correction of pelvic malunion by pelvic osteotomy if >6 months from onset of signs of obstipation. Perform subtotal colectomy instead.
- Do not perform enema immediately before surgery for megacolon. It is more difficult to control contamination of the abdomen with liquid feces during surgery.

PREVENTION

Early repair of pelvic fractures that cause obstruction of pelvic canal

CLIENT EDUCATION

Warn owners that diarrhea can be severe after subtotal colectomy but that it usually resolves within 8 weeks. If the cecum is removed during surgery, consider treatment for bacterial overgrowth if diarrhea persists >8 weeks.

Conjunctivitis, Dogs

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Inflammation of the conjunctiva, a thin mucous membrane lining the inner surface of the upper and lower eyelids (palpebral conjunctiva) and both sides of the third eyelid. In the conjunctival fornix ("cul-de-sac"), the conjunctiva reflects onto the globe (bulbar conjunctiva) and becomes continuous with the corneal epithelium. The conjunctiva is an immunologically active structure with an abundance of immune cells, blood vessels, and lymphatics. Conjunctivitis is one of the most commonly diagnosed ocular disorders in dogs.

SYNONYMS

Canine adenovirus 1: infectious canine hepatitis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Typically no age predisposition, although allergic conjunctivitis and follicular conjunctivitis typically occur in younger dogs
- No sex predisposition

GENETICS & BREED PREDISPOSITION

Breeds predisposed to:

- Pannus (Chronic Superficial Keratitis), see p. 825
- Plasmacellular conjunctivitis: German shepherd, collie
- Keratoconjunctivitis sicca, see p. 628
- Abnormal eyelid conformation (e.g., Entropion/Ectropion, p. 348)
- Deep orbits, narrow skull conformation, and inadequate tear drainage (i.e., medial canthal pocket syndrome): dolichocephalic breeds including Afghan hound, Doberman pinscher, standard poodle
- Ligneous conjunctivitis (rare): Doberman pinscher

RISK FACTORS

- Outdoor activities (e.g., hunting: allergic conjunctivitis, follicular conjunctivitis)
- Unvaccinated animals, dog shelters, dog shows (see Distemper, Canine, p. 317; canine adenovirus [CAV-1, CAV-2] conjunctivitis)

CONTAGION & ZOONOSIS

Canine distemper virus and CAV-1, CAV-2: contagious dog-to-dog

ASSOCIATED CONDITIONS & DISORDERS

Allergic dermatitis/skin lesions, otitis externa (allergic conjunctivitis)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Unilateral or bilateral:

- Primary: allergic, follicular, immune-mediated, bacterial, parasitic
- Secondary: underlying ocular and/or systemic (infectious or noninfectious) disease, environmental, neoplasia, idiopathic (e.g., ligneous conjunctivitis)

HISTORY, CHIEF COMPLAINT

- Painful, red eye (unilateral or bilateral)
- Ocular discharge

PHYSICAL EXAM FINDINGS

- Conjunctival hyperemia
- Conjunctival edema (chemosis)
- Lymphoid follicles on conjunctiva
- Thick, opaque palpebral conjunctival membrane formation (ligneous conjunctivitis)
- Ocular discharge (see p. 777)
- Blepharospasm (squinting)
- Protrusion of the third eyelid

ETIOLOGY AND PATHOPHYSIOLOGY

- Primary:
  - Allergic conjunctivitis
  - Follicular conjunctivitis (chronic antigenic stimulation)
  - Immune-mediated conjunctivitis (clinical signs together with plasmacellular infiltration on cytologic/histologic evaluation suggestive of immune-mediated condition)
  - Bacterial conjunctivitis (*Staphylococcus* spp. and other gram-positive organisms uncommon; more often secondary to keratoconjunctivitis sicca or eyelid abnormalities)
  - Parasitic conjunctivitis (*Thelazia* spp.)
- Secondary:
  - Other ocular causes of red eye (see p. 967) including:
    - Keratoconjunctivitis sicca (see p. 628)
    - Mechanical ocular irritation (e.g., entropion, ectropion, trichiasis, distichiasis, ectopic cilia, eyelid mass, exophthalmos [cranial displacement of the globe], lagophthalmos [incomplete closure of the eyelids], foreign body)
    - Corneal ulceration (see p. 250)
    - Anterior uveitis (see p. 1151)
    - Ocular trauma
    - Glaucoma (see p. 448)
    - Blepharitis
    - Dacryocystitis (see p. 280)
    - Scrolled cartilage of the third eyelid and/or prolapsed gland of the third eyelid (see p. 1089)
  - Environmental:
    - Irritation from dust, smoke, or chemicals
    - Actinic-related/solar conjunctivitis in dogs lacking pigment along margin of third eyelid
  - Systemic infectious diseases:
    - Viral (canine distemper, CAV-1, CAV-2)
    - Systemic mycoses (see Blastomycosis, p. 138; Coccidioidomycosis, p. 222; Cryptococcosis, p. 266; Histoplasmosis, p. 538)
    - Leishmaniasis (see p. 643)
  - Systemic noninfectious diseases (e.g., systemic histiocytosis, polycythemia vera)
  - Neoplasia (e.g., lymphosarcoma, multiple myeloma, mast cell tumor, squamous cell carcinoma, melanoma)
  - Idiopathic:
    - Ligneous conjunctivitis
      - Conjunctival injury and exaggerated, inflammatory immune response implicated in human form of disease
      - May be associated with membrane formation involving the oral mucosa, upper respiratory tract, or urinary tract

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Conjunctivitis in dogs arises most commonly as a result of other causes of red eye (i.e., secondary), including KCS, mechanical ocular irritation, and systemic disease. Determining whether the conjunctivitis is primary versus secondary in nature requires physical examination and ophthalmic examination (), and is crucial to direct the appropriate treatment.

DIFFERENTIAL DIAGNOSIS

Primary conjunctivitis must be differentiated from secondary conjunctivitis (i.e., other causes of red eye; see Etiology and Pathophysiology).

INITIAL DATABASE

Complete ophthalmic examination, including:

- Examination of all conjunctival surfaces, including lacrimal puncta, with diffuse light and magnification
- Conjunctival swabs for bacterial ± fungal culture(s) and sensitivity (done before other diagnostic tests)
- Conjunctival scrapings for cytologic evaluation: diagnosis of bacterial or fungal infection, intracytoplasmic inclusions in conjunctival epithelial cells in distemper infection
- Schirmer tear test (normal is >15 mm/min)
- Fluorescein dye application (monitor nares for exit of dye to determine if nasolacrimal system patent)
- Tear film break-up time (TFBUT; mean TFBUT = 19.7 seconds; <10 seconds is considered accelerated)
- Intraocular pressures (normal is 15-25 mm Hg)

ADVANCED OR CONFIRMATORY TESTING

- Conjunctival samples may be submitted for PCR testing for infectious diseases (e.g., distemper virus).
- Conjunctival samples for indirect fluorescent antibody staining (distemper virus, adenovirus)
- Flush nasolacrimal system if occlusion suspected (see online chapter: Dacryocystitis).
- Conjunctival biopsy and histopathologic examination (neoplasia; ligneous conjunctivitis)

TREATMENT

TREATMENT OVERVIEW

Determining the underlying cause of canine conjunctivitis (primary versus secondary) is critical to direct the appropriate therapy. Many causes of secondary conjunctivitis can be vision threatening (e.g., chronic KCS) and/or have an association with life-threatening systemic disease (e.g., systemic mycoses). Therapeutic goals are to treat underlying cause, eliminate infection if present, and eliminate ocular pain.

ACUTE AND CHRONIC TREATMENT

- Primary:
  - Allergic or follicular or immune-mediated/plasmacellular:
    - Topical corticosteroid or corticosteroid/antibiotic combination (e.g., 0.1% dexamethasone ± neomycin/polymyxin B solution or ointment) q 6-8 h, tapered slowly based on response to treatment; may recur; address contributing factors (e.g., atopy, food allergy). Corneal ulceration contraindicates this treatment (p. 250).
    - Topical cyclosporine A (CsA; 0.2%-2%) q 12 h (plasmacellular conjunctivitis); usually required long term
  - Bacterial:
    - Topical broad-spectrum antibiotics (e.g., bacitracin/neomycin/polymyxin B; or based on culture and sensitivity results) q 6-8 h for 7-10 days
  - Parasitic:
    - *Thelazia* spp.: flushing the conjunctival sac with tetramisole (0.5% solution)
- Secondary–treat underlying cause:
  - Ligneous:
    - Topical cyclosporine A (0.2%-2%) q 12 h
    - Azathioprine, 1.5-2 mg/kg PO q 24 h until clinical improvement; then gradually tapered to as low a dose as possible (e.g., 1 mg/kg PO q 24 h, then every other day, then weekly for maintenance)
    - ±Prednisone orally 1-2 mg/kg PO q 24 h until clinical improvement; then gradually tapered over 3 to 4 weeks until maintenance dose reached

Indefinite maintenance therapy usually required for immune-mediated causes of conjunctivitis (i.e., plasmacellular conjunctivitis [see Pannus (Chronic Superficial Keratitis), p. 825]) and ligneous conjunctivitis.

PROGNOSIS AND OUTCOME

- Variable depending on cause
- Usually good if underlying cause addressed
- Some breeds with medial canthal pocket syndrome develop chronic conjunctivitis and may need indefinite topical treatment.
- Immune-mediated causes of conjunctivitis typically require lifelong treatment.

PEARLS & CONSIDERATIONS

COMMENTS

Do not use topical corticosteroids if corneal ulceration is noted.

PREVENTION

Conjunctivitis due to breed predisposition: avoid breeding affected or closely related dogs.

Conjunctivitis, Cats

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

An inflammation of the conjunctiva, a thin mucous membrane that lines the inner surface of the upper and lower eyelids (palpebral conjunctiva) and both sides of the third eyelid. In the conjunctival fornix ("cul-de-sac"), the conjunctiva reflects onto the globe (bulbar conjunctiva) and becomes continuous with the corneal epithelium. Conjunctivitis is one of the most common feline ocular diseases.

SYNONYMS

Red eye, *Chlamydophila felis* (formerly *Chlamydia psittaci*), feline herpesvirus (FHV-1), feline viral rhinotracheitis, eosinophilic conjunctivitis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Younger cats: FHV-1, *C. felis, Mycoplasma* spp., eosinophilic conjunctivitis
- Older cats: lipogranulomatous conjunctivitis, neoplasia

GENETICS & BREED PREDISPOSITION

Lightly colored (white cats) predisposed to actinic-related conjunctivitis, lipogranulomatous conjunctivitis, squamous cell carcinoma

RISK FACTORS

- Multicat household, catteries, boarding kennels, veterinary hospitals, cat shows, free-roaming cats (infectious conjunctivitis)
- Underlying systemic viral infection (feline leukemia virus [FeLV], feline immunodeficiency virus [FIV]) may predispose to FHV-1 infection.
- Stress and immunosuppression may reactivate FHV-1 and *Chlamydophila felis* infection.

CONTAGION & ZOONOSIS

- FHV-1, *C. felis, Mycoplasma* spp.: contagious cat-to-cat
- *C. felis*: identified in humans with conjunctivitis

ASSOCIATED CONDITIONS & DISORDERS

Most cats with upper respiratory syndrome (see p. 1127) present with conjunctivitis.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Unilateral (e.g., trauma, topical irritants, intraocular neoplasm, uveitis) versus bilateral (e.g., infectious conjunctivitis, systemic illness)
- Primary (infectious causes common in cats; see above) versus secondary (underlying ocular and/or systemic disease [e.g., uveitis, lymphosarcoma])

HISTORY, CHIEF COMPLAINT

- Painful, red eye (unilateral or bilateral)
- Ocular discharge
- Signs of upper respiratory tract infection (FHV-1), including sneezing, nasal discharge, inappetence
- Recurrent signs of red, painful eye and/or ocular discharge (FHV-1)

PHYSICAL EXAM FINDINGS

- Conjunctival hyperemia
- Conjunctival edema (chemosis)
- Lymphoid follicles on conjunctiva
- Smooth, cream or white conjunctival nodules (lipogranulomatous)
- Ocular discharge (see p. 777 ; sometimes dark brown to black, waxy discharge in Persian, Himalayan, Siamese cats)
- Blepharospasm
- Protrusion of the third eyelid

ETIOLOGY AND PATHOPHYSIOLOGY

- Primary:
  - Viral: FHV-1 (see p. 524) is one of the most important causative agents of feline conjunctivitis; has high affinity for conjunctival and respiratory epithelia and causes epithelial necrosis. Other viruses involved in feline upper respiratory syndrome, but less likely to cause conjunctivitis, include calicivirus and reovirus.
  - Bacterial: *C. felis, Mycoplasma* spp., other bacterial infections *(e.g. Staphylococcus* spp., *Bacillus* spp., *Corynebacterium* spp.); uncommon in cats
  - Immune-mediated: eosinophilic conjunctivitis, allergic conjunctivitis (rare in cats)
- Secondary:
  - Other ocular causes of red eye (see p. 967), including: mechanical ocular irritation (e.g., entropion, trichiasis, distichiasis, exophthalmos, cranial displacement of the globe), lagophthalmos (incomplete closure of the eyelids), foreign body, corneal ulceration (see p. 250), anterior uveitis (see p. 1151), ocular trauma, glaucoma (see p. 448), blepharitis
  - Obliteration of lacrimal puncta/ducts secondary to symblepharon (adhesions of conjunctiva to surrounding tissues)
  - Actinic-related conjunctivitis
  - Lipogranulomatous conjunctivitis:
    - Likely a reaction to sebaceous secretions from damaged meibomian glands
    - May be a form of chalazion (see Eyelid Defects: Trauma, Masses, p. 373)
    - Possible role of actinic radiation
  - Systemic infectious diseases:
    - Viral (FeLV, FIV)
    - Systemic mycoses
  - Neoplasia (e.g., squamous cell carcinoma, lymphosarcoma)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of conjunctivitis is made on physical exam. A complete ophthalmic examination (see p. 1313) identifies the cause in many instances and is indicated in every case. In cats where examination alone does not provide a conclusive diagnosis, options (with attendant advantages and drawbacks) include referral to a veterinary ophthalmologist, pursuing diagnostic testing in-house, and monitoring response to treatment.

DIFFERENTIAL DIAGNOSIS

Primary conjunctivitis must be differentiated from secondary conjunctivitis (i.e., other causes of red eye; see Etiology and Pathophysiology above).

INITIAL DATABASE

Complete ophthalmic examination (see p. 1313), including:

- Examination of all conjunctival surfaces, including lacrimal puncta, with diffuse light and magnification
- Conjunctival swabs for bacterial ± fungal culture(s) and sensitivity (done before other diagnostic tests)
- Conjunctival scrapings for cytology; diagnosis of bacterial or fungal infection, *C. felis* and *Mycoplasma* spp. inclusions; eosinophils (eosinophilic conjunctivitis)
- Schirmer tear test (normal is >15 mm/min but can be variable in cats)
- Tear film break-up time (TFBUT): 16.7 (±4.5) seconds is normal in cats; decreased in cats with conjunctivitis.
- Fluorescein dye application (monitor nares for exit of dye to determine if nasolacrimal system patent).
- Intraocular pressures (normal is 15-25 mm Hg)

ADVANCED OR CONFIRMATORY TESTING

- Conjunctival samples may be submitted for PCR testing for infectious diseases (FHV-1, *C. felis, Mycoplasma* spp., FeLV).
- Conjunctival samples for indirect fluorescent antibody staining (FHV-1)
- Flush nasolacrimal system if suspect occlusion (see online chapter: Dacryocystitis).
- Conjunctival biopsy and histopathology (neoplasia)

TREATMENT

TREATMENT OVERVIEW

The treatment of feline conjunctivitis should be directed at the underlying etiology(ies). Depending on the underlying cause(s), conjunctivitis in cats may become chronic (e.g., *C. felis*) and/or recurrent (e.g., FHV-1) and require prolonged therapy. Lysine may help limit recurrences in some FHV-1-infected cats (see p. 524). Therapeutic goals are to treat the underlying cause, eliminate infection if possible, and eliminate ocular pain.

ACUTE GENERAL TREATMENT

- Primary:
  - FHV-1 or bacterial:
    - Topical broad-spectrum antibiotics (e.g., tobramycin) q 6-8 h for 7-10 days (to prevent secondary bacterial conjunctivitis if FHV-1-induced)
    - Consider oral administration of lysine (500 mg PO q 12 h: lifelong treatment) to reduce herpesviral replication in cats with frequent recurrences and/or associated herpesviral keratitis (see p.524).
  - *C. felis* and/or *Mycoplasma* spp.:
    - Topical tetracycline ointment, q 6-8 h; continued for 10-14 days after clinical signs have resolved
  - Eosinophilic:
    - Topical corticosteroids (e.g., prednisolone acetate 1% suspension or 0.1% dexamethasone solution or ointment) q 6-8 h, tapered to indefinite maintenance dose
    - Topical cyclosporine A (CsA; 0.2%-2%) q 8-12 h as indefinite treatment
- Secondary—treat underlying cause:
  - Lipogranulomatous:
    - Surgical excision typically curative

CHRONIC TREATMENT

- FHV-1: see p. 524
- *C. felis* and/or *Mycoplasma* spp.:
  - Prolonged topical tetracycline if concurrent infection with FIV is confirmed
  - Oral antibiotics (e.g., doxycycline, 5 mg/kg PO q 12 h for 3-4 weeks for difficult cases)

POSSIBLE COMPLICATIONS

FHV-1 may cause:

- Corneal Sequestration, Cats, p. 248
- Symblepharon
- Keratoconjunctivitis sicca,

PROGNOSIS AND OUTCOME

- Variable depending on cause
- Usually good
- Conjunctivitis caused by *C. felis* may become chronic.
- Recurrent conjunctivitis is observed with FHV-1 infection.

PEARLS & CONSIDERATIONS

COMMENTS

- FHV-1 infection may not only cause conjunctivitis but may also cause keratitis in cats.
- Topical corticosteroids should be avoided in cats with conjunctivitis, unless eosinophilic or lipogranulomatous conjunctivitis is confirmed cytologically and/or histologically.

TECHNICIAN TIP

Some ophthalmic drugs have virtually identical names for their formulations with and without corticosteroids. This similarity presents a risk of using the wrong drug. It is extremely useful for technicians to carefully read the label of the tube/vial and identify whether it contains corticosteroids *prior* to topical application (read label of tube/bottle), and to check the medical record for consistency. Substitution error (especially administering corticosteroids when they are contraindicated) can be devastating and has been made by veterinarians, technicians, and clients.

PREVENTION

Reduction of known stresses is useful (FHV-1).

CLIENT EDUCATION

- Monitor for recurrent signs of conjunctivitis (FHV-1).
- Stress factors (e.g., concurrent systemic disease [FeLV, FIV], systemic or topical corticosteroids, general anesthesia, multicat household, moving) can trigger flare-up of FHV-1-induced conjunctivitis.

Spiess AK, Sapienza JS, Mayordomo A: Treatment of proliferative feline eosino-philic keratitis with topical 1.5% cyclospo-rine: 35 cases. Vet Ophthalmol 12:132–137, 2009.

AUTHOR: URSULA M. DIETRICH

EDITOR: CHERYL L. CULLEN

Coma

BASIC INFORMATION

DEFINITION

A state of unconsciousness unresponsive to all stimuli; a well-recognized neurologic emergency

EPIDEMIOLOGY

RISK FACTORS

- Any condition that increases intracranial pressure (ICP)
- Older animals: neoplasia
- Younger animals: trauma and toxins

CONTAGION & ZOONOSIS

Consider rabies.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Obtunded: conscious state with mild to moderate reduction in alertness
- Stupor: unconscious state that requires strong stimuli (usually noxious; toe pinch) to evoke a response (often reduced)

HISTORY, CHIEF COMPLAINT

- Acute onset or rapid deterioration: consider toxin, trauma, rapidly bleeding tumor, or embolism/infarction
- Chronic slow progression: consider tumor, metabolic disease, or encephalitis

PHYSICAL EXAM FINDINGS

- Recumbent with no response
- Patient may present in shock
- Neurologic exam: focus on level of consciousness (response to toe pinch and loud noise), pupillary size and light reflexes, ability to elicit physiologic nystagmus, limb rigidity, and respiratory patterns to determine prognosis

ETIOLOGY AND PATHOPHYSIOLOGY

- There are two general causes of unconsciousness:
  - Diffuse cerebral cortical injury
  - Interruption of the ascending reticular activating system located in the brainstem
- Diffuse cortical injury generally carries a better prognosis than brainstem injury.
- Brainstem (midbrain, medulla) injury may be suspected based on:
  - Deficits in pupillary light response or pupil size: midbrain (assuming exam reveals no evidence of ocular or optic nerve lesion)
  - Inability to elicit normal physiologic nystagmus: medulla (assuming no evidence of middle/inner ear abnormality on exam)
  - Limb rigidity: medulla (assuming no spinal cord or neuromuscular signs)
  - Respiration abnormalities: medulla or midbrain (barring primary airway/lung lesion)
    - Kussmaul (rapid, deep, labored breathing, associated with diabetic coma)
    - Cheyne-Stokes (abnormal breathing pattern with alternating periods of apnea and deep, rapid breathing; the cycle begins with slow, shallow breaths that gradually increase in depth and rate and is then followed by a period of apnea).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- The diagnosis should be suspected in any recumbent animal that does not show a response to initial physical examination and stimulation, and then established following a neurologic examination that confirms the patient is recumbent and unresponsive to all stimuli (including noxious stimuli).

DIFFERENTIAL DIAGNOSIS

- Intracranial:
  - Trauma, tumor, hemorrhage, status epilepticus, embolism/ischemic encephalopathy, granuloma, abscess, developmental disorders (hydrocephalus, storage diseases), and infections (rabies, feline infectious peritonitis, canine distemper, fungal, parasitic)
- Systemic:
  - Toxins: lead, barbiturates, antidepressants, tranquilizers, alcohol, ethylene glycol
  - Metabolic: hypoglycemia, diabetic ketoacidosis, hepatic encephalopathy, uremic encephalopathy, hypoadrenocorticism, myxedema coma
  - Hyperosmolar syndromes: hyperosmolar nonketotic diabetes mellitus, ethylene glycol, hypernatremia
  - Hyperviscosity: polycythemia, hyperglobulinemia
  - Miscellaneous: severe hypovolemia/shock, post arrest, heat stroke, hyponatremia

INITIAL DATABASE

Laboratory tests:

- CBC (infection or thrombocytopenia)
- Serum biochemistry panel (metabolic disorders)
- Urinalysis:
  - Glucose, ketones (diabetes mellitus/ketoacidosis)
  - Calcium oxalate monohydrate crystals (ethylene glycol intoxication)
  - Ammonium biurate crystals (portosystemic shunt)
  - Low urine specific gravity (USG)/ casts (renal disease [consider other causes of low USG])
- Prothrombin time/partial thromboplastin time or activated clotting time (coagulopathies)
- Serum bile acids (liver failure) Imaging:
- Thoracic radiographs (metastatic lesions, trauma, or infections)
- Skull radiographs (trauma/skull fractures)

ADVANCED OR CONFIRMATORY TESTING

MRI or CT followed by cerebrospinal fluid analysis after systemic disease is eliminated

TREATMENT

TREATMENT OVERVIEW

- Coma can result from a number of underlying conditions; therefore, the initial therapy should focus on stabilization of the cardiovascular (perfusion), respiratory (oxygenation and ventilation), and neurologic (cerebral oxygen delivery and ICP) systems, followed by specific therapy tailored to the underlying cause.

ACUTE GENERAL TREATMENT

Airway and breathing:

- Endotracheal intubation assists ventilation and protects the airways (comatose patients cannot swallow; salivary secretions, regurgitation, and vomiting may cause airway obstruction and aspiration pneumonia). Avoid cough reflexes, which increase ICP.
- Provide supplemental oxygen (maintain Pao2 > 60 mm Hg, SaO2 > 90%).
- Caution: nasal oxygen lines can induce sneezing, which increases ICP.
- Ensure ventilation (maintain Pco2 between 35-45 mm Hg).

Circulation:

- Place intravenous catheter (avoid jugular veins if ICP elevated).
- Correct hypovolemia.
  - Fluid choice is controversial.
    - Crystalloids usually sufficient. Administer ¼ shock dose (15 mL/kg, dogs; 10 mL/kg, cats) repeatedly in rapid IV increments until cardiovascularly stable.
  - Avoid overhydration.
- Provide maintenance fluids, and replace ongoing fluid losses.
- With cardiac disease or hyperosmolar syndromes, administer fluids cautiously.

Decrease ICP:

- In comatose patient, assume ICP elevated until proven otherwise.
- Elevate head 20-30 degrees.
- Avoid pressure on jugular veins.
- Give mannitol (0.5-2 mg/kg IV over 20-30 minutes) if diagnosis is unconfirmed or patient shows neurologic deterioration.
- Avoid mannitol in dehydrated, hypovolemic patients and when underlying cardiac disease or hyperosmolar states are present.

Supportive care:

- Control seizures:
  - Diazepam (0.5-1 mg/kg IV; can repeat twice in 15 minutes. If ineffective, then use constant rate infusion or different drug); *or*
  - Phenobarbital (2-15 mg/kg slow IV bolus [monitor respiration]); *or*
  - Propofol (if severe hepatopathy/hepatic coma) (1-6 mg/kg IV bolus; can repeat or switch to constant rate infusion [monitor respiration]).
- Treat hypoglycemia with IV dextrose:
  - Dose: 0.5 g/kg slow IV. Dilute 50% dextrose, 1 mL/kg, into 0.9% NaCl, 3 mL/kg, and administer IV slowly.
  - Avoid hyperglycemia.
- Glucocorticoids (e.g., methylprednisolone sodium succinate, 30 mg/kg IV initial dose, then according to standard protocols, or dexamethasone, 0.1 mg/kg IV) may be beneficial (neoplasia) or harmful (trauma).
- Try to confirm diagnosis before giving glucocorticoids.
- If life-threatening deterioration occurs before the diagnosis is confirmed, rapid-acting intravenous glucocorticoids can be administered for suspected neoplasia or encephalitis.

Specific therapy:

See specific diseases.

POSSIBLE COMPLICATIONS

- Hypotension
- Hypothermia
- Brain herniation
- Cardiac arrhythmias
- Hypoventilation
- Aspiration pneumonia
- Seizures

RECOMMENDED MONITORING

- Rapid deterioration possible: monitor until stable and deterioration unlikely.
- Neurologic examination every 30-60 minutes
- Continuous electrocardiogram
- Blood pressure every 30-60 minutes (systolic: > 90 mm Hg but < 180 mm Hg; mean: > 60 mm Hg but < 140 mm Hg)
- Blood gases (PaCO2 and Pao2) every 60 minutes or capnography and pulse oximetry continuously
- Blood glucose and electrolytes as needed

PROGNOSIS AND OUTCOME

- Varies with underlying disease

- Generally guarded until diagnosis confirmed
- Declines as level of consciousness decreases
- Worse with systemic complications
- Unresponsive pupils, decerebrate rigidity, abnormal respiratory patterns, and loss of physiologic nystagmus carry a grave prognosis.
- Miotic responsive pupils suggest cortical lesions and a better prognosis.
- Can use modified Glasgow Coma Scale for prognosis in dogs with head trauma (see p. 464).
- Failure to improve over 5-7 days warrants poor prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- Animals that display decerebrate rigidity are also comatose.
- Cranial nerve reflexes (depending on location of the lesion) and spinal reflexes are often present.
- Bradycardia with concurrent hypertension suggests elevated ICP.
- Can use caloric test to evaluate nystagmus (infusion of warm or cold water into the ear canal normally results in nystagmus).
- Administration of lidocaine during intubation (0.75 mg/kg IV) may suppress gag and cough reflexes, which would otherwise increase ICP.

TECHNICIAN TIPS

- Physical therapy, turning to change recumbencies, lubrication of the eyes, and moistening the mouth every 4 hours are important elements of support for comatose patients.
- A urinary catheter assists with monitoring urine output and preventing urine scald.

CLIENT EDUCATION

- Full neurologic recovery can take weeks to months.
- Long-term neurologic deficits and seizures can occur.

Color Disorders of the Skin and Haircoat

BASIC INFORMATION

DEFINITION

Very common spectrum of innate or acquired pigmentary abnormalities of the skin or hair

SYNONYMS

- Hyperpigmentation: melanoderma, melanotrichia
- Hypopigmentation: depigmentation, leukoderma, leukotrichia, poliosis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Some conditions present at birth (e.g., albinism).
- Most are acquired at any age in dogs and cats.

GENETICS & BREED PREDISPOSITION

- Hyperpigmentation:
  - Acanthosis nigricans: dachshund
  - Recurrent flank alopecia: boxer, English bulldog, Airedale terrier
  - Papillomavirus-associated plaques: pug, miniature schnauzer, shar-pei
- Hypopigmentation:
  - Vitiligo: rottweiler, Belgian sheepdog, Siamese cat, others
  - Waardenburg-Klein syndrome: dalmatian, bull terrier, others
  - Premature graying: golden retriever, Labrador retriever, Irish setter
  - Dermatomyositis: Shetland sheepdog, collie
  - Color dilution alopecia: blue or fawn Doberman pinschers and other dogs
  - Canine cyclic hematopoiesis: collie (rare)
  - Chédiak-Higashi syndrome: Persian cat (rare)

RISK FACTORS

Depends on underlying cause

CONTAGION & ZOONOSIS

Dermatophytosis and *Sarcoptes scabiei* (may exhibit hyperpigmentation)

GEOGRAPHY AND SEASONALITY

- “Snow nose”: decreased nasal pigmentation during winter months
- Recurrent flank alopecia: often seasonal

ASSOCIATED CONDITIONS& DISORDERS

- Postinflammatory hyperpigmentation or hypopigmentation: see Differential Diagnosis
- Waardenburg-Klein syndrome: blue eyes, deafness
- Uveodermatologic syndrome: uveitis, blindness
- Dermatomyositis: may exhibit myositis
- Chédiak-Higashi syndrome: immunologic deficiency
- Canine cyclic hematopoiesis: usually lethal before age 6 months

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Acquired change in skin or coat color tends to be gradual.
- Question owners about sun exposure, changes in overall health, any evidence of inflammation (e.g., pruritus).

PHYSICAL EXAM FINDINGS

- Note distribution of color change, and examine skin for lesions, particularly for evidence of inflammation (e.g., erythema, lichenification).
- Certain physical abnormalities are associated with specific pigmentation disorders (e.g., uveitis, myositis, deafness, enlarged lymph nodes).

ETIOLOGY AND PATHOPHYSIOLOGY

Normal pigmentation of the skin and hair is a highly complex process under the influence of numerous genetic and acquired factors. Both depigmentation and hyperpigmentation can be seen as a result of inflammatory dermatoses.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Causes of color disorders of dogs and cats are myriad but often visually distinctive.

DIFFERENTIAL DIAGNOSIS

- Acquired hyperpigmentation:
  - Postinflammatory: common in dogs; can occur with any chronic inflammatory process, but particularly common with hypersensitivity disorders, *Malassezia,* demodicosis, pyoderma. In cats, it is almost exclusively seen with dermatophytosis. Inflammation also sometimes affects hair color (melanotrichia) in dogs and in Siamese and Himalayan cats.
  - Endocrinopathy: hyperadrenocorticism, hypothyroidism, alopecia X, sex hormone dermatoses
  - Neoplasia: feline Bowen's disease, other pigmented tumors
  - Acanthosis nigricans in dachshunds: localized to axillae. A reaction pattern with multiple causes (friction, infection, hypersensitivity) is more likely than a primary genetic form.
  - Lentigenes: macular melanosis (orange cats)
  - Other: recurrent flank alopecia, sun exposure, drug therapy–induced, papillomavirus-associated plaques
- Acquired hypopigmentation:
  - Postinflammatory: common. On the nasal planum, consider discoid lupus erythematosus, as well as pemphigus erythematosus or foliaceus, uveodermatologic syndrome, other immune-mediated diseases. Pyoderma, dermatomyositis, and other inflammatory conditions also may cause depigmentation in affected areas.
  - Neoplasia: particularly epitheliotropic lymphoma, which may cause striking leukotrichia
  - Vitiligo: multifactorial genetic cause likely. Symmetric patchy loss of pigment from hair, skin, and mucosa, most often on the face (including nose and lips).
  - Nasal hypopigmentation: noninflammatory conditions include “snow nose,” in which partial depigmentation of the nasal planum occurs in winter.
  - Nutrition (e.g., reddish-brown coat in black cats due to tyrosine deficiency)
  - Lightening of the coat can occur with excessive exposure to chlorinated water, sunlight, or in hair cycle arrest (e.g., endocrine disease).
  - Others: drug-induced, periocular leukotrichia/depigmentation in Siamese cats
- Congenital hyperpigmentation or hypopigmentation:
  - Color dilution alopecia, albinism, Waardenburg-Klein syndrome, canine cyclic hematopoiesis, Chédiak-Higashi syndrome, Dudley nose

COLOR DISORDERS OF THE SKIN AND HAIRCOAT Depigmentation of the nasal planum and leukotrichia in a golden retriever with cutaneous lymphoma.

INITIAL DATABASE

May include:

- Skin scrapings
- Skin cytologic examination
- Skin biopsies
- Trichograms (microscopic examination of plucked hairs, useful for assessing color dilution alopecia)
- CBC, serum biochemistry profile, urinalysis

ADVANCED OR CONFIRMATORY TESTING

For specific diseases, additional testing may include:

- Screening tests for endocrinopathy (hyperadrenocorticism, hypothyroidism)
- Ocular examination (uveodermatologic syndrome)
- Fungal examination: Wood's light, fungal culture
- Muscle evaluation (dermatomyositis)
- Auditory evaluation (Waardenburg-Klein syndrome)
- Serologic testing for deep fungal infections, leishmaniasis

TREATMENT

TREATMENT OVERVIEW

The goal is to restore normal pigmentation to skin and hair.

CHRONIC TREATMENT

Depends on underlying cause:

- Many conditions do not require or respond to treatment.
- Inflammation, endocrinopathy, or neoplasia may be treatable.
- Uveodermatologic syndrome requires aggressive therapy to save vision.
- Reduce sun exposure in alopecic dogs.

PROGNOSIS AND OUTCOME

- Good prognosis for acquired hyperpigmentation, providing the underlying condition can be controlled; variable for other conditions.
- Improvement may be very slow for all conditions.

PEARLS & CONSIDERATIONS

COMMENTS

- When examining a nasal planum exhibiting hypopigmentation or depigmentation, inflammatory or infiltrative processes (e.g., discoid lupus erythematosus) typically cause loss of the normal cobblestone architecture. Skin biopsies are usually indicated. Conversely, processes with little or no inflammation (e.g., vitiligo, “snow nose”) spare the normal surface pattern.
- The best sites to biopsy the nasal planum (or other mucocutaneous junction) exhibiting depigmentation are gray, rather than completely depigmented. These areas are most likely to show active inflammation or pigment loss.
- Abundant melanosomes can be seen on surface cytologic examination from hyperpigmented skin. Although these small oval structures are easy to mistake for bacteria, they are distinctly brown rather than blue/purple on a Diff-Quik preparation.

Collapsing Trachea

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A common condition in small- and toy-breed dogs, characterized by a weakening of tracheal cartilage support for large airways, resulting in cough and impaired conduction of air

SYNONYMS

Collapsed trachea, tracheal collapse

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Primarily a disease of middle-aged, small-breed dogs; rarely reported in large-breed dogs
- No known sex predilection

GENETICS & BREED PREDISPOSITION

Breeds commonly affected include the Yorkshire terrier, toy and miniature poodle, and Pomeranian.

RISK FACTORS

Obesity may exacerbate frequency and severity of signs.

ASSOCIATED CONDITIONS & DISORDERS

Small-breed dogs with collapsing trachea often have concurrent noninfectious chronic tracheitis and bronchitis.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Grades of tracheal collapse:

- I: minor protrusion of dorsal membrane into airway lumen, <25% reduction in diameter; generally not associated with clinical signs
- II: 50% reduction in airway lumen, tracheal rings elongated and mildly flattened
- III: 75% reduction in airway lumen, tracheal rings markedly flattened
- IV: >90% reduction in airway lumen, severely flattened tracheal rings, possibly with dorsal deviation of ventral tracheal surface; generally associated with frequent, constant, or severe clinical signs

HISTORY, CHIEF COMPLAINT

- Owners often complain of a recurrent loud, honking cough, with gagging or retching commonly observed at the end of a series of coughs.
  - Signs may worsen with excitement, heat, eating or drinking, or exercise.
- Milder clinical signs may have been present since early in life.
- Severely affected animals may exhibit cyanosis or syncope in addition to frequent coughing.

PHYSICAL EXAM FINDINGS

- Dry cough elicited with tracheal palpation
  - This finding is nonspecific, however, since many other respiratory disorders, including pulmonary parenchymal disorders (e.g., pulmonary edema), may cause a cough to be elicited easily with tracheal palpation.
- With cervical collapsing trachea, wheezes may be ausculted over the cervical tracheal region.

- With thoracic collapsing trachea, loud snapping noises may be ausculted due to the dynamic opening and collapse of large airways (sound is due to airway opening during inspiration).
- Increased expiratory effort may be seen.

ETIOLOGY AND PATHOPHYSIOLOGY

- Decreased rigidity of tracheal cartilage rings results in dynamic collapse during inspiration with cervical involvement, and during expiration with thoracic involvement.
- The etiology is unknown, but suggested mechanisms include:
  - Failure of chondrogenesis
  - Acquired secondary to chronic small airway disease
  - Cartilage degeneration
  - Trauma
  - Loss of innervation of the trachealis dorsalis muscle

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in at-risk breeds based on the presence of a recurrent cough and/or wheezing; confirmation requires advanced diagnostics such as radiographs, fluoroscopy, or bronchoscopy.

DIFFERENTIAL DIAGNOSIS

- Sterile chronic bronchitis
- Congestive heart failure
- Infectious tracheobronchitis
- Bronchial compression due to left atrial enlargement or lymphadenopathy
- Pneumonia
- Tracheal or laryngeal obstruction
- Other causes of syncope (see p. 1065)

INITIAL DATABASE

- Routine laboratory testing is usually unremarkable.
- Thoracic and lateral cervical radiographs may reveal collapse.
  - Ideally, obtain images during inspiration for cervical collapse and expiration for thoracic collapse.
  - Can underestimate the degree of collapse

ADVANCED OR CONFIRMATORY TESTING

- Fluoroscopy is usually helpful in identifying dynamic collapse, with an elicited cough.
- Bronchoscopy can identify severity, characterize the collapse location, and facilitate collection of airway wash samples to rule out concurrent infectious and inflammatory conditions.

TREATMENT 

TREATMENT OVERVIEW

Treatment consists of cough suppressants, anti-inflammatory medication, bronchodilators, and in severe cases, surgically or fluoroscopically/endoscopically placed stents to help decrease the severity and frequency of cough and associated clinical signs.

ACUTE GENERAL TREATMENT

- Oxygen and judicious use of sedatives and cough suppressants may be necessary in an acute crisis.
- Butorphanol (0.02-0.1 mg/kg SQ q 4-6 h) can lessen acute severe cough and respiratory distress.
- Low-dose acepromazine (0.05-0.1 mg/kg IM) can provide sedation that breaks the cycle of airway irritation and coughing when a bout of extremely severe, collapsing trachea-related coughing occurs.

CHRONIC TREATMENT

- Obesity leads to decreased lung expansion and increased breathing effort. Therefore, weight loss is important in any obese dog diagnosed with collapsing trachea.
- Antitussives help reduce irritation or damage to the tracheal epithelium from chronic cough:
  - Hydrocodone, 0.22 mg/kg PO q 6-12 h; *or*
  - Butorphanol, 0.55-1.1 mg/kg PO q 8-12 h; *or*
  - Diphenoxylate hydrochloride and atropine, 0.2-0.5 mg/kg PO q 12 h
- Antiinflammatory therapy may be needed to decrease laryngeal or tracheal inflammation:
  - Prednisone 0.5-1 mg/kg PO q 12-24 h tapered and discontinued after 5-7 days of use
  - Only short-term use is recommended.
- Bronchodilators may benefit dogs with intrathoracic collapse or expiratory effort that do not improve with initial therapy:
  - β2 Agonists
    - Terbutaline (total amount per dose): small dogs, 0.625-1.25 mg PO q 12 h; medium dogs, 1.25-2.5 mg PO q 12 h; large dogs, 2.5-5 mg PO q 12 h; *or*
    - Albuterol: 0.05 mg/kg PO q 8 h
  - Methylxanthines
    - Not all long-acting theophylline products are equivalent in bioavailability in dogs. Implications are that failure to respond to a certain product should prompt the consideration of switching bronchodilators (to a different brand of theophylline or a different class of bronchodilator altogether [e.g., a ^{2} agonist]), and that certain animals may develop signs of toxicosis when receiving doses that are well tolerated by others.
      - Extended-release theophylline is recommended at 10 mg/kg PO q 12 h; *or*
      - Aminophylline or theophylline, 10 mg/kg PO q 8 h
- Surgical implantation of external prosthetic rings can be considered inpatients with grade II-IV collapse that fail medical management.
  - Rings are more practical for cervical collapse but can be attempted for thoracic collapse through cranial retraction of the trachea. Several potential drawbacks exist, including implant failure and extension of the collapsing process beyond the length of the implant over time.
- Intraluminal stents placed under fluoroscopic guidance can be considered in patients that fail medical management. Such stents can be used for cervical or thoracic collapse. Stents are typically placed with endoscopic or fluoroscopic guidance (see p. 1342).

POSSIBLE COMPLICATIONS

- Cough suppressants: somnolence, sluggishness at higher doses
- Stents: stent migration, stent fracture, exuberant granulation tissue, tracheitis

RECOMMENDED MONITORING

Clinical signs

PROGNOSIS AND OUTCOME

- The prognosis for survival is good. With appropriate treatment, most dogs show improvement but varying degrees of persistent clinical signs. The prognosis for cure is poor because collapsing trachea is irreversible and progressive.
- Dogs with severe clinical signs (cyanosis, syncope) have a guarded prognosis for comfortable survival if not effectively treated with medical therapy. Prognosis for these dogs is often improved with stents.

PEARLS & CONSIDERATIONS

COMMENTS

- Hydrocodone cough suppressants may be more difficult to obtain. Of those available, many are combined with other medications (acetaminophen, guaifenesin, and various antihistamines) that may not be safe or routinely recommended.
- By reducing bronchial smooth-muscle contraction during cough (lessens dynamic component of cough) and slowing the velocity of air flow during coughing (by increasing bronchial diameter), bronchodilators may help patients with collapsing trachea even though the drugs do not act directly at the site of the lesion.

PREVENTION

Affected dogs should probably not be bred.

TECHNICIAN TIPS

When performing radiographs to evaluate for collapsing trachea, taking inspiratory films of the neck and expiratory films of the chest may help better demonstrate a dynamic collapse.

CLIENT EDUCATION

For most dogs, the tracheal collapse is managed with weight control, antitussives, and periodic administration of anti-inflammatory drugs.

AUTHOR: LAURA RIDGE COUSINS

EDITOR: RANCE K. SELLON

Collapse

BASIC INFORMATION

DEFINITION

Loss of the ability to support weight and ambulate without assistance; may include the loss of consciousness

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs, cats
- Age and sex depend on underlying disease.

GENETICS & BREED PREDISPOSITION

Exercise-induced collapse in Labrador retrievers; intervertebral disk extrusion in chondrodystrophic breeds

RISK FACTORS

Increased ambient temperature, obesity

CONTAGION & ZOONOSIS

Common-source infections:

- Agents causing polyarthritis, such as *Borrelia burgdorferi*
- Agents affecting the neuromuscular junction, such as *Clostridium botulinum*

GEOGRAPHY AND SEASONALITY

Areas with a high incidence of infectious agents that can cause collapse

RISK FACTORS

Diabetes mellitus, cardiomyopathies, hypoadrenocorticism, immune-mediated hemolytic anemia, hemangiosarcoma, cervical vertebral instability (wobbler's syndrome)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Neuromuscular: paresis/paralysis but mentation normal
- Neurologic: alterations in intracranial (mentation, cranial nerves) and/or spinal (reflexes, reactions) function, without an underlying systemic cause
- Orthopedic: signs of joint or bone pain, reduced range of motion, or fracture
- Metabolic/endocrine: characteristic systemic signs
- Cardiovascular: characteristic signs of heart disease and/or vascular disturbances
- Respiratory: overt respiratory signs (usually dyspnea) in the absence of systemic, neuromuscular, or cardiovascular causes

HISTORY, CHIEF COMPLAINT

Dependent on underlying cause. Often includes one or more of the following: weakness, inability to rise, incontinence (urine or feces), anxiety/distress, abdominal distension, vomiting, diarrhea, respiratory distress, unconsciousness.

PHYSICAL EXAM FINDINGS

- Dependent on underlying cause:

- Nonspecific signs commonly include recumbency, alterations in mentation (disorientation, unconsciousness), vomiting, variable heart rate (normal, bradycardic or tachycardic), variable pulse quality (absent, weak to hyperdynamic), and pale to hyperemic mucous membranes.

- Some underlying causes may be more likely in the presence of certain physical findings:
  - Asynchronous pulse quality (cardiac arrhythmias), muffled heart sounds (pericardial effusion/cardiac tamponade, pleural effusion if muffled lung sounds also), stertorous upper airway noises (upper airway obstruction), abdominal fluid wave (hemoabdomen, right-sided congestive heart failure, or pyoabdomen/sepsis), moist lung sounds (respiratory, cardiovascular, or pulmonary hemorrhage), flaccid to fasciculating muscles (neuromuscular), decreased to increased spinal reflexes (neuromuscular or neurologic), neck or back pain (orthopedic, neurologic), joint effusion (orthopedic).

ETIOLOGY AND PATHOPHYSIOLOGY

Collapse is caused by loss of normal, coordinated function of muscles that support the body.

- Neuromuscular: reduced nerve conduction, disturbance of neuromuscular junction, or primary myopathy (rare)
- Neurologic: intracranial or spinal failure to generate or communicate impulses for normal mentation and/or limb function
- Orthopedic: failure of the skeleton and/or joints to support weight
- Metabolic/endocrine: limitation of metabolic fuel for muscles, nerves, or central nervous system (e.g., hypoglycemia, hypocalcemia, hypokalemia)
- Cardiovascular: inadequate perfusion of muscles and/or central nervous system
- Respiratory: inadequate oxygenation of blood and therefore of tissues

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

The majority of conditions causing collapse can be identified with a good history, physical examination (including checking stool for toxins), and complete but basic diagnostic tests such as blood work and thoracic and abdominal radiographs.

DIFFERENTIAL DIAGNOSIS

- Neuromuscular/Musculoskeletal: myasthenia gravis, polyradiculoneuritis, tick paralysis, botulism, polyarthritis, toxins (metaldehyde, strychnine, marijuana)
- Neurologic: intervertebral disk extrusion, fibrocartilaginous emboli, spinal fracture, spinal tumor, meningitis, intracranial neoplasia, narcolepsy (rare)
- Metabolic/endocrine: anemia, shock (hemorrhagic, anaphylactic), sepsis, insulin overdose, insulinoma, eclampsia, hypoparathyroidism, renal disease, hepatic dysfunction, hypoadrenocorticism, heat stroke, toxins that affect oxygen binding to hemoglobin such as carbon monoxide and acetaminophen toxicity, additional toxins such as xylitol, paintball ingestion
- Cardiovascular: arrhythmias, arterial thromboembolism, cardiac tamponade
- Respiratory: pneumonia, laryngeal paralysis, brachycephalic upper airway syndrome, laryngeal masses, pharyngeal swelling/foreign body, tracheal collapse, tracheal foreign body, nasopharyngeal polyp

INITIAL DATABASE

- CBC, biochemical profile, electrolytes
- Electrocardiogram, blood pressure (multiple limbs if thromboembolism suspected)
- Thoracic and abdominal radiographs
- Remove any ectoparasites (ticks) Results variable depending on underlying cause

ADVANCED OR CONFIRMATORY TESTING

As dictated by history, physical findings, and initial test results:

- Arterial blood gas, saline agglutination testing, tickborne disease titers, arthrocentesis, adrenocorticotropic hormone stimulation, abdominal ultrasound, echocardiography, MRI or myelogram, cerebrospinal fluid analysis, pharyngeal examination, laryngeal function assessment, abdomino/thoraco/pericardiocentesis, acetylcholine receptor antibody titers, Holter monitor/event recorder, insulin/glucose ratio, parathormone and ionized calcium, edrophonium (Tensilon) response test.

TREATMENT

TREATMENT OVERVIEW

Correct acute/life-threatening disturbances (severe biochemical or electrolyte abnormalities, severe anemia, hypotension, body temperature abnormalities). Address underlying problem.

ACUTE GENERAL TREATMENT

- Intravenous fluids, oxygen supplementation, and/or intubation if needed, blood transfusion, dextrose supplementation (hypoglycemia), electrolyte supplementation, insulin (combined with dextrose) for hyperkalemia, analgesia/sedation if indicated
- Antibiotics, antiinflammatories, diuretics, and antiarrhythmic medications may be indicated depending on underlying problem.
- Dexamethasone (0.2-1 mg/kg IV) may be given if a hypoadrenocortical crisis is suspected; it will not interfere with diagnostic testing.

CHRONIC TREATMENT

Dependent on underlying disease process

NUTRITION/DIET

Hypoglycemic patients benefit from nutritional support in the form of frequent meals, hand feeding, or feeding tube placement (see p. 1270)

POSSIBLE COMPLICATIONS

Edrophonium can cause acute cholinergic crisis.

RECOMMENDED MONITORING

Blood glucose, electrolytes, ECG, blood pressure

PROGNOSIS AND OUTCOME

In general, prognosis is guarded but varies from good to poor depending on underlying disease process.

PEARLS & CONSIDERATIONS

COMMENTS

- Many of the pathologic processes that cause collapse are not common, and establishing the diagnosis can be difficult.
- Common diseases, such as hemoabdomen secondary to mass rupture and intervertebral disk disease, should be considered first, and the diagnostic evaluation can proceed to less common etiologies afterwards.
- Two diseases leading to collapse that are commonly overlooked in general practice are pericardial effusion and hypoadrenocorticism.

TECHNICIAN TIP

A good history is essential for identifying (or ruling out) important possible causes of collapse. Useful points to discuss with owners include travel history, exposure to medications/sugar free products/other potential toxins, inquiring whether the individual animal is curious by nature and prone to chewing or ingesting foreign material, and encouraging owners to investigate the animal's home environment looking for toxins.

Platt SR, Garosi LS: Neuromuscular weakness and collapse. Vet Clin North Am Small Anim Pract 34(6):1281–1230, 2004.

AUTHOR: ADAM J. REISS

EDITOR: ETIENNE CÔTÉ

Colitis, Chronic

BASIC INFORMATION

DEFINITION

A common cause for persistent (>3 weeks' duration) signs of colonic inflammation, characterized by large-bowel diarrhea with tenesmus/dyschezia, urgency, and increased frequency of defecation. Feces often contain mucus and/or fresh blood. Systemic signs attributable to nutrient malabsorption (e.g., anorexia, weight loss) are uncommon.

EPIDEMIOLOGY

SPECIES, AGE, SEX

More common in middle-aged and older dogs and cats as a consequence of infiltrative mucosal disorders (e.g., inflammatory bowel disease [IBD] and neoplasia). Infectious disorders (e.g., *Trichuris vulpis*, gastrointestinal [GI] histoplasmosis, *Tritrichomonas foetus*) may be seen in younger dogs and cats (less common).

GENETICS & BREED PREDISPOSITION

Boxers are predisposed to histiocytic ulcerative colitis (HUC). German shepherds and purebred cats are at increased risk for lymphocytic-plasmacytic IBD.

CONTAGION & ZOONOSIS

Some bacterial enteropathogens (e.g., *Clostridium perfringens,* potentially contagious) may cause chronic colitis if not detected early. Also, some helminth parasites (*Trichuris* spp., potentially contagious) and protozoa *(Giardia* spp., potentially zoonotic; *Tritrichomonas* spp., potentially contagious and zoonotic) may cause persistent signs of colitis in pets.

GEOGRAPHY AND SEASONALITY

Midwestern United States for GI histoplasmosis

ASSOCIATED CONDITIONS & DISORDERS

Colonic motility disorders (e.g., irritable bowel syndrome in dogs and colonic constipation/obstipation in cats) may mimic mucosal inflammation and cause signs of large-bowel diarrhea with tenesmus. Note that these diseases are due to functional defects in colonic motility and have no mucosal/structural disease.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Dietary responsive disorders: includes both food intolerance (nonimmunologically mediated) and dietary sensitivity (immunologically-mediated; see p. 402). Food-responsive causes for GI signs, including large-bowel diarrhea, are common in both dogs and cats.
- Infectious disorders: includes select nematode/protozoal parasites, bacteria, and fungal organisms (especially GI histoplasmosis). *Tritrichomonas foetus* is being recognized with increased frequency as a cause for chronic intermittent colitis in young cats.
- Infiltrative mucosal diseases: includes fungal, benign (e.g., IBD), and malignant (e.g., mucosal neoplasia) diseases

HISTORY, CHIEF COMPLAINT

Persistent large-bowel diarrhea, which is characterized by tenesmus (straining to defecate), increased frequency of defecation, mucoid feces, and fresh (red) blood. Note that some disorders (e.g., IBD, GI histoplasmosis, GI lymphoma) may affect the small intestines as well, causing mixed large/small-bowel signs.

PHYSICAL EXAM FINDINGS

- The animal is often well fleshed without systemic signs (e.g., unthriftiness, weight loss) of illness. Fungal disease, severe IBD, and neoplasia may selectively cause fever, alterations in appetite, and peripheral/mesenteric lymphadenopathy.
- Rectal examination: evaluate the character of the feces, obtain fecal samples for parasitic examination, procure exfoliative cytologic specimens, and evaluate the rectum for possible mass lesions.

ETIOLOGY AND PATHOPHYSIOLOGY

- Large-bowel diarrhea is characterized by increased amounts of mucus, owing to the large numbers of mucus-secreting goblet cells in the colon.
- Hematochezia indicates severe mucosal disruption of the distal colon and rectum.
- Parasites, both helminth and protozoa: *Trichuris vulpis* (dogs), *Tritrichomonas foetus* (cats), *Giardia lamblia* (dogs, cats)
- Dietary causes: incriminating antigens or dietary ingredients (nonimmunologic)
- Specific bacterial pathogens: cause colonic inflammation via invasion or enterotoxin production. Adherent/invasive *E. coli* is a newly recognized bacterial enteropathogen associated with HUC in boxers.
- Infiltrative mucosal disorders: benign, malignant, or infectious (e.g., fungal)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis of many causes for chronic colitis will require histologic evaluation of mucosal biopsy specimens.

DIFFERENTIAL DIAGNOSIS

- Specific causes: see Etiology and Pathophysiology above.
- Occasionally patients with rectal diseases (e.g., perineal hernia, perineal fistula, diverticula, or rectal polyps or masses) will present with signs of large-bowel disease. These are generally distinguished by digital examination and careful inspection; normal pelvic and rectal structure on examination more strongly suggests large-bowel disease in such cases.

INITIAL DATABASE

- Physical examination: perform abdominal palpation and digital examination, with collection of feces.
- Fecal examination for nematode and protozoal parasites. Both fecal flotations and fecal smears should be performed. Note that multiple (three) zinc sulfate flotation tests using fresh feces may be required for identification of *Giardia* spp. trophozoites.
    - Commercial ELISA kits are also sensitive for the detection of *Giardia* antigen.
- Rectal cytology may indicate evidence of bacterial pathogens (e.g., vegetative spores of *Clostridia* or increased numbers of fecal leukocytes indicative of acute mucosal inflammation). Exfoliative cytology (e.g., rectal scrape using a uterine curette or a curette of the same type used for bone graft harvesting) is also a useful tool for confirming the presence of *Histoplasma* organisms contained within colonic macrophages.
- PCR for detection of *Tritrichomonas foetus* infection
- Abdominal imaging (survey radiographs, pneumocolonography, and/or ultrasonography) may identify fecal impaction, mass lesions, or evidence of significant mesenteric lymphadenopathy. Generally, ultrasonography is a poor screening tool for colonic disease, owing to the obstructive effect of air in the colonic lumen on the ultrasound beam, and because intestinal wall thickness is difficult to standardize.

ADVANCED OR CONFIRMATORY TESTING

- Colonoscopy with procurement of multiple mucosal biopsy specimens is required to diagnose most infiltrative diseases. Exfoliative cytology at the time of GI endoscopy is a useful adjunct to mucosal biopsy.
- Proctoscopy can also be used to examine and obtain biopsy specimens of the distal colon and rectum when the disease is confined to distal aspects or when colonoscopy is unavailable.
- Colonic biopsies should not be obtained routinely by laparotomy, since the bacterial content of the colon and attendant risk of bacterial peritonitis after biopsy of a diseased colon is markedly greater than in the small intestine.

TREATMENT

TREATMENT OVERVIEW

Treatment of chronic colitis is based on the specific definitive diagnosis, because empirical therapies are often inadequate or deleterious (e.g., use of corticosteroids in animals with GI histoplasmosis).

CHRONIC TREATMENT

- Treat for suspect nematode and protozoan parasites (even if fecal exams are negative for parasites) using appropriate broad-spectrum anthelmintics or antiprotozoal (fenbendazole, 50 mg/kg PO q 24 h for 3-5 days) medications. Confirm efficacy of therapy with repeat follow-up fecal examinations.
- Feed a hypoallergenic diet to animals with dietary-responsive disorders and IBD. Reduction in the quantity of dietary antigens will assist in reducing mucosal inflammation with these disorders. Other animals with colitis but not requiring a specific antigen-restricted diet will benefit from being fed a low-fat, fiber-enriched, and highly digestible commercial ration.
- Choose diets (or supplement the diet) with increased n-3: n-6 fatty acids to reduce mucosal inflammation.
- Avoid all treats and supplements containing protein or flavors during the dietary trial period.
- Use diets with added soluble or mixed fiber or add small to moderate amounts of soluble fiber to the diet to reduce tenesmus and facilitate colonic epithelial repair.
- Only use antibiotics in animals with confirmed bacterial causes (e.g., colonization with enteropathogenic bacteria) for their signs. Antimicrobials used in this fashion are best chosen based on susceptibility testing to the incriminating pathogen. Exceptions to this caveat are animals with HUC (which may respond to oral fluoroquinolone therapy, enrofloxacin 10 mg/kg PO q 24 h) and lymphocytic-plasmacytic colitis (IBD), which may respond to metronidazole (10 mg/kg PO q 12 h, used as an immunomodulator) alone or in combination with other immunosuppressive drugs.
- Sulfasalazine (20-30 mg/kg PO q 8 h, typically for 3-6 weeks in dogs) or newer mesalamine drugs, and glucocorticoids (e.g., prednisone or prednisolone, 1 mg/kg PO q 12 h for dogs; 1-2 mg/kg PO q 12 h for cats) are first-choice immunosuppressive drugs for therapy of colonic IBD.
- Drugs effective against GI histoplasmosis: see p. 538
- Treatment for colonic neoplasia: see p. 37

NUTRITION/DIET

- Appropriate dietary management may include elimination, fiber-supplemented, or low-residue diets. The remission of signs due to food-responsive causes for chronic colitis will require feeding an elimination (intact protein or hydrolysate) diet.
- Fiber supplementation is an important component of therapy because these dietary additives bind colonic irritants, normalize dysmotility, and promote colonic epithelial repair and renewal.

POSSIBLE COMPLICATIONS

- Cure is not possible with colonic IBD, but the prognosis for control of signs is good with effective therapy.
- Animals treated with amphotericin B for GI histoplasmosis are at risk for drug-induced renal disease.
- Myelosuppression may occur with use of multidrug chemotherapy for malignant colonic neoplasia.

RECOMMENDED MONITORING

Ideally, animals responsive to elimination diets (e.g., those having dietary responsive causes for chronic colitis) should be returned to their normal (incriminating) diet to see if large-bowel signs recrudesce. This is impractical in most instances.

PROGNOSIS AND OUTCOME

The prognosis varies according to the underlying cause, from good (dietary-responsive disorders when the inciting dietary constituent is removed) to poor (metastatic colonic neoplasia).

PEARLS & CONSIDERATIONS

COMMENTS

- Major causes of chronic colitis include dietary, infectious, and infiltrative disorders.
- Most animals with chronic signs of large intestinal disease will require a thorough diagnostic evaluation to rule out the varied causes for colonic inflammation. Prophylactic deworming and dietary trials with an elimination diet and/or soluble fiber supplementation are easy and cost-effective empirical therapies to offer clients prior to more extensive diagnostic testing.
- Colonoscopy with mucosal biopsy is imperative for diagnosis of most forms of chronic colitis that fail rational empirical therapies.

PREVENTION

- Prophylactic deworming

- Avoid dietary indiscretion.
- Perform dietary trials.

CLIENT EDUCATION

Dietary modification to a diet suitable for colonic disease may be required for the life of the pet.

AUTHOR: ALBERT E. JERGENS

EDITOR: DEBRA L. ZORAN

Colitis, Acute

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A common disorder characterized by sudden onset (<72 hours) of colonic inflammation (large-bowel diarrhea and straining to defecate), manifesting with diarrhea that is typically mild, of small volume, and contains mucus and/or fresh blood (also see Diarrhea, Acute,). Systemic signs of illness are generally absent.

SYNONYM

“Stress” colitis

EPIDEMIOLOGY

SPECIES, AGE, SEX

Predominantly seen in young dogs and cats (<1 year old) as a consequence of parasitism, bacterial enteropathogens, or dietary indiscretion

RISK FACTORS

Age (predominantly young animals), recently kenneled animals, dietary factors, free-roaming pets, gastrointestinal tract parasitism

CONTAGION & ZOONOSIS

Helminth parasites (*Trichuris* spp.), protozoa (*Giardia* spp., *Tritrichomonas* spp.), and bacteria (*Campylobacter* spp., *Clostridium* spp., enterotoxigenic *Escherichia coli, Salmonella* spp.) have potential for contagion, common-source infection, and/or zoonosis.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Large-bowel diarrhea, which is characterized by tenesmus (straining), increased frequency of defecation, mucoid feces, and fresh (red) blood

PHYSICAL EXAM FINDINGS

Generally well fleshed without systemic signs (e.g., unthriftiness or weight loss) of illness. Rectal examination fails to reveal significant abnormalities except the character of feces.

ETIOLOGY AND PATHOPHYSIOLOGY

- Parasites: both helminth and protozoa
- Dietary causes: gluttony, spoiled food, dietary indiscretion with ingestion of foreign or abrasive materials (e.g., cat litter, rocks, indigestible materials such as hair in long-haired cats)
- Specific bacterial pathogens may cause colonic inflammation via invasion or enterotoxin production.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Acute colitis rarely requires extensive diagnostic evaluation. A thorough history, physical examination, routine feces examination for nematode or protozoal parasites, and fecal/rectal smears for cytologic evaluation generally suffice.

DIFFERENTIAL DIAGNOSIS

Specific causes: see Etiology and Pathophysiology above.

INITIAL DATABASE

- Physical examination: abdominal palpation and digital rectal examination with collection of feces
- Fecal examination for nematode and protozoal parasites. Both fecal flotations and direct fecal smears should be performed. Note that multiple (three) zinc sulfate flotation tests using fresh feces may be required for identification of *Giardia* spp. trophozoites (see p. 447).
- Commercial ELISA kits are also sensitive for the detection of *Giardia* antigen.
- Rectal cytologic evaluation may indicate evidence of bacterial pathogens (e.g., vegetative spores of *Clostridia*) or increased numbers of fecal leukocytes indicative of acute mucosal inflammation.

ADVANCED OR CONFIRMATORY TESTING

Generally not indicated. Animals that fail to respond to empirical therapy (see below) will require confirmatory testing (e.g., fecal cultures, PCR, or other assays) for suspect bacterial pathogens.

TREATMENT

TREATMENT OVERVIEW

Initial management of animals with acute colitis is nonspecific and supportive. In most instances, signs are self-limiting and/or respond readily to empirical therapy.

ACUTE GENERAL TREATMENT

- Treat for suspect nematode and protozoan parasites using appropriate broad-spectrum anthelmintics or antiprotozoal medications (e.g., fenbendazole, 50 mg/kg PO q 24 h for 3 days).
- Avoid the use of antibiotics in animals, except those with confirmed bacterial causes for their gastrointestinal signs. Empirical use of commercial probiotics (FortiFlora, Purina) for 3-5 days may facilitate clinical recovery, although clinical trial data supporting its use are lacking.

NUTRITION/DIET

- Feed a bland or mixed-fiber diet (either commercial or homemade), giving small volumes at increasingly frequent interval for 3-5 days.
- Avoid all treats and dietary supplements during the dietary trial period.
- If using a bland diet, add fiber (small amounts of soluble fiber such as psyllium mucilloid, 1 teaspoon/10 kg at each feeding) to the diet to reduce tenesmus and facilitate colonic epithelial repair.

RECOMMENDED MONITORING

Have clients communicate their pet's progress after 48-72 hours of therapy.

PROGNOSIS AND OUTCOME

Generally excellent for full recovery

PEARLS & CONSIDERATIONS

COMMENTS

In general practice, acute colitis is a common complaint that is very responsive to supportive therapy. Elimination of infectious and parasitic causes is the key to treating acute colitis.

PREVENTION

- Prophylactic deworming
- Avoid dietary indiscretion.

- Avoid allowing pets to roam freely.
- In cats with recurrent colitis due to hair, frequent brushing, administration of hairball laxatives, or removing excess hair (shaving) may be indicated to control signs.

TECHNICIAN TIPS

Always perform multiple fecal examinations to exclude parasitism as a cause for colitis.

CLIENT EDUCATION

Monitor for failure to respond to empirical treatments.

AUTHOR: ALBERT E. JERGENS

EDITOR: DEBRA L. ZORAN

Cognitive Dysfunction

BASIC INFORMATION

DEFINITION

The decline in behavioral condition with advanced age, in the absence of causative physical or medical conditions

SYNONYMS

Senility, cognitive dysfunction syndrome (CDS)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Cats: typically >10 years old
- Dogs: typically >6 years old (large breeds), >12 years (small breeds)

GENETICS & BREED PREDISPOSITION

Dogs and cats, like humans, may have “susceptibility genes” for the development of lesions associated with clinical cognitive syndromes. The understanding of taupathies that exists for human medicine does not currently exist for veterinary medicine.

ASSOCIATED CONDITIONS & DISORDERS

Concurrent anxiety-related conditions are common.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Disorientation, changes in social and interactive behavior (becoming “needier” or, conversely, more aloof), changes in locomotor and sleep cycle behaviors, and loss of “housetraining”
- In early-onset cognitive dysfunction, animals may have only slightly altered sleep cycles and appear more anxious.

PHYSICAL EXAM FINDINGS

- May be unremarkable
- Possible abnormalities include worn claws or scraped nose if “trapped” in corners or if exhibiting ritualistic locomotor behavior.
- Weight loss (from excessive locomotion and/or inappetence due to anxiety)
- When examined on video, the behaviors exhibited by an animal with CDS often seem without purpose; in extreme cases, animals appear to be moving without purpose, as if they cannot stop.

ETIOLOGY AND PATHOPHYSIOLOGY

- Dogs, like humans, develop lesions of amyloid plaques, the density of which appears to roughly correlate with the level of impairment in some patients.
- Unlike humans, dogs do not appear to develop neurofibrillary tangles that are associated with the tauopathy, Alzheimer's disease.
- Both cats and dogs experience a decrease in brain cortical mass and a relative increase in ventricular volume with aging. These changes may be more extreme in patients with cognitive dysfunction.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Cognitive dysfunction is an insidious-onset, slowly progressive disorder that is almost always suspected based on history and signalment (geriatric patient). Routine tests are indicated to identify confounding systemic metabolic abnormalities, if any. Confirmation using brain imaging and cerebrospinal fluid (CSF) analysis is only undertaken if the clinical picture suggests a different disorder is possible (e.g., cranial nerve or other deficits are more consistent with a disorder other than cognitive dysfunction).

DIFFERENTIAL DIAGNOSIS

- Generalized anxiety disorder
- Anxiety: usually transient; associated with changes in physical capabilities (e.g., diminished or changing sensory or locomotor capabilities)
- Separation anxiety: old-age onset
- Panic disorder
- Attention-seeking behavior
- Meningoencephalitis
- Hepatic encephalopathy
- Brain neoplasia
- Hyperthyroidism (cat), hypothyroidism (dog)

INITIAL DATABASE

- CBC, serum biochemistry profile, and urinalysis: generally unremarkable
- Neurologic examination: generally unremarkable
- Thyroid profile: rule out hyperthyroidism (cats) or hypothyroidism (dogs)

ADVANCED OR CONFIRMATORY TESTING

If neurologic signs are present or develop, a full neurologic evaluation, including clinical neurologic exam (see p. 1311), CSF analysis (p. 1228), and brain CT or MRI (pp. 1233 and 1302, respectively) may be indicated. If MRI indicates only increased ventricle size and all other laboratory and physical findings are unremarkable, a presumptive diagnosis of cognitive dysfunction may be made.

TREATMENT 

TREATMENT OVERVIEW

Goals of treatment are a decrease in the rate at which the animal appears to mentally fail, while relieving pain and distress associated with changes in physical and mental status,

ACUTE GENERAL TREATMENT

- Avoid exposure stimuli known to distress the animal.
- Early rewarding of any normal, preferred, or good interactive or elimination behaviors and encouraging normal locomotion
- There should be absolutely no punishment—physical, verbal, deprivational, or mental—for any undesirable behavior that occurs as a result of this condition. Such actions will render the patient more anxious.
- Protect the patient from attendant wanderings or odd behaviors while keeping it comfortable. The latter may involve containing it in an area with an absorbent surface when left alone.
- Mental stimulation in the early stages is important and may delay clinical progression. Treat balls, food toys, games involving puzzle solving, safe exercise, interactive tasks (“get the mouse,” “bring the ball,” etc.), and olfactory stimulation are useful.

CHRONIC TREATMENT

- As stated, plus physically and mentally stimulating exercises, such as swimming, massage, range of motion exercises.
- Encourage relaxation.
- If “loss of housetraining” occurs, ensure that the animal is taken out frequently to minimize the cost of “mistakes;” reward frequently as for a young pup and if needed diaper dog to decrease both client and dog distress.
- Encourage reestablishment of daily cycles by feeding at regular hours and at least a few hours before bedtime, and administer a benzodiazepine (alprazolam, clonazepam) before bed if needed.
- Protect the pet from accidents (e.g., falling into the swimming pool, falling down stairs).
- Specialized diets rich in antioxidants decrease the rate of cognitive dysfunction progression, improve behavioral function, and may have a protective effect (e.g., Hill's B/D [Brain Diet]; Purina Veterinary Diets EN).
- In the United Kingdom, nutraceutical food additives are available and have been shown to improve function in dogs with cognitive changes (e.g., Aktivait, Vet Plus UK).
- Newer additives also are recommended as preventative agents (e.g., Senilife, CEVA; Novifit [SAM-e; Virbac]; omega-3 fatty

acids [Nordic Naturals])
- The monoamine oxidase inhibitor, selegiline (Anipryl), 0.5 mg/kg PO q 24 h (may double dose after 1 month if ineffective) is the drug of choice and is licensed for use for the treatment of canine cognitive dysfunction in the United States.

POSSIBLE COMPLICATIONS

Any concurrent untreated anxiety-related or behavioral conditions generally worsen with age and will render the signs of cognitive dysfunction worse.

RECOMMENDED MONITORING

Examination, CBC, serum chemistry profile, urinalysis, ± thyroid profile as needed, and at least q 6-12 months if medications. Any ongoing medical condition could worsen any older animal's anxiety and make the signs of cognitive dysfunction worsen or appear to worsen.

PROGNOSIS AND OUTCOME

- The course is inexorable, but with diet, exercise, and appropriate stimulation, patients in the early stages can have years of quality life.
- Prognosis is improved by early diagnosis, comprehensive treatment, including preventative treatment with antioxidants and cognitive stimulation in middle age, and client compliance.

PEARLS & CONSIDERATIONS

COMMENTS

- If the clients videotape the animal early in the development of the condition, they will be better able to monitor changes, assess treatment, and make quality-of-life decisions.
- Clients often are made the saddest by the feeling that they are losing their emotional and intellectual connection with their pet. Treatment must acknowledge this concern and address it when possible.
- Other cats or dogs in the household can often help calm these patients and help them with activities they may now find challenging.

TECHNICIAN TIP

- When their cognitive functions decline, these patients may require extra care and handling, especially when known to the hospital staff for many years. It is a common mistake of veterinarians and technicians alike to assume a pet can behave the same as always when he/she ages, and being aware of such potential changes can help prevent injury.

PREVENTION

- Diets rich in antioxidants may decrease risk.
- Mental and physical activity is essential and may have a much larger role to play than originally thought. For cats and dogs, olfactory stimulation is likely coupled with cognition, and some mental stimulation should involve work for food, food puzzles, food games, or some mental exercise that involves olfaction.

CLIENT EDUCATION

- Clients must understand that problematic behaviors attendant with cognitive dysfunction are not willful acts of disobedience by a vengeful pet.
- Treatment of this condition is an ongoing process and will continue for the life of the pet. Relapses may occur with treatment discontinuation or added stressors.

AUTHOR & EDITOR: KAREN L. OVERALL

Coccidiosis, Intestinal

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A diarrheal disease caused by infection of the intestinal tract with Apicomplexan parasites in the genus *Cystoisospora*

SYNONYM

Isospora

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats
- Young animals or animals that are stressed are more likely to have clinical signs than are older animals.

RISK FACTORS

Recent weaning or overcrowded conditions

CONTAGION & ZOONOSIS

Oocysts of *Cystoisospora* species can infect and cause latent infections in a number of paratenic hosts. There is no risk of zoonotic infection with dog or cat *Cystoisospora* species.

GEOGRAPHY AND SEASONALITY

Cystoisospora species have a worldwide distribution and are present year round.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Diarrhea with or without vomiting are the most common complaints. Diarrhea is not bloody but is often foul smelling, pasty, and semiformed to liquid.

PHYSICAL EXAM FINDINGS

Weight loss (or poor growth), dull haircoat, dehydration, and slightly elevated temperature may be present.

ETIOLOGY AND PATHOPHYSIOLOGY

- Intestinal coccidiosis in cats is caused by *Cystoisospora felis* and *Cystoisospora rivolta.* Intestinal coccidiosis in dogs is caused by *Cystoisospora canis* and *Cystoisospora ohioensis* complex *(C ohioensis, C neorivolta, C. burrowsi).*
- Intestinal damage is caused by rupture of host cells lining the intestinal villi of the small intestines. Villous atrophy and villous erosions occur secondary to parasite multiplication.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Nonspecific diarrhea is confirmed to be caused by *Cystoisospora* by simple microscopic fecal examination.

DIFFERENTIAL DIAGNOSIS

Giardiasis or other protozoal enteric infections, viral- or bacterial-induced diarrhea, dietary indiscretion, other parasitic (helminths) diseases of the intestines

INITIAL DATABASE

- Fecal examination and demonstration of characteristic oocysts.
- Parvovirus ELISA may be indicated in affected puppies with severe diarrhea to rule out concurrent parvoviral enteritis.
- Kittens should be tested for feline leukemia virus or feline immunodeficiency virus (older than 4 months).

ADVANCED OR CONFIRMATORY TESTING

None needed

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are remission of diarrhea and cessation of oocyst production.

ACUTE GENERAL TREATMENT

- Sulfadimethoxine (Albon oral suspension 5%):
  - 55 mg/kg PO once, followed 24 h later by 27.5 mg/kg PO q 24 h in dogs.
  - Treatment is continued until clinical signs have resolved for 48 hours.
  - To prevent dehydration, adequate water intake must be maintained during treatment.
  - Supportive care includes fluids; providing a warm, dry environment; and an appropriate diet.
- Off-label:
  - Toltrazuril (Baycox) 30 mg/kg PO as a single treatment
  - Ponazuril (Marquis) 30 mg/kg PO as a single treatment
  - A combination of sulfadimethoxine with ormetoprim (Primor) 55 mg/kg PO q 24 h (for up to 21 days) is also effective.
  - Amprolium (Corid) 300-400 mg/kg PO q 24 h for 5 days or 110-220 mg/kg for 7-12 days. Amprolium is bitter, and care should be taken that the appropriate dose is ingested and not spit out.

CHRONIC TREATMENT

Same as for acute

DRUG INTERACTIONS

See sulfonamides (p. 1665).

RECOMMENDED MONITORING

Adult animals with documented coccidiosis should be evaluated for other causes of intestinal disease (e.g., inflammatory bowel disease, lymphoma) or immunocompromise (e.g., Cushing's disease).

PROGNOSIS AND OUTCOME

Good; most animals will respond readily to anticoccidial treatment.

PEARLS & CONSIDERATIONS

COMMENTS

- It is virtually impossible to prevent exposure to coccidia in dogs and cats. Clinical disease often develops around weaning or after other stressful events like shipping or moving locations.
- The strategic use of newer anticoccidials (ponazuril or toltrazuril) at times when animals are likely to develop coccidiosis may become common practice in the future. An example of a strategic treatment would be administration of ponazuril a few days prior to or at weaning to prevent development of coccidiosis in recently weaned puppies.

PREVENTION

Reduce environmental contamination as much as possible (control populations, keep the environment clean, and remove fecal contamination of all litter boxes and living areas).

CLIENT EDUCATION

Coccidian parasites of dogs and cats are not infectious for humans.

AUTHOR: DAVID S. LINDSAY

EDITOR: DEBRA L. ZORAN

Coccidioidomycosis

BASIC INFORMATION

DEFINITION

A respiratory or systemic fungal infection caused by *Coccidioides immitis* or *Coccidioides posadasii;* occurs predominantly in the southwestern United States

SYNONYMS

San Joaquin Valley fever, valley fever

EPIDEMIOLOGY

SPECIES, AGE, SEX

Young adult, male, medium- to large-breed dogs that have access to the outdoors are more commonly infected. Cats are infrequently diagnosed with coccidioidomycosis but often develop severe clinical illness.

RISK FACTORS

- Being predominantly outdoors during the day
- Amount of roaming space >1 acre
- Walking in the desert
- ± Immunosuppression

In endemic areas, a decreased risk has been associated with walking preferentially on sidewalks.

CONTAGION & ZOONOSIS

- Coccidioidomycosis occurs in humans, who may become infected from the same environmental source as dogs and other animals.
- Direct transmission from infected animals to humans is extremely unlikely, because the yeast phase (present at body temperature) is not transmitted by aerosol. Transmission of *Coccidioides* to a human following a cat bite has been reported.
- Conversion of the yeast phase to the mycelial phase, which produces infectious spores (arthroconidia) that may be inhaled, could occur on bandages, necropsy specimens, tissue samples, or instruments; such material should be dealt with safely and immediately (e.g., disinfected or autoclaved).
- The mycelial/hyphal form of *Coccidioides,* which grows in vitro and in nature, is highly infectious by the aerosol route; in-house culture of possibly infected specimens is contraindicated.

GEOGRAPHY AND SEASONALITY

- Coccidioidomycosis occurs mainly in the southwestern United States, including the central valley of California *(Coccidioides immitis);* southern regions of Arizona, Nevada, Utah, and New Mexico; and western Texas *(Coccidioides posadasii).* To a lesser extent, it occurs in regions of Mexico and Central and South America (particularly Venezuela). Having lived in or traveled through these regions up to several years prior to the onset of illness is almost always a component of the history.
- Because the disease is acquired through inhalation of airborne spores, the incidence increases following soil disturbance (dust storms, earthquakes).
- Latent infection may be present for years before causing overt signs.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Chronic cough (pulmonary or hilar lymph node involvement); may be dry and harsh or moist and productive. Severe pulmonary involvement may be associated with respiratory distress.
- Other presenting complaints include inappetence, weight loss, lethargy, lameness, cutaneous masses with or without draining tracts, signs of head or neck pain, signs of vision loss, or neurologic signs such as seizures and ataxia. Dogs with pericardial

involvement may present with signs of right-sided heart failure.
- Cats are more likely to present with skin lesions than dogs.

PHYSICAL EXAM FINDINGS

Harsh lung sounds, dyspnea, and tachypnea are common. Systemic signs may include fever, depression, and weakness. Lameness may be noted +/− firm swellings over long bones. Cutaneous masses with or without draining tracts may be present. Other findings include lymphadenopathy, cranial and cervical hyperesthesia, ascites, and signs of uveitis, focal chorioretinitis, or panophthalmitis.

ETIOLOGY AND PATHOPHYSIOLOGY

- *Coccidioides* spp. are dimorphic fungi; they have both yeast and mycelial (hyphal) forms:
  - The mycelial form exists in soil and produces arthroconidia that are dispersed by wind and easily inhaled.
  - Inhalation of 10 or fewer arthroconidia is sufficient to cause infection that produces clinical signs.
  - After inhalation, arthroconidia enter the pulmonary alveoli and cause subpleural lesions.
  - In this location, the fungus changes morphology to the yeast form, which grows as spherules containing endospores in tissue. The spherule releases endospores which can disseminate following phagocytosis and form new spherules. This, together with the pyogranulomatous inflammatory response, results in clinical illness.
  - The incubation period from the time of inhalation to the appearance of respiratory signs is typically 1-3 weeks, sometimes months.
- Disease may remain localized to the respiratory tract or become systemic with dissemination to lymph nodes, bones, eyes, skin, pericardium, and central nervous system (CNS).
- The course of illness may be protracted over several months to years.
- Many animals develop transient, subclinical infections, and some may recover from localized respiratory illness without therapy.
  - Approximately 28% of dogs living in an endemic region develop antibodies to *Coccidioides* spp. by the age of 2 years, and approximately 6% develop clinical infection.

COCCIDIOIDOMYCOSIS Geographic area in which coccidioidomycosis is endemic. Areas of highest prevalence are cross-hatched.

(From Rippon JW: Medical mycology, ed 3, Philadelphia, 1988, Saunders, p 436. Reprinted with permission.)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A definitive diagnosis of coccidioidomycosis is made by cytologic or histologic visualization of the organism. If the organism cannot be identified, the diagnosis is based on history, clinical signs, physical examination findings, and results of serologic tests.

DIFFERENTIAL DIAGNOSIS

- Cough:
  - Initially, a dry hacking cough may be mistaken for infectious tracheobronchitis.
  - Other differentials include collapsing trachea, chronic bronchitis, pulmonary eosinophilic diseases, bacterial pneumonia, mycobacteriosis, nocardiosis, other mycotic or parasitic causes of pneumonia, neoplasia, and congestive heart failure.
- Bone lesions: bacterial osteomyelitis, other fungal infections, bone neoplasia
- Skin lesions: draining tracts due to other systemic mycoses, bony lesions such as infected sequestra, abscesses due to bite wounds or other penetrating injuries, or neoplasia
- Ocular lesions: other systemic infectious illnesses and immune-mediated diseases

INITIAL DATABASE

- CBC may reveal an inflammatory leukogram and a mild nonregenerative anemia.
- Hypoalbuminemia (almost all cases) and hyperglobulinemia (approximately 50% of cases) are common. Hypercalcemia has not been described with this form of fungal infection.
- Urinalysis is usually unremarkable.
- Thoracic radiographs are frequently abnormal and are indicated in any patient suspected of having coccidioidomycosis:
  - Common findings include a diffuse interstitial or nodular interstitial pulmonary pattern and hilar lymphadenopathy, which may be profound.
  - Alveolar infiltrates, miliary interstitial patterns, or nodules with or without pleural effusion or evidence of pericardial effusion may also be seen.
- Radiographs of long bones may reveal mixed proliferative and lytic lesions, typically located distally (distal diaphysis, metaphysis, epiphysis).

ADVANCED OR CONFIRMATORY TESTING

- Coccidioidomycosis can be definitively diagnosed via cytologic examination of exudates, sputum or aspirates, or histopathologic examination of tissue:
  - Spherules are large (1-10 times the diameter of a red blood cell), round structures typically surrounded by neutrophils and macrophages.
  - Transtracheal washes and lymph node aspirates are often falsely negative. Cytologic evaluation of fluid from draining tracts or of pleural effusion is more likely to yield organisms, which appear on Romanowsky stains as sometimes crinkled, deeply basophilic structures.
  - Organisms can be difficult to find histopathologically on bone biopsies but are readily identified within bony microabscesses. Silver stains and periodic acid-Schiff stains may assist with organism identification.
- Serologic testing is available for dogs and cats. Several serologic tests are available for both immunoglobulin M (IgM) and IgG. Serologic tests may be positive in subclinically infected dogs. The agar gel immunodiffusion assay (AGID) is commonly used, which detects IgM and IgG.
  - As with other forms of serology, IgM reflects the acute antibody response. A positive titer can be noted within 2 weeks of exposure (i.e., during or just after the incubation period) and may last 4-6 weeks. Tests for IgM use tube precipitin (TP) antigens.
  - IgG indicates exposure or infection. Tests for IgG use complement fixation (CF) antigens. The magnitude of the titer is considered important, with higher titers (=1:64) suggesting disseminated or severe pulmonary infections. Titers < 4 may be consistent with previous exposure and recovery.
  - IgG titer is expected to decrease slowly but may not reach zero with successful treatment.
  - Positive IgG titers from dogs living in endemic areas are more likely due to exposure than from active infection.
  - Negative serologic tests in dogs infected with *Coccidioides* spp. are uncommon to rare.

TREATMENT

TREATMENT OVERVIEW

Antifungal therapy with ketoconazole, itraconazole, or fluconazole is most commonly employed. Itraconazole and fluconazole have fewer adverse effects than ketoconazole. Fluconazole is the treatment of choice for CNS or ocular involvement.

ACUTE GENERAL TREATMENT

- Supportive care for systemic illness and respiratory distress as warranted:
  - See Oxygen Supplementation,p. 1318.
  - See Hypotension, Systemic, p. 1068.
- Mild respiratory cases may resolve without medications, but antifungal therapy is often instituted to avoid dissemination. Broad-spectrum antibiotics and immunosuppressive medications should be avoided.
- Azole antifungal drugs. Care should be taken to obtain generic azole preparations from a reliable source. Liver parameters +/− serum drug levels should be monitored periodically during therapy.
  - Ketoconazole (5-10 mg/kg PO q 12 h). Effective, least costly; may produce adverse hepatic effects or vomiting/inappetence.
  - Itraconazole (5 mg/kg PO q 12 h). More effective than ketoconazole in some cases, less so in others (not predictable). Costly. May have fewer adverse effects. Unless significant inflammation is present, may not penetrate the eye and CNS.
  - Fluconazole (5 mg/kg PO q 12 h). Highly lipid soluble, best penetration of eye and CNS tissues.
- Cats generally receive 25-50 mg total of the antifungal azole agent q 12-24 h.
- Amphotericin B can be used in patients that do not tolerate (e.g., anorexia, vomiting, hepatic dysfunction) or are not responding to azole drugs. The dose for dogs is 0.5 mg/kg IV q 48-72 h, given over 4-6 h in 5% dextrose, for 1 month. Side effects include nephrotoxicity and perivascular irritation/sloughing. Renal parameters should be assessed prior to each dose. Lipid forms of amphotericin B are less nephrotoxic but more expensive. Amphotericin B does not penetrate the CNS.
- Surgical treatment via subtotal pericardectomy and epicardial excision has been used successfully for relief of right-sided heart failure in dogs with effusive-constrictive pericarditis.

CHRONIC TREATMENT

The decision to stop antifungal therapy should be based on resolution of clinical signs, radiographic lesions, and serologic titers. Therapy must persist at least 2 months beyond resolution of clinical signs and radiographic abnormalities, which may be >12 months with disseminated disease, especially if there is bone involvement. Titers can be monitored to assess response to therapy; rising titers suggest an inadequate response to therapy.

DRUG INTERACTIONS

- Some patients receiving azole drugs can develop liver dysfunction, vomiting or diarrhea, thrombocytopenia, and skin reactions.
- Compatibility of other medications with antifungal agents should be investigated before use.
- Caution should be taken in patients receiving o,p'DDD, warfarin, digoxin, phenobarbital, phenytoin, methylprednisolone, and cyclosporine, because azole drugs may raise serum levels of these medications substantially.

POSSIBLE COMPLICATIONS

If clinically significant respiratory signs are left untreated, systemic spread of illness is likely.

PROGNOSIS AND OUTCOME

- Prognosis for patients with disease limited to the respiratory tract is fair to good.
- Patients with disseminated disease have a guarded to poor prognosis for full recovery, depending on the severity of disease and degree of dissemination. Patients with CNS involvement have a poor prognosis.

PREVENTION

To minimize the risk of infection in endemic areas, keep animals away from desert soil and locations where soil is disrupted (e.g., construction sites), and discourage digging.

PEARLS & CONSIDERATIONS

COMMENTS

Fungal culture of *Coccidioides* should not be attempted within a veterinary practice, because the hyphae are the infectious form of the fungus and are highly infectious to humans as well as domestic animals.

TECHNICIAN TIPS

Bandages used for covering cutaneous draining tracts may be infectious to humans if the lesion is due to *Coccidioides* infection; therefore, bandages should be avoided in such situations, or if indispensable, should be changed on a daily basis and disinfected or destroyed (autoclaved) immediately when removed.

Cobalamin Deficiency

BASIC INFORMATION

DEFINITION

A reduced cellular concentration of the B vitamin, cobalamin, usually secondary to insufficient intestinal uptake due to malnutrition/malabsorption.

SYNONYM

Vitamin B12 deficiency

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Acquired form: dogs and cats (mean age for cats: 7.1 years)
- Hereditary form: young kittens and puppies (6-12 weeks old)

GENETICS & BREED PREDISPOSITION

Chinese shar-pei, giant schnauzer, beagle, border collie, Australian shepherd

RISK FACTORS

- In theory, a pure vegetarian diet may cause cobalamin deficiency (reported in humans); unlikely in dogs and cats eating commercial pet food.
- Surgical resection of the ileum (site of cobalamin absorption)
- Exocrine pancreatic insufficiency (EPI): in dogs and cats, the pancreas is a major source of intrinsic factor, which is necessary for ileal absorption of cobalamin.
- Severe and chronic small-intestinal disease may damage ileal cobalamin receptors.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Hereditary (rare); defect in receptors for uptake
- Secondary (most common): caused by EPI, small-intestinal bacterial overgrowth and antibiotic-responsive diarrhea (SIBO/ARD), chronic enteropathies (e.g., inflammatory bowel disease [IBD], lymphosarcoma, histoplasmosis), any form of chronic malabsorption/malnutrition; interference with ileal cobalamin uptake

HISTORY, CHIEF COMPLAINT

- Hereditary form: gastrointestinal (GI) disorders, failure to thrive, hematologic and biochemical abnormalities (normocytic nonregenerative anemia/"pernicious anemia," leukopenia), proteinuria, seizures
- Acquired form: clinical signs of GI disease most common; hematologic and biochemical abnormalities rare

PHYSICAL EXAM FINDINGS

- Most dogs and cats with cobalamin deficiency only show clinical signs of GI disease dependent on the underlying cause (chronic diarrhea, vomiting, weight loss, poor body condition).
- Neurologic signs have been reported occasionally in dogs and cats with selective cobalamin deficiency (i.e., hyperammonemic encephalopathy, organic acidemia).
- Neutropenia and anemia (usually normocytic) are usually features of the hereditary form and occur very rarely in acquired disease.

ETIOLOGY AND PATHOPHYSIOLOGY

- Cobalamin (Vitamin B12) is a water-soluble vitamin produced exclusively by microorganisms. Animals are unable to synthesize cobalamin and are dependent on nutritional sources. Cobalamin (Cbl) is an important cofactor for a variety of biochemical reactions (e.g., amino acid metabolism and DNA synthesis).
- Dietary cobalamin binds to intrinsic factor (pancreatic), which in dogs and especially cats is mainly produced in the pancreas, serving as a transporter for absorption at the distal small intestine.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Cobalamin deficiency is usually suspected as a possible secondary complication with GI or pancreatic disease. Measurement of serum cobalamin levels is the clinical diagnostic test of choice.

DIFFERENTIAL DIAGNOSIS

- Chronic GI disease
- EPI, IBD, SIBO/ARD, intestinal lymphoma, histoplasmosis

INITIAL DATABASE

- CBC, serum biochemistry profile: to rule out other systemic disease

ADVANCED OR CONFIRMATORY TESTING

- Measurement of serum cobalamin
  - Reference range established at the GI Laboratory at Texas A&M University:
    - Dogs: 251-908 ng/L, Cats: 290-1500 ng/L
    - Other laboratories may have different reference ranges.
- Measurement of methylmalonic acid (MMA) in serum or urine: not commercially available
  - Increased serum or urinary MMA indicate cobalamin deficiency at the cellular level
- Serum trypsin-like immunoreactivity to rule out EPI
- Serum folate to rule out SIBO/ARD

TREATMENT

TREATMENT OVERVIEW

The goal of treatment is to correct cobalamin deficiency at the cellular level and correct clinical signs/symptoms (i.e., GI, hematologic, immunologic, and neurologic)

CHRONIC TREATMENT

- Repeated high doses by parenteral administration are necessary.
  - Cyanocobalamin is the primary choice, but hydroxycobalamin can also be used.
  - Multivitamin preparations contain an insufficient amount of cobalamin and are not recommended.
- Recommended empirical dosing schedule of cyanocobalamin:
  - 150-250 mcg per injection in cats; 250-1200 mcg per injection in dogs
  - SQ q 7 days for 6 weeks, then q 14 days for 6 weeks, then q 30 days for 1 injection, then reevaluate serum cobalamin concentration 1 month later
  - If the underlying disease process has resolved and cobalamin body stores have been replenished, serum cobalamin concentration should be supra-normal at the time of reevaluation.
  - If serum cobalamin concentration is in the normal range, treatment should be continued at least in monthly intervals.
  - If serum cobalamin concentration at the time of recheck is subnormal, further workup is required to definitively diagnose the underlying disease process; cobalamin supplementation should be continued weekly or biweekly.

POSSIBLE COMPLICATIONS

Cobalamin is nontoxic and can be parenterally administered in large doses with minimal risk of side effects.

RECOMMENDED MONITORING

- Depending on the underlying cause of cobalamin deficiency and the clinical signs, every few months
- In animals with the congenital form, a more frequent check may be necessary until an optimal dose regimen has been established.

PROGNOSIS AND OUTCOME

- In the congenital form, the response to parenteral cyanocobalamin is usually excellent, leading to reversal of clinical abnormalities.
- In the acquired form, prognosis depends on the underlying disease:
  - Usually excellent in animals with EPI in combination with pancreatic enzyme replacement therapy
  - Hypocobalaminemia has been associated with a poor outcome in dogs with severe chronic enteropathies.

PEARLS & CONSIDERATIONS

- Animals with GI disease and cobalamin deficiency have a diminished capacity of oral cobalamin absorption and recycling via enterohepatic circulation. This leads to a more rapid depletion of body stores, and those animals require frequent parenteral administration of cobalamin.
- Patients with severe cobalamin deficiency often do not respond to therapy of the underlying GI disorder until cobalamin is supplemented.
- A recent study has shown that cats with chronic GI disease and cobalamin deficiency that were unresponsive to previous therapy responded with weight gain quickly after initiation of cobalamin supplementation.
- Cobalamin deficiency on a cellular level may even occur when serum cobalamin concentration is at the low end of the normal range (<350 ng/L), and parenteral cobalamin supplementation should also be considered in these patients.

EDITOR: DEBRA L. ZORAN

Clostridial Enterocolitis

BASIC INFORMATION

DEFINITION

Clostridial enterocolitis or enterotoxicosis is a form of intestinal disease that causes diarrhea in dogs and cats and is suspected to be caused by *Clostridium perfringens*. It typically causes large intestinal diarrhea that may be acute and self-limiting or may be chronic in nature.

SYNONYMS

Acute nosocomial colitis, canine nosocomial diarrhea

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs are more commonly affected than cats. Acute disease can occur in any age animal, whereas chronic disease can occur in middle-aged to older animals.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Some or all may be present.

- Large-intestinal diarrhea. Small volumes of feces, increased frequency of defecation, and straining are common, and mucus and/or fresh blood may be visualized in the feces. Vomiting and flatulence may also be present in some patients. Many patients show no clinical signs other than the diarrhea.
- A small number of patients may also have small-bowel diarrhea marked by large volumes of watery feces and abdominal discomfort.

PHYSICAL EXAM FINDINGS

- Findings are nonspecific and relate to large-intestinal diarrhea. There may be abdominal discomfort during palpation. There may also be signs of pain during digital rectal examination.
- Acute nosocomial diarrhea associated with *C. perfringens* is often seen 1 to 5 days after boarding or kenneling. This syndrome appears to be self-limiting and responds well to supportive care.

ETIOLOGY AND PATHOPHYSIOLOGY

- *C. perfringens* is an anaerobic, spore-forming, gram-positive bacillus that is also found in normal dogs and cats.
- Sporulation of toxigenic strains causes release of enterotoxin A. This enterotoxin can cause mucosal damage and fluid secretion in the colon.
- Other factors must also be involved. Enterotoxin-related damage cannot be the sole explanation for this disorder, because enterotoxin has been identified in the feces of normal animals.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is conclusively established with fecal bacterial cultures, but in most cases the transient nature of the illness means that a definitive diagnosis is neither achieved nor clinically necessary.

DIFFERENTIAL DIAGNOSIS

- All causes of large-intestinal diarrhea, both primary gastrointestinal and systemic/nonprimary gastrointestinal, need to be considered (see p. 303).
- Primary gastrointestinal disease includes parasites, inflammatory bowel disease, neoplasia, fungal disease, idiopathic colitis, and histiocytic ulcerative colitis.
- Systemic/extraintestinal causes of acute diarrhea include anxiety/nervousness, other intraabdominal disorders, and intoxications (e.g., organophosphates).

INITIAL DATABASE

- CBC, biochemical profile, urinalysis, fecal flotation: generally unremarkable
- Fecal ELISA for *Giardia* or other pathogens
- Fecal smear with Gram stain
- Rectal scraping for cytologic evaluation (to rule out histoplasmosis, lymphoma); see p. 1334
- Fecal analysis is very important in all cases of large-bowel diarrhea, because this test is noninvasive and may yield important clues to the problem, even if the diagnosis is elusive.

ADVANCED OR CONFIRMATORY TESTING

- Advanced diagnostic evaluation may include fecal culture and evaluation for the presence of enterotoxin in feces.
- Abdominal imaging with radiographs or ultrasound is often normal but can be warranted to rule out extragastrointestinal diseases.
- Colonoscopy is rarely indicated to diagnose this condition, but in severe cases may be necessary to rule out other causes of colitis:
  - Mucosal hyperemia or ulceration are typical.
  - Histopathologic analysis of biopsies may indicate neutrophilic colitis, the presence of other inflammatory bowel disease, or may be normal.
- Fecal cytologic evaluation may indicate the presence of sporulating clostridial organisms, which have the appearance of safety pins. However, the presence of these organisms does not confirm that a *Clostridium* is the cause of the clinical disease.
- Anaerobic fecal cultures will typically identify high concentrations of *C. perfringens* (>3-5 organisms/field on oil immersion).
- Other available diagnostic tests include ELISA enterotoxin assays and PCR enterotoxin genotyping.

TREATMENT

TREATMENT OVERVIEW

Therapeutic goals are to provide supportive care and eliminate large-bowel diarrhea. These patients may be dehydrated, anorexic, and lethargic. Supportive care should be directed toward correcting volume deficits, correcting electrolyte disturbances, and reducing intestinal discomfort (including vomiting) so the patient will eat and be more comfortable.

ACUTE GENERAL TREATMENT

- Treatment with intravenous crystalloid solutions to correct volume deficits is very important.
- The use of antimicrobials, including amoxicillin (20 mg/kg PO q 8 h), clindamycin (10-20 mg/kg PO q 12 h), tylosin (5-10 mg/kg PO q 12 h), or metronidazole (15-20 mg/kg PO q 12 h) for 5-7 days is generally beneficial. Parenteral antibiotics with anaerobic bactericidal activity (e.g., ampicillin, 20 mg/kg IV q 6-8 h) are indicated if the patient is systemically ill.

CHRONIC TREATMENT

- Long-term antimicrobial therapy may be required along with dietary management.
- In some cases, the antibiotic therapy may be discontinued so long as the high-fiber diet is maintained.

NUTRITION/DIET

Dietary management with high-fiber diets has been shown to reduce clinical signs and speed recovery.

RECOMMENDED MONITORING

Based on the presence or absence of diarrhea

PROGNOSIS AND OUTCOME

The prognosis depends on the presenting condition of the patient. In most cases, the prognosis is excellent.

PEARLS & CONSIDERATIONS

- There is no gold standard on how to treat this disease; treatment is adapted based on specific abnormalities identified on physical exam and diagnostic testing.
- There is still some question as to whether Koch's postulates have been fulfilled regarding causality of *C. perfringens* and this form of enteritis.

CLIENT EDUCATION

In most cases, the signs associated with this disease subside with supportive care, but some patients may be chronically affected.

Cleft Palate

BASIC INFORMATION

DEFINITION

Congenital, physical defect of the lips, hard and/or soft palate

SYNONYMS

Primary cleft palate: harelip, cleft lip. Secondary cleft palate: cleft of the soft palate or cleft of the soft and hard palate.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats of either sex
- Incidence higher in brachycephalic dog breeds and Siamese cats
- Nursing difficulties noted in puppies and kittens soon after birth

GENETICS & BREED PREDISPOSITION

- Inherited as either autosomal recessive or irregularly dominant genes
- Mating of parents with cleft palate results in 41% incidence in offspring.

RISK FACTORS

See Etiology and Pathophysiology.

ASSOCIATED CONDITIONS & DISORDERS

- Aspiration pneumonia
- Sneezing, nasal discharge, chronic rhinitis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

The upper lip and most rostral hard palate supported by the palatine processes of the incisive bones constitute the *primary palate.* The hard palate that is supported by the palatine processes of the maxillary bones and the horizontal laminae of the palatine bones and the soft palate constitute the *secondary palate.*

- Primary palate defects: unilateral, midline, or bilateral; unilateral defects are more often found on left side.
- Secondary palate defects:
  - Midline cleft of hard and soft palate or soft palate only
  - Unilateral cleft of soft palate
  - Hypoplasia of soft palate

HISTORY, CHIEF COMPLAINT

- Primary palate defects:
  - Lip defects only: owner may note physical appearance
  - Most rostral hard palate defects: mild nasal congestion, sneezing, and discharge
- Secondary palate defects (depends on extent of defect): failure to create negative pressure for nursing, nasal discharge (drainage of milk from the nares during or after nursing), coughing, gagging, sneezing, nasal reflux, rhinitis, tonsillitis, laryngotracheitis, aspiration pneumonia, poor weight gain, and general unthriftiness

PHYSICAL EXAM FINDINGS

- Small stature
- Nasal discharge, sneezing
- Auscultation: dyspnea, increased lung sounds, wheezing, or crackles (aspiration pneumonia)
- Oral examination:
    - Primary palate defects: “harelip” only (unilateral, midline, or bilateral lip defect); rostral hard palate defect only (uni- or bilateral); or defects of both the lip and most rostral hard palate; can also be associated with abnormalities of the secondary palate.
    - Secondary palate defects: midline hard palate cleft can usually be visualized, but soft palate defect may be difficult to evaluate without chemical restraint.

ETIOLOGY AND PATHOPHYSIOLOGY

Etiology:

- Hormonal: gestational corticosteroid administration
- Infectious: viral-induced
- Mechanical: intrauterine trauma
- Metabolic
- Nutritional
- Toxic: secondary to drug, viral toxins
- Hereditary:
    - Autosomal recessive or irregularly dominant genes
    - Growth of palatine bones in the fetus may compete with growth of the skull, especially in broad-skulled (brachycephalic) dogs, to achieve normal closure of the palatine plates.

Pathophysiology:

- Defects of the primary and secondary palate result from a *failure of fusion* of paired (and one unpaired) structures during development.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis occurs in one of two contexts: clinical signs are suggestive of the disorder (classically, milk discharge from nostrils in a nursing puppy or kitten), or the defect is identified as an incidental finding during routine examination. In either situation, complete assessment of the defect is done under sedation or anesthesia, generally followed immediately by surgical correction (consider referral).

DIFFERENTIAL DIAGNOSIS

Acquired palate defects (traumatic, infectious)

INITIAL DATABASE

- CBC, serum biochemistry panel, urinalysis: assessment of unthrifty patients
- Thoracic radiographs: evaluation of possible aspiration pneumonia

ADVANCED OR CONFIRMATORY TESTING

Oral examination under general anesthesia: define extent of secondary palate defects

TREATMENT

TREATMENT OVERVIEW

Essential elements are:

- Treat and resolve aspiration pneumonia prior to surgery.
- Nutritional support (tube feeding) until the patient is of adequate age and health for surgery

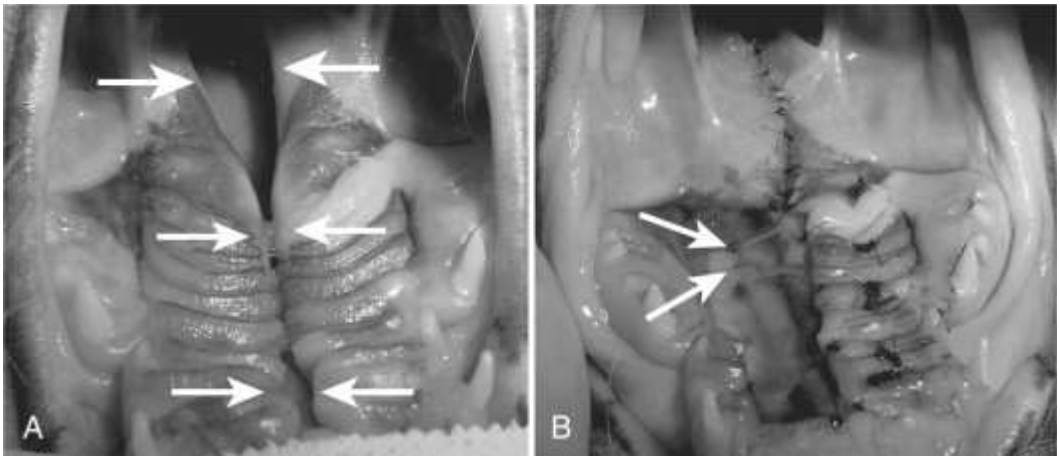
- Complete closure of palate defects

ACUTE GENERAL TREATMENT

Treat aspiration pneumonia (see p. 885)

CHRONIC TREATMENT

- Repair of primary palate defects:
  - Most rostral hard palate defect: reconstructed by creating overlapping flaps of oral (and nasal) tissue or advancement, rotation and transposition flaps harvested from oral tissue only; removal of one or more incisors and canine tooth on the affected side will facilitate flap management.
  - Lip defect: reconstructive cutaneous surgery to provide symmetry (elective)
- Repair of secondary palate defects:
  - Midline hard palate defect: overlapping flaps (preferred technique); medially positioned flaps or unilateral rotation (single pedicle) flaps may be used; the harvested mucoperiosteal flaps must be supplied by major palatine arteries; exposed bone is left to granulate and epithelialize.
  - Midline soft palate defect: medially positioned flaps (with at least a two-layer closure) or overlapping flaps
  - Unilateral soft palate defect: tonsillectomy at affected side, followed by creation and suturing of two nasopharyngeal and two oropharyngeal flaps
  - Soft palate hypoplasia: bilateral tonsillectomy, followed by bilateral creation and suturing of two nasopharyngeal and two oropharyngeal flaps
- Pain control: maxillary nerve block (0.5% bupivacaine hydrochloride) intraoperatively followed by opioids (e.g., hydromorphone, 0.1-0.2 mg/kg IV or IM as needed up to q 2-4 h) and postoperative opioid medication (butorphanol, 0.2-0.4 mg/kg PO q 4-6 h) or nonsteroidal antiinflammatories (e.g., carprofen, 2 mg/kg PO q 12 h) for 4-7 days
- Antibiotics: usually not required unless risk of aspiration or existing aspiration pneumonia
- Wound management: oral application of dilute chlorhexidine solution or gel for 4 weeks; Elizabethan collar to prevent pawing at surgical site



CLEFT PALATE A, Congenital cleft palate. This 14-week-old dog is under general anesthesia and in dorsal recumbency; rostral is towards the bottom of the image. A congenital defect of the secondary palate (midline cleft of the hard and soft palate) is seen *(arrows)*. **B**, Congenital cleft palate, repaired. The hard palate defect was repaired utilizing the overlapping flap technique (note the exposed major and accessory palatine arteries *[arrows]*); the donor area is left to granulate and epithelialize. The soft palate defect was repaired utilizing the medially positioned flap technique.

NUTRITION/DIET

Preoperatively in juvenile patients:

- Tube feeding (oroesophageal) with milk replacer or other suitable diet (e.g., Hill's a/d) until surgical candidate (best at 3-4 months of age):
  - Supplies nutritional needs
  - Minimizes rhinitis
  - Allows patient to mature: anesthetic purposes, greater strength of palatal tissue, more working room in the oropharynx to effect repair

Postoperatively:

- Soft food, no chewing toys/treats for 4 weeks; esophagostomy or gastrostomy tubes to bypass the oral cavity are rarely needed.

POSSIBLE COMPLICATIONS

Dehiscence due to:

- Excess tension if inadequate mobilization of tissue for closure
- Palatal flap necrosis if major palatine artery is compromised during surgery
- Tongue movements, chewing on hard material, self-trauma (consider E-collar, postoperative tube feeding)

RECOMMENDED MONITORING

Reexamination in 2 weeks for removal of skin sutures at lips

PROGNOSIS AND OUTCOME

- Multiple procedures may be required to close a palate defect. Follow-up surgeries should not be attempted before healing (granulation and epithelialization) of all tissues involved (6-8 weeks).
- Poor prognosis for congenital soft palate hypoplasia (restoration of a pharyngeal sphincteric ring and normal swallowing function may not be achieved).
- Guarded prognosis for secondary palate defects without surgical repair (risk of aspiration)

PEARLS & CONSIDERATIONS

COMMENTS

The best chance of success is with the first surgical procedure; avoid electrocoagulation for hemostasis, handle flaps as carefully as possible, and avoid creating closure that is under tension; referral to an experienced oral surgeon is recommended.

PREVENTION

- Selective breeding
- Avoid gestational corticosteroid administration and other insult during pregnancy (see Etiology and Pathophysiology).

TECHNICIAN TIPS

Technicians caring for these patients pre-and postoperatively should be skilled in correct tube-feeding technique.

CLIENT EDUCATION

Management of patients with cleft palate requires intensive nursing care at home for 2-4 months until surgery can be performed.

1ST EDITION AUTHOR: ELLEN B. DAVIDSON DOMNICK

Cleaning Products Toxicosis

BASIC INFORMATION

DEFINITION

Accidental exposure (dermal, oral, or ocular) of pets to household cleaning products, including soaps, detergents, bleaches, and disinfectants. Bleaches are discussed in greater detail in Acid or Alkali (Corrosives) Toxicosis, p. 19.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs more commonly involved than cats
- Cats more sensitive to cationic detergents, phenol, and pine oil–containing products

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Observed or suspected exposure to a household cleaning product
- Rapid onset of clinical signs (minutes to a few hours)

PHYSICAL EXAM FINDINGS

- Hypersalivation, vomiting, diarrhea, lethargy (soaps; anionic, nonionic, and Zwitter detergents)
- Oral ulcers (phenol, cationic detergents)
- Corneal ulcer, conjunctivitis/blepharitis (phenol, cationic detergents)
- Central nervous system depression, aspiration (pine oil)
- Distinct smells: bleach, pine oil
- Salivation, vomiting (bleach, pine oil)

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

- Soaps are salts of fatty acids made by the reaction of alkali with fatty acids.
- Detergents are nonsoap surfactants in combination with inorganic ingredients such as phosphates, silicates, or carbonates.
- Detergents are classified into nonionic, anionic, cationic, or Zwitter agents according to charge present in solution. The classification depends on the active substance in the product (listed on label on product container).
    - Nonionic detergents: most heavy-duty laundry liquids, nonphosphate granular products, and many low-sudsing laundry products; alkyl ethoxylate, alkyl phenoxy polyethoxy ethanol, polyethylene glycol stearates
    - Anionic detergents: soap, emulsifiers for ointments and creams, dishwashing liquids, solvent/detergent degreasers; alkyl sodium sulfonates, alkyl sodium sulfates, dioctyl sodium sulfosuccinates, sodium lauryl sulfates, tetrapropylene benzene sulfonate
    - Cationic detergents (quaternary ammonium compounds): benzethonium chloride, benzalkonium chloride, alkyl dimethyl 3,4-dichlorobenzene, cetyl pyridinium chloride
    - Zwitter detergents: most shampoos, bath products, and nonirritant toiletries
- Disinfectants: chemicals applied on inanimate objects to inhibit or kill microorganisms (e.g., quaternary ammonium compounds [cationic detergents], phenols, pine oils, bleaches).
- Most household bleach products contain sodium hypochlorite 3%-6%. Nonchlorine/colorfast bleaches contain sodium peroxide, or sodium perborates.

Mechanism of Toxicosis:

- Depending on dosage and concentration, soaps, anionic, nonionic, and Zwitter detergents, and chlorine bleaches are mildly irritating to the mucous membranes. Oral or cutaneous burns are rare.
- Inhalation of chlorine fumes can cause pulmonary irritation, coughing, and if severe, dyspnea and noncardiogenic pulmonary edema.

- Quaternary ammonium compounds are structurally similar to dexamethonium (neuromuscular blocking agent) and hexamethonium (ganglionic blocking agent). Therefore, systemic effects may resemble organophosphate insecticide toxicosis (see p. 792). They also cause corrosive damage to skin and oral mucosa.
- Phenol (1%-5%) can cause oral or dermal burns. Phenol (or other phenolic derivatives) can also cause respiratory stimulation and alkalosis followed by metabolic acidosis.
- Pine oil disinfectants are irritating to the mucous membranes.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis relies principally on history: suspicion or direct knowledge of exposure to a cleaning product (chewed up container, chemical smell in the breath or on the skin); it is further supported by presence of oral/dermal ulcers, hypersalivation, vomiting, excessive licking motions, and diarrhea.

DIFFERENTIAL DIAGNOSIS

- Corrosives toxicosis (alkali, acids)
- Uremia (oral ulcers)
- Acute vomiting: foreign body obstruction, viral or bacterial gastroenteritis, garbage toxicosis, pancreatitis

INITIAL DATABASE

- CBC: leukocytosis with cationic detergents, phenol; within normal limits for others
- Serum biochemistry profile: electrolyte changes (from severe vomiting or dehydration; cationic detergents, phenols) may be present.
- Urinalysis: results should be unremarkable.
- Fluorescein staining for corneal ulcers (cationic detergents, phenol)

ADVANCED OR CONFIRMATORY TESTING

- Thoracic radiographs: indicated if coughing, dyspnea, or fever of unknown origin. May show evidence of aspiration pneumonia and/or noncardiogenic pulmonary edema
- Abdominal imaging (radiographs, ultrasound): to rule out other causes of acute severe vomiting
- Endoscopic examination of esophagus to rule out perforation within 12-24 hours (cationic detergents, phenol)

TREATMENT

TREATMENT OVERVIEW

Unlike many intoxications, induction of vomiting is contraindicated (or unnecessary, as many patients vomit spontaneously) in several types of cleaning fluid intoxications. Rather, treatment involves dilution via administration of oral liquid, such as milk, and prophylactic protection of gastrointestinal mucosa. Therapeutic goals are:

- Decontamination of patient
- Protect gastrointestinal (GI) mucosa
- Supportive therapy

ACUTE GENERAL TREATMENT

- Decontamination of patient:
  - Oral dilution: *Best option.* Immediately administer milk or water (approximately, 0.25 to 0.5 cups [125-250 mL] for a 30-lb [14-kg] dog and 1 to 2 tablespoons [5-10 mL] for a 10-lb [4.5-kg] cat). Follow with milk of magnesia (0.2-0.3 mL/kg PO).
  - Emesis induction (see p. 1364) in cases of toxicosis with soaps, detergents (other than cationic); *rarely needed.* Use within 2-4 hours only if very large amounts have been ingested. *Do not induce vomiting for cationic detergents, phenol, or pine oils.*
  - Activated charcoal: rarely needed; 1-3 g/kg PO with a cathartic such as 70% sorbitol (3 mL/kg). Not needed for cationic detergents, phenol, or pine oils.
  - Dermal: wash exposed area (cationic detergents, phenol) with water for 20-30 minutes.

    - Ocular: flush eyes with tepid tap water (or saline) for 20-30 minutes. Repeat fluorescein stain to assess for corneal ulcers.
- Protect GI mucosa (cationic detergents, phenol):
    - H2 receptor antagonists:
        - Famotidine: dogs/cats, 0.5 mg/kg PO, SQ, IM, IV q 12 h
    - Control vomiting. Maropitant 1 mg/kg SQ or 2 mg/kg PO q 24 h for 5 days
    - Sucralfate: dog, 0.5-1 g PO q 8-12 h; cat, 0.25-0.5 g PO q 8-12 h
- Supportive care:
    - Intravenous fluids for rehydration (e.g., lactated Ringer's solution) or maintenance
    - Broad-spectrum antibiotics (e.g., ampicillin, 22 mg/kg IV q 8 h, plus enrofloxacin, 5 mg/kg IM or diluted 1:1 with sterile saline and given slowly IV q 12 h [q 24 h in cats]) if caustic burns and/or secondary infection
    - Manage pain (caustic burns): opiates (e.g., fentanyl patch or butorphanol 0.1-1 mg/kg IM, IV, or SQ).
- Nutrition: feed watery slurry or soft mashed food while visible mucosal erosions are present.

RECOMMENDED MONITORING

- CBC, serum chemistry profile: electrolyte changes and other effects of vomiting
- Monitor oral cavity, perioral skin for caustic burns (cationic detergents, phenol) to determine when to introduce solid food.
- Pulse oximetry, thoracic radiography if aspiration (pine oils)

PROGNOSIS AND OUTCOME

- Excellent with soaps, detergents (other than cationic), and household bleaches
- Good to guarded if pulmonary edema develops (bleaches) or if caustic burns are present (cationic detergents, phenols in cats)

PEARLS & CONSIDERATIONS

COMMENTS

Soaps, detergents (other than cationic), and household bleaches have a low order of toxicity and can be treated by immediate dilution (oral administration of milk or water). Exposure to cationic detergents can lead to oral ulcers/burns and systemic effects (ataxia, weakness, seizures).

PREVENTION

Keep household cleaning products out of reach of pets.

Claw Disorders

BASIC INFORMATION

DEFINITION

- Onychodystrophy: claw deformity caused by abnormal growth
- Onychomadesis: sloughing of the claw
- Onychomycosis: fungal infection of the claw
- Onychorrhexis: brittle claws that tend to split or break
- Paronychia: inflammation of soft tissue around the claw
- Symmetric lupoid onychodystrophy (SLO): a lupus-like condition that causes sloughing (onychomadesis) of multiple claws

In dogs and cats, the term *claw* is more appropriate than *nail.* Strictly speaking, the term *nail* should be restricted to human and other primates.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Most claw conditions have no specific age or sex predilections other than those listed here:

- SLO: in dogs aged from 3 to 8 years, rare in cats
- Subungual squamous cell carcinoma (SCC): in older dogs
- Subungual melanomas: common in older dogs, rare in older cats
- Onychomycosis: *Malassezia* common but dermatophytosis rare in both dogs and cats

GENETICS & BREED PREDISPOSITION

- SLO: often noted in German shepherds
- Subungual SCC: seen in large breeds (75%) and in breeds with a black coat (66%, such as in the black Labrador retriever and black poodle)

RISK FACTORS

Nonneoplastic claw disorders: immuno-suppression, feline leukemia virus (FeLV) infection, vascular insult, trauma, improper trimming/care of claws, diabetes mellitus

ASSOCIATED CONDITIONS & DISORDERS

- In cats and dogs: hyperadrenocorticism, diabetes mellitus, hypothyroidism, dermatomyositis, arteriovenous fistula, cold-agglutinin disease, drug reaction, vaccine reaction, vasculitis, trauma, leishmaniasis
- In cats only: hyperthyroidism, primary pulmonary bronchiolar adenocarcinoma, pulmonary SCC, cutaneous SCC with metastasis

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Owners can observe licking at affected digit(s), signs of pain, lameness, claw sloughing, or may have noted a swollen toe or a mass during claw trim. A single foot or multiple feet can be involved. The claw disorder can be part of a more generalized skin condition.

PHYSICAL EXAM FINDINGS

- Bacterial claw infections
  - One or many affected digits
  - Paronychia, toe swelling, purulent discharge, and possible separation and purulent discharge from the claw
  - Regional lymphadenopathy, with fever and possible osteomyelitis
  - Other clinical signs of immunocompromising conditions

- Onychomycosis
  - Dermatophytic claw infections result in paronychia with minimal pain, irritation, and pruritus. Typically only one or two affected digits with friable and misshapen claws. Usually accompanied with focal or multifocal skin lesions.
  - A notable "brown line" on the claws (consisting of a waxy discharge) is a clue for *Malassezia* overgrowth and is typically associated with inter-digital dermatitis, paronychia, and pruritus, as well as other possible evident areas of cutaneous involvement (see p. 682 and 891).
- SLO
  - Onychomadesis starting with a single abnormal claw on two or more paws; within 2-9 weeks, all claws on all four paws are affected.
  - Regrowth of short, misshapen, dry, soft, brittle, and crumbling claws
  - Paronychia is uncommon unless a secondary bacterial infection is present.
- Subungual SCC
  - Single, swollen, painful toe with paronychia and associated erosive/ulcerative dermatitis and often loss of the claw
  - Multiple digits can be affected over time in black Labradors, black standard poodles, and giant schnauzers.
- Subungual melanoma
  - Solitary, well-circumscribed, dome-shaped, firm, wart-like growth
  - Varies in size from 0.5-10 cm in diameter
  - Possibly pigmented or nonpigmented and ulcerated

ETIOLOGY AND PATHOPHYSIOLOGY

- Bacterial claw infection
  - Infection is secondary (e.g., trauma if one or two claws are infected; if many claws are infected, consider hypothyroidism, hyperadrenocorticism, immune-mediated condition [pemphigus], or SLO).
  - *Staphylococcus pseudintermedius* is the most common bacterium isolated.
  - Concurrent demodicosis occurs in both single- and multiple-digit involvement.
  - Leishmaniasis should be considered in endemic areas (the Mediterranean, limited areas in the United States).
- Onychomycosis
  - *Microsporum canis* in cats
  - *Trichophyton mentagrophytes* in dogs
  - *Malassezia* spp. in dogs and cats
  - *Microsporum gypseum* and candidiasis (yeast) less common
- Symmetric lupoid onychodystrophy: currently regarded as an idiopathic condition. SLO may either be a clinical manifestation of many different diseases or an immune-mediated condition itself. Current emphasis is to look for potential underlying conditions, including hypersensitivity disorders (drug, food, environmental allergens) and hormonal and metabolic abnormalities before committing a pet to lifelong therapy.
- Subungual SCC
  - Neoplasm generally originating from the germinal epithelium of the claw
  - Reverse also possible (metastasis from a primary pulmonary neoplasm/carcinoma to toe), a sequence that is more common in cats than in dogs
- Subungual melanoma: malignant proliferation of melanocytes involving the claw beds in older dogs

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis originates with observation of claw abnormalities on physical exam. Complementary testing is selected based on history, remainder of exam (especially whether one or several claws is/are affected), and results of the initial database.

DIFFERENTIAL DIAGNOSIS

- Single claw affected
  - Trauma-induced condition
  - Neoplasia (subungual SCC, subungual melanoma high-grade mast cell tumors, fibrosarcoma, neurofibrosarcoma, eccrine carcinoma, osteosarcoma, subungual keratoacanthoma)
  - Primary pulmonary bronchiolar adenocarcinoma, pulmonary SCC, and cutaneous SCC with metastasis to digits in cats
- Multiple claw involvement
  - SLO
  - Immune-mediated diseases (pemphigus complex, bullous pemphigoid, drug eruption, vasculitis, cold-agglutinin disease)
  - Metabolic disease (hypothyroidism, hyperadrenocorticism, feline hyperthyroidism); rare

INITIAL DATABASE

- Cytologic examination of claw exudates
  - Suppurative or pyogranulomatous inflammation with engulfed bacteria: consistent with bacterial claw infection
  - Broad-based budding yeast consistent with *Malassezia* infection (see p. 682)
  - Evidence of acantholytic cells: indicative of pemphigus
  - Round cell tumor cells: consistent with melanoma
- Fungal culture (Dermatophyte Test Medium):
  - Indicated if a single claw/claw bed is involved (see p. 292 and p. 1248)
- CBC, serum biochemistry profile, urinalysis:
  - Evidence of systemic conditions (diabetes mellitus, hyperadrenocorticism, systemic lupus erythematosus [SLE])
- Thyroid profile:
  - Indicated if multiple claws are affected and other consistent clinical signs are present. Hypothyroidism (in dogs) and hyperthyroidism (in cats) are rare concurrent/causative conditions.

ADVANCED OR CONFIRMATORY TESTING

- Bacterial culture and sensitivity: often *Staphylococcus pseudintermedius*
- Biopsy for histopathologic exam and special stains
  - Usually via toe amputation; longitudinal claw and ungula bed excision may be complex and painful.
  - SLO: hydropic and lichenoid interface dermatitis
  - Rule out other immune-mediated conditions (pemphigus, bullous pemphigoid).
  - Identify fungal hyphae and arthrospores or bacterial organisms.
  - About 10% of melanomas (identified by histologic examination) behave malignantly.
- Antinuclear antibody (ANA) test to rule-in the possibility of SLE
- FeLV/feline immunodeficiency virus (FIV) serology
- Radiographs:
  - Rule out osteomyelitis with bacterial claw disease.
  - Bony lysis of third phalanx (P3) and tissue swelling due to neoplasia, particularly subungual SCC
  - Thoracic radiographs: metastasis check
- Fine-needle lymph node aspirates, abdominal ultrasound
  - If SCC or melanoma is confirmed histologically

TREATMENT

TREATMENT OVERVIEW

The goal of treatment is to achieve permanent cure or control of the disease. Sometimes palliative treatment is the only option (e.g., SLO).

ACUTE AND CHRONIC TREATMENT

- Claw fracture or avulsion: The clinician should trim or file (using a Dremel tool) any fractured claws, using sedation, analgesia, local/general anesthesia as necessary; remove loose claws and bandage foot. In severe conditions or patients with neoplasia, P3 amputation may be necessary.
- Bacterial claw infections
  - Antibiotic therapy for 2 weeks beyond clinical resolution: cephalosporin (e.g., cephalexin, 22 mg/kg PO q 8 h, or 30 mg/kg PO q 12 h), amoxicillin-clavulanate (22 mg/kg PO q 12 h), or potentiated sulfonamide (e.g., trimethoprim-sulfa, 15-30 mg/kg PO q 12 h).
  - Topical creams/ointments: silver sulfadiazine
  - Foot scrubs: 2%-4% chlorhexidine topical soaks q 12-24 h for 7 days beyond clinical resolution
- Onychomycosis (dermatophytic)
  - Long-term antifungal/anti-yeast treatment on a daily or pulse basis (6 months or longer); e.g., 3 days on and 4 days off (ketoconazole) or 1 week on and 1 week off (itraconazole)
  - Ketoconazole (10 mg/kg PO q 24 h), itraconazole (5-10 mg/kg PO q 24 h), fluconazole (5 mg/kg PO q 24 h), or terbinafine (10-40 mg/kg PO q 24 h) given with food for maximal absorption unless using liquid azoles
  - Treatment is continued 1-3 months beyond complete claw regrowth and a negative repeat fungal culture from claw trimmings.
  - Topical antifungal products include chlorhexidine, miconazole, clotrimazole, terbinafine, enilconazole, or lime sulfur.
- Symmetric lupoid onychodystrophy:
  - Varying combinations of these treatments are used based on individual response and tolerance.
  - Omega-3 fatty acids (36 mg/kg PO q 24 h) and omega-6 fatty acids (500-1000 mg PO q 24 h) for a minimum of 3

months, then as maintenance therapy
    - Vitamin E (10-20 IU/kg PO q 12 h to q 8 h) for a minimum of 3 months or longer if improved
    - Elimination diet for 8 to 12 weeks to rule out adverse food reaction as a trigger.
    - Tetracycline and niacinamide (500 mg of each for dogs >10 kg; 250 mg of each for dogs <10 kg) PO q 8 h, until improvement (about 2 to 3 months); then taper the medication monthly. Doxycycline (5-10 mg/kg q 12 h) may be substituted for tetracycline.
    - Prednisolone (2-4 mg/kg PO q 24 h induction, weaning based on a favorable response) alone or with azathioprine (2.2 mg/kg PO q 24-48 h; dogs only) as corticosteroid-sparing agents; monitor for myelosuppression, hepatotoxicity, opportunistic infection.
    - Pentoxifylline (10-30 mg/kg PO q 8-12 h) until resolution of lesions, then taper the medication monthly.
    - Cyclosporine (5 mg/kg PO q 12 h microemulsion [Atopica, Neoral]) until resolved, then taper to lowest frequency that controls relapse of clinical signs.
    - Onychectomy (P3 amputation) as a last resort
- Subungual SCC
    - Post-staging amputation of the affected digit to the proximal inter-phalangeal level
    - SCC is locally invasive and metastasis rate is low; no need for chemotherapy or radiation therapy.
- Subungual melanoma
    - Radical surgical excision of both malignant and benign areas
    - Follow-up chemotherapy or radiation therapy

PROGNOSIS AND OUTCOME

- Bacterial claw infections
    - Generally good for complete resolution
    - Protracted therapy (about 3 to 6 months) may be necessary.
    - Response may be influenced by underlying immunosuppressive factors.
- Onychomycosis
    - Prognosis is good to guarded, owing to incomplete resolution in dermatophytic onychomycosis.
    - May require either P3 amputation or pulse antifungal therapy for life
    - Prognosis for *Malassezia* is good if underlying etiology is addressed.
    - Response may be influenced by underlying etiologies or immunosuppressive factors.
- SLO
    - Chronic and recurrent problem if not treated
    - Clinical improvement is usually seen within 3 to 4 months; if not, change therapies.
    - Claw regrowth is good, although claws may be slightly deformed or friable.
    - Refractory cases may require P3 amputation.
- Subungual SCC
    - Locally invasive with low metastatic potential: regional node or distant metastasis in <30% of cases
    - The 1- and 2-year survival rates are 95% and 75%, respectively, if subungual. Rates are 60% and 40%, respectively, if not specifically from the subungual region, as determined via dermatohistopathologic exam.
- Subungual melanomas
    - Good if benign; poor if malignant. About 50% of dogs die because of distant metastasis.

PEARLS & CONSIDERATIONS

COMMENTS

- When reevaluating the claws, look for normalization of growth patterns at the base of the claw.
- In SLO, taper immunomodulatory medications gradually, and treat for several months beyond clinical resolution.

TECHNICIAN TIP

Shortening claws using a claw file or Dremel tool tends to be more readily accepted by pets affected with fragile claws.

PREVENTION

Routine claw care will result in early detection of claw and claw bed disorders.

CLIENT EDUCATION

Patience is required, as claws grow slowly.

EDITOR: MANON PARADIS

Citrus Oil Extract Toxicosis

BASIC INFORMATION

DEFINITION

Adverse effects typically caused by excessive dermal exposure of D-limonene. Typical signs of intoxication are excessive salivation, weakness, ataxia, hypothermia, tremors, and erythema. Clinical signs are usually temporary, and an affected animal generally recovers fully within a few hours to a couple of days. Toxicosis usually occurs when concentrated products are not diluted properly.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats of all ages, breeds, and both sexes are vulnerable.
- Cats are more sensitive than dogs.

RISK FACTORS

- Inappropriate dilution or excessive use (i.e., more than 5 to 10 times the manufacturer's recommended use)
- Risk of D-limonene or linalool toxicity increases when formulated with other solvents or essential oils

GEOGRAPHY AND SEASONALITY

Toxicosis more prevalent in summer months during flea season

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of exposure (use of spray, shampoo, or dip containing citrus oil extracts)
- Hypersalivation, hypothermia, muscle weakness
- Ataxia and tremors

PHYSICAL EXAM FINDINGS

- A distinct citrus smell virtually always is present on the animal and is an important diagnostic finding.
- Hypersalivation
- Muscle weakness
- Tremors, shivering, or ataxia
- Body temperature: mild to severe hypothermia
- Irritation of eyes and skin. Cutaneous erythema, especially in the scrotal and perineal areas, is a common finding.

ETIOLOGY AND PATHOPHYSIOLOGY

- Crude citrus oil extracts including D-limonene and linalool have some insecticidal properties and are used in shampoos, sprays, or dips for control of fleas on dogs and cats.
- Concentration of D-limonene and linalool in most sprays is less than 1%. Shampoos usually contain D-limonene 5%. Some dips contain 78.2% D-limonene and must be diluted before use on animals.
- Limonene (occurs in D or L form) is a monoterpene that occurs naturally in some fruits (citrus), trees, and bushes. It is commonly used as a flavoring agent, fragrance, feed additive, and in many household cleaning products.
- Linalool is found in nature as a monoterpene in volatile oils, various herbs, leaves, flowers, wood, and citrus products. It is used as a fragrance in soaps, detergents, and perfumes and as a flavoring agent in beverages, chewing gum, and candy.
- The exact mechanism of action of these products in mammals is not clear. Linalool has been ruled out to be a cholinesterase inhibitor.
- It has been suggested that these products cause centrally and peripherally acting vasodilation, resulting in hypothermia and muscle weakness.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Suspect toxicosis based on history and exam: history/evidence of exposure, presence of citrus-like smell on the skin, and any combination of hypersalivation, erythema, hypothermia, hypotension, and weakness.

DIFFERENTIAL DIAGNOSIS

- Intracranial disease
- Toxicosis from pyrethrins/pyrethroids
- Portosystemic shunt

INITIAL DATABASE

- The diagnosis is generally established based on history and physical exam alone. Additional diagnostic testing may be used for ruling out other disorders with similar presenting signs.
- CBC, serum biochemistry profile, urinalysis: typically unremarkable

TREATMENT

TREATMENT OVERVIEW

Treatment consists of providing supportive care (intravenous fluids, maintaining body temperature and blood pressure within the normal range) as needed and dermal decontamination. Hospitalization may be necessary only for very severe cases.

ACUTE GENERAL TREATMENT

- Dermal decontamination:
  - In case of dermal exposure, it is recommended to bathe the patient with an unmedicated detergent or soap and warm water. Drying the patient thoroughly is essential to minimize the risk of hypothermia. Bathing can be repeated until the citrus smell is gone.
- Thermoregulation:
  - Keeping the patient warm and monitoring the body temperature frequently are essential to minimize hypothermia while not overcompensating and causing hyperthermia.
  - Use of heating pads as needed and warm water enema if hypothermia is severe should be considered. However, warm water enema usage will eliminate rectal temperature as a reliable way of measuring core body temperature.
  - Avoid overcompensation (risk of iatrogenic hyperthermia). Active rewarming of the patient should be terminated and switched to passive warmth retention with ongoing monitoring, once the body temperature >98° F (36.7° C).
- Supportive care:
  - Intravenous fluids if necessary (e.g., dehydration, hypotension, electrolyte deficits)

PROGNOSIS AND OUTCOME

- Usually good to excellent; recovery within hours to a couple of days
- Deaths have been reported in cats.

PEARLS & CONSIDERATIONS

COMMENTS

- Animals treated with citrus oil extracts have a distinct smell.
- Hypersalivation is an immediate sign of D-limonene toxicosis in cats; it may last from 15 minutes to 1 hour. Severely affected cats show hypothermia and tremors.
- Linalool exposure produces signs that are more severe and last for longer duration than D-limonene.
- D-limonene and linalool are well absorbed orally.
- When dips are used in higher concentration than recommended, limonene may be absorbed in significant quantities through

the skin, causing systemic effects.

PREVENTION

Follow manufacturer's instructions for dilutions.

EDITOR: SAFDAR A. KHAN

1ST EDITION AUTHOR: MOAZZAM KHAN

Cirrhotic/Fibrosing Liver Disease

BASIC INFORMATION

DEFINITION

- Fibrosis: replacement of hepatic parenchyma with extracellular matrix (ECM), collagen, and connective tissue
- Cirrhosis: diffuse hepatic fibrosis with concurrent formation of regenerative nodules that results in irreversible loss of normal hepatic architecture
- Sometimes referred to as *primary hepatitis,* this disorder is being recognized with increasing frequency in a variety of breeds.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Incidence is highest in middle-aged to older dogs (>7 years) with chronic liver disease.
- Middle-aged cats with chronic cholangiohepatitis may suffer from biliary cirrhosis.
- Copper storage hepatopathy (~1-5 years) and idiopathic fibrosis are seen in younger dogs (<2 years).
- Male cocker spaniels, female Doberman pinschers, and Labrador retrievers appear more susceptible.

GENETICS & BREED PREDISPOSITION

- Doberman pinschers, cocker spaniels, Scottish terriers, and Labrador retrievers have a familial predisposition for chronic active (idiopathic) hepatitis (see online chapters: Hepatitis [Chronic] of Doberman Pinscher Dogs and Hepatitis [Chronic] of Cocker Spaniel Dogs).
- Copper storage disease is inherited in Bedlington terriers, West Highland white terriers, Skye terriers, and dalmatians.
- German shepherds and standard poodles develop juvenile idiopathic hepatic fibrosis.

RISK FACTORS

Idiopathic chronic hepatitis (chronic active hepatitis) in dogs, excess hepatic copper or iron storage, extrahepatic biliary obstruction, drug administration (phenobarbital, others)

ASSOCIATED CONDITIONS & DISORDERS

- Portal hypertension, ascites, hepatic encephalopathy, coagulopathies, urolithiasis, acquired portosystemic shunts, gastric ulceration, fat malabsorption and steatorrhea, hypoglycemia, and hypoalbuminemia may result from fibrosing liver disease.
- Rare occurrence of pulmonary edema (hypoalbuminemia), renal failure (hepatorenal syndrome), or transient erythropoietic protoporphyria

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Chronic condition of variable intensity that usually includes lethargy, anorexia, and weight loss
- Vomiting, diarrhea, melena, and polyuria/polydipsia also frequently are part of the history.
- Icterus or signs of coagulopathy uncommonly are reported by owners.
- Owners may report abdominal distension from ascites as “weight gain,” even as the patient loses muscle mass.

PHYSICAL EXAM FINDINGS

- May be unremarkable except for weight loss and muscle wasting
- Icterus occurs commonly.
- Ascites and evidence of coagulopathy in advanced cases
- Microhepatia may be present (dogs), although cats with biliary cirrhosis may have large livers.
- Manifestations of cerebral dysfunction (depression, stupor, others) due to hepatic encephalopathy (see p. 501)

ETIOLOGY AND PATHOPHYSIOLOGY

- ECM deposition (fibrosis) is stimulated by inflammatory mediators (or congenital or idiopathic).
- Chronic fibrosis and regenerative nodule formation results in cirrhosis. Chronic progressive collagen deposition irreversibly destroys normal hepatic architecture.
- Normal hepatic blood flow and bile flow are disrupted, perpetuating hepatocellular injury.
- Any chronic inflammatory hepatic condition may be responsible, although a specific cause is not often identified (i.e., idiopathic).
- Possible underlying etiologies include cholangitis/cholangiohepatitis (cats), copper storage disease (dogs), drugs and/or toxins (aflatoxin, anticonvulsants, azole antifungals, trimethoprim-sulfa), immune-mediated, leptospirosis, canine infectious hepatitis, hypoxia, extrahepatic biliary obstruction, or a single episode of massive hepatic necrosis (i.e., postnecrotic cirrhosis).
- Hepatic vascular resistance may increase, resulting in portal hypertension, ascites, acquired shunts, and encephalopathy.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Although plasma markers of this condition are being developed (transforming growth factor beta-1), histopathologic analysis of a liver biopsy specimen remains central to the diagnosis of this disorder. It is particularly important to look for excess copper accumulation as a treatable cause of progressive hepatic lesions.

DIFFERENTIAL DIAGNOSIS

- Chronic active/idiopathic hepatitis (dogs)
- Cholangitis/cholangiohepatitis (cats)
- Noncirrhotic portal hypertension
- Biliary obstruction
- Pancreatitis
- Hepatic neoplasia (primary or metastatic)
- Feline infectious peritonitis, toxoplasmosis
- Chronic fibrosing pancreatitis
- Congenital portosystemic shunt
- Hepatic lipidosis (cats)

INITIAL DATABASE

- CBC:
  - Nonregenerative anemia (normocytic, normochromic, or microcytic)
  - Acanthocytes (cats)
- Serum biochemistry panel:
  - Elevated hepatic enzyme activities (alkaline phosphatase, alanine aminotransferase, aspartate aminotransferase, γ-glutamyl transferase)
  - Hyperbilirubinemia
  - Low blood urea nitrogen (BUN) (variable)
  - Hypoalbuminemia and hyperglobulinemia (variable)
  - Hypocholesterolemia (variable)
  - Hypoglycemia (variable)
  - Electrolyte abnormalities (hypokalemia, hyponatremia)
- Urinalysis:
  - Isosthenuria
  - Ammonium biurate crystalluria (variable)

ADVANCED OR CONFIRMATORY TESTING

- Abdominocentesis and fluid analysis of ascites: pure transudate (hypoalbuminemia) or modified transudate (portal hypertension)
- Coagulation studies: prolonged activated clotting time, partial thromboplastin time (PT), activated partial thromboplastin time (APTT), proteins induced by vitamin K antagonism or absence (PIVKA), buccal mucosal bleeding time. Of these, the PIVKA test is most sensitive, although PT and APTT are acceptable and more readily available. It has not been shown that any of these studies will help predict bleeding following hepatic biopsy.
- Serum bile acids: elevated (fasting and postprandial). Bile acids will be abnormal (and therefore an unnecessary test) in cases where the total bilirubin concentration is elevated.
- Radiographs: small liver (dogs), large liver (cats), loss of abdominal detail

- Abdominal ultrasound:
  - Nodular hyperechoic/mixed echogenicity of hepatic parenchyma with abdominal effusion
  - Acquired portosystemic shunt(s)
  - Possible ascites
- Ultrasound-guided percutaneous gallbladder aspirate
- Laparoscopy or laparotomy:
  - Small, firm, irregular liver
- Liver biopsy for histopathologic analysis: confirmatory
  - Fibrosis: inflammatory (bridging) or noninflammatory (sinusoidal, triads)
  - Cirrhosis, nodular regeneration, loss of normal hepatic architecture
  - Note: suspicion of cirrhotic/fibrosing liver disease should prompt the consideration of wedge biopsy of the liver rather than ultrasound-guided core biopsy, because a firm, severely fibrotic liver may be difficult to penetrate safely with core biopsy instruments, especially if ascites is present. Additionally, needle core biopsies are often inaccurate in cirrhotic livers.

TREATMENT

TREATMENT OVERVIEW

Very few treatment options are proven to directly impact the progression of this condition unless a specific etiology (e.g., copper accumulation, drug-induced) can be targeted. Fortunately, very few of the myriad of potentially beneficial nonspecific treatments (e.g., antioxidants, liver protectants) are thought to have significant adverse effects.

ACUTE GENERAL TREATMENT

- Intravenous fluids (balanced electrolyte solution) as needed:
  - Avoid 0.9% NaCl with ascites and hypoalbuminemia.
  - Avoid lactate with hepatic failure.
  - Potassium (20-40 mEq/L or more, based on serum potassium concentration) and dextrose (2.5%-5%) supplementation may be necessary.
  - Dextrans, hetastarch, or plasma transfusion for oncotic pressure support
    - Plasma advantages include presence of albumin (contributes positively to protein balance), presence of clotting factors, and persistence in circulation (versus protein-losing enteropathy or nephropathy, in which the transfused proteins may be lost quickly); drawbacks include cost and short shelf life (fresh) or need to freeze (fresh frozen).
- Therapeutic abdominocentesis when necessary (i.e., respiratory compromise, significant abdominal discomfort); (see p. 1192)

CHRONIC TREATMENT

See also Hepatic Encephalopathy, p. 501.

- Antibiotics:
  - Specific to infectious agent if identified as underlying etiology (rarely in dogs)
  - For signs of hepatic encephalopathy, consider:
    - Metronidazole (7.5 mg/kg PO q 12 h), *or*
    - Amoxicillin-clavulanate (15 mg/kg PO q 12 h), *or*
    - Ampicillin (20 mg/kg PO q 8 h), *or*
    - Neomycin (20 mg/kg PO q 8 h)
- Antiinflammatory: with histopathologic confirmation of chronic noninfectious inflammation, consider prednisolone (1-4 mg/kg PO q 24-48 h, taper if possible) and/or azathioprine (1 mg/kg PO q 24-48 h).
- Antifibrotic: Colchicine (0.03 mg/kg PO q 24 h), although no published data support its use or clearly demonstrate a beneficial effect; veterinary data regarding safety and efficacy are lacking at present. Prednisone (antiinflammatory) and D-penicillamine (copper chelator; 10-15 mg/kg PO q 12 h) also have antifibrotic properties.
- Lactulose (0.25-0.5 mL/kg PO q 8 h, titrated to achieve loose fecal consistency) with cleansing and/or retention enemas (povidone-iodine diluted 1:10 with tap water or lactulose diluted 1:3 with tap water) to decrease ammonia production/absorption in cases of hepatic encephalopathy. Generally, patients with advanced disease requiring this level of therapy have a grave prognosis.
- Ursodiol (10-15 mg/kg PO q 24 h) as a choleretic in cases of cholestasis
- Alpha-tocopherol (200-600 IU PO q 24 h), *S*-adenosylmethionine (20 mg/kg PO q 24 h), and milk thistle/silymarin (optimal dose unknown) may act as hepatoprotective antioxidants.
- Spironolactone (1-2 mg/kg PO q 12 h) or furosemide (1-2 mg/kg PO q 12 h) in cases of ascites
- Vitamin K1 (1-2 mg/kg SQ or IM) if overt clinical bleeding is identified or if PT or APTT are prolonged greater than twice

normal
- Sucralfate (1 g/25 kg PO q 8-12 h) and/or famotidine (Pepcid 0.5 mg/kg q 24 h) as gastrointestinal ulcer therapy

NUTRITION/DIET

- Most commercial geriatric, liver, or renal diets are appropriate.
- Adjust protein consumption in the face of hepatic encephalopathy (decreased/optimal quantity, replace meat proteins with dairy and/or vegetable protein).
- Fermentable fiber in cases of hepatic encephalopathy
- Water-soluble vitamin supplementation
- Avoid mineral supplements containing copper.

DRUG INTERACTIONS

- Animals with hepatic failure are anesthetic risks. Barbiturates should be avoided, and benzodiazepines should be used with care. Isoflurane or sevoflurane are the gas anesthetics of choice. Propofol, although hepatically metabolized, may be administered to effect (usually requiring a small fraction of normal doses) for controlling seizures due to hepatic encephalopathy.
- Lidocaine, theophylline, propranolol, captopril, and tetracyclines should be avoided.
- Diuretics may worsen hepatic encephalopathy, promote dehydration or metabolic alkalosis, and should be used only in otherwise stable patients for the long-term delay of return of ascites.
- Corticosteroids should be avoided in animals with active infection, may precipitate hepatic failure and/or gastric ulceration, and cause sodium retention (may use dexamethasone [no mineralocorticoid activity] as an alternative to prednisone).
- Nonsteroidal antiinflammatory drugs may exacerbate gastrointestinal ulceration.
- Avoid medications that rely solely or predominantly on hepatic metabolism for effectiveness or clearance.

POSSIBLE COMPLICATIONS

Hepatic encephalopathy, septicemia, hemorrhage/coagulopathy, disseminated intravascular coagulation

RECOMMENDED MONITORING

Body weight, abdominal girth, liver enzymes, albumin, BUN, and bile acids should be monitored on a monthly basis.

PROGNOSIS AND OUTCOME

- In one report, 94% of dogs with hepatic fibrosis/cirrhosis were dead within 1 week of diagnosis.
- Dogs with idiopathic hepatic fibrosis/cirrhosis have been reported to survive for up to 6 years, and intensive therapy may extend the survival of cirrhotic patients, although the prognosis is usually very poor with advanced disease.
- Histopathologic findings may be helpful as a prognostic indicator.
- Patients that are anorectic, patients with hepatic fibrosis/cirrhosis causing clinical signs of hepatic encephalopathy, the presence of a coagulopathy (prolonged PT, APTT, or thrombocytopenia), ascites, hypoglobulinemia, or with histologically severe changes (cirrhosis, advanced fibrosis) usually have a poor prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- Hepatic fibrosis and cirrhotic changes indicate a progressive, terminal condition that is unfortunately often not recognized or appreciated until the patient is in an advanced state of the disease. An underlying etiology is not often identified, making specific therapy impossible. A histopathologic diagnosis is essential in cases of suspected hepatic fibrosis/cirrhosis.
- Even with severe cirrhotic/fibrosing liver disease, patients may have little active liver inflammation and therefore can have normal or near-normal serum liver enzyme activities.
    - Bile acids (especially postprandial) are much more sensitive for detection.

PREVENTION

- Being aware of breed predispositions and early testing of appropriate animals (i.e., Bedlington terriers) may lead to early intervention.
- Avoid oversupplementation with copper-containing products.

CLIENT EDUCATION

Encephalopathic patients that can be clinically stabilized need attention to nutrition: even extremely small amounts of meat protein (e.g., one small meat-based treat) may precipitate severe signs of hepatic encephalopathy.

Chylothorax

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Accumulation of fluid with a high triglyceride concentration (chyle) within the pleural space

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Cats and dogs of any age can develop chylothorax.
- Some diseases associated with chylothorax are more common in middle-aged to older patients.

GENETICS & BREED PREDISPOSITION

Possible breed predispositions include Afghan hounds and Shiba Inu dogs, and purebred cats, especially Asian breed cats.

RISK FACTORS

- Trauma
- Intestinal or generalized lymphangiectasia
- Congestive heart failure (CHF); cats more commonly develop chylothorax as part of CHF than dogs do.
- Thoracic neoplasia
- Thoracic surgery if there is damage to the left brachiocephalic vein

ASSOCIATED CONDITIONS & DISORDERS

Fibrosing pleuritis

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Typical clinical signs include:
  - Tachypnea
  - Increased inspiratory effort
  - Shallow respiration
  - Restrictive breathing pattern
  - Open-mouth breathing
  - Lethargy or exercise intolerance
  - Coughing
  - Possibly cyanosis
- Some animals, especially cats, may show minimal clinical signs until effusion volume is quite large.

PHYSICAL EXAM FINDINGS

- Respiratory distress
- Thoracic auscultation:
  - Muffled heart and lung sounds ventrally
    - Careful auscultation for cardiac murmurs or arrhythmias is warranted, or for displacement of heart sounds to one side or caudally that may suggest a mass effect.
  - Increased bronchovesicular lung sounds dorsally
  - Abnormalities of thoracic auscultation can be very subtle in cats.
- Thoracic percussion: hyporesonance ventrally
- Jugular vein distension or pulsation may be present in animals with heart failure or pericardial disease.
  - Large-volume pleural effusions can contribute to increased central venous pressure and possibly jugular venous distention (i.e., appearance is identical to that seen when the jugular vein is raised manually for blood sampling) or

jugular pulsation.
    - Radiation of a normal carotid pulse to the overlying jugular vein should not be misinterpreted as jugular pulsation.
- Peripheral lymphadenomegaly may be noted with some causes of thoracic neoplasia.
- Peritoneal effusion
- Decreased cranial thoracic compressibility (cats) if associated with mediastinal mass

ETIOLOGY AND PATHOPHYSIOLOGY

- Chyle is the fluid formed from lymphatic drainage of the gastrointestinal tract (composed of lymph and chylomicrons), which is collected in a small abdominal reservoir, the cisterna chyli. The sole outflow of the cisterna chyli is the thoracic duct, a single or paired structure that courses dorsally though the thorax and empties into the cranial vena cava.
- Impaired or disrupted lymphatic drainage:
    - Trauma and subsequent rupture of the thoracic duct
    - Neoplasia, including mediastinal, thoracic wall, or affecting thoracic duct
    - Thoracic lymphangiectasia
        - May be associated with intestinal lymphangiectasia
    - Infectious causes such as fungal granulomas
- Increased central venous hydrostatic pressure (thoracic duct empties into cranial vena cava):
    - CHF (right-sided in dogs, left or right-sided in cats)
    - Pericardial disease:
        - Pericardial effusion
        - Restrictive pericardial disease
    - Pulmonary thromboembolism
    - Heartworm disease
- Chylothorax has been reported in a small number of dogs post lung-lobe torsion correction.
- In many cases, the cause of chylothorax cannot be determined (classification as idiopathic).
- Pleural effusion causes hypoxemia through a combination of hypoventilation and ventilation/perfusion mismatching.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Patients with chylothorax will typically present with clinical signs of pleural effusion, and the presence of the effusion can be confirmed by imaging (radiographs, ultrasonography) or thoracocentesis. The confirmation of chylous fluid is achieved via fluid analysis and the comparison of serum and fluid triglyceride levels.

DIFFERENTIAL DIAGNOSIS

- Other causes of pleural effusion:
    - Hypoalbuminemia
    - CHF
    - Intrathoracic neoplasia
    - Lung-lobe torsion
    - Pyothorax
    - Pseudochylothorax
    - Hemothorax
- Pneumothorax
- Pulmonary parenchymal disease

INITIAL DATABASE

- Thoracic radiographs:
    - Interlobar fissure lines
    - Reduced visualization of the heart, especially on dorsoventral views
    - Retraction of lung margins from the thoracic wall, with an interposed fluid opacity
    - Blunting of the lung margins at the costophrenic angles
    - Increased opacity dorsal to the sternum on lateral views, with rounding of the lung margins ventrally
    - The diaphragm is often obscured.
    - Widened mediastinum
    - Avoid ventrodorsal views, as this increases the risk of respiratory distress.
- Thoracocentesis: chyle is often grossly white or pink and opaque and remains so after centrifugation.
    - Chyle may be classified as a modified transudate (<3000-5000 nucleated cells/mcL) or a nonseptic exudate (>5000

nucleated cells/mcL).
    - Early chylothorax usually has a predominance of lymphocytes.
    - With chronicity, increased numbers of nondegenerate neutrophils and some macrophages may appear.
- Postdrainage thoracic films are advised to check for radiographic signs of pulmonary parenchymal, mediastinal, or cardiac disease.
    - Atelectatic lung lobes may give a false impression of lung masses.
    - Fibrosing/constrictive pleuritis secondary to chronic chylothorax may prevent complete reexpansion post drainage and can cause many of the radiographic abnormalities seen with pleural fluid.
- Thoracic ultrasonography can detect pulmonary or mediastinal masses/lesions, lymphadenomegaly, pulmonary consolidation, lung-lobe torsion, or confirm presence of effusion if in doubt.
    - If the patient is stable, ultrasound is ideally performed before effusion is completely drained to provide an acoustic window.
    - Thoracic ultrasound can detect small volume effusions, guide thoracocentesis if fluid is compartmentalized, or guide fine-needle aspiration of masses or other pathology.

ADVANCED OR CONFIRMATORY TESTING

- CBC:
    - Lymphopenia is possible.
    - Leukogram changes are rarely specific.
- Serum biochemistry profile:
    - Hypocalcemia and hypoalbuminemia/hypoproteinemia are possible if chylothorax is secondary to intestinal lymphangiectasia.
- Urinalysis: generally unremarkable
- Echocardiography can help rule in or rule out myocardial, valvular, or pericardial disease as the cause.
- Biochemical analysis of pleural fluid:
    - Compared to serum concentrations, increased pleural fluid triglyceride and decreased pleural fluid cholesterol levels are consistent with chylous effusion.
- Pseudochylous effusions (rare) have a pleural-fluid cholesterol concentration greater than the serum cholesterol concentration, and pleural-fluid triglyceride concentration lower than the serum triglyceride concentration.
- Occasionally in fasted or anorexic animals, pleural fluid is not milky and can have a reduced triglyceride concentration; consider checking the pleural fluid and serum triglyceride levels postprandially.
- CT or MRI may aid assessment of structural abnormalities in the thoracic cavity.

TREATMENT

TREATMENT OVERVIEW

Treatment of chylothorax is directed at two principal goals: alleviation of signs of respiratory distress when present, and identification and treatment of an underlying cause when one exists.

ACUTE GENERAL TREATMENT

- Oxygen if respiratory distress
- Thoracocentesis is the initial therapy of choice.
    - Complete drainage is not necessary to relieve/improve clinical signs and may be hazardous if fibrosing pleuritis is present, limiting the degree of lung expansion.

CHRONIC TREATMENT

- Specific treatment of the underlying disease, when identified, may be enough to resolve chylothorax.
- Intermittent thoracocentesis during the treatment period may be needed as respiratory signs dictate.
    - If regular thoracocentesis is performed, monitor electrolytes; hyponatremia (secondary to loss in pleural fluid) and hyperkalemia (secondary to reduced renal excretion) can develop.
- If fluid accumulation is rapid, thoracostomy tubes may be required.
- If the underlying disease cannot be determined, medical therapy may be attempted initially.
    - A low-fat diet, either commercial or homemade, helps reduce the flow of chyle.
    - Rutin (50 mg/kg PO q 8 h) has been used for treating lymphedema in humans and has been used in canine and feline chylothorax with some apparent success and no documented adverse effects.
- If medical therapy is unsuccessful, surgical intervention is indicated.
    - Some clinicians advocate surgical intervention as the initial treatment of choice to reduce the risk of fibrosing pleuritis.
    - The optimal timing for surgery in chylothorax is controversial and remains undetermined. Delaying surgery increases

the risk of development of fibrosing/restrictive pleuritis.
    - The most common procedure is ligation of the thoracic duct and its branches, often in combination with lymphangiography.
        - Thoracic duct rupture is rarely detected by lymphangiography.
        - Ligation is accomplished via an intercostal or transdiaphragmatic approach.
        - Lymphangiography is often repeated after ligation to ensure all branches have been ligated.
        - Success rates reported for cats vary from 20%-53% (complete resolution).
        - For dogs, resolution rate is reported at 53%.
        - En bloc ligation of the thoracic duct without lymphangiography has been described in dogs, with similar success rates (50%).
    - After ligation, abdominal lymphaticovenous anastomoses form to transport chyle to the venous system, bypassing the thoracic duct.
    - Thoracoscopic thoracic duct ligation combined with mesenteric lymphangiography has been described.
- A number of other techniques have been suggested in combination with thoracic duct ligation.
    - Pleurodesis promotes development of diffuse adhesions between the parietal and visceral pleura but is not recommended.
    - Passive pleuroperitoneal drainage techniques have been described, but success rates are low, owing to drain obstruction.
    - Active pleuroperitoneal or pleurovenous drainage techniques have been used, but disadvantages include cost, thrombosis, catheter obstruction, air embolism, venous occlusion, sepsis, abdominal distension (if pleuroperitoneal), and potential lack of owner compliance.
    - Omentalization of the pleural space exploits the large surface area and lymph-draining capability of the omentum.
    - Thoracic duct ligation with pericardectomy has been recently reported.
        - A thickened pericardium may increase right-sided venous pressures, impeding drainage of chyle after thoracic duct ligation.
        - Reported success rates approach 100% for dogs and 80% for cats.

POSSIBLE COMPLICATIONS

- Incomplete resolution of chylothorax can occur with any treatment technique.
- Surgical and anesthetic risks for invasive procedures
- Fibrosing pleuritis, pleural thickening by fibrous tissue that restricts normal lung expansion, is a consequence of chronic chylothorax.

RECOMMENDED MONITORING

- Clinical signs
- Thoracic radiographs to assess pleural fluid accumulation/resolution
- Postoperative patients should also be monitored for reaccumulation of fluid.

PROGNOSIS AND OUTCOME

- Some patients will have resolution of chylothorax if the underlying disease can be corrected.
- For patients with idiopathic chylothorax or thoracic lymphangiectasia, the described approach of combining pericardectomy with thoracic duct ligation appears to show the best results.
- If the underlying disease cannot be managed successfully, the prognosis is poorer.

PEARLS & CONSIDERATIONS

COMMENTS

- Cats with pleural effusion can be clinically fragile and must be handled carefully if dyspneic (e.g., during restraint).
- Long-standing chylous pleural effusion can lead to fibrotic pleural disease, an irreversible cause of respiratory impairment.

PREVENTION

There is no reliable means of preventing the development of chylothorax.

TECHNICIAN TIPS

- Animals with large-volume pleural effusions can be very fragile and susceptible to stress with handling. Therefore minimal handling is important.
- Supplemental oxygen can be very helpful in a dyspneic patient with pleural effusion.
- Avoid dorsal recumbency for radiographs in animals with pleural effusions.
- The basics for an emergency thoracocentesis include clippers, skin preparation materials, a butterfly needle or needle with an extension set, three-way stopcock, and syringes.
- The complications of thoracocentesis include pneumothorax and hemothorax. If the patient suddenly develops a high respiratory rate or effort after pleural drainage, alert your clinician as soon as possible.

CLIENT EDUCATION

Chylothorax can be a frustrating disease and requires diagnostic assessment to identify treatable underlying causes.

AUTHOR: GRAHAM SWINNEY

EDITOR: RANCE K. SELLON

Chronic Kidney Disease, Overt (“Symptomatic”)

BASIC INFORMATION

DEFINITION

- Chronic kidney disease (CKD): kidney damage present for over 3 months. Azotemia and/or inadequately concentrated urine (specific gravity <1.035 in cats; <1.030 in dogs) is not necessary for CKD to be present.
- IRIS Staging System for CKD: classification scheme for CKD in dogs and cats is based on serum creatinine, with substages for proteinuria and blood pressure. Developed by International Renal Interest Society:
  - Stage I: creatinine <1.4 mg/dL, dogs; <1.6 mg/dL, cats. Nonazotemic. Some other renal abnormality present (e.g., inadequate concentrating ability without identifiable nonrenal cause; abnormal renal palpation and/or abnormal renal imaging findings; proteinuria of renal origin; abnormal renal biopsy results).
  - Stage II: creatinine 1.4-2 mg/dL, dogs; 1.6-2.8 mg/dL, cats. Mild renal azotemia (lower end of the range lies within the reference range for many labs, but the insensitivity of creatinine as a screening test means that animals with creatinine values close to the upper reference range often have excretory failure). Clinical signs usually mild or absent.
  - Stage III: creatinine 2.1-5 mg/dL, dogs; 2.9-5 mg/dL, cats. Moderate renal azotemia. Systemic clinical signs may be present.
  - Stage IV: creatinine >5 mg/dL dogs and cats. Severe renal azotemia. Many extrarenal clinical signs present.
- Overt CKD: CKD that is responsible for clinical signs in a patient. This generally corresponds to IRIS stage III or IV.
- Azotemia: elevated blood urea nitrogen and/or creatinine. Uremia is the constellation of clinical signs associated with renal failure (i.e., not all azotemic animals are uremic).
- CKD is one of the most common diseases of older cats and is very common in dogs.
- For information on incidentally discovered CKD (not producing overt signs), see p. 205.

SYNONYMS

Clinical CKD; decompensated CKD; symptomatic CKD; CKD: chronic interstitial nephritis, tubulointerstitial nephritis, nephrosclerosis, kidney failure; chronic renal failure (CRF; no longer a preferred term)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- More common in cats than in dogs
- Common in older animals but can occur in animals of any age

GENETICS & BREED PREDISPOSITION

- Increased frequency in Maine coon, Abyssinian, Siamese, Russian blue, and Burmese cats
- Familial nephropathies may lead to early-onset CKD. Familial nephropathies reported in Abyssinian cats, Persian cats, basenjis, beagles, Bedlington terriers, Bernese mountain dogs, boxer dogs, bull terriers, Cairn terriers, chow chows, cocker spaniels, Doberman pinschers, golden retrievers, keeshonds, Lhasa apsos, Newfoundlands, Norwegian elkhounds, Pembroke Welsh corgis, rottweilers, Samoyeds, shar-peis, shih tzus, soft-coated Wheaten terriers, standard poodles

RISK FACTORS

Advanced age, prior episode of acute renal failure, prior nephrotoxic exposure, pyelonephritis, nephrolith/ureterolith, glomerulonephritis, amyloidosis

ASSOCIATED CONDITIONS & DISORDERS

Anemia, dehydration, urinary tract infection, renal secondary hyperparathyroidism, systemic hypertension, hypokalemia, metabolic acidosis, ulcers (gastric or oral), vomiting, weight loss

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Incidentally diagnosed in apparently healthy animals (see p. 205)
- Overtly ill (“symptomatic”) but stable patients (managed as outpatients)
- Decompensated patients (require hospitalization until stabilized)

HISTORY, CHIEF COMPLAINT

(Some or all may be present.)

- Polyuria/polydipsia is common.
- Anorexia +/−
- Weight loss +/−
- Vomiting occurs in decompensated (uremic) animals.
- Lethargy +/−
- Halitosis +/−
- Altered consciousness (general dullness) often found in decompensated (uremic) animals
- Seizures (rarely seen in end-stage uremia)
- Bleeding problems (rarely spontaneous bleeding; increased risk of bleeding with invasive procedures)

PHYSICAL EXAM FINDINGS

(Some or all may be present.)

- Dehydration +/−
- Frequently: small, irregular kidneys; rarely large kidneys; in cats, renal asymmetry common with former obstructive nephropathy or chronic ascending pyelonephritis
- Signs of renal pain unusual
- Uremic halitosis +/−
- Oral ulceration with severe azotemia
- Poor haircoat +/−
- Poor body condition +/− mild pallor if anemic

ETIOLOGY AND PATHOPHYSIOLOGY

- CKD can be the end result of a variety of insults to the kidney, which may start as tubular, glomerular, or interstitial.
- Even if an inciting cause can be cured, after a certain amount of damage has been sustained, renal failure may be progressive (generally when creatinine >3.5 mg/dL).
- The specific etiology of CKD is frequently undetermined:
    - Tubulointerstitial nephritis most common cause (70% of cats, 60% of dogs)
    - Glomerulonephritis also a common cause (30% of dogs, 15% of cats)
    - Other demonstrable causes: amyloidosis, renal dysplasia, polycystic kidney disease, tubulonephrosis, lymphoma, chronic pyelonephritis, nephroliths or ureteroliths resulting in partial obstruction, vasculitis, infarction, and sequelae to acute renal failure with incomplete resolution
    - Obstructive nephropathy from ureterolithiasis is increasingly recognized in cats.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

CKD may be diagnosed based on structural (e.g., renal size/shape changes, polycystic disease) or functional (e.g., proteinuria, azotemia, inadequately concentrated urine) abnormalities. Azotemia is usually present in symptomatic patients.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of azotemia:

- Prerenal azotemia (dehydration, hypoadrenocorticism, gastrointestinal bleeding)
    - Urine specific gravity is usually > 1.030 (dogs) or > 1.035 (cats)
- Renal azotemia (acute renal failure, chronic kidney disease)
- Postrenal azotemia (urinary tract obstruction, rupture)
    - Dysuria and/or additional clinical pathologic abnormalities (e.g., hyperkalemia)

INITIAL DATABASE

- Assess hydration: azotemia may be caused or worsened by dehydration.
- Serum biochemical profile: azotemia, variable hyperphosphatemia, hypokalemia, hypercalcemia or hypocalcemia, metabolic acidosis are all common in overt CKD.
- CBC: anemia due to lack of erythropoietin (EPO), gastrointestinal (GI) bleeding, anemia of chronic disease common. EPO deficiency results in nonregenerative anemia with normal to increased total protein, whereas GI blood loss results in low total protein.
- Urinalysis: isosthenuric urine specific gravity typical. Active sediment may suggest urinary tract infection (UTI).
- Urine culture: incidental, clinically silent UTI may occur with CKD; pyelonephritis may be the cause of CKD.
- Thyroid level (elderly cats): rule out hyperthyroidism as concurrent disorder.
    - Correction of hyperthyroidism can worsen renal function in cats with CKD.
    - In cats that have both hyperthyroidism and CKD concurrently, treatment emphasis is placed on the disease most responsible for clinical signs.
- Blood pressure (BP): hypertension (systolic BP >160-180 mm Hg, diastolic BP >95 mm Hg) present in 20% of cats with CKD; may cause end-organ damage (especially heart, eyes, central nervous system, kidneys)
- Abdominal imaging: abdominal radiography or ultrasonography may further elucidate cause of CKD (i.e., obstructing or partially obstructing nephroliths or ureteroliths, renal neoplasia, cystic disease, perinephric pseudocysts). Alterations of shape, size, and echogenicity of kidneys are common.

ADVANCED OR CONFIRMATORY TESTING

- Urine protein/creatinine ratio. In dogs and cats with CKD, pathologic proteinuria (urine protein/creatinine [UPC] ratio >0.5 in dogs, >0.4 in cats; urinary sediment is inactive, and culture is negative) may indicate potential benefit from angiotensin-converting enzyme inhibition.
- Glomerular filtration rate (GFR) measurement: rarely measured when azotemia is present.
- Renal biopsy: indicated primarily with renomegaly (rule out lymphoma, feline infectious peritonitis, amyloidosis)

TREATMENT

TREATMENT OVERVIEW

The goals of treatment are to alleviate uremic signs and delay progression of kidney disease.

ACUTE GENERAL TREATMENT

- Compensated state: see Chronic Treatment below.
- Decompensated state (e.g., dehydrated, anorexic, vomiting):
    - Hospitalization is ideal, since oral therapies often are poorly tolerated
    - Rehydration over 24-36 hours usually appropriate
        - Intravenous crystalloid fluid therapy (e.g., lactated Ringer's solution, Plasmalyte, 0.9% saline).
        - Fluid rate: maintenance (66 mL/kg/d) plus replacement of dehydration (percent dehydration [as a decimal, e.g., 10% = 0.1] × kg body weight = liters deficit) plus ongoing losses (estimated volume of polyuria, vomiting).
    - Maintenance:
        - Maintenance rate plus 5%-6% body weight per 24 hours to promote diuresis
        - Practically, twice the calculated maintenance rate is sufficient for most after rehydration.
        - Potassium supplementation of fluids based on electrolyte measurement (not to exceed 0.5 mEq/kg/h; see p. 577).
    - Other treatments described for chronic therapy may be applicable (e.g., H2 blockers, antiemetics; see Chronic Treatment below), but injectable forms are used until oral medications are tolerated.

CHRONIC TREATMENT

- Delay of progression: see p. 205
- Additional therapies may be used, depending on presence of particular uremic signs.
    - Anorexia or vomiting: decrease gastric acidity. Histamine blockers (famotidine, 0.5 mg/kg IV, SQ, PO q 24 h; ranitidine, 0.5-2.5 mg/kg SQ, PO q 24 h [avoid rapid IV administration, which may cause nausea] q 12-24 h); or proton pump inhibitors (e.g., omeprazole, 0.7 mg/kg PO q 24 h).
    - Persistent vomiting: antiemetics (maropitant, 2 mg/kg PO q 24 h for 5 days approved for dogs only [often used off label for cats]; or metoclopramide, 0.2-0.4 mg/kg SQ q 6 h or 0.01-0.02 mg/kg/h as constant rate infusion; phenothiazines). 5HT serotonin antagonists for intractable vomiting (ondansetron, 0.22 mg/kg IV q 8-12 h, or dolasetron). GI ulceration (e.g., hematemesis, melena, anemia, elevated blood urea nitrogen/creatinine ratio): sucralfate, 0.25-1 g PO q 8 h until signs resolve.
    - Hyperphosphatemia: diet ± medications.

        - Phosphate binders to prevent absorption of phosphorus from ingested food
            - Aluminum hydroxide or aluminum carbonate, 30-90 mg/kg/d, divided and administered with meals; dose titrated based on serum phosphorus concentration).
            - Calcium acetate, 60-90 mg/kg/d; hypercalcemia possible side effect
            - Chitosan (Epakitin) 1 gram/5 kg twice daily with food
            - Lanthanum carbonate is a newer phosphate binder that is occasionally used in veterinary medicine (100 mg/kg/d PO).
    - Hypokalemia (more likely in cats than dogs): potassium gluconate (2 mEq per 4.5 kg per day) or potassium citrate (75 mg/kg PO q 12 h).
    - Acidosis (more likely in cats than dogs): consider treatment if total CO2 < 16 mEq/L or pH < 7.2. Potassium citrate, 75 mg/kg PO q 12 h (also addresses hypokalemia), sodium bicarbonate, 10 mg/kg PO q 12 h.
    - Anemia: transfusion based on clinical need. Darbepoetin (Aranesp 0.45-1 mcg/kg SQ q 7 days until hematocrit rises; then q 14-21 days to maintain low-normal hematocrit) plus iron supplementation can be used for stimulating red blood cell production. Risk of pure red cell aplasia from cross-reactive antibodies appears lower with darbepoetin, compared to human recombinant erythropoietin (Epogen, Procrit).
    - Hypertension: calcium channel blockers recommended. If proteinuria is present or calcium channel blocker is insufficient, add ACE inhibitor (see p. 1068).
    - Chronic dehydration or persistent signs of uremia: subcutaneous fluid administration. Dose is empirical, based on subjective assessment of the patient's well-being, hydration status, and presence of other disorders (e.g., heart disease). Typically for cats without heart problems, 100 to 150 mL daily to every other day.
    - Renal secondary hyperparathyroidism (see p. 976)
- Renal transplantation may be appropriate for some animals/owners. Maybe preceded by hemodialysis (see p.1286). Greatest chance of success in mildly to moderately azotemic cats without concurrent illness or infection.

NUTRITION/DIET

- Appropriate high-quality restricted protein and restricted phosphorus diets (“renal diet”) slow progression and decrease clinical uremia.
    - Acceptance of diet changes can be problematic, particularly in severely affected patients.
    - Maintaining adequate caloric intake to avoid weight loss takes precedence over nutrient composition of the diet (see p. 1377).
    - Renal diets should be introduced when uremia (illness) is minimized.
    - Nutritional support occasionally requires appetite stimulation (cats: cyproheptadine, 1 to 2 mg PO q 12 h; mirtazapine, 3.75 mg PO q 72-96 h) or tube feeding.

DRUG INTERACTIONS

- Phosphate binders can interfere with absorption of orally administered medications, especially antibiotics.
- Sucralfate works best in an acid environment and should be given at least 30 minutes before antacid therapy.
- Nephrotoxic drugs (e.g., aminoglycosides) or drug combinations (e.g., NSAIDs plus ACE inhibitors) should be avoided whenever possible.
- Drugs which undergo renal elimination may need adjustment in dose strength or frequency in animals with CKD.

POSSIBLE COMPLICATIONS

- Anorexia, vomiting, GI ulceration, hyperphosphatemia, hypokalemia, acidosis, anemia, and hypertension are common sequelae of CKD.
- Volume overload (pleural effusion, pulmonary edema, dyspnea, or peripheral fluid accumulation) is a concern at high rates of fluid administration, particularly in anemic animals or those with concurrent heart disease.
- Platelet dysfunction in CKD increases risks of bleeding (gingival, GI, bruising, bleeding after invasive procedures).

RECOMMENDED MONITORING

- Routine recheck, including physical exam, weight, chemistry panel, CBC, or packed cell volume. Frequency depends on disease severity.
    - Stage I-II: recheck every 6 months.
    - Stage III: recheck every 2-3 months.
    - Stage IV: recheck monthly.
- Urinalysis and urine culture should be performed at least twice a year.
- Blood pressure measurement should be performed at least every 3 months, or 1-week after antihypertensive drug dose adjustments.
- Changes in clinical signs warrant recheck as well.

PROGNOSIS AND OUTCOME

- Longevity is difficult to predict in an individual patient, with a range of days to years.
- Median survival times are 2 years in cats with stage III CKD and 1 month in cats with stage IV CKD.

PEARLS & CONSIDERATIONS

COMMENTS

- At an early stage of decompensation, renal transplant can be considered for otherwise healthy cats.
- Renal biopsy is rarely informative in cats with chronic kidney disease and small kidneys (the inciting cause is rarely identified).
- Urine culture and sensitivity in patients with CKD is essential at the time of diagnosis and periodically thereafter.
    - UTIs commonly occur without an active urine sediment on urinalysis in CKD patients.
    - Correction of the UTI may improve renal function if subclinical pyelonephritis is present; few other complicating factors can be treated so easily and effectively.

TECHNICIAN TIPS

Technicians can be invaluable in teaching owners how to administer subcutaneous fluids. They can also help emphasize the importance of allowing the animal a constant source of fresh water.

CLIENT EDUCATION

- CKD is in incurable condition in which treatments are aimed primarily at improving the quality of life.
- Renal transplantation is expensive and limited in availability. With successful renal transplant, intensive lifelong medication and frequent rechecks are required, but quality of life can be excellent.

Chronic Kidney Disease, Occult (“Asymptomatic”)

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Chronic kidney disease (CKD): kidney damage present for over 3 months. Azotemia and/or inadequately concentrated urine (specific gravity < 1.035 in cats; < 1.030 in dogs) is not necessary for CKD to be present.
- IRIS Staging System for CKD: classification scheme for CKD in dogs and cats is based on serum creatinine, with substages for proteinuria and blood pressure. Developed by International Renal Interest Society:
  - Stage I: creatinine < 1.4 mg/dL, dogs; < 1.6 mg/dL, cats. Nonazotemic. Some other renal abnormality present (e.g., inadequate concentrating ability without identifiable nonrenal cause; abnormal renal palpation and/or abnormal renal imaging findings; proteinuria of renal origin; abnormal renal biopsy results).
  - Stage II: creatinine 1.4-2 mg/dL, dogs; 1.6-2.8 mg/dL, cats. Mild renal azotemia (lower end of the range lies within the reference range for many labs, but the insensitivity of creatinine as a screening test means that animals with creatinine values close to the upper end of the reference range often have excretory failure). Clinical signs usually absent.
  - Stage III: creatinine 2.1-5 mg/dL, dogs; 2.9-5 mg/dL, cats. Moderate renal azotemia. Systemic clinical signs usually present.
  - Stage IV: creatinine > 5 mg/dL dogs and cats. Severe renal azotemia. Many extrarenal clinical signs present.
- Occult CKD: CKD in which no clinical signs are present. This generally corresponds to IRIS stage I or II.
- CKD is one of the most common diseases of older cats and is very common in dogs
- For information on CKD causing overt clinical signs, see p. 207.

SYNONYMS

Latent CKD, preclinical CKD, asymptomatic CKD, compensated CKD, incidentally discovered CKD, stage I or II CKD, chronic renal failure (CRF; this term is no longer preferred for use)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- More common in cats than dogs
- Any age, but more common in older animals

GENETICS & BREED PREDISPOSITION

Familial nephropathies are reported in a number of dog and cat breeds (see p. 207). These nephropathies may lead to an early onset of renal failure.

RISK FACTORS

Advanced age, prior episode of acute renal failure, prior nephrotoxic exposure, pyelonephritis, nephrolith/ureterolith.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Incidental CKD is usually detected via routine geriatric or preanesthetic screening, or during investigation of unrelated illness.

PHYSICAL EXAM FINDINGS

Frequently no abnormal physical exam findings. The patient may have small or irregular kidneys.

ETIOLOGY AND PATHOPHYSIOLOGY

- CKD can be the end result of a variety of insults to the kidney, which may start as tubular, glomerular, or interstitial, because each nephron works as a unit. If the glomerulus is irreversibly damaged, the associated tubule will degenerate, and vice

versa.
- As nephrons are lost, the remaining nephrons hypertrophy. Although initially adaptive, glomerular hypertension damages the nephron, leading to further nephron loss. After a certain amount of damage has been sustained (generally when creatinine > 3.5 mg/dL), kidney disease may be progressive despite resolution of initiating cause.
- The specific etiology of CKD is frequently undetermined:
  - Tubulointerstitial nephritis most common cause (70% of cats, 60% of dogs)
  - Glomerulonephritis also a common cause (30% of dogs, 15% of cats)
  - Other demonstrable causes: amyloidosis, renal dysplasia, polycystic kidney disease, tubulonephrosis, lymphoma, chronic pyelonephritis, nephroliths or ureteroliths resulting in partial obstruction, vasculitis, infarction, and sequelae to acute renal failure with incomplete resolution
  - Obstructive nephropathy from previous or current ureterolithiasis is increasingly recognized in cats.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

CKD may be diagnosed based on structural (e.g., renal size/shape changes, polycystic disease) or functional (e.g., proteinuria, azotemia, inadequately concentrated urine) abnormalities.

DIFFERENTIAL DIAGNOSIS

Azotemia:

- Prerenal azotemia (e.g., dehydration, high-protein diet, gastrointestinal bleeding), typically characterized by concentrated urine specific gravity
- Azotemia with inadequately concentrated urine may be due either to kidney disease or to dehydration (i.e., prerenal azotemia) combined with extrarenal impairment of urine concentration:
  - Drug therapy (e.g., diuretics, glucocorticoids)
  - Osmotic diuresis (e.g., diabetes mellitus)
  - Impaired medullary concentration gradient (e.g., hypoadrenocorticism, portosystemic shunting)
  - Central diabetes insipidus
  - Nephrogenic diabetes insipidus (e.g., hypercalcemia, pyometra, pyelonephritis)
- Postrenal azotemia (urinary obstruction, rupture) is generally easily differentiated from kidney disease by dysuria.

INITIAL DATABASE

- CBC: usually unremarkable; occasionally mild anemia
- Serum biochemistry profile: azotemia may or may not be present; sometimes hyperphosphatemia, hypokalemia.
- Urinalysis: frequently isosthenuric or minimally concentrated specific gravity (dogs <1.030; cats < 1.035). Active sediment may indicate urinary tract infection. Proteinuria can be quantified by urine protein/creatinine ratio
- Urine culture is indicated to rule out infection
- Abdominal radiographs or ultrasound: kidneys may be small and irregular or show other structural changes.
- Blood pressure: hypertension present in 20% of cats with stage I-II CKD and up to 75% of dogs with protein-losing nephropathy.

ADVANCED OR CONFIRMATORY TESTING

- Glomerular filtration rate (GFR) measurement: can confirm inadequate GFR, particularly when azotemia is mild and cause of impaired urine concentration unclear. Iohexol clearance, creatinine clearance, and nuclear scintigraphy are most commonly used.
- Urine protein/creatinine ratio; if increased when urine sediment exam is inactive, suggests glomerular disease
- CKD in cats may complicate the diagnosis of concurrent hyperthyroidism by suppressing total thyroxine. Combined measurement of free thyroxine with total thyroxine or thyroid-stimulating hormone are indicated to increase sensitivity of diagnosis for hyperthyroidism.

TREATMENT

TREATMENT OVERVIEW

The treatment goal is to slow progression of kidney disease.

ACUTE GENERAL TREATMENT

As patients are asymptomatic, acute treatment is not needed.

CHRONIC TREATMENT

- For dogs and cats with protein-losing nephropathy, angiotensin-converting enzyme inhibition (ACEi) may slow progression of renal failure (enalapril or benazepril, 0.25-0.5 mg/kg PO q 12-24 h).
- ACEi is not proven to slow progression of kidney disease in cats with UPC <0.4. It may play a beneficial role when proteinuria is present.
- As kidney disease progresses, animals may decompensate (show overt signs caused by CKD). See p. 207 for specific therapeutic recommendations.

NUTRITION/DIET

Restricted-quantity (but high-quality) protein and restricted-phosphorus diet (“renal diet”) slows progression in dogs with CKD:

- Although cats are obligate carnivores, and diet recommendations cannot be generalized, renal diets are recommended.
- There are many different brands of renal diet, and palatability varies with the individual patient.
- Homemade renal diets may also be used but should be formulated carefully.
- It is important to maintain adequate caloric intake.

DRUG INTERACTIONS

- Avoid nephrotoxic drugs (e.g., aminoglycosides) or drug combinations (e.g., nonsteroidal antiinflammatory drugs with ACEi).
- Dosage adjustment of most drugs is unnecessary.

RECOMMENDED MONITORING

- Stable patients with incidental CKD should be monitored every 6 months.
- Recheck should include body weight, CBC (or minimally packed cell volume), biochemical profile with electrolytes, and blood pressure measurement.
- Clinical signs of hypokalemia, hyperphosphatemia, anemia, and hypertension may not occur until devastating; early interventions can be based on detection by routine screening.
- Urinalysis and urine culture twice a year, owing to increased risk of clinically silent urinary tract infection.

PROGNOSIS AND OUTCOME

- Some animals with incidental CKD may remain stable and free of clinical signs for years, while others progress more rapidly.
- The rate of progression to overt CKD is unpredictable.
- Median survival time of cats with stage II CKD is 3 years (range: 1 month to 8 years)

PEARLS & CONSIDERATIONS

COMMENTS

Occult CKD may progress very slowly or more rapidly; the course of progression cannot be predicted. Advanced age, plasma creatinine, and proteinuria are generally associated with more rapid progression. If potentially nephrotoxic drugs are used (e.g., ACE inhibitors), ensure adequate hydration and monitor carefully for deterioration in renal function.

TECHNICIAN TIP

It is often best to find a renal diet palatable to the pet when renal disease is inapparent or mild, rather than waiting until the animal is overtly sick as a result of renal disease. The technician can help clients identify and try various renal diets.

CLIENT EDUCATION

Animals should be promptly presented for care for signs of clinical illness. Progression of renal failure may lead to decompensation, and patients with CKD are less able to cope with extrarenal illness. Vomiting from any cause may lead to dehydration, which may worsen renal function, leading to exacerbation of vomiting, anorexia, and dehydration. Prompt fluid therapy (either IV or SQ,

depending on severity and underlying illness) may be needed to stop the cycle.

Chondrosarcoma

BASIC INFORMATION

DEFINITION

Chondrosarcoma (CSA) is a malignant mesenchymal tumor that produces chon-droid and fibrillar matrix, but never osteoid.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- In dogs, CSA is the second most common primary bone tumor, accounting for 5%-10% of all primary bone tumors:
  - Median age is around 8 years, but CSA has been reported at ages ranging from 1 to 15 years.
  - There is no gender predilection.
- In cats, primary bone tumors are uncommon, and CSA is third in incidence behind osteosarcoma and fibro-sarcoma. CSA also can occur in the soft tissues at sites of previous vaccinations (see p. 610).

GENETICS & BREED PREDISPOSITION

- CSA is most common in medium- to large-breed dogs weighing between 20 and 40 kg.
- Mixed-breed dogs, golden retrievers, boxers, and German shepherd dogs are overrepresented.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- The majority of CSAs arise from flat bones. Approximately 30% occur in the nasal cavity, accounting for 15% of all nasal tumors; 20% of CSAs arise from the ribs, accounting for 30%-40% of all primary rib tumors.
- A total of 20% of CSAs arise from the appendicular skeleton, often but not always at sites where osteosarcoma typically occurs. CSA accounts for only 3%-5% of all primary bone tumors in the appendicular skeleton.
- Other reported sites include facial bones, skull, vertebrae, pelvis, digits, and os penis.
- Rarely, CSA can arise in soft tissue (extraskeletal) sites.

HISTORY, CHIEF COMPLAINT

- Patients often present with a visible mass at the affected site. Additional clinical signs vary with the site of skeletal involvement.
- Nasal CSA usually is associated with unilateral or bilateral epistaxis. Other clinical signs include sneezing, dyspnea, and swelling over the nasal cavity.
- Appendicular CSA usually is associated with lameness.

PHYSICAL EXAM FINDINGS

- Findings for CSA will depend on the anatomic location. Often, but not always, a firm to hard mass will be palpable.
- Patients with nasal CSA often have reduced airflow through the nares, and hemorrhagic discharge may be present. More advanced tumors may be associated with a visible mass effect (externally or orally). The ipsilateral eye may not retropulse or may be exophthalmic.
- Rib CSA most commonly arises near the costochondral junction. Any rib may be affected.
- Patients with appendicular and digitalCSA are variably lame, ranging from minimal to non–weight-bearing.

ETIOLOGY AND PATHOPHYSIOLOGY

Etiology is largely unknown. Osteochondromatosis (multiple cartilaginous exostoses) lesions can undergo malignant transformation into CSA or, less commonly, osteosarcoma.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

CSA is not the most common primary bone tumor, but it still should be considered as a differential whenever an aggressive bone lesion is identified and especially when the lesion involves the rib or nasal cavity. Histopathology is required to confirm the diagnosis.

DIFFERENTIAL DIAGNOSIS

- General differential diagnoses for aggressive bone lesions:
  - Other primary bone tumors (osteosarcoma, fibrosarcoma, hemangiosarcoma)
  - Metastatic bone tumors (transitional cell, prostatic, mammary, thyroid, anal sac apocrine gland carcinomas)
  - Tumors that locally invade adjacent bone (nasal carcinoma; oral squamous cell carcinoma, melanoma, fibrosarcoma, ameloblastoma; synovial cell sarcoma; histiocytic sarcoma; digital squamous cell carcinoma, melanoma)
  - Hematopoietic tumors (myeloma, lymphoma). Radiographic lesions typically are purely lytic.
  - Bacterial or fungal osteomyelitis
- Additional differentials for epistaxis:
  - Thrombocytopenia or coagulopathy
  - Fungal rhinitis (usually *Aspergillus*)
  - Systemic hypertension
  - Foreign body

INITIAL DATABASE

- Radiographic imaging of the primary tumor:
  - The aggressive bone changes associated with CSA are the same as those seen with osteosarcoma (see p. 801).
  - Nasal neoplasia is most often associated with soft-tissue opacity in the nasal cavity and/or frontal sinuses, as well as destruction of the turbinates, nasal septum, vomer, or surrounding palatine, maxillary, and/or frontal bones.
  - Primary rib tumors often can be distinguished from tumors originating from the lung by the presence of an extrapleural sign, characterized by a smoothly marginated indentation of the lung that tapers gradually at the junction of the thoracic wall.
- After a radiographic or histologic diagnosis, patients should be completely staged with a CBC, chemistry panel, urinalysis, and three-view thoracic radiographs.

ADVANCED OR CONFIRMATORY TESTING

- For axial tumors, CT imaging is recommended to more accurately stage local disease and help with planning surgery and/or radiation therapy. CT imaging can be done in place of radiographic studies.
  - For nasal tumors, CT is superior to radiographs for detecting soft-tissue opacity within the nasal cavity and surrounding sinuses, bony destruction, and extension through the cribriform plate into the brain.
  - If a patient is undergoing CT, concurrent imaging of the lungs is recommended as a more sensitive way to screen for pulmonary metastasis.
- Histopathologic evaluation is required to confirm the diagnosis of CSA.
  - For nasal tumors and large, nonresectable tumors, an incisional biopsy is recommended. For resectable tumors, an incisional biopsy is not contraindicated, but it is reasonable to surgically remove the local disease, with biopsy submission after surgery.

TREATMENT

TREATMENT OVERVIEW

Nasal CSA, like most other nasal tumors, is most effectively treated with radiation therapy. For CSAs arising in other locations, surgery is indicated whenever possible. Palliative therapy, which focuses on controlling pain and other clinical signs associated with the tumor, is recommended for advanced-stage tumors or when definitive therapy is declined.

ACUTE GENERAL TREATMENT

- Treatment of nasal CSA (see also Nasal Tumors):
  - Radiation therapy is the treatment of choice. Definitive treatment schemes typically use total doses of 48-57 Gy administered in 16-19 fractions of 3 Gy each.
  - Surgery is not an effective treatment modality for nasal tumors. It was used prior to the advent of orthovoltage radiation therapy, but it is no longer routinely recommended, because most radiation treatment facilities currently use megavoltage units (cobalt-60 or linear accelerator).
- The treatment of choice for rib CSA is wide surgical resection. Multiple ribs and/or underlying lung may need to be removed.

Prosthetic mesh may be needed to obtain thoracic wall closure, and diaphragmatic advancement techniques may be necessary for caudal thoracic tumors.
    - Adjuvant radiation therapy is recommended if excision is incomplete, but there is little information regarding efficacy.
- The treatment of choice for appendicular CSA is amputation. Limb salvage techniques may be considered for tumors arising from the distal radius or ulna.
- For CSA arising from other sites, wide surgical excision is recommended whenever possible. When excision is incomplete, adjuvant radiation therapy may help improve local control, but there is limited information regarding efficacy.
- There is no information regarding the efficacy of chemotherapy for the treatment of CSA in veterinary patients.
    - In humans with CSA, the use of adjuvant chemotherapy remains controversial, but there is preliminary evidence that chemotherapy might benefit patients with very aggressive variants (dedifferentiated and mesenchymal CSA). Protocols typically include doxorubicin with or without cisplatin, ifosfamide, and/or methotrexate.
- Palliative care is indicated for patients with advanced local disease or visible metastasis, and when owners decline definitive therapy.
    - Nonsteroidal antiinflammatory (NSAID) choices include: aspirin (10-25 mg/kg PO q 8-24 h), carprofen (2 mg/kg PO q 12 h), deracoxib (1-2 mg/kg PO q 24 h; may use 3-4 mg/kg PO q 24 h for first 7 days only), meloxicam (0.1 mg/kg PO q 24 h), firocoxib (5 mg/kg PO q 24 h).
    - Other oral analgesic drugs include acetaminophen with codeine (Tylenol #4 [300 mg acetaminophen, 60 mg codeine]) 0.5-2 mg/kg PO q 6-8 h, with dosing based on codeine, tramadol (2-5 mg/kg PO q 6-12 h), gabapentin (10-15 mg/kg PO q 8-12 h).
    - Pamidronate decreases bone resorption, increases bone mineral density, and can reduce the pain associated with bone tumors. It has been studied most thoroughly for the treatment of osteosarcoma (see p. 801).
    - Palliative radiation therapy very effectively controls the pain associated with bony tumors. Most information regarding efficacy is from the treatment of osteosarcoma, but similar benefits are seen in patients with chondrosarcoma.
    - Patients with pulmonary metastasis or nasal congestion often benefit from antiinflammatory doses of oral corticosteroids such as prednisone, 0.5-1 mg/kg PO q 24 h (do not combine corticosteroids with NSAIDs).

RECOMMENDED MONITORING

Patients should be evaluated every 2-3 months for evidence of local recurrence and metastatic disease. At a minimum, this includes a thorough physical examination and three-view thoracic radiographs. Imaging of the site of the primary tumor may be indicated as well, depending on location, completeness of excision, and clinical signs.

PROGNOSIS AND OUTCOME

- Prognosis for dogs with nasal CSA:
    - Distant metastasis is uncommon.
    - With definitive radiation therapy (megavoltage), 1-year progression-free survival rate is around 50%, and 2-year progression-free survival rate is around 30%.
        - Patients with nasal CSA are three times less likely to have local recurrence than patients with nasal adenocarcinoma.
        - For patients with nasal tumors in general, extension into the frontal sinuses and/or erosion through the bones of the nasal passage is associated with a threefold increase in risk of local recurrence. Unilateral versus bilateral involvement is not a significant prognostic factor.
    - With palliative care alone, survival times are around 3 months.
- For dogs with nonnasal CSA:
    - Some 15%-30% will develop metastatic disease, with the lungs being the most commonly affected site.
    - With aggressive surgery, median survival is >3 years, and many dogs will enjoy long-term local control. However, depending on tumor location and completeness of excision, up to 40% will develop local recurrence.
    - With palliative care alone, survival times of > 1 year are still possible.

AUTHOR: DENNIS B. BAILEY

EDITOR: KENNETH M. RASSNICK

Cholecystitis

BASIC INFORMATION

DEFINITION

Inflammation of the gallbladder wall; can be acute, chronic, necrotizing and/or emphysematous

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Necrotizing and emphysematous cholecystitis occur infrequently in dogs and are extremely rare in cats.
- Acute cholecystitis may occur in cats secondary to bacterial cholangitis/cholangiohepatitis.
- Mean age: 9.5 years
- Male dogs are at increased risk.

GENETICS & BREED PREDISPOSITION

Older, female, small-breed dogs appear to be at increased risk for cholelithiasis. Shetland sheepdogs appear to be predisposed.

RISK FACTORS: Age (increased risk with age), history of previous cholecystitis, and concurrent systemic disease are associated with increased risk of cholecystitis.

ASSOCIATED CONDITIONS & DISORDERS

- Cholangitis (inflammation of the bile ducts), choledochitis (inflammation of the common bile duct), and cholangiohepatitis (inflammation of the biliary tree and periportal hepatic parenchyma)
- Cholelithiasis, gallbladder rupture/perforation, and subsequent bile peritonitis (septic or sterile) can be sequelae to cholecystitis.
- Can occur as the result of gallbladder mucocele
- Diabetes mellitus and cystic duct obstruction: emphysematous cholecystitis (weak association)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Chronic and emphysematous forms may be incidental findings noted on abdominal ultrasound or abdominal radiographs (emphysematous—gas within gallbladder).
- Acute and necrotizing forms generally result in systemic illness.

HISTORY, CHIEF COMPLAINT

- Presenting complaints are generally vague. May include vomiting, diarrhea, depression, lethargy, weight loss, abdominal pain.
- Profound weakness or collapse can occur with gallbladder perforation and peritonitis.

PHYSICAL EXAM FINDINGS

- Nonspecific findings may include tachycardia, tachypnea, fever, dehydration, and cranial abdominal pain.
- Icterus often is present when there is concurrent extrahepatic biliary obstruction.

ETIOLOGY AND PATHOPHYSIOLOGY

- Necrotizing cholecystitis (type I):
  - Secondary to infection with subsequent loss of viability of the gallbladder wall
  - Gallbladder perforation does not occur despite wall necrosis.
- Acute (type II) and chronic (type III) cholecystitis:
  - Etiology is poorly defined.

- Bacterial infection (ascending from the common bile duct or via hematogenous spread) suspected
- Type II cholecystitis results in gallbladder perforation and peritonitis.
- Type III cholecystitis results in cholecystic adhesions (omental and hepatic adhesions) and/or fistulation.

- Emphysematous cholecystitis:
  - Invasion of the wall with gas-forming bacteria
  - Tympanic cholecystitis is the result of gas distension of the lumen of the gallbladder by gas-forming bacteria.
  - Severe tympanic cholecystitis can be associated with emphysematous cholecystitis (gas dissection into the gallbladder wall).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Cholecystitis should be a differential for any patient with cranial abdominal pain and elevated serum hepatic enzyme activities or total bilirubin concentration. Cholecystitis should be the primary differential in a patient with bile peritonitis without a history of trauma. A definitive diagnosis is based on surgical findings and histopathologic analysis.

DIFFERENTIAL DIAGNOSIS

- Other hepatobiliary disease
- Pancreatitis
- Proximal small bowel disease

INITIAL DATABASE

- CBC results are variable depending upon severity and suddenness in onset of cholecystitis.
- Increased serum liver enzyme activities and bilirubin concentration are possible.
- Hypoglycemia possible in cases involving septic peritonitis
- Hyperglycemia may be seen in cases with concurrent diabetes mellitus and emphysematous cholecystitis.
- Abdominal radiographs may show air or calculi in gallbladder. Loss of cranial abdominal detail may be apparent (peritonitis).
- Abdominal ultrasound is highly reliable for the identification of gallbladder rupture (86% sensitivity).
  - Loss of gallbladder wall continuity, hyperechoic fat in the cranial portion of the abdomen, and free abdominal fluid are possible findings. Choleliths may be seen.

ADVANCED OR CONFIRMATORY TESTING

- Definitive diagnosis requires surgical biopsy and histopathologic evaluation of a specimen of the gallbladder wall.
  - Cultures of bile and/or gallbladder mucosa should be performed (*Escherichia coli* and *Klebsiella* spp. most common, but aerobic and anaerobic culture and sensitivity are warranted).
- Laparoscopic evaluation and liver biopsy may prove useful. Conversion to an open procedure and cholecystectomy should be anticipated.
- Ultrasonographic-guided, percutaneous cholecystocentesis: bile cytology and bacterial culture and sensitivity.
- Cholangiography: radiographic imaging of the biliary system; rarely performed.
- Abdominal paracentesis (p. 1192) or diagnostic peritoneal lavage (see online chapter: Diagnostic Peritoneal Lavage) should be performed if ultrasound is not available.
- Scintigraphy is an accurate indicator of canine extrahepatic biliary obstruction (EHBO).

TREATMENT

TREATMENT OVERVIEW

Surgical removal of a severely compromised or perforated GB and relief of EHBO are essential. Nonsurgical management may be appropriate in select cases without compromise of the GB wall's integrity.

ACUTE GENERAL TREATMENT

- Immediate surgical intervention in cases with gallbladder wall rupture and/or concurrent bile peritonitis
- Patients that are systemically ill must be aggressively supported before surgical management (fluids, antibiotics, colloids).

CHRONIC TREATMENT

Select cases of cholecystitis can be managed without surgical intervention, provided (1) there are no signs of systemic illness such as severe lethargy, vomiting, or anorexia; (2) there is no evidence of EHBO or compromise of the gallbladder's integrity; and (3) serum biochemical values (liver enzymes and bilirubin) are decreasing over time or have normalized. Treatments that may be used in conservative (nonsurgical) management of these select cases include long-term antibiotic therapy (e.g., ampicillin, 10-20 mg/kg IV q 8 h; or amoxicillin-clavulanic acid, 10-20 mg/kg PO q 12 h until culture and sensitivity results are available), choleretics (ursodiol, 15 mg/kg PO q 24 h), and treatment of any underlying disease (e.g., pancreatitis, diabetes mellitus).

POSSIBLE COMPLICATIONS

- Gallbladder rupture and bile peritonitis (septic versus nonseptic)
- Recurrence of cholecystitis with inappropriate treatment
- EHBO

RECOMMENDED MONITORING

- Intensive monitoring in a critical care setting is indicated in markedly compromised patients (e.g., necrotizing cholecystitis, bile peritonitis).
- Serial serum biochemistry profiles and serial abdominal ultrasounds as indicated
- Monitoring coagulation profiles and vitamin K supplementation (0.5 mg/kg IM q 12 h until relief of obstruction) is indicated in patients with complete EHBO.

PROGNOSIS AND OUTCOME

- Mortality rates of 25%-39% with canine necrotizing cholecystitis
- Overall mortality rates of 50% with canine bile peritonitis (0% with nonseptic effusions and 73% with septic effusions)
- Septic peritonitis, preoperative elevated creatinine concentration, and immediate postoperative hypotension are associated with a poor clinical outcome.

PEARLS & CONSIDERATIONS

COMMENTS

- Select cases can be managed medically.
- Surgical management is indicated in all cases involving gallbladder compromise, bile peritonitis, or EHBO (excluding select cases of pancreatitis).

TECHNICIAN TIP

Early enteral nutrition is very important to a positive outcome. In severely debilitated patients, esophagostomy and nasogastric feeding should be implemented postoperatively.

CLIENT EDUCATION

- Recurrence is possible if cholecystectomy is not performed.
- Early intervention likely improves outcome.

EDITOR: KEITH P. RICHTER

Cholecalciferol Toxicosis

BASIC INFORMATION

DEFINITION

Cholecalciferol (vitamin D3) is used as both a dietary supplement and a rodenticide. Toxicity is characterized by clinical manifestations of hypercalcemia and hyperphosphatemia: anorexia and lethargy due to renal failure, cardiac arrhythmias, and seizures.

SYNONYM

Vitamin D3

EPIDEMIOLOGY

SPECIES, AGE, SEX

- All species susceptible; dogs more likely to be involved
- Young animals may be more sensitive

RISK FACTORS

Preexisting disease such as chronic kidney disease can increase severity of adverse effects.

CONTAGION & ZOONOSIS

Relay toxicosis (intoxication via consumption of prey that has itself consumed cholecalciferol) has not been reported.

GEOGRAPHY AND SEASONALITY

More cases in the fall and the winter months when more rodenticides are used

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History or evidence of consuming bait
- Lethargy, anorexia, vomiting, diarrhea, polyuria, and polydipsia 12-72 hours post ingestion
- Renal failure 24-72 hours post ingestion

PHYSICAL EXAM FINDINGS

- Anorexia, lethargy
- Dehydration
- Signs of abdominal pain
- Hematemesis, melena
- Dyspnea, cardiac arrhythmias (especially bradycardia)
- Seizures (uncommon)

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

- Cholecalciferol rodenticides
- Dietary supplements (over-the-counter and prescription)
- Common trade names are: Mouse-B-Gon, Rat-B-Gon, Quintox, Rampage, and True Grit. Most baits contain 0.075% cholecalciferol (0.75 mg cholecalciferol/gram bait).
- One IU of cholecalciferol (e.g., in dietary supplements) is equivalent to 0.025 mg of cholecalciferol.

Mechanism of Toxicosis:

- Cholecalciferol is metabolized to calcitriol (1,25 dihydroxyvitamin D).
  - Calcitriol increases intestinal absorption of calcium, stimulates resorption of calcium from bone, and increases renal tubular resorption of calcium.
- Toxic effects are due to hypercalcemia and hyperphosphatemia, resulting in metastatic mineralization of soft tissues, particularly kidney, myocardium, intima of large vessels, and gastrointestinal tract.
- Parathyroid hormone synthesis is suppressed.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on history of exposure to bait and evidence of hypercalcemia and hyperphosphatemia. Other causes of hypercalcemia need to be ruled out in cases where exposure history is not available; many possible causes (e.g., neoplasia, primary hyperparathyroidism) can be identified as unlikely on the basis of serum phosphorus level.

DIFFERENTIAL DIAGNOSIS

- Hypercalcemia:
  - Toxicologic:
    - Synthetic vitamin D3 ointment ingestion containing calcipotriene (Dovonex) or tacalcitol (Curatoderm) used for treating psoriasis in humans
    - Chronic overdose of vitamin D3 supplements
  - Spontaneous, nontoxicologic:
    - Hypercalcemia of malignancy(lymphoma, perianal adenocarcinoma, multiple myeloma, others)
- Primary renal failure
- Primary hyperparathyroidism
- Feline idiopathic hypercalcemia
- Addison's disease (hypoadrenocorticism)
- Granulomatous diseases (e.g., blastomycosis, schistosomiasis)

INITIAL DATABASE

- CBC, serum biochemistry profile:
  - Baseline if possible (<8 hour post exposure)
  - Calcium, phosphorus, blood urea nitrogen (BUN), creatinine should be included
  - Monitor daily for 4 days
  - Ca (mg/dL) P (mg/dL) product; if >60, an increased risk of soft-tissue mineralization exists
  - Note that immature animals that are actively remodeling bone may normally have Ca P that exceeds 60 but it is not associated with soft tissue mineralization.
- Urinalysis:
  - Isosthenuria (specific gravity 1.008-1.012) or hyposthenuria (specific gravity of 1.002-1.007) are common; isosthenuria indicates renal failure if concurrent azotemia
- Radiographs for soft-tissue calcification
- Ultrasound may suggest soft-tissue mineralization

ADVANCED OR CONFIRMATORY TESTING

- Serum 25-hydroxycholecalciferol level is elevated with cholecalciferol toxicosis. This assay will not detect calcipotriene found in psoriasis ointments (see p. 169).
- Serum parathyroid hormone levels are low with cholecalciferol toxicosis and hypercalcemia of malignancy but are normal with primary hyperparathyroidism, feline idiopathic hypercalcemia, and chronic kidney disease.
- Plasma parathyroid hormone–related protein may be detectable with hypercalcemia of malignancy but will be absent with other causes of hypercalcemia.
- Necropsy: fresh or frozen kidney. Total wet weight kidney calcium is typically elevated (300-1000 ppm [normal ranges, 100-150 ppm]).
- Histopathologic evaluation of lungs, kidney, aorta, myocardium, and gastric mucosa can reveal soft-tissue mineralization and necrosis.

TREATMENT

TREATMENT OVERVIEW

- For recent exposures prior to elevations in serum calcium and phosphorus, treatment consists of decontamination (induction of emesis and administration of activated charcoal) and measures to minimize effects of the toxicant.
- For animals with elevated serum calcium and phosphorus levels, treatment is aimed at lowering serum calcium and phosphorus promptly and preventing or managing acute renal failure.
- Complicated cases may involve days of intravenous fluid therapy and associated care. Referral to a specialty clinic that can provide 24-hour care should be considered.

ACUTE GENERAL TREATMENT

- Confirmed cholecalciferol ingestions >0.1 mg/kg require decontamination of the patient and monitoring.
- Decontamination of patient: induction of vomiting within 4 hours of ingestion (hydrogen peroxide 3%, 0.25-0.5 mL/kg PO once [dogs], or xylazine hydro-chloride, 0.44 mg/kg IM [cats])
- Repeated doses of activated charcoal (dose according to packaging label of product; e.g., 10 mL/kg of activated charcoal suspension PO made from 2 g activated charcoal suspended in 10 mL tap-water) and a cathartic, given q 8 h 24 hours
- Monitor serum electrolytes for development of hypernatremia 2-4 hours following repeated activated charcoal dosing.
- Treat hypercalcemia in animals showing overt clinical signs:
    - Saline diuresis 0.9% saline at 90 (cats) to 130 (dogs) mL/kg/d
        - Avoid calcium-containing fluids.
        - Adjust dose if cardiac disease or other vascular volume-limiting condition.
    - Furosemide 2.5-4.5 mg/kg PO, SQ, IM, or IV q 6-8 h
        - Do not use thiazide diuretics (calcium-retaining). Example: hydrochlorothiazide.
    - Prednisolone 1-3 mg/kg PO q 8-12 h
    - High doses of dexamethasone at 1-2 mg/kg IV or SQ q 24 h have been recommended.
    - Because dexamethasone has 10 times the glucocorticoid potency of prednisone, these high doses can cause substantial gastrointestinal ulceration and hemorrhage and should only be used as a last resort.
    - Specific antagonists (must choose one or the other; do not combine):
        - Pamidronate (preferred): 1.3-2 mg/kg as a slow IV infusion. Repeat in 5-7 days if needed. May cause a transient increase in BUN or creatinine.
        - Calcitonin (use if supportive treatments are not effective): 4-6 IU/kg-SQ q 8-12 h. Some animals become refractory to salmon calcitonin.

CHRONIC TREATMENT

- Continue treatment until serum calcium stabilizes or Ca × P < than 60 (days to weeks of treatment).
- Treat other signs (renal failure, seizures, arrhythmias).
- Gradually wean off prednisolone/dexamethasone and furosemide when calcium levels reach normal range.
- Avoid sunlight.

NUTRITION

- Phosphate binders: aluminium hydroxide 10-30 mg/kg PO q 8 h. Discontinue phosphate binders when serum phosphorus level stabilizes.
- Low-calcium diet

POSSIBLE COMPLICATIONS

- Soft-tissue mineralization (irreversible)
- Pulmonary edema (mineralization and leakage of pulmonary vessels), hemorrhage, or aspiration pneumonia
- Sudden death associated with myocardial or aortic mineralization
- Gastric ulceration, hematemesis, shock, and collapse
- Hypocalcemia if animals are not weaned from treatment after calcium levels are normalized

RECOMMENDED MONITORING

Monitor serum calcium and phosphorus for 5 to 7 days after values are normalized, then 2-3 times a week for 2 weeks, and then once at 1 month post exposure.

PROGNOSIS AND OUTCOME

- Prognosis good if animal receives prompt treatment, and if soft-tissue mineralization has not occurred

- Prognosis poor to guarded with prolonged elevations in calcium and phosphorus, causing soft-tissue mineralization

PEARLS & CONSIDERATIONS

COMMENTS

- Dietary supplements generally list cholecalciferol, or vitamin D, in IU. One IU of cholecalciferol is equivalent to 0.025 mcg of cholecalciferol.
- Practitioners should be aware that products with the same brand name may contain various active ingredients. For example, Rampage may contain bromethalin or cholecalciferol. It is imperative that active ingredients be verified on the package.
- In nonsurvivors, total wet kidney calcium concentrations can be used for differentiating between ethylene glycol toxicosis (3000-12,000 ppm) and cholecalciferol toxicosis (300-1000 ppm).

TECHNICIAN TIPS

- In dogs, hypercalcemia frequently causes anorexia, so monitoring a dog's appetite may provide an early indication of increasing serum calcium levels.

CLIENT EDUCATION

- Provide information about pet proofing homes.
- Remind clients that rodenticides may be appealing to pets.

EDITOR: SAFDAR A. KHAN

1ST EDITION AUTHOR: CHARLOTTE MEANS

Chole(cysto)lithiasis

BASIC INFORMATION

DEFINITION

Formation of stones in the extrahepatic bile duct system (choleliths) and/or specifically in the gallbladder (cholecystoliths)

SYNONYM

Gallstones

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs: older, small-breed, spayed females appear to be predisposed.

Cats: middle-aged to older adults

ASSOCIATED CONDITIONS & DISORDERS

Cats:

- In some cats, possible association with cholangitis, pancreatitis, inflammatory bowel disease

Dogs:

- Cholecystitis
- Gallbladder perforation
- Bile peritonitis due to gallbladder rupture
- Rarely biliary adenocarcinoma

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Cholelithiasis without specific clinical signs:
  - Incidental finding on abdominal radiographs or ultrasound performed for another reason
- Cholelithiasis associated with clinical signs of:
  - Gastrointestinal disease
  - Biliary obstruction
  - Peritonitis when cholelithiasis is associated with biliary disruption/rupture

HISTORY, CHIEF COMPLAINT

- Generally nonspecific: malaise and gastrointestinal signs predominate.
- Dogs: vomiting, anorexia, lethargy, weakness, polydipsia, polyuria, weight loss
- Cats: vomiting, dehydration, anorexia, lethargy
- Note: choleliths may be an incidental finding in both dogs and cats and may not be associated with any clinical signs.

PHYSICAL EXAM FINDINGS

- Icterus is commonly apparent when cholelithiasis is associated with cholangitis, cholecystitis, and/or gallbladder obstruction.
- Fever may be noted in dogs, in association with infection and/or bile peritonitis.
- Signs of abdominal pain are not consistently noted, even when biliary obstruction is present.

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology unknown
- In dogs and cats, most choleliths contain mainly calcium rather than cholesterol, as seen in humans.
- Choleliths may obstruct the extrahepatic biliary system (see p. 135).
- Decreased absorption of fat and fat-soluble vitamins, notably vitamin K, and subsequent coagulopathy
    - Decreased bile secretion into the intestine may result in decreased binding of endotoxin, predisposing to endotoxemia.
- Cholelithiasis has been associated with concurrent cholecystitis and gallbladder rupture, resulting in bile peritonitis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Inasmuch as presenting history and physical examination findings are frequently nonspecific, the diagnosis of this problem generally requires diagnostic imaging. Abdominal ultrasonography is the modality of choice.

DIFFERENTIAL DIAGNOSIS

- Cholelithiasis with extrahepatic biliary obstruction and jaundice:
    - Hyperbilirubinemia due to hemolysis:
        - Immune-mediated hemolytic anemia or other diseases causing severe intravascular hemolysis
    - Hepatic disease: cholangiohepatitis (cats), idiopathic chronic hepatitis (dogs), cirrhotic/fibrosing liver disease, neoplasia, copper/other toxins (dogs), acetaminophen toxicosis (cats)
    - Extrahepatic biliary obstruction: pancreatitis, cholangitis, neoplasia, stricture, foreign body obstruction, diaphragmatic hernia
- Cholelithiasis without biliary obstruction:
    - Other causes of vomiting and anorexia, because choleliths are an incidental finding:
        - Viral enteritis
        - Pancreatitis
        - Foreign body obstruction
        - Gastric, intestinal, or pancreatic neoplasia
        - Inflammatory bowel disease
        - Ingested toxins
        - Hepatic and renal diseases

INITIAL DATABASE

- CBC:
    - Possible anemia, though usually mild
    - Inflammatory leukogram
- Serum biochemistry profile:
    - Elevated bilirubin concentration
    - Elevated liver enzyme concentration
    - Possible elevations of amylase and lipase concentrations
    - Hypokalemia
- Survey abdominal radiographs:
    - May delineate radiopaque choleliths
- Survey thoracic radiographs:
    - Rule out metastatic disease if neoplasia is suspected

ADVANCED OR CONFIRMATORY TESTING

- Abdominal ultrasound examination:
    - Common bile duct dilation:
        - Further delineate choleliths
        - >5 mm diameter is diagnostic of bile duct obstruction in the cat
    - Evaluate gallbladder in dogs with concurrent cholecystitis:
        - Wall thickness
        - Contents: choleliths, mucocele
        - Presence of attached omentum
        - Surrounding fluid
            - Evaluate intestine for increased wall thickness and loss of layering associated with neoplasia or inflammatory bowel disease

- Peritoneal fluid analysis (obtained during abdominal ultrasound examination):
  - Bilirubin concentration (elevated: bile peritonitis)
  - Cytologic examination and microbiologic culture and sensitivity testing: septic peritonitis
- Coagulation profile

TREATMENT

TREATMENT OVERVIEW

- If the choleliths are an incidental finding, no treatment is required. The patient should be monitored for development of clinical signs associated with cholelithiasis.
- If signs of biliary stasis, disruption, or obstruction are noted, then patient stabilization and surgical intervention will be necessary.

ACUTE GENERAL TREATMENT

- Rehydration by intravenous administration of balanced electrolyte solution
- Normalization of serum electrolyte concentrations
- Parenteral antibiotics effective against gram-negative bacteria and anaerobes:
  - Empirical therapy:
    - Cefoxitin, 30 mg/kg IV q 4-6 h perioperatively, then q 6 h; or
    - Metronidazole, 7.5-15 mg/kg IV q 12 h with
    - Enrofloxacin, 5-15 mg/kg q 24 h for dogs, 5 mg/kg q 24 h for cats
  - Specific long-term therapy based on culture and sensitivity test results
- Possible administration of fresh frozen plasma (if hypoproteinemia, coagulopathy)
- Vitamin K administration
- Removal of choleliths/relief of extrahepatic biliary obstruction
- Duodenotomy and retrograde flushing of the biliary system
- Choledochotomy for removal of one or two large choleliths
  - Cholecystectomy:
    - Results in the best long-term prognosis if all stones are removed and biliary system is patent
  - Common bile duct stenting
  - Cholecystoduodenostomy/jejunostomy
  - Tube cholecystostomy
- Treatment of bile peritonitis if biliary disruption has occurred (see p. 865)

CHRONIC TREATMENT

Maintenance of bile flow: ursodeoxycholic acid 10-15 mg/kg PO q 24 h; contraindicated while gallbladder obstruction is present.

NUTRITION/DIET

Provide access for enteral feeding if patient is anorexic (see p. 1267 ,p. 1270, and p. 1322).

POSSIBLE COMPLICATIONS

Recurrence of cholelithiasis, bile leakage, pancreatitis, peritonitis, endotoxemia, sepsis, death

RECOMMENDED MONITORING

- If clinical signs were/are present:
  - Clinical and laboratory parameters assessing perfusion, including capillary refill time, pulse rate and quality, blood pressure, urine output, arterial pH, and lactate concentrations
  - Respiratory function
  - Serum liver enzymes and bilirubin concentrations
  - Coagulation profile
- If incidental finding:
  - Physical exam and serum biochemistry profile every 6 months

PROGNOSIS AND OUTCOME

- Fair in clinically ill animals if all choleliths removed and a cholecystectomy is performed
- Guarded if cholelithiasis is associated with biliary leakage and aseptic bile peritonitis
- Poor in patients with septic bile peritonitis
- Open prognosis in patients without clinical signs (incidental finding)

PEARLS & CONSIDERATIONS

COMMENTS

Given the association of biliary obstructive disease (cholelithiasis) in cats with cholangitis/cholangiohepatitis and inflammatory bowel disease, a liver biopsy and culture, bile culture, and small intestinal biopsies should be obtained at the time of surgery in this species.

Cholangitis/Cholangiohepatitis Complex of Cats

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Inflammation of the biliary tree and surrounding hepatocellular parenchyma. May occur as a primary process, a coexisting condition, or secondary to a variety of other feline diseases.
- Cholangitis: inflammation is centered around the bile ducts.
- Cholangiohepatitis: extension of cholangitis into the surrounding hepatic parenchyma
- Cholangitis/cholangiohepatitis (CCH) has been referred to as both a "complex" (CCHC) and a "syndrome" (CCHS).
    - In either case, this designation emphasizes the fact that a variety of distinct forms of disease is included within a single umbrella term (see disease forms/subtype, below).
- The CCHC of cats is one of the most common feline hepatobiliary disorders.

SYNONYMS

- Acute neutrophilic CCH: suppurative CCH
- Chronic, lymphoplasmacytic CCH: nonsuppurative, lymphoplasmacytic, or lymphoproliferative CCH

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Himalayan, Persian, and Siamese cats may be predisposed.
- Patients with this disease range in age from <1 to >16 years old, but most are middle-aged.
- Cats presenting with acute (suppurative) disease tend to be several years younger than those with chronic (nonsuppurative) disease.
- Male cats appear to be overrepresented.

RISK FACTORS

Extrahepatic biliary obstruction, inflammatory bowel disease (IBD), pancreatitis, cholestatic disease, cholelithiasis, bacterial infection or splenic abscess, feline infectious peritonitis (FIP), toxoplasmosis, immunodeficiencies, choledochal stent placement, drugs (diazepam, tetracyclines, others).

CONTAGION & ZOONOSIS

Not considered either a contagious or zoonotic disease. There is a single report of *H. pylori* isolation from samples of feline bile.

ASSOCIATED CONDITIONS & DISORDERS

Triaditis is the term used for describing the combination of CCH with IBD and pancreatitis. IBD or pancreatitis is seen in 50%–85% of the cases of CCHC, with both present in up to 40% of CCHC patients. Cholangitis/cholangiohepatitis can also be associated with hepatic lipidosis, or secondary to a variety of other diseases/conditions (see Risk Factors above).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- On the basis of histopathologic findings, three distinct entities exist within the CCHC, as defined by the World Small Animal Veterinary Association Liver Diseases and Pathology Standardization Research Group:
    - Acute neutrophilic (suppurative)
    - Chronic (lymphoplasmacytic or mixed)
    - Lymphocytic (nonsuppurative)
- The forms can be quite different clinically (history, initial presentation, chief complaint, etiology, progression, and outcome).
- Chronic lymphocytic cholangitis is a form seen predominantly in Europe and is progressive.
    - Some pathologists classify this as low-grade (well-differentiated) lymphoma.
- Lymphocytic portal hepatitis is a separate entity confined to portal triads and is often an incidental finding in older cats.

HISTORY, CHIEF COMPLAINT

- Patients with the suppurative form of CCH usually present for an acute onset of illness: anorexia, fever, and vomiting in an icteric cat with abdominal discomfort.
- Patients with the nonsuppurative form of CCH usually present for a more chronic condition with subtle nonspecific signs, and less commonly present with acute signs.
- Patients with concurrent IBD and pancreatitis ("triaditis") may present with a wide variety of signs and varying degrees of severity, depending on the severity of inflammation in these other organs.
- Patients with either form are usually icteric, and a few may have ascites.
- Patients with the chronic condition may rarely be polyphagic, although usually they will be presented for lethargy, anorexia, vomiting, and weight loss.

PHYSICAL EXAM FINDINGS

- Suppurative CCH: The patient is usually febrile, dehydrated, and icteric and may have abdominal discomfort with palpation.
- Patients with the nonsuppurative form of CCH may have minimal physical exam abnormalities or may present icteric.
    - Hepatomegaly may be appreciated with abdominal palpation.

ETIOLOGY AND PATHOPHYSIOLOGY

- Bacterial infection *(Escherichia coli, Streptococcus, Clostridium, Salmonella [serovar typhimurium], Enterococcus faecium*, other enteric organisms, anaerobes); ascending infection of the biliary tract (acute suppurative/neutrophilic cholangitis)
- In association with other infectious agents (i.e., toxoplasmosis, FIP)
- Immune-mediated disorder (chronic nonsuppurative/lymphocytic cholangitis)
- Extrahepatic biliary obstruction
- Secondary or concurrent pancreatitis, especially with suppurative form; pancreatic and bile ducts enter duodenum through a common opening in the cat (see p. 135)
- IBD

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Lethargy and anorexia in a cat with elevated liver enzymes is consistent with CCH but also several other hepatobiliary disorders. The diagnosis is confirmed histologically from a liver biopsy.

DIFFERENTIAL DIAGNOSIS

- Hepatic lipidosis
- Hepatic neoplasia (especially lymphoma)
- Extrahepatic biliary duct obstruction
- Pancreatitis
- Inflammatory bowel disease
- FIP
- Sepsis

INITIAL DATABASE

- CBC:
    - Leukocytosis; neutrophilia with a left shift and/or toxic neutrophils
    - Lymphocytosis (nonsuppurative CCH)
    - Mild nonregenerative anemia with poikilocytes and/or Heinz bodies
- Serum biochemistry panel:
    - Elevated liver enzyme activities (alanine aminotransferase, ALP, aspartate aminotransferase, γ-glutamyltransferase)
    - Possibly elevated total bilirubin concentration
    - Increased bile acids concentration (fasting and postprandial)
    - Hyperglobulinemia (nonsuppurative CCH)
- Other:
    - High feline pancreatic lipase immunoreactivity (fPLI) possible with pancreatitis
    - Low serum cobalamin concentration with severe IBD
    - Possible clotting time abnormalities (prothrombin time, activated partial thromboplastin time, activated clotting time [ACT], proteins induced by vitamin K absence [PIVKA]), or portal vein thrombus (PVT).

- Hepatomegaly (radiographs or laparoscopy)

ADVANCED OR CONFIRMATORY TESTING

- Abdominal ultrasound:
  - Hepatic parenchyma: mixed echogenicity, multifocal hyperechogenicity, diffuse hypoechogenicity, or a coarse or nodular appearance (nonspecific)
  - Prominent portal vasculature
  - Gallbladder distension, cholelithiasis, biliary sludge, thickened gallbladder wall
  - Abdominal lymphadenopathy
  - Evidence of pancreatic or intestinal inflammation
  - Ascites (nonsuppurative CCH; high protein, low cellularity)
- Fine-needle aspiration (FNA) of the liver:
  - Hepatocellular vacuolation (concurrent lipidosis is possible).
  - Cellular infiltration: neutrophils, lymphocytes, or mixed, +/− intraluminal biliary inflammation
  - Bacterial culture and sensitivity.
  - In general, FNAs result in a greater number of false-negative and false-positive diagnoses compared to core or wedge biopsies.
- Percutaneous ultrasound-guided cholecystocentesis
  - Minimally invasive; identification, culture and sensitivity for bacterial isolates
- Liver biopsy (wedge [laparotomy, laparoscopy] or ultrasound-guided core):as above for FNA, plus:
  - Periportal hepatocellular necrosis, bile duct dilation and proliferation (suppurative)
  - Periductal fibrosis, diminished bile duct number, and sclerosing cholangitis (nonsuppurative)
- Laparoscopy:
  - Abdominal lymphadenopathy
  - Ability to obtain wedge biopsy sample
- Laparotomy, as above for laparoscopy:
  - Assess biliary system for extrahepatic biliary obstruction.
  - Feeding tube placement possible

TREATMENT

TREATMENT OVERVIEW

In addition to supportive care and specific treatment, the treatment plan must address concurrent conditions (frequent) for optimal patient outcomes.

ACUTE GENERAL TREATMENT

- Treatment should be tailored to the individual patient.
- Fluids (Normosol, lactated Ringer's solution) with potassium supplementation
- Antibiotics (based on culture and sensitivity when possible):
  - Amoxicillin-clavulanate, 62.5-125 mg/cat PO q 12 h, 1-2 weeks beyond normalizing liver enzymes, *or*
  - Amoxicillin, 10-20 mg/kg PO q 12 h, *or*
  - Cephalexin or cefadroxil, 22 mg/kg PO q 8 h, *or*
  - Enrofloxacin, 5 mg/kg PO q 24 h, combined with metronidazole, 7.5 mg/kg PO q 12 h
  - Vancomycin has been reported for one case of multidrug-resistant *Enterococcus faecium*
- Ursodeoxycholic acid (10-15 mg/kg PO q 24 h) for choleresis, unless physical obstruction to gallbladder outflow exists
- Vitamin K1 (5 mg/cat PO q 24 h) in cases of coagulation abnormalities
- Cannulation for removal of inspissated bile, surgery for extrahepatic biliary obstruction, and necessary treatments for associated conditions (especially pancreatitis, IBD, hepatic lipidosis).

CHRONIC TREATMENT

- Long-term management is highly dependent on an accurate diagnosis and requires histopathologic analysis of a liver biopsy.
- Continued antibiotics and ursodeoxycholic acid (see Acute General Treatment above) 3-6 months if suppurative CCH
- Prednisolone (for chronic or nonsuppurative CCH; 4 mg/kg/d initially, gradual taper over 2-4 months) combined with metronidazole (see Acute General Treatment above)
- Refractory cases of nonsuppurative CCH may require chemotherapeutics (e.g., methotrexate [0.13 mg PO q 8 h for 3 doses at 7-day intervals, if tolerated], cyclosporine [3-5 mg/kg PO q 12 h], or chlorambucil [4 mg/m^2 PO q 48 h]). Given the potential for severely detrimental side effects with these drugs and the need for close monitoring, their use is recommended only in consultation with an internist.

- Vitamin E (a-tocopherol acetate, 10-30 IU/kg) for all forms of CCHS
- *S* -adenosylmethionine (20 mg/kg PO q 24 h [enteric-coated tablet]) for all forms of CCHS
- Ursodeoxycholic acid, carnitine (see Acute General Treatment above)
- Continued treatment of concurrent conditions such as pancreatitis and/or IBD
- Treatment for ascites if present (furosemide [1-3 mg/kg PO q 12 h, ACE inhibitors [enalapril, 0.5 mg/kg PO q 12-24 h], salt restriction)
- For biliary cirrhosis (sclerosing CCHC), consider the addition of pulsatile therapy with methotrexate (0.13 mg PO q 8 h for 3 doses at 7-day intervals if tolerated), being cognizant of potentially adverse side-effects (GI, hepatic toxicity, renal toxicity, bone marrow suppression).

NUTRITION/DIET

- Route determined by clinical condition
- Protein restriction in cats is problematic because they are strict carnivores; protein restriction should be avoided unless there is clear evidence of hepatic encephalopathy (rare).
- Consider supplementation with L-carnitine (250 mg/cat PO q 24 h), taurine(250-500 mg/cat PO q 24 h), thiamine(B1) 50-100 mg PO q 24 h for 3 days, and vitamin B12 (1 mg SQ repeated weekly).

POSSIBLE COMPLICATIONS

- Hepatic lipidosis with prolonged anorexia or inadequate nutritional support
- Diabetes mellitus with corticosteroid treatment of nonsuppurative disease or IBD
- Hepatic sclerosis
- Progression of acute to chronic disease
- Necrotizing cholecystitis, choleliths
- Portal vein thrombosis

RECOMMENDED MONITORING

- Hepatic enzyme activity and total bilirubin concentration (at 2-week intervals until stable, then monthly)
- PIVKA and/or clotting times if abnormalities are present or to monitor vitamin K1 therapy
- Consider repeat bile acids measurement to monitor liver function.

PROGNOSIS AND OUTCOME

- Acute suppurative cholangiohepatitis may be a single curable event, or it may recur (especially if antibiotic therapy is curtailed prematurely), but the prognosis is generally good with timely diagnosis and appropriate treatment.
- Nonsuppurative cholangiohepatitis is a chronic condition but carries a fair to good prognosis with lifelong therapy.
- Concurrent pancreatitis and/or IBD may also affect the prognosis negatively.

PEARLS & CONSIDERATIONS

COMMENTS

- The cholangitis/cholangiohepatitis complex of cats is a complex or constellation of distinct clinical signs, biochemical abnormalities, and structural derangements. The underlying etiology may be distinct as well, and determining whether an infectious process is a contributing factor has a critical bearing on treatment decisions. Following the appropriate and sufficient diagnostic steps in the workup of a cat with inflammatory liver disease is critical for therapeutic success.
- Acute (suppurative) CCH is often infectious in nature (and therefore treated initially with antibiotics), whereas chronic (nonsuppurative) CCH may have an immune-mediated basis (and is therefore treated with immunosuppressive drugs).

PREVENTION

Avoid and/or treat contributing or concurrent conditions such as chronic pancreatitis or IBD.

CLIENT EDUCATION

- Vigilant monitoring is important for early detection of anorexia, lethargy, vomiting, or abdominal discomfort, because suppurative cholangiohepatitis may recur.
- Compliance with medication administration may be a lifelong commitment.

- Proper nutritional support (optimal high-protein diet) is important.

AUTHOR: CRAIG B. WEBB

EDITOR: KEITH P. RICHTER

Chocolate Toxicosis

BASIC INFORMATION

DEFINITION

Clinical signs caused by ingestion of chocolate products and byproducts

SYNONYM

Methylxanthine toxicosis

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs are most commonly affected; all breeds, ages, both sexes susceptible.

RISK FACTORS

Animals with cardiac or seizure disorders may be at increased risk for signs.

GEOGRAPHY AND SEASONALITY

Toxicosis can occur year-round; most prevalent (greater opportunity for exposure) during holiday seasons such as Easter, Christmas, and Valentine's Day.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Severity and onset of signs depend on amount and type of chocolate ingested.
- Chocolate and its by products contain methylxanthines—theobromine (primary) and caffeine (secondary)—plus sugars and fat.
- See table for methylxanthine content of products.
- Variable individual sensitivity to methylxanthines
- Methylxanthine dosages:
    - 20-40 mg/kg: mild to moderate clinical signs
    - 40-50 mg/kg: cardiac arrhythmias; potentially life-threatening
    - >60 mg/kg: seizures

HISTORY, CHIEF COMPLAINT

- Known ingestion of chocolate most common
- Onset of signs up to 6-12 hours post ingestion possible
- Initially: polydipsia, bloating, vomiting, diarrhea; restlessness
- Can progress to polyuria, agitation, tremors, rigidity, ataxia, seizures, collapse, coma

PHYSICAL EXAM FINDINGS

- Agitation, nervousness
- Tachycardia
- Tachypnea
- Hypertension
- Hyperthermia
- Cardiac arrhythmias (premature ventricular contractions, sinus tachycardia, sinus bradycardia, others)
- Ataxia, tremors, seizures

ETIOLOGY AND PATHOPHYSIOLOGY

- Behavior changes, central nervous system stimulation, and cardiovascular abnormalities: competitive inhibition of cellular adenosine receptors
- Enhanced cardiac and skeletal muscle contractility: increase in free intracellular calcium concentrations from inhibition of sarcoplasmic calcium reuptake and increased calcium entry into cells
- Death likely due to cardiac arrhythmias, respiratory failure, or hyperthermia-induced disseminated intravascular coagulation (DIC)
- High sugar and fat contents in chocolate: gastrointestinal signs, possibly pancreatitis

*Exact methylxanthine content varies with growing conditions for cocoa beans as well as individual commercial formulations of products. Approximate methylxanthine dose ingested (in mg/kg) is: 1. Add product's theobromine concentration, in mg/oz (above) + product's caffeine concentration, in mg/oz (above). 2. Multiply this number by number of ounces of chocolate product ingested. 3. Divide by dog's body weight in kg. Metric conversion 1 oz = 28.5 g.

Approximate Methylxanthine Content of Various Products*

Product	Theobromine	Caffeine
Cocoa powder	737 mg/oz	42 mg/oz
Baker's chocolate	393 mg/oz	118 mg/oz
Semisweet chocolate	138 mg/oz	22 mg/oz
Instant cocoa mix powder	136 mg/oz	15 mg/oz
Milk chocolate	56 mg/oz	6 mg/oz
White chocolate	0.25 mg/oz	0.85 mg/oz
Unprocessed cocoa bean shell mulch	285-1140 mg/oz (54-849 mg/oz in processed mulch)	20-103 mg/oz

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis based on any combination of history, presence of chocolate in the vomitus, and clinical signs consistent with chocolate toxicosis

DIFFERENTIAL DIAGNOSIS

- Other toxicoses that can cause central nervous system (CNS) excitation: amphetamines, pseudoephedrine, phenylpropanolamine, metaldehyde, cocaine, antidepressants, antihistamines
- Causes of cardiac arrhythmias (see p. 1165 , p. 1027, and p. 1025)
- Causes of dyspnea/tachypnea (see p. 327)
- Causes of hyperthermia (see p. 480)
- Causes of systemic hypertension (see p. 1068)

INITIAL DATABASE

- ECG (see p. 1253)
- Blood pressure (see p. 1209)
- Serum biochemistry panel:
  - Renal values in animals with severe clinical signs
  - Serum electrolyte levels in animals with overt clinical signs
- Evaluation of pancreas (serum assays, ultrasound) in animals with severe or persistent gastrointestinal clinical signs

TREATMENT

TREATMENT OVERVIEW

Intensity of treatment is guided by dose of intoxication (type and amount of chocolate ingested), time since ingestion (expected efficacy of emesis induction and charcoal administration; onset of clinical signs), and presence or absence of preexisting cardiac or renal disorders. Mild intoxications may be treated as benign gastroenteritis cases (after patient decontamination).

ACUTE GENERAL TREATMENT

- Manage clinical signs:
  - CNS signs/neuromuscular
    - Diazepam (0.5-2 mg/kg IV) for seizures
    - Barbiturates, gas anesthetics if diazepam ineffective
    - Methocarbamol (50-200 mg/kg slow IV; do not exceed 330 mg/kg/24 h) for tremors, rigidity
- Cardiac arrhythmias:
  - Beta-blockers for severe, sustained supraventricular tachyarrhythmias, especially if preexisting heart disease
    - Propranolol (0.04-0.06 mg/kg slow IV over 2-3 minutes; max 0.2 mg/kg), *or*
    - Esmolol (0.2-0.5 mg/kg IV or 25-200 mcg/kg/min IV CRI), *or*
    - Metoprolol (0.2-0.4 mg/kg PO q 8 h)
  - Lidocaine for rapid sustained ventricular arrhythmias
    - Dogs: 1-4 mg/kg IV, then 30 to 50 mcg/kg/min if necessary (if beta-blockers ineffective). Cats (use with caution): 0.5-2 mg/kg IV.
  - Atropine (0.01-0.02 mg/kg IV) for bradyarrhythmias
- Control hyperthermia:
  - Fluids, fans (see p. 480)
  - Control vomiting (if needed)
    - Maropitant 1 mg/kg SQ q 24 h or 2 mg/kg PO q 24 h up to 5 days; *or*
    - Metoclopramide 0.2-0.5 mg/kg PO or SQ q 6-12 h
- Decontaminate patient after life-threatening issues addressed:
  - Subclinical (or stabilized clinical) patient only
    - Emesis: effective up to 8-12 h post ingestion (see p. 1364)
- Gastric intubation, gavage, lavage (see p. 1281)
  - Consider when emesis is contraindicated (comatose, anesthetized)
- Activated charcoal:
  - 1-4 g/kg (or labeled dosage) after emesis/lavage; repeat q 8 h during clinical signs of toxicosis
- Animals without clinical signs/pre-clinical cases: monitor 8-12 hours for development of signs:
  - Maintain urine output (IV fluid diuresis) potassium supplementation
- Urinary catheter placement:
  - Caffeine is reabsorbed from the urine; urinary catheter helps increase caffeine excretion.

NUTRITION/DIET

Bland diet may be indicated for 3-5 days for diarrhea.

DRUG INTERACTIONS

Erythromycin, cimetidine, corticosteroids may delay methylxanthine clearance and should be avoided.

POSSIBLE COMPLICATIONS

- DIC from hyperthermia
- Myoglobinuria from seizure-induced rhabdomyolysis; renal failure
- Pancreatitis

RECOMMENDED MONITORING

- ECG, blood pressure, body temperature
- Serum electrolytes
- Fluid ins/outs
- Urinalysis
- Pancreatic ultrasound enzymes

PROGNOSIS AND OUTCOME

- Prognosis is generally good with prompt and thorough care.
- If severe clinical signs are not controlled, prognosis is guarded to poor.
- Signs generally resolve in 12-72 hours, depending on methylxanthine dose, severity of signs, and aggressiveness of treatment.

PEARLS & CONSIDERATIONS

COMMENTS

- The darker the chocolate, the more dangerous it is.
- To estimate amount of methylxanthine ingested, add amount of caffeine and theobromine together (see table), multiply by number of ounces ingested, and divide by body weight in kilograms.
- Half-life in dogs: theobromine = 17.5 hours; caffeine = 4.5 hours
- Chocolate may form a clump in the stomach, delaying absorption and onset of clinical signs for up to 12 hours.

PREVENTION

- Keep chocolate-containing products away from pets.
- Avoid leaving chocolate-containing gifts unsupervised (e.g., under the Christmas tree).

TECHNICIAN TIPS

Induction of emesis even several hours after exposure can prevent signs or substantially reduce the severity of signs.

CLIENT EDUCATION

Pets fed small amounts of chocolate may develop a taste for it and actively seek out chocolate, leading to intoxication.

1ST EDITION AUTHOR: SHARON M. GWALTNEY-BRANT

Chlamydiosis, Cat

BASIC INFORMATION

DEFINITION

A bacterial infection associated mainly with acute and chronic conjunctivitis in cats

SYNONYMS

- *Chlamydia psittaci* infection (outdated; current name is *Chlamydophila felis)*
- *Chlamydophila felis* infection
- Feline pneumonitis (outdated term; the organism is primarily a conjunctival pathogen)

EPIDEMIOLOGY

SPECIES, AGE, SEX

The prevalence of *C. felis* in cats with upper respiratory tract disease has ranged from 10%-31%. Cats < 5 years old, and especially < 1 year old, are predisposed. There is no strong sex predilection.

RISK FACTORS

Young age is the most significant risk factor.

CONTAGION & ZOONOSIS

Highly contagious between cats (aerosol, direct contact, fomites). *C. felis*-associated conjunctivitis has been described in a single immunocompromised human. Other reports associating *C felis* infection with keratoconjunctivitis in people did not provide definitive evidence of infection. The DNA of *C. felis* has also been detected uncommonly in respiratory samples from humans. Maintenance of hygienic conditions and prompt treatment of cats should help prevent human disease.

GEOGRAPHY AND SEASONALITY

Worldwide distribution; may be more common in summer.

ASSOCIATED CONDITIONS & DISORDERS

May be associated with concurrent feline respiratory viral infections such as feline herpesvirus 1 or feline calicivirus infection.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Ocular discharge and redness
- Occasionally decreased appetite
- Nasal discharge
- Sneezing

PHYSICAL EXAM FINDINGS

- Ocular signs: blepharospasm, chemo-sis, conjunctivitis, serous to mucopurulent ocular discharge
- Serous to mucopurulent nasal discharge (always accompanied by conjunctivitis)
- Possible fever
- Possible vaginal discharge

ETIOLOGY AND PATHOPHYSIOLOGY

- *C. felis* is an obligately intracellular bacterium related to gram-negative bacteria.
- The life cycle alternates between an extracellular, infectious elementary body, and an intracellular reticulate body.
- Reticulate bodies divide within a cytoplasmic vacuole called an *inclusion*, and are released from the host cell as elementary bodies.
- Natural transmission probably occurs by close contact with other cats and their aerosols, and via fomites.
- The incubation period is 3-5 days, and infection may persist for months.
- Feline chlamydiosis is a systemic disease, and organisms are shed from the conjunctiva, vagina, and rectum.
- Recently, another chlamydial species has been identified in cats, *Neochlamydia hartmannellae;* the clinical significance of this organism is yet to be determined.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis may be suspected based on clinical signs (i.e., marked persistent conjunctivitis) and response to appropriate antimicrobials.

DIFFERENTIAL DIAGNOSIS

- Infectious causes:
  - Feline herpesvirus 1
  - Feline calicivirus
  - *Bordetella bronchiseptica*
  - *Mycoplasma* spp.
  - *Cryptococcus neoformans*
  - *Aspergillus* spp.
- Noninfectious causes:
  - Eyelid and nasal neoplasia (including nasopharyngeal polyps)
  - Dental disease
  - Congenital eyelid malformations
  - Palate defects
  - Chemical irritants
  - Foreign bodies
  - Trauma
  - Immune-mediated/inflammatory (e.g., eosinophilic keratoconjunctivitis)

INITIAL DATABASE

Conjunctival scrapings: may reveal inclusion bodies within epithelial cells when stained with Giemsa. Low sensitivity and specificity.

ADVANCED OR CONFIRMATORY TESTING

- Human ELISA antigen kits for *Chlamydia trachomatis:* performed on conjunctival swabs, variable sensitivity and specificity
- Cell culture: available in specialized laboratories, requires special transport media, and sensitivity varies depending on equipment and technical expertise
- PCR: performed on conjunctival swabs; sensitivity and specificity varies with the laboratory; quality control may be problematic in some laboratories; ensure positive and negative extraction controls are included with each run
- Positive serologic titers: correlate well with infection in unvaccinated cats, but reliable assays not yet readily available

TREATMENT

TREATMENT OVERVIEW

The cornerstone of treatment is antibiotics (doxycycline), with supportive care as needed.

ACUTE GENERAL TREATMENT

- Doxycycline, 10 mg/kg PO q 24 h for at least 4 weeks
- Treat all cats in the household simultaneously.
- Because infection is systemic, use of topical ocular treatment alone is not likely to be effective.

- Doxycycline is superior to azithromycin.
- A 4-week course of amoxicillin-clavulanic acid (2.5 mg/kg PO q 12 h) may also eliminate *C. felis*.

POSSIBLE COMPLICATIONS

- Risk of teeth discoloration in kittens if tetracyclines are used in the last 2-3 weeks of pregnancy or for kittens in the first few months of life.
    - Little evidence that this occurs with doxycycline; amoxicillin-clavulanic acid is an acceptable alternative in this situation.
- Administration of doxycycline liquid oral suspension minimizes the risk of doxycycline-induced esophagitis associated with tablets (or follow tablet administration with a water bolus by syringe).

RECOMMENDED MONITORING

Consider retesting with PCR or cell culture in problem cattery situations after treatment to ensure infection has been eliminated.

PROGNOSIS AND OUTCOME

- Excellent in households with low numbers of cats
- Fair in cattery situations; recurrent cases involve large numbers of cats and poor compliance. All cats in the household must be treated with the full course of antimicrobials and proper hygiene and quarantine maintained. Concurrent infections with feline calicivirus and feline herpesvirus 1 are a common problem.

PEARLS & CONSIDERATIONS

COMMENTS

- There is some evidence that *C. felis* may infect the reproductive tract and cause vaginal discharge. Abortion and infertility have been documented in some cats infected with *C. felis*, but in general it appears that *C. felis* does not cause feline reproductive disease.
- There is experimental evidence that *C. felis* may be associated with lameness in cats.

PREVENTION

- Maintenance of environmental hygiene in catteries and disinfection of fomites with a 1:32 solution of bleach in tap water, to which detergent may be added
- Modified live and inactivated cell culture vaccines are available, which do not prevent infection or clinical signs, although the latter are reduced in severity.
    - Associated with atypical reactions in a small percentage of cats, including fever, anorexia, and lameness 7-21 days after vaccination
    - May be useful as part of a control program in catteries with endemic chlamydiosis

EDITOR: DOUGLASS K. MACINTIRE

Cheyletiellosis

BASIC INFORMATION

DEFINITION

Cheyletiellosis is a highly contagious, zoonotic skin disease of dogs, cats, and rabbits caused by the surface-living mite, *Cheyletiella* spp.

SYNONYM

Walking dandruff

EPIDEMIOLOGY

SPECIES, AGE, SEX

Young animals are more frequently affected.

GENETICS & BREED PREDISPOSITION

Long-haired cats appear to be more commonly affected.

RISK FACTORS

More common in dogs and cats from shelter and breeding establishments or that have been in boarding and grooming facilities.

CONTAGION & ZOONOSIS

- *Cheyletiella* spp. mites are very contagious and not host specific; they may transfer readily between dogs, cats, and rabbits.
- Cheyletiellosis is a zoonotic disease; humans are at risk if exposed to an infested pet (whether or not overt clinical signs are present in the pet).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Reason for presentation can be any combination of scaling, pruritus, or zoonosis.

PHYSICAL EXAM FINDINGS

- Scaling (“dandruff”) noted primarily over the dorsum and neck *and/or*
- Mild to moderate pruritus or over-grooming in cats *and/or*
- Dorsal erythema, papules and crusting can be noted occasionally, particularly in cats (miliary dermatitis)
- Among the exfoliated epidermal cells, *Cheyletiella* mites can be seen moving. hence the name “walking dandruff.” The term should not be overinterpreted; the mites are much smaller than skin scales, and a pet has to be very still to enable the clinician to see the subtle movement of mites carrying scales and/or the mites themselves.
- Some pets not noted by the owner to have clinical signs are presented for evaluation because of suspected zoonotic lesions in a human in contact with the animal.

ETIOLOGY AND PATHOPHYSIOLOGY

- *Cheyletiella* is a relatively large mite (0.05 mm, barely visible to the naked eye) with prominent hooklike mouth parts; it lives on the skin surface and feeds on surface debris and exudates. These mites form pseudotunnels in the surface keratin.
- The mite eggs, smaller than lice eggs, are loosely attached to hair shafts.
- The entire life cycle is completed on the host within approximately 3 weeks.
- Although adult mites may survive in the environment for 10 days off the host, eggs are shed into the environment with the pet's hair and may be an important source of reinfestation beyond those 10 days.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected from the history and clinical signs, which include any combination of scaling, pruritus, and/or zoonosis (possibly in presence of an animal without cutaneous lesions).

DIFFERENTIAL DIAGNOSIS

In dogs, differential diagnosis depends on the clinical presentation.

- If only scaling is present, differential diagnoses include:
  - Ectoparasites (fleas, lice)
  - Ill thrift or nutritional imbalance (e.g., intestinal parasitism, poor nutrition)
  - Cornification disorders (ichthyosis, primary seborrhea)
- If pruritus is present, differentials include:
  - Ectoparasites (lice, sarcoptic mange)
  - Hypersensitivities (flea bites, atopic dermatitis, food)
  - Pyoderma
  - Fungal infections *(Malassezia*, dermatophytosis)

In cats, miliary dermatitis due to other causes such as hypersensitivity (flea bites, food, environmental) and dermatophytosis should be considered, as well as other causes of generalized scaling and pruritus.

In humans, the pruritic papular eruption (papular urticaria) induced by a hypersensitivity reaction to *Cheyletiella* mites is often undistinguishable from other zoonotic (fleas, *Sarcoptes* spp., *Dermanyssus* spp.) or nonzoonotic arthropod (harvest mites, straw itch mites, bedbugs) bite reactions.

INITIAL DATABASE

- Confirmation relies on the collection and identification of the mites.
- Mites and eggs can be harvested using adhesive acetate tape (transparent “Scotch tape”) preparations, superficial skin scrapings, flea combing, fecal flotation, or simply by collecting dislodged scales from the skin surface following rubbing/petting the animal's back.
- The epidermal debris is examined with a magnifying lens or put on a glass slide, mixed with mineral oil, covered with a cover slip and examined under microscope at low power.
- The mites and eggs can be found in fairly large numbers, but occasionally they may be difficult to recover, especially in adult cats, owing to their grooming habits.

ADVANCED OR CONFIRMATORY TESTING

- *Cheyletiella* eggs and mites can sometimes be identified in a fecal flotation.
- Therapeutic trials with reliable acaricides are essential to confirm or rule out cheyletiellosis in pruritic or scaling animals with negative samplings, as well as when a human in contact has a pruritic papular eruption evocative of skin lesions caused by zoonotic arthropod bite reactions.

TREATMENT

TREATMENT OVERVIEW

- The goal of treatment is to thoroughly eradicate the mites. All affected and in-contact animals should be treated with an appropriate acaricide regardless of presence or absence of clinical signs.
- All suspected cheyletiellosis cases should be treated even if the parasite has not been isolated.
- Environmental treatment may be required in severe cases.

ACUTE GENERAL TREATMENT

- Selamectin (Revolution/Stronghold [Pfizer]) and moxidectin/imidacloprid (Advantage Multi/Advocate [Bayer]) are not approved for the treatment of cheyletiellosis but appear effective when applied topically every 2-4 weeks for a treatment course of 2 months.

- Off-labeled ivermectin remains a popular treatment option in cats and can still be a therapeutic alternative in dogs but should never be used in collies or related breeds carrying the ABCB1 (MDR1) mutation (see p. 706). The injectable product (Ivomec 1% injection for cattle and swine [Merial]) is usually given at a dosage of 0.3 mg/kg q 7 days PO or q 14 days SQ for a 6- to 8-week course of treatment. The 0.5% alcohol based pour-on ivermectin formulation (Ivomec Pour-On for cattle [Merial]) is also effective and practical when applied to the interscapular skin q 14 days at 0.5 mg/kg for 3-4 treatments.
- Milbemycin oxime (Interceptor [Novartis]) was shown to be effective in dogs but may require up to 9 weekly oral doses (at 2 mg/kg) for eradication of the mites.

POSSIBLE COMPLICATIONS

In collies and other herding breeds, the MDR1 (ABCB1) mutation can cause intoxication with commonly recommended dosages of ivermectin or other off-label macrocyclic lactones (see pp. 625 and p. 706).

PROGNOSIS AND OUTCOME

- Prognosis is excellent.
- In humans, the zoonotic infestation is transient, with resolution of the pruritic papular eruption when the mites are eradicated from the dog.

PEARLS & CONSIDERATIONS

COMMENTS

- Infested animals may show no clinical signs.
- Cheyletiellosis is possible even if there is only one animal with clinical signs among a household full of dogs and cats without any clinical signs whatsoever.
- Due to cross sensitization, a positive intradermal skin test result for the house dust mite antigen is seen in 50% of dogs with cheyletiellosis. All clinical signs resolve and intradermal reaction to house dust mites are generally negative within a few months following acaricidal therapy. This illustrates the importance of ruling out cheyletiellosis prior to testing for atopic dermatitis.

CLIENT EDUCATION

- Humans transiently infected with *Cheyletiella* spp. mites may develop an uncomfortable, pruritic papular eruption, especially on the arms, trunk, and buttocks. This should spontaneously resolve within 3 weeks when the mites are eradicated from the animals and the environment. Symptoms should prompt the person to consult with a physician.

AUTHOR EDITOR: MANON PARADIS

Chemotherapy: Adverse Reactions

BASIC INFORMATION

DEFINITION

Chemotherapy targets rapidly dividing cells. However, normal proliferating cells (gastrointestinal [GI] epithelial, bone marrow, others) may be affected, resulting in adverse reactions. In addition, some chemotherapy agents cause unique toxicities.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Drugs that should not be administered to cats:
  - Cisplatin: fatal pulmonary edema
  - 5-Fluorouracil: fatal neurologic signs
- Toxicities not generally observed clinically in cats:
  - Cyclophosphamide: hemorrhagic cystitis
  - Doxorubicin: despite documented histologic changes, cardiotoxicity not seen clinically

GENETICS & BREED PREDISPOSITION

Several herding breeds (collie, Australian shepherd, Shetland shepherd, German shepherd, border collie, Old English sheepdog, and others), sight hounds (longhaired whippet and silken wind-hound), and mixed breed dogs have been reported to have mutations in the ABCB1 gene, which may result in decreased expression of P-glycoprotein (P-gp) and increased risk of toxicity with drugs that are substrates for this protein (see p. 706).

RISK FACTORS

- ABCB1 mutation (see Genetics & Breed Predisposition above): increased toxicity with P-gp substrates including vincristine, vinblastine, doxorubicin, and others
- Significant infiltration of bone marrow by neoplastic cells: myelosuppression
- Neoplastic GI involvement: GI toxicity
- Clinically ill patients may be more likely to develop adverse effects and should receive concurrent supportive care.
- Preexisting cardiomyopathy: increased risk of doxorubicin cardiotoxicity
- Preexisting renal dysfunction: increased risk of toxicity with renally excreted drugs; increased risk of cisplatin nephrotoxicity
- Preexisting hepatic dysfunction: increased risk of toxicity with drugs eliminated by the liver and possible increased risk of hepatotoxicity

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Administration of associated chemotherapeutic agent

PHYSICAL EXAM FINDINGS

- Adverse reactions occurring during administration:
  - Allergic reactions (L-asparaginase, doxorubicin, taxanes [rarely used])
    - Facial swelling, erythema, urticaria, panting, agitation, vomiting, diarrhea, dyspnea, tachypnea, collapse, hypotension
  - Extravasation injury (vincristine/vinblastine, doxorubicin, actinomycin D, dacarbazine, mechlorethamine, cisplatin)
    - No immediate signs
    - Erythema, inflammation, licking site 7-14 days post treatment
    - Can progress to slough of skin and subcutis
  - Acute vomiting—Common: cisplatin, dacarbazine, streptozotocin. Less common: doxorubicin, cyclophosphamide, mechlorethamine, procarbazine
    - Vomiting during/within 24 hours of chemotherapy
- Delayed adverse reactions:

    - GI toxicity—Common: doxorubicin, MOPP (mechlorethamine, vincristine, procarbazine, prednisone) protocol, cisplatin, dacarbazine. Less common: vincristine, vinblastine, cyclophosphamide, CCNU (lomustine, rare), mitoxantrone, carboplatin, actinomycin
        - Vomiting, diarrhea, lethargy, anorexia 2-5 days after chemotherapy
        - Vincristine: may cause paralytic ileus and associated GI signs
        - Doxorubicin: may cause life-threatening hemorrhagic colitis
    - Myelosuppression/sepsis—Most common: CCNU, carboplatin. Possible: doxorubicin, mitoxantrone, cyclophosphamide (especially when combined with vincristine).
        - Usually no overt manifestations
        - Possible: lethargy, loss of appetite, fever with febrile neutropenia/sepsis, generally 1 week post administration
        - Neutrophil count nadir (lowest) typically occurs 7 days after ad ministration.
        - Neutrophil nadir and onset of signs with cisplatin, carboplatin, and CCNU (in cats) is more variable; can occur 1, 2, or 3 weeks post chemotherapy (rarely later) and may be prolonged
- Unique adverse reactions:
    - Cardiac toxicity (doxorubicin)
        - Arrhythmias, exercise intolerance, weakness, collapse, tachypnea, tachycardia
    - Hemorrhagic cystitis (cyclophosphamide, ifosfamide)
        - Stranguria, pollakiuria, hematuria, incontinence, pain
    - Nephrotoxicity (cisplatin, streptozotocin; uncommon: doxorubicin [cats], CCNU; extremely rare: carboplatin)
        - Often no clinical signs
        - With progression, polyuria, polydipsia, lethargy, decreased appetite
    - Hepatotoxicity (CCNU, streptozotocin)
        - Often no clinical signs
        - If progresses, icterus, lethargy, loss of appetite, GI signs, and abdominal effusion

ETIOLOGY AND PATHOPHYSIOLOGY

- Allergic reactions—L-asparaginase: type I hypersensitivity reaction. Doxorubicin: directly stimulates mast cell degranulation.
- Extravasation injury: vesicant injury to local tissue; multiple mechanisms
- Acute vomiting: irritation of chemoreceptor trigger zone
- Gastrointestinal toxicity: injury to GI crypt epithelium
- Myelosuppression/sepsis: injury to proliferating bone marrow cells causes neutropenia and possibly thrombocytopenia. Severe neutropenia allows opportunistic infection, usually by GI bacteria (usually gram-negative, but gram-positive and anaerobic infections possible).
- Cardiac toxicity: doxorubicin induces acute arrhythmias by increasing circulating catecholamines. Free radical formation by doxorubicin causes cumulative injury to myocardium and fibrosis (doses = 180-240 mg/m^2) because of low levels of cardiac catalase and because doxorubicin decreases glutathione peroxidase activity. In addition, changes in transcriptional activity alter cardiac protein expression. Consequences include arrhythmias and decreased contractility, progressing to dilated cardiomyopathy weeks to months after treatment.
- Hemorrhagic cystitis: metabolite of cyclophosphamide (acrolein) directly toxic to the bladder urothelium
- Nephrotoxicity: cisplatin, streptozotocin: tubular injury and decreased glomerular filtration (cisplatin)
- Hepatotoxicity: CCNU causes hepatocellular and ductal epithelial injury with inflammation and cholestasis, eventually progressing to cirrhosis.

DIAGNOSIS

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis:
    - Neutropenia, possibly thrombocytopenia (myelosuppression)
    - Azotemia, low urine specific gravity (nephrotoxicity)
    - Hematuria (hemorrhagic cystitis)
    - Elevated liver enzymes (hepatotoxicity)
- Additional tests (e.g., diagnostic imaging) as determined by history, exam, and lab test results

TREATMENT

TREATMENT OVERVIEW

Control of toxic effects and prevention of secondary complications are the therapeutic goals.

ACUTE GENERAL TREATMENT

- Adverse reactions occurring during administration:
  - Allergic reactions
    - Depends on severity.
    - Dexamethasone, SP 0.2-0.5 mg/kg IV
    - Diphenhydramine, 1-2 mg/kg IM
    - Intravenous fluids, 90 mL/kg/h (dog) or 50 mL/kg/h (cat)
    - Epinephrine if severe (Dilute 1 mL of 1:1000 solution in 9 mL of 0.9% NaCl. Give 0.1 mL/kg of 1:10,000 solution IV.)
  - Extravasation injury
    - Aspirate drug back before removing catheter.
    - Apply compresses (cold for doxorubicin; warm for vincristine/vinblastine) for 10 minutes q 6 h for 72 hours after extravasation.
    - Vincristine/vinblastine: infuse 1 mL 1% hyaluronidase for each mL extravasated.
    - Doxorubicin: administer dexrazoxane (anecdotal dose used by author: 400-600 mg/m^2 IV in a different vein within 3 hours of administration; repeat at 24 and 48 hours). Topical DMSO (dimethyl sulfoxide) gel q 8 h for 14 days (wear gloves when applying) may also be helpful.
    - Wound management: E collar, clip/clean, topical or systemic antibiotic, topical or systemic antiinflammatory
    - Surgical débridement/grafting if severe
  - Acute vomiting
    - Stop administration
    - Nothing by mouth
    - Antiemetic therapy (See section on delayed vomiting for drugs and dosages below.)
    - IV fluid support if indicated
- Delayed adverse reactions:
  - Gastrointestinal toxicity
    - Nothing by mouth
    - Patient acting normally, self-limiting vomiting: antiemetics (maropitant citrate [dogs] 2 mg/kg PO q 24 h for up to 5 days (in cats has been used at 1 mg/kg PO q 24 h); metoclopramide [dogs or cats] 0.2-0.5 mg/kg PO q 8 h); water trial then bland diet trial. Decreased appetite: tempting bland foods, appetite stimulant (mirtazapine [dogs] 0.6 mg/kg, not to exceed 30 mg/d, PO q 24 h, [cats] 3-4 mg/cat PO q 72 h; or cyproheptadine [cats]: 1-2 mg PO q 12-24 h).
    - Patient acting normally, diarrhea not bloody or watery: bland diet, consider metronidazole, 15 mg/kg PO q 12 h for colitis.
    - Patient lethargic, vomiting/diarrhea continuing, or watery or bloody diarrhea: admit to hospital for supportive care.
      - Intravenous fluids
      - Antiemetics
        - Maropitant citrate (dogs and cats): 1 mg/kg SQ q 24 h, up to 5 days, *or*
        - Metoclopramide (dogs/cats): 0.2-0.5 mg/kg SQ q 8 h or IV as a CRI at 1.1-2.2 mg/kg/d (if maropitant does not control nausea; also for vincristine-induced ileus).
        - If refractory:
          - Dolasetron: (dogs/cats) 0.6-1 mg/kg IV slowly q 12-24 h
          - Ondansetron: (dogs) 0.1-1 mg/kg IV slowly q 12-24 h; (cats) 0.1-0.15 mg/kg IV slowly q 6-12 h
      - H2 receptor antagonist
        - Famotidine, 0.5-1 mg/kg IV slowly q 12-24 h
      - Antibiotic therapy if bloody vomiting/diarrhea, neutropenic, or febrile
      - Parenteral feeding if prolonged vomiting, enteral feeding tube if prolonged anorexia (rare)
      - Usually resolves in 2-3 days
  - Myelosuppression/sepsis
    - Usually no treatment required. Counts generally normalize within 2-3 days (except carboplatin-prolonged nadirs and CCNU in cats).
    - If neutrophil count < 1000 cells/mcL, consider prophylactic antibiotics for dogs. A common choice is amoxicillin/clavulanic acid, 20 mg/kg PO q 12 h for 4-7 days. For breeds other than Doberman pinschers and if dogs have normal tear production, sulfadiazine-trimethoprim, 15 mg/kg PO q 12 h for 5-7 days is an option. Cats do not usually need prophylactic antibiotics.
    - If febrile or ill, admit to hospital for intravenous fluids and intravenous antibiotics:
      - Base on culture and sensitivity if available (urine, blood, infected site)
      - Empirical treatment option while culture results pending: ampicillin, 22 mg/kg IV q 8 h, with enrofloxacin, 5 mg/kg (cats) or 10 mg/kg (dogs); dilute and give slowly IV q 24 h.
- Unique adverse reactions:
  - Cardiac toxicity (doxorubicin)

        - No treatment beyond management of cardiac disease
        - Avoid additional doxorubicin.
    - Hemorrhagic cystitis (HC)
        - Treat bacterial cystitis if present.
        - Generally self-limiting, but may take weeks to months to resolve. Some dogs show lifelong signs of cystitis.
        - Antiinflammatory: nonsteroidal antiinflammatory drug or prednisone
        - Analgesic: tramadol, 2-4 mg/kg q 8 h PO or another opioid agent
        - Oxybutynin hydrochloride (0.2 mg/kg PO q 8-12 h) has been recommended for straining, pollakiuria
        - Instillation of diluted dimethyl sulfoxide into the bladder may be helpful if refractory. Consultation with an oncologist is recommended for refractory HC.
        - After HC, cyclophosphamide should not be administered again. Often chlorambucil is substituted.
    - Nephrotoxicity
        - Discontinue drug.
        - Treatment usually not necessary, but if clinical or acute renal failure, hospitalize for therapy.
    - Hepatotoxicity
        - Discontinue drug.
        - *S* -adenosyl-L-methionine (SAMe): anecdotally may be helpful; 18 mg/kg PO q 24 h or divided dose q 12 h. Administer on empty stomach.
        - Treat hepatic dysfunction if indicated.

CHRONIC TREATMENT

Cardiac toxicity, chronic bone marrow toxicity, nephrotoxicity, and hepatotoxicity may require ongoing therapy.

DRUG INTERACTIONS

Many possible interactions of chemotherapy agents with each other and other drugs. It is the responsibility of veterinarians treating patients with chemotherapy to review possible interactions associated with each agent before administration.

RECOMMENDED MONITORING

For all patients undergoing chemotherapy:

- CBC at the expected time of the neutrophil nadir the first time they receive each drug. CBC rechecked as indicated, especially before administration of potentially myelosuppressive chemotherapy.
- Serum chemistry profile should be performed every 2-3 months or more frequently if indicated (see p. 503 , p. 501).
- Urinalysis should be performed every 6 months or more often if indicated.

PROGNOSIS AND OUTCOME

With appropriate treatment and supportive care, most patients will recover from delayed adverse reactions and those that occur during administration. Cardiac toxicity, chronic bone marrow toxicity, nephrotoxicity, and hepatoxicity generally do not resolve but may improve or stabilize.

PEARLS & CONSIDERATIONS

COMMENTS

- Clinicians treating veterinary cancer patients must know the complications associated with chemotherapeutic agents and be able to take appropriate preventive measures and manage adverse effects.
- It is essential to understand the metabolism and excretion of chemotherapy agents when treating patients with organ dysfunction, because dose reductions or avoidance of certain drugs may be necessary.
- It is also essential to understand drug interactions that might exacerbate toxicity with chemotherapeutic agents.

TECHNICIAN TIPS

- Multiple toxicities are possible during chemotherapy administration. It is critical that technicians administering these drugs know these toxicities and how to prevent them, recognize them, and manage them.
- Signs of serious chemotherapy toxicity may be as subtle as lethargy and loss of appetite. It is important to educate clients to communicate with the veterinarian and veterinary technicians if their pet is not normal to them.
- The majority of adverse effects associated with chemotherapy occur on a predictable timetable. Veterinarians and technicians

treating patients with these drugs should know when relevant toxicities would be expected and be able to recognize signs of these toxicities.
- It is important to remember that veterinary cancer patients receiving chemotherapy can develop illnesses unrelated to their cancer or chemotherapy.

PREVENTION

- Double-check all dose calculations, route of administration, and patient's history, exam, and lab test results prior to administration. Consider testing breeds at risk for MDR-1 mutation.
- Allergic reactions
  - L-Asparaginase: premedicate (20 minutes pretreatment): diphenhydramine, 2 mg/kg IM, then monitor patient 30-60 minutes post treatment. If allergic reaction, patient should not receive this drug again.
  - Doxorubicin: administer slowly (1 mg/min, not faster than 10 minutes for doses <10 mg). If allergic reaction, premedicate with diphenhydramine (as above) dexamethasone SP, 0.5 mg/kg SQ, and administer more slowly.
- Extravasation injury
  - Administer chemotherapy through intravenous catheter placed perfectly on first attempt in vein not punctured within 24 hours.
  - Comfortably restrain patient; sedate if fractious.
  - Flush catheter with 3 to 5 mL of 0.9% NaCl before and after administration.
  - Monitor site during treatment.
- Acute vomiting
  - Administer chemotherapy slowly.
  - Pretreatment antiemetic agents are given prior to cisplatin, streptozotocin, or dacarbazine administration. Options include:
    - Maropitant citrate (dog and cat): 1 mg/kg SQ 1 hour prior to chemotherapy. Effective.
    - Butorphanol (dog): 0.2-0.4 mg/kg IM 20 minutes prior to chemotherapy. Not used as frequently now that maropitant is available.
    - Dolasetron: (dog/cat) 0.6-1 mg/kg slow IV immediately prior to chemotherapy
    - Ondansetron: (dog) 0.1-1 mg/kg PO or IV slowly 30 minutes prior and 90 minutes after starting cisplatin; (cat) 0.1-0.3 mg/kg IV slowly 15 minutes before and 12 hours after chemotherapy
  - For less emetogenic agents:
    - Maropitant citrate: (dog/cat) 1 mg/kg SQ or (dog) 2 mg/kg PO; (cat) 1 mg/kg PO 1 hour prior to chemotherapy
    - Metoclopramide: (dog/cat) 0.2-0.5 mg/kg PO or SQ q 8 h starting at least 30 minutes before treatment
- Gastrointestinal toxicity
  - Double-check chemotherapy doses.
  - If patient hospitalized with gastrointestinal toxicity, reduce subsequent doses of that drug by 20%.
  - Prophylactic antiemetic if history of gastrointestinal toxicity (maropitant citrate, [dog] 2 mg/kg PO, [cat] 1 mg/kg PO q 24 h up to 5 days; or metoclopramide, 0.2-0.5 mg/kg PO q 8 h)
- Myelosuppression/sepsis
  - CBC before myelosuppressive chemotherapy. Do not treat if <2500 neutrophils/L or <150,000 plate-lets/mcL. If suspect platelet count is below normal due to chronic bone marrow injury, recommend consultation with oncologist before further chemotherapy.
  - Due to the potential for cumulative thrombocytopenia, CCNU chemotherapy may need to be discontinued if a pretreatment CBC reveals a platelet count that has decreased below the reference range.
  - Double-check chemotherapy doses.
  - CBC at expected neutrophil nadir the first time patient receives each agent
  - If neutrophil count at nadir is <1000 cells/mcL, reduce subsequent doses of that drug by 20%.
  - If overdose, treat with recombinant human granulocyte colony stimulating factor (rhG-CSF) 5 mcg/kg q 24 h SQ for 3-5 days starting 24 hours after treatment.
- Cardiac toxicity
  - Do not treat dogs with cardiotoxic agents if they have myocardial dysfunction.
  - Cardiac evaluation for breeds at risk for dilated cardiomyopathy and dogs with cardiac abnormalities (heart murmur, arrhythmia, cardiomegaly) before doxorubicin
  - Limit total lifetime cumulative doxorubicin dose to <180-240 mg/m^2; substitute noncardiotoxic agents (mitoxantrone, actinomycin-D) after 150 mg/m^2.
  - Dexrazoxane: 10 mg for every 1 mg of doxorubicin given IV within 30 minutes of each dose. Not helpful once cardiac injury present. Not used routinely in veterinary oncology, owing to cost.
- Hemorrhagic cystitis
  - Administer in morning.
  - Give furosemide (2 mg/kg PO, IV, or SQ) with cyclophosphamide.
  - Ad lib access to water
  - Encourage frequent urination.
  - After HC, cyclophosphamide should not be administered again. Often chlorambucil is substituted.
- Nephrotoxicity

    - Urine specific gravity and serum creatinine before every dose of cisplatin, streptozotocin
    - Serum biochemistry profiles and urinalyses for all patients at least every 3 months, more frequently if indicated
    - Fluid diuresis protocol required with cisplatin, streptozotocin
- Hepatotoxicity
    - Check liver enzymes with every other dose of CCNU or streptozotocin or more frequently if indicated; discontinue drug if an increase in liver enzymes is noted.
    - It is unknown whether SAMe can help prevent this toxicity.

CLIENT EDUCATION

Provide information that allows clients to recognize adverse effects of chemotherapy and encourage them to seek veterinary care promptly.

Chagas Disease

BASIC INFORMATION

DEFINITION

Chagas disease is a relatively rare, geographically specific condition caused by infection with the hemoflagellate protozoa, *Trypanosoma cruzi*. It results in chagasic myocarditis, which is characterized by brady- and/or tachyarrhythmias with or without a dilated cardiomyopathy clinical picture indistinguishable from idiopathic dilated cardiomyopathy.

SYNONYMS

American trypanosomiasis, chagasic myocarditis

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs:

- Young dogs (<1 year of age) develop a more severe form of the acute stage of the disease which is often rapidly progressive and fatal.
- Hunting dogs may be at increased risk because of increased exposure to the vector and reservoir hosts, but house dogs have been infected.

CONTAGION & ZOONOSIS

- Humans and dogs may be infected via common source (reduviid beetle) but not directly zoonotic or contagious. Exception: blood-blood contact (e.g., animal blood on open human wound).

GEOGRAPHY AND SEASONALITY

In the United States, most canine cases occur in Texas and elsewhere along the U.S.-Mexico border. *T. cruzi* infection is a major human health problem in South America, Mexico, and Central America.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

The disease occurs in three stages:

- Acute stage, 0-4 weeks post inoculation: severe ventricular tachyarrhythmias and often fatal (sudden death or severe heart failure) in puppies and dogs <1 year of age.
- An extended latent period lasting 1-60 months. No clinical signs, but chronic changes develop. Abnormalities are found as incidental findings (e.g., on echocardiography or electrocardiography [ECG]).
- Chronic stage: overt clinical signs due to congestive heart failure or cardiac arrhythmias occurring weeks to years postinfection.

HISTORY, CHIEF COMPLAINT

Most commonly related to heart failure with or without tachy- or bradyarrhythmias. History of travel to/residence in southernmost United States, Mexico, or Central or South America.

PHYSICAL EXAM FINDINGS

- Acute stage: normal if mature dog; as below for latent stage and chronic stage for young dogs and puppies; peripheral lymphadenopathy possible.
- Latent stage: normal or signs consistent with progressive cardiac remodeling, such as weak femoral arterial pulse, soft heart murmur, arrhythmia with or without pulse deficits

- Chronic stage: brady- or tachyarrhythmias with/without pulse deficits, weak pulse, soft heart murmur, crackles or wheezes or increased bronchovesicular sounds, absent lung sounds, signs of right-sided heart failure (abdominal distension from ascites/hepatomegaly, jugular distension, positive hepatojugular reflux test). Bradyarrhythmias (e.g., AV block) seem to be more common in the chronic stage of the disease.

ETIOLOGY AND PATHOPHYSIOLOGY

- Acute stage (0-4 weeks postinoculation)
- Trypomastigotes (flagellated form) enter the blood via infected reduviid bite (*Triatoma gerstaeckeri* vector in United States) or ingestion of infected reduviid bug or infected reservoir host (armadillo, opossum, raccoon, mouse, squirrel, rat, dog). Blood transfusion–mediated and transplacental and transmammary transmission also occur.
- Trypomastigotes are taken up by monocytes and macrophages in cardiac and skeletal tissue (possibly nervous tissue) and transform into amastigotes (nonflagellated form) then multiply rapidly, leading to cell rupture.
- The amastigotes transform back to trypomastigotes prior to cell rupture. Rising parasitemia occurs, peaking at 2-3 weeks post inoculation and decreasing by 4 weeks post inoculation.
- Latent stage (4 weeks to 5 years postinoculation)
- After 4 weeks, clinical signs diminish or disappear while chronic changes develop (via myocardial necrosis/fibrosis, local coronary spasm, and possible immune-mediated pro gression +/− low levels of persistent parasitism).
- Chronic stage (months-years post inoculation)
- Progressive myocardial changes lead to systolic dysfunction (dilated cardiomyopathy), pathologic bradycardias (advanced 2nd-degree or 3rd-degree AV block), and/or congestive heart failure; ventricular tachyarrhythmias are less common than in the acute stage.
- Protective immunity does not develop in infected dogs or people.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

In puppies/young dogs with signs of heart disease living in (or traveling to) endemic areas, every effort should be made to find the organism on a blood smear or buffy coat smear. In mature dogs, a Chagas titer should be performed.

DIFFERENTIAL DIAGNOSIS

- Dilated cardiomyopathy (idiopathic)
- Other causes of myocarditis (see p. 743)
- Other causes of right heart failure (see p. 468)
- Other causes of AV block (see p. 117)

INITIAL DATABASE

- Young dog or puppy (listed from most to least useful):
  - Blood smear or buffy coat (better) stained with Giemsa or Wright stain: definitive diagnosis if organism is seen (trypomastigotes; flagellate organisms, two to three times as long as the diameter of erythrocytes). Ascitic or pleural fluid can also be tested if available.
  - With respiratory signs: thoracic radiographs are indicated. Cardiomegaly, with or without evidence of congestive heart failure (e.g., pulmonary edema), can occur.
  - With weakness, collapse, or arrhythmia in the absence of respiratory distress: ECG is indicated before radiographs (expect ventricular premature complexes/ventricular tachycardia, or 2nd/3rd-degree AV block).
  - Echocardiography is indicated to identify chamber dilation and poor systolic function if present.
  - Serum biochemistry profile: liver enzymes may show mild to moderate elevation.
  - CBC: lymphocytosis is common.
  - Serum cardiac troponin I: elevated; not specific for chagasic myocarditis
- Mature dog (listed from most to least useful):
  - Chagas titer in dogs suspected of chagasic myocarditis. Titer is typically positive by 3 weeks postinfection.
  - If dog presents with respiratory signs, thoracic radiographs should be performed and may demonstrate cardiomegaly, with or without evidence of congestive heart failure (e.g., pulmonary edema)
  - If dog presents for weakness, collapse, or arrhythmia in the absence of respiratory distress, then ECG +/− Holter monitoring (24-hour ambulatory ECG) would be indicated before radiographs.
  - Echocardiogram is indicated to define cardiac lesion responsible for clinical presentation
  - Serum biochemistry profile: liver enzymes may be mild to moderately elevated. Blood smears and buffy coat smears typically will be negative.
  - Serum cardiac troponin I may or may not be elevated; elevations are nonspecific.

CONFIRMATORY TESTING

- Acute infection:
  - Cytologic identification of trypomastigotes in blood smear, buffy coat smear, abdominal effusion, lymph node aspirates
  - Histopathologic identification of amastigotes in myocardium
- Chronic infection:
  - Serologic testing: titer is typically positive by 3 weeks post infection.
    - Indirect fluorescent antibody (offered by Texas Veterinary Medical Lab [http://tvmdl.tamu.edu/] and Idexx [www.idexx.com])
    - ELISA
    - Radioimmunoprecipitation
- Flow cytometry
- Histopathologic evaluation of tissues, as above

TREATMENT

TREATMENT OVERVIEW

Supportive treatment for arrhythmias and congestive heart failure is recommended. There is no effective treatment to eliminate the organism. Therapeutic goals are:

- Control of the organism (elimination of infection is not considered possible)
- Palliation of clinical signs caused by congestive heart failure and/or arrhythmias
- Prevention of progressive ventricular systolic dysfunction (nonspecific cardioprotective therapies)

ACUTE AND CHRONIC TREATMENT

- See Heart Failure, Acute/Decompensated, p. 468
- See AV Block,
- See Ventricular Tachyarrhythmias,
- Nifurtimox and benznidazole may be useful in the acute stage but are not FDA approved for dogs, are difficult to obtain, and have clinically significant side effects.
- Glucocorticoids: antiinflammatory dose (prednisone 0.5-1 mg/kg PO q 12-24 h) may improve survival.
- Ketoconazole, gossypol, and allopurinol have been investigated, but proof of benefit is lacking.
- Albaconazole has been shown to re duce parasite proliferation without cure.
- Verapamil decreases mortality in acutely infected mice and reduces the severity of disease in chronically infected mice; no evidence of benefit in dogs.

POSSIBLE COMPLICATIONS

Refractory heart failure and/or cardiac arrhythmias. These complications may occur rapidly (weeks to months) in young dogs and puppies and typically occur between 8 and 36 months after the acute stage in mature dogs.

PROGNOSIS AND OUTCOME

- Overt clinical signs may occur rapidly (weeks to months) in young dogs and puppies, and typically occur between 8 and 36 months after the acute stage in mature dogs.
- Acute infection: dogs recognized with acute infections may live 0-60 months postdiagnosis or longer. Young dogs (<1 year of age), puppies, and dogs with overt signs of heart failure and/or severe ventricular arrhythmias typically have a more guarded prognosis.
- Chronic infection: dogs with systolic ventricular dysfunction or arrhythmias but no external manifestations of disease may live for years before developing clinical signs. Once clinical signs develop, appropriate palliative therapy may prolong life. Dogs with clinical signs of heart failure or severe arrhythmias have a guarded long-term prognosis, but appropriate palliative therapy can prolong their lives by months to years.

PEARLS & CONSIDERATIONS

TECHNICIAN TIP

Blood specimens in veterinary practice often are handled with less care than in human medical settings; in areas where Chagas disease is endemic, blood specimens and products from infected animals should be handled with caution by all staff (risk of blood-to-blood zoonosis).

PREVENTION

- Limitation of exposure to the vector (upgrading housing, using insecticides, limiting ingestion of raw reservoir hosts, and otherwise limiting contact between dogs and reservoir hosts). Blood donors should be screened, and breeding bitches in endemic/high-risk areas should also be screened to prevent transplacental and transmammary infection.
- Vector control and limiting canine contact with reservoir hosts is the primary form of prevention.
- Blood donors from endemic areas should be screened.

1ST EDITION AUTHOR: KHRISTEN J. CARLSON

Cervical Spondylomyelopathy

BASIC INFORMATION

DEFINITION

A combination of vertebral malformation and malarticulation that affects caudal cervical vertebrae and associated ligamentous structures

SYNONYMS

CSM, caudal cervical spondylomyelopathy (CCSM), cervical malformation/malarticulation syndrome, cervical vertebral instability, spondylolisthesis, “wobbler syndrome”

EPIDEMIOLOGY

SPECIES, AGE, SEX: Most commonly encountered in middle-aged to older large-breed dogs of either sex. Some reports describe a predilection in males (2 : 1 to 4 : 1) over females.

GENETICS & BREED PREDISPOSITION

Doberman pinschers appear to be most prone to developing CSM. Other commonly-affected breeds include rottweilers, German shepherds, and dalmatians.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Most cases have histories that include progressive gait abnormalities noted for months to years.
- Occasionally, CSM patients experience an acute-onset, rapid development of neurologic dysfunction.
- With CSM, abnormalities of thoracic limb gait are usually present but can be subtle and may be overlooked. When apparent, these abnormalities manifest as a stiff, stilted thoracic limb gait.
- Other less common historic/clinical complaints include nonambulatory tetraparesis or tetraplegia, neck pain, and thoracic limb lameness.

PHYSICAL EXAM FINDINGS

- Neurologic exam findings are consistent with a C6-T2 spinal cord lesion.
  - In ambulatory dogs, a characteristic “choppy,” short-strided forelimb gait with a wide-based, ataxic hind limb gait is common.
  - Chronicity may be suspected by soft-tissue lesions of the hind paws, including excessive wear of the nails and scuffing of the skin of the dorsum of the digits (common).
  - Patellar reflexes may be increased, and there may be delayed postural reactions in the pelvic limbs (including when the patient's weight is supported—delayed hopping response from proprioceptive deficits).
  - The remainder of the neurologic examination is unremarkable.
- Classic lower motor neuron signs to the thoracic limbs are not frequently encountered in ambulatory patients (more common in nonambulatory tetraparetic or tetraplegic dogs).
- Careful palpation of the ventral processes of the cervical vertebrae, as well as side-to-side movements of the head and neck, usually reveal some evidence of pain/cervical hyperesthesia.

ETIOLOGY AND PATHOPHYSIOLOGY

- Affected dogs are believed to have a malformation/malarticulation of caudal cervical vertebrae. The resultant instability of these abnormal vertebral segments leads to hypertrophy of supportive soft-tissue structures including the intervertebral disk. Such hypertrophy and movement lead to spinal cord impingement.
- Genetic (affected breeds), nutritional (overfeeding during growth), and conformational (long neck with large head) influences have been suggested as causative or contributory.
- Vertebral malalignment (“tipping”) as seen radiographically can be part of the malformation but is not necessarily indicative of a spinal cord lesion.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Cervical spondylomyelopathy is suspected when a large-breed, middle-aged to older dog has chronic progressive ataxia affecting the hind limbs more than the forelimbs. Being able to elicit pain during careful cervical manipulation on physical exam, and evidence of chronic soft-tissue trauma to the distal hind paws, further increases the likelihood of the diagnosis. Confirmation requires diagnostic imaging: MRI is ideal, but myelography is also effective.

DIFFERENTIAL DIAGNOSIS

- Type I disk extrusion
- Type II disk protrusion
- Neoplasia
- Spinal cord cyst

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis: generally unremarkable
- Thoracic and cervical radiographs: if other diagnoses (e.g., vertebral neoplasia) are being considered
- Imaging of the cervical spine
    - Myelography or MRI are both acceptable.
    - MRI is preferable because it images within the spinal cord parenchyma, provides superior detail, and is better tolerated by the patient.
    - With either modality, static as well as dynamic views of the spine should be obtained.

TREATMENT

TREATMENT OVERVIEW

There are two goals of treatment for all cases: a return to normal or near-normal gait and elimination of cervical pain. These goals can be achieved through the use of medications in mild cases or cases where other factors (comorbidities, financial restrictions, etc.) limit treatment to medical intervention alone. Over time in many or most cases, lesions progress to such a degree that early surgical intervention is advantageous.

ACUTE GENERAL TREATMENT

- Exercise restriction
- Low-dose oral prednisone therapy (e.g., 0.5 mg/kg PO q 12 h)

CHRONIC TREATMENT

Most patients respond only transiently if at all to medical therapy. Surgical distraction/stabilization is recommended in most cases. Some cases may require dorsal decompression.

POSSIBLE COMPLICATIONS

- Tetraparesis/tetraplegia with lesion progression
- Severe chronic cervical pain
- Self-trauma to distal limbs; secondary infections

PROGNOSIS AND OUTCOME

The majority of dogs (>80%) respond favorably to surgical distraction/stabilization. Dogs that require dorsal decompression typically have a prolonged convalescent period (i.e., they may be nonambulatory for several months postoperatively).

PEARLS & CONSIDERATIONS

COMMENTS

- Poor responses to surgical correction tend to be dramatic and are usually due to either failure of surgical implants or spinal cord compression at a site cranial or caudal to the operative site.
- The radiographic appearance alone does not correlate to the clinical impact of the lesion; imaging and examination are complementary.

TECHNICIAN TIPS

- Affected patients are often large, heavy dogs that require assistance to rise and to walk. Self-protection to minimize the risk of back injuries is essential, and technicians caring for these dogs should be familiar with proper ergonomic methods for lifting and walking with such patients.
- Neck pain in these dogs may be significant, and the neck should be handled gently; use a harness if the patient is ambulatory.

CLIENT EDUCATION

- Avoid neck extension or side-to-side movement of the neck in these dogs.
- Purpose-made foot covers/booties made from dense, resistant fabric with rubberized soles for traction may be very helpful for reducing self-trauma to the hind paws.

AUTHOR & EDITOR: CURTIS DEWEY

Cerebellar Abiotrophy

BASIC INFORMATION

DEFINITION

The spontaneous, premature, progressive degeneration of fully developed cerebellar tissue. Specifically, it involves the loss and degeneration of Purkinje cells (most commonly) within the cerebellar cortex. In contrast, cerebellar hypoplasia is the incomplete development of the cerebellum as a result of an in utero or perinatal insult or genetic abnormality.

SYNONYM

Cerebellar cortical degeneration

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs > cats
- The age of onset varies by breed and species:
  - Early (birth to 3-4 weeks of age): beagle, miniature poodle, rough-coated collie, Irish setter, Airedale terrier, coton de tulear, Finnish harrier, Jack Russell terrier, Rhodesian ridgeback, and Samoyed
  - Onset from 6 weeks to 6 months of age: Australian kelpie, Bernese mountain dog, border collie, bull mastiff, coton de tulear, Gordon setter, Kerry blue terrier, and Labrador retriever
  - Mixed-breed cats: between the ages of 6 and 16 weeks
  - Late-onset: English sheepdog, American Staffordshire terrier, Brittany spaniel, and the Siamese and domestic short-haired cat

GENETICS & BREED PREDISPOSITION

The genetic basis, where established, is an autosomal recessive pattern, affecting both sexes equally.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Animals are normal at birth and present for progressive cerebellar ataxia or other cerebellar clinical signs beginning at the age appropriate for the particular breed.
- There is no known trauma history or toxin exposure, and the animals are usually otherwise healthy.

PHYSICAL EXAM FINDINGS

- Clinical signs reflect cerebellar dysfunction and may include:
  - Cerebellar ataxia
  - Base wide stance
  - Truncal swaying
  - Intention tremors
  - Nystagmus
  - Poor menace response with normal vision
  - Hypermetric gait with preservation of strength
  - Opisthotonos
- Postural responses and spinal reflexes are within normal limits
  - When hopping these patients, the response may be spastic and hypermetric in character.

ETIOLOGY AND PATHOPHYSIOLOGY

The cause of cerebellar abiotrophy is unknown, but it is believed to be an intrinsic metabolic defect such as a defect in glutamate metabolism, causing excitotoxic injury to the cerebellar Purkinje cells.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Cerebellar abiotrophy is a clinical diagnosis of exclusion; a definitive diagnosis is reached only through histopathologic assessment of cerebellar tissue.

DIFFERENTIAL DIAGNOSIS

- Cerebellar abiotrophy should not be confused with cerebellar hypoplasia, because hypoplasia is a nonprogressive disorder, and clinical signs are present at the onset of ambulation.
- Differential diagnoses include in-herited lysosomal storage diseases (gangliosidosis, mannosidosis, hereditary neuroaxonal dystrophy, others), inflammatory causes such as granulomatous meningoencephalitis, and congenital causes such as quadrigeminal cisternal cysts and caudal occipital malformation syndrome. Less common differential diagnoses are encephalitides caused by *Cryptococcus neoformans*, canine distemper virus, feline infectious peritonitis, *Toxoplasma gondii*, and tickborne agents.

INITIAL DATABASE

- The diagnosis is based on signalment, history, and physical and neurologic clinical exams (see p. 1311).
- Typically, initial results of diagnostic tests are normal and not useful in the antemortem diagnosis of this disorder.

ADVANCED OR CONFIRMATORY TESTING

Definitive diagnosis of cerebellar abiotrophy is gained histologically at the time of necropsy. The only gross abnormality noted is a decreased cerebellar mass (<10% of the total brain weight). Unique to the Kerry blue terrier is a pallor, gelatinous change, and cavitation of the caudate nuclei. In advanced cases of cerebellar abiotrophy, a decrease in the size of the cerebellum is appreciated on MRI, though this does not differentiate this disorder from cerebellar hypoplasia.

TREATMENT

TREATMENT OVERVIEW

Because there are no effective treatments for this progressive disorder, treatment is palliative.

BEHAVIOR/EXERCISE

Patients with cerebellar disease are at risk for injuring themselves owing to a lack of balance and coordination. Therefore, keeping them safe, possibly confined, and away from stairs and furniture from which they can fall is advisable.

PROGNOSIS AND OUTCOME

Prognosis is grave because this disease is progressive (slowly in certain breeds and rapidly in others). Rarely, the clinical signs may stabilize, as seen in the rough-coated collie.

PEARLS & CONSIDERATIONS

COMMENTS

- Cerebellar abiotrophy must be differentiated from cerebellar hypoplasia, which is a nonprogressive disease that results from the abnormal development of the cerebellum, with some differentiation of tissue.
- Unlike abiotrophy, which involves an intrinsic metabolic defect, hypoplasia results from an extrinsic cause, most notably a parvovirus. For example, kittens infected with the feline panleukopenia virus either in utero or in the perinatal period may develop cerebellar dysfunction secondary to cerebellar hypoplasia. The virus causes inflammation and destruction of cells in the external germinal layer of the cerebellum, which results in failure to reach normal size.
- Another difference between hypoplasia and abiotrophy is that with hypoplasia, clinical signs are first noted at the onset of ambulation. Because of the disease's nonprogressive nature, most cats will compensate for the dysfunction, or the clinical

signs may lessen. Therefore, this disease carries a more favorable prognosis than cerebellar abiotrophy.

AUTHOR: KERRY SMITH BAILEY

EDITOR: CURTIS W. DEWEY

Caudal Occipital Malformation Syndrome

BASIC INFORMATION

DEFINITION

A congenital malformation of the skull (caudal occipital bone region) that results in intracranial overcrowding and compression of the cervicomedullary junction at the level of the foramen magnum.

SYNONYMS

Chiari type I malformation, Chiari-like malformation, COMS, occipital bone hypoplasia

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Small-breed dogs predisposed; Cavalier King Charles spaniel (CKCS) overrepresented
- Variable age of onset of signs; mean age at diagnosis is 3-6 years. Age of onset/presentation appears to be decreasing, with more dogs being presented at younger than 1 yr of age.

GENETICS & BREED PREDISPOSITION

- Cavalier King Charles spaniel
  - Most common
  - Evidence of heritability, but mode of inheritance has not been determined
- Yorkshire terriers
- Miniature/toy poodles
- Maltese
- Brussels griffon

ASSOCIATED CONDITIONS & DISORDERS

- The vast majority of dogs with COMS also have syringomyelia, usually affecting the cervical spinal cord.
- Other malformations of the craniocervical junction have recently been identified in dogs, which may occur alone or in conjunction with abnormalities of the occipital region: hydrocephalus, intracranial intraarachnoid cysts (quadrigeminal cysts), and malformation of the C1 and/or C2 vertebrae (similar to basilar invagination in people).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Dogs present for a wide variety of clinical manifestations, the most common of which are cerebellovestibular dysfunction and cervical myelopathy.
- A unique presentation of dogs with COMS that have concurrent cervical syringomyelia is incessant scratching at the shoulder region and head/neck region (suspected paresthesia). This appears to be most consistent in the CKCS breed.
- In a small percentage of COMS cases, seizure activity is the chief complaint.
- Clinical signs are often intermittent, often worsening in periods of stress or excitement.

PHYSICAL EXAM FINDINGS

- General examination is usually normal.
- Neurologic examination (see p. 1311) is usually indicative of cervical myelopathy (e.g., upper motor neuron signs to all four limbs), cerebellovestibular dysfunction (head tilt, resting nystagmus, circling, loss of balance, cerebellar ataxia, intention tremor, loss of menace response despite normal vision), or both.
- Neck and/or head pain is often detected on palpation.

ETIOLOGY AND PATHOPHYSIOLOGY

- The underlying problem is a malformed caudal occipital bone region, which is probably an inherited trait.
- The malformed occiput leads to cerebellar compression and constriction of the cervicomedullary junction at the level of the foramen magnum.
- Over time, the meninges at the constricted cervicomedullary junction become progressively hypertrophied.
- Pressure in intracranial and spinal compartments increases over time; CSF and/or extracellular fluid (more likely) is preferentially diverted into the spinal cord (with resultant syringo-hydromyelia).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is strongly suspected based on breed and presenting clinical signs, especially characteristic neurologic deficits. Exclusion of differential diagnoses is required, and confirmation of COMS is achieved with diagnostic imaging (MRI +/− CT) and cerebrospinal fluid (CSF) analysis.

DIFFERENTIAL DIAGNOSIS

Differential diagnosis depends on the nature of the neurologic dysfunction in an individual patient:

- For example, in a dog with COMS that has multifocal central nervous system dysfunction, a likely differential diagnosis is granulomatous meningoencephalomyelitis.
- In a dog with COMS manifesting with neck pain alone, a likely differential diagnosis is intervertebral disk disease.

INITIAL DATABASE

- The diagnosis of COMS is dependent on MRI, especially the midsagittal T2-weighted view.
- In some cases, CT may also be necessary to completely assess bony abnormalities.
- CSF analysis is often performed to rule out concurrent inflammatory brain/spinal cord disease.

TREATMENT

TREATMENT OVERVIEW

The therapeutic goal is to halt disease progression and achieve either improvement or resolution of clinical signs of neurologic dysfunction; in most cases, this can be achieved most effectively with surgical correction.

ACUTE GENERAL TREATMENT

- Most dogs respond favorably to oral prednisone therapy (e.g., 0.5 mg/kg PO q 12 h, tapering if chronic use).
- Excessive scratching activity is usually ameliorated with oral gabapentin (10 mg/kg, PO, q 8 h).
- Pregabalin (2 mg/kg, PO, q 12 h initial dose) may also be effective for pain and scratching.
- Oral tramadol (2-4 mg/kg q 8-12 h) may also help relieve pain associated with this disorder.

CHRONIC TREATMENT

In most cases, surgical decompression of the foramen magnum (FMD) is indicated to achieve long-term therapeutic success.

POSSIBLE COMPLICATIONS

- Adverse effects of long-term corticosteroid administration
- Potential surgical complications include intraoperative/early postoperative death (rare), postoperative worsening of neurologic status (uncommon and usually temporary), and need for future reoperation (typically due to excessive scar formation at FMD site).

PROGNOSIS AND OUTCOME

- Most dogs respond favorably to medical therapy; however, the disease tends to progress over time. In one study, 5 of 10 dogs with COMS that were treated medically were euthanized within 2 years because of disease progression.
- Surgical therapy (FMD) is associated with an 81% success rate. A reoperative rate of 25%-47% has been reported. The

reoperative rate for FMD appears to be much lower when the decompression is combined with cranioplasty.

PEARLS & CONSIDERATIONS

COMMENTS

- Incessant scratching at the region of the shoulder (paresthesia) is a disproportionately common chief complaint with COMS and syringomyelia.
- Success of surgery appears to be inversely related to duration of clinical signs before surgical intervention.
- Anecdotally, the author and colleagues have seen substantially fewer postoperative recurrences (requiring reoperation) in cases that underwent cranioplasty in conjunction with FMD (<10%).

Cataracts

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Any opacity, regardless of size, of the lens or its capsule is termed a *cataract*. A cataract results from a change in the lens protein composition or lens fiber arrangement and is one of the most common canine ocular abnormalities.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats
- Variable age of onset depending on breed and cause
- Cataracts affect 16.8% of mixed-breed dogs ages 7-15+ years.

GENETICS & BREED PREDISPOSITION

- In dogs, most cataracts have an inherited component; most common mode of inheritance is autosomal recessive.
- Breeds of dogs with the highest prevalence of cataracts include: smooth fox terrier, Havanese, bichon frise, Boston terrier, poodles (toy, miniature, standard), silky terrier, American cocker spaniel, and miniature schnauzer. Cataracts have been reported in most purebred dog breeds.
- Canine cataracts can also occur secondary to diabetes mellitus, which has a genetic predisposition in some breeds (see p. 297)
- Presumed congenital feline cataracts reported in Persian, Birman, Himalayan, and domestic shorthair

RISK FACTORS

Diabetes mellitus, hypocalcemia, anterior uveitis, age, nutritional imbalance (milk replacement formulas), intoxication, retinal degeneration, retinal detachment, lens luxation, electric shock, radiation therapy/injury, when primary beam near or on globe

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Cataracts are classified by age at onset, location, and severity, in addition to etiology.

- Age at onset: congenital, present at birth; juvenile, few months to 6 years; senile, >6 years
- Location: capsule, anterior/posterior; cortex, anterior/posterior or equatorial; nucleus
    - Severity: incipient, <10% of retinal examination obstructed; immature (early, 10%-50% of retinal examination obstructed; late, 50%-99% of retinal examination obstructed); mature, 100% of retinal examination obstructed; hypermature, liquefaction/resorption with associated lens-induced uveitis (see p. 1151); morgagnian: nucleus falls ventrally in the capsule

HISTORY, CHIEF COMPLAINT

- Vision disturbance
- Cloudy white pupil
- The chief complaint may reflect a systemic cause of cataracts (e.g., polyuria/polydipsia, weight loss with diabetes mellitus)

PHYSICAL EXAM FINDINGS

- Opacity of the lens (unilateral or bilateral) with any or all of the following:
    - Anterior uveitis (see p. 1151)
    - Glaucoma (see p. 448)
    - Lens subluxation/luxation (see p. 644)
    - Retinal degeneration, retinal detachment (see and p. 985)
    - Systemic abnormalities may be present when cataracts are caused by a generalized disorder (e.g., weight loss with diabetes mellitus).

ETIOLOGY AND PATHOPHYSIOLOGY

- Regardless of etiology, all cataracts occur through a change in the lens protein composition or lens fiber arrangement:
  - Inherited: numerous breeds of dogs, some cats
  - Diabetes mellitus: increased blood glucose results in diffusion of increased glucose into the lens, overwhelming standard metabolism of the lens, causing excess glucose to be shunted to the sorbitol pathway, which forms polyols and subsequently osmotically draws water into the lens, causing opacification (dogs)
  - Secondary to intraocular disease: Uveitis, glaucoma, retinal degeneration/detachment, lens luxation
  - Trauma to lens: blunt or penetrating
  - Age-related
  - Nutritional: in puppies and kittens fed milk replacer. Proposed mechanism: amino acid deficiency, such as arginine, at crucial stage during lens development
  - Hypocalcemia (see p. 576)
  - Radiation therapy/injury (see p. 963) when primary beam near or on globe
  - Medications (e.g., long-term oral ketoconazole; mostly in young, large-breed dogs given higher doses [6-13.9 mg/kg/d])
  - Toxins (e.g., dinitrophenol; diazoxide)
  - Electric shock
- Not all cataracts are progressive.
- Cataracts can progress to become hypermature and result in lens-induced uveitis and increased risk of vitreal degeneration, retinal detachment, and secondary glaucoma

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of cataract is suspected based on observation of a cloudy pupil in an animal that may be visually compromised. It is confirmed by the finding of a lens opacity following complete dilation of the pupil.

DIFFERENTIAL DIAGNOSIS

- Nuclear/lenticular sclerosis: normal aging change; usually seen in animals =7 years old; does not cause vision loss; center of lens becomes opalescent to hazy, but tapetal reflection in pupil (usually greenish) is still visible, versus cataracts, which obstruct this reflection
- Hyperlipidemia, which may result in lipid aqueous flare. This will obstruct the ability to see the iris and pupil. Most common in the miniature schnauzer.
- Diseases causing diffuse corneal edema (bluish-white opacity on *cornea*, not in pupil; may obstruct ability to see the pupil) including glaucoma, anterior uveitis, corneal endothelial degeneration or dystrophy
- Diseases causing secondary cataracts:
  - Retinal degeneration or detachment
  - Anterior uveitis (cataracts typically incomplete if due to inflammation; uveitis may also occur secondary to cataracts; if cataracts occupying large extent of lens in predisposed breed, assume lens-induced uveitis)
  - Lens luxation

INITIAL DATABASE

- Complete ophthalmic examination(see p. 1313) including:
  - Menace response
  - Evaluation of pupil size, symmetry, and pupillary light reflexes
  - Intraocular pressure (IOP): rule out glaucoma (>25-30 mm Hg)
  - After IOP assessment (assuming normal result), dilate pupil with 1% tropicamide
  - Penlight or transilluminator to characterize the cataract, evaluate for concurrent uveitis
  - Fundic (posterior segment) examination using indirect or direct ophthalmoscopy
- Blood and urine glucose determination (dogs primarily)

ADVANCED OR CONFIRMATORY TESTING

- CBC, serum biochemistry profile, and urinalysis to rule out systemic metabolic disease (e.g., diabetes mellitus, hypocalcemia) as cause of cataracts and/or to assess patient before considering referral for possible cataract surgery
- Ocular ultrasound if the cataract is immature or worse in severity and precludes accurate evaluation of the posterior segment of the eye
- Electroretinogram (ERG; see p. 1253) to assess retinal function (routinely conducted by veterinary ophthalmologists before

cataract surgery)

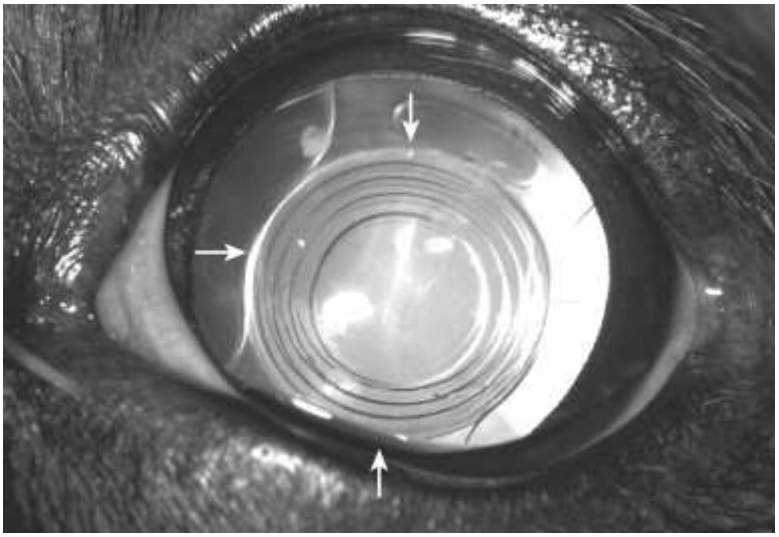
TREATMENT

TREATMENT OVERVIEW

- Incipient and nonprogressive early immature cataracts do not require treatment.
- Progressive immature, mature, and hypermature cataracts are treated to:
  - Restore vision (i.e., cataract surgery)
  - Prevent secondary sequelae of cataracts: uveitis, glaucoma, and retinal detachment
  - Referral to a veterinary ophthalmologist may help greatly in triage, diagnosis, and treatment of cataracts.

ACUTE GENERAL TREATMENT

- Treat associated uveitis with topical mydriatics and antiinflammatories (see p. 1151).
- Treat secondary glaucoma accordingly (see p. 448).
- Referral for cataract surgery if cataract is vision threatening and animal systemically stable (e.g., concurrent diabetes mellitus is controlled):
  - Cataract surgery requires preliminary ocular ultrasound and ERG that indicate the posterior segment of the eye is normal.
  - Phacoemulsification (ultrasonic lens fragmentation) to remove the cataract:
    - Followed by implantation of an artificial intraocular lens to restore emmetropia (normal vision, neither far- nor near-sighted)
    - Without an intraocular lens implant, animals are 14 diopters hyperopic (far-sighted) with little useful vision.



CATARACTS Canine eye 6 months after cataract surgery and foldable, acrylic intraocular lens implantation. The pupil has been dilated, and the intraocular lens implant is centered within the pupil.

CHRONIC TREATMENT

- After cataract surgery, treat as directed by the veterinary ophthalmologist:
  - Topical antibiotics and antiinflammatories
  - Exercise restriction/Elizabethan collar: 2 weeks
  - Antiinflammatory therapy may be continued in a decreasing fashion for months or, in some cases, indefinitely.
  - Frequent reevaluation of intraocular lens position, IOP, retinal examination, and inflammation control
- If cataract surgery is not an option:
  - Monitor cataracts for progression, and treat associated uveitis with topical antiinflammatories (see p. 1151) long term.
  - Use IOP-lowering drugs in combination with antiinflammatories if secondary glaucoma develops (see p. 448).
  - Enucleation or evisceration and intrascleral prosthesis of end-stage, blind, painful globes

DRUG INTERACTIONS

Corticosteroids (topical ophthalmic or oral) may interfere with management of diabetes mellitus.

POSSIBLE COMPLICATIONS

- Without cataract surgery, the following can occur: uveitis, glaucoma, lens luxation, retinal detachment, blindness.
- After cataract surgery, the following can occur: uveitis, glaucoma corneal ulceration, surgical wound/incisional dehiscence, intraocular infection (see p. 583), retinal detachment, intraocular lens displacement, lens capsule fibrosis (lessened through the use of new foldable, acrylic IOL implants), corneal endothelial degeneration and secondary corneal edema, keratoconjunctivitis sicca.

RECOMMENDED MONITORING

- Without cataract surgery, monitor for cataract progression and secondary complications (see Possible Complications above) q 2-4 mon, or more or less frequently, depending on the extent of cataract, rate of cataract development, and presence or absence of associated ocular complications.
- After cataract surgery, monitor according to veterinary ophthalmologist's recommendations; generally involves:
  - Reevaluations at postoperative weeks 2, 8, and 20
  - Long-term follow-up q 6-12 mon for life
  - In addition to routine ophthalmic examinations, Schirmer tear test, IOP, menace response, and pupillary light reflexes should be evaluated each time the animal is presented to the veterinarian.

PROGNOSIS AND OUTCOME 

- Rate of cataract progression variable depending on cause and location of the cataract and age of the animal
- Success of cataract surgery (i.e., phaco-emulsification), as determined by a positive visual outcome, is 90%-95%.
- Success is increased with early referral (i.e., before animal is blind) and surgery, and with diligent postoperative monitoring and treatment.

PEARLS & CONSIDERATIONS 

COMMENTS

- Early referral and prompt surgical intervention before the onset of hyper-maturity and lens-induced uveitis will result in a more successful outcome.
- Animals affected with cataracts, regardless of the severity, should not be used for breeding unless it is known specifically that the cataract is of nongenetic origin.

PREVENTION

- Ophthalmic screening of animals used for breeding by a board-certified veterinary ophthalmologist and registration through the Canine Eye Registration Foundation (http://www.vmdb.org/cerf.html) will help to remove affected animals from the breeding population.
- Prompt treatment of intraocular inflammation will decrease the likelihood of secondary cataracts.
- Early diagnosis and proper management of diabetes mellitus will help prevent cataract formation, but even the most well-managed diabetics may still develop cataracts. Once present, cataracts caused by diabetes mellitus are irreversible and will not resorb, even with good diabetic control.
- In the future, use of aldose reductase inhibitors and antioxidants may have a role in the delay and prevention of cataracts.

CLIENT EDUCATION

- It is essential that clients understand that not all cataracts are progressive.
- If a cataract is progressive, the client must make a decision with regard to surgery.
- Although surgery is associated with some risks, not opting for surgery is also associated with risks of lens-induced uveitis, secondary glaucoma, retinal detachment, and ocular pain.
- Animals undergoing cataract removal surgery that do not receive an intraocular lens implant have vision that, in human equivalence, is worse than 20/400 and corresponds to being “legally blind.”

Castor Bean Toxicosis

BASIC INFORMATION

DEFINITION

Acute clinical signs, commonly including vomiting and diarrhea, initially and frequently progressing to coma and death. May occur in dogs or cats, as a result of eating castor beans.

SYNONYMS

African coffee tree, Mexico weed, mole bean, Palma Christi, wonder tree, *Ricinus communis*

EPIDEMIOLOGY

SPECIES, AGE, SEX

All breeds, ages, and both sexes susceptible; dogs involved more often than cats

RISK FACTORS

Presence of castor beans in pet's environment

GEOGRAPHY AND SEASONALITY

- Year round; more cases in October and November when castor beans mature and are released from their spiny pods
- Castor beans for jewelry and other ornamental purposes are available throughout the year.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of exposure to castor bean plant or ornamentals (e.g., jewelry)
- Lag period: 6-12 hours (up to 48 hours) before signs appear
- Vomiting and diarrhea (with or without blood), anorexia, lethargy

PHYSICAL EXAM FINDINGS

- No remarkable physical exam findings if recent exposure (<6 hours)
- Within 6-48 hours of exposure, anorexia, depression, lethargy, mild to severe vomiting, diarrhea, and abdominal tenderness may begin.
- In severe cases, dehydration, weakness, tremors, or seizures can ensue.
- Tachycardia, hypotension, and shock may be present (potentially fatal).
- Presence of castor beans or leaves in the vomitus

ETIOLOGY AND PATHOPHYSIOLOGY

- Castor bean is a large decorative, ornamental, Caribbean plant now present throughout the warmer parts of the United States. The beans are commercially grown for castor oil or may be used for ornamental purposes (e.g., jewelry). The plant produces spiny pods that burst open after drying, releasing seeds. The seeds have color markings resembling some ticks or beetles.
- All parts of the castor bean plant contain ricin and therefore are considered toxic if ingested; the highest concentration of ricin is in the bean. Ricin, a heterodimeric glycoprotein, is a cellular toxin (toxalbumin) that inhibits protein synthesis, causing cell death. Cell death results in vomiting, diarrhea, abdominal pain, and hemorrhages.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A working diagnosis made based on history/evidence of exposure (evidence of chewed up leaves/seeds in vomitus) and onset of vomiting, diarrhea, anorexia, or lethargy several hours after the ingestion.

DIFFERENTIAL DIAGNOSIS

- Dietary intolerance/garbage toxicosis
- Sago palm toxicosis
- Pancreatitis
- Viral and bacterial gastroenteritis
- GI tract obstruction

INITIAL DATABASE

- CBC: leukocytosis
- Serum biochemistry profile
  - Elevated alanine aminotransferase, aspartate aminotransferase, and lactate dehydrogenase, indicative of liver damage
  - Increased blood urea nitrogen and serum creatinine: may be renal or prerenal
  - Increased serum albumin and globulin possible, suggesting dehydration
- Changes may be seen 12-24 hours after ingestion.

ADVANCED OR CONFIRMATORY TESTING

Postmortem findings may include necrosis and hemorrhages in the heart, stomach, GI tract, lungs, liver, kidney, and pancreas.

TREATMENT 

TREATMENT OVERVIEW

- Risk of death means that treatment is implemented based on reasonable clinical suspicion alone (history of possible or proven exposure). If clinical signs are absent, treatment consists of patient decontamination and a period of monitoring. With overt clinical signs, intensive supportive care is indicated. Therapeutic goals are decontamination of patient, protecting GI mucosa, and supportive care.

ACUTE GENERAL TREATMENT

- Decontamination of patient:
  - Emesis: only animals not showing any clinical signs (see p. 1364). May be effective within several hours after exposure, especially if seeds have been ingested, since seeds are hard to digest
  - Gastric lavage (see p. 1281): only if a potentially lethal dose has been ingested (see Pearls & Considerations below) and emesis cannot be induced (comatose animal)
  - Activated charcoal 2-4 g/kg PO; may be effective even several hours after exposure if seeds have been ingested. Protect airway with cuffed endotracheal tube if patient is unconscious.
- Protect GI mucosa:
  - Administer GI protectants such as sucralfate (0.5-1 g/dog, or 125-250 mg/cat) PO q 8-12 h and H2 blockers (e.g., famotidine, 0.5 mg/kg PO, SQ, IM, or IV q 12-24 h
  - Control severe vomiting with metoclopramide (0.1-0.4 mg/kg PO, SQ or IM q 6 h) or maropitant (1 mg/kg, SQ, q 24 h for up to 5 doses), provided no evidence of GI obstruction is present.
- Supportive care:
  - IV fluids for 2-3 days or as long as needed, typically at 1.5 to 2 times maintenance rates
  - Diazepam for seizures (0.5-2 mg/kg IV PRN)
  - Lactulose (15-30 mL PO q 6-8 h in dogs; 0.25-1 mL PO q 8-12 h in cats) may reduce the risk of hepatic encephalopathy if acute hepatic injury (see p. 503) has occurred
  - SAMe (*S*-adenosylmethionine), 18 mg/kg PO in dogs and cats q 24-72 h for 1-3 months for hepatic injury
  - Dietary management: soft bland diet in small amounts for 1-5 days

CHRONIC TREATMENT

Management of chronic hepatopathy (see p. 212)

POSSIBLE COMPLICATIONS

Possible liver or renal compromise

RECOMMENDED MONITORING

- CBC
- Liver enzymes on presentation: q 24, 48 h, or until resolution of signs
- Kidney profile on presentation: q 24, 48 h, or until resolution of signs
- Serum electrolytes
- Blood pressure and heart rate

PROGNOSIS AND OUTCOME 

- Prognosis depends on the amount ingested and whether the beans were chewed or broken (prognosis worse) and if spontaneous vomiting occurred after the ingestion (prognosis better— self-decontamination).
- Most dogs respond well to supportive treatment.
- Poor prognosis if multiple organ damage, shock, or seizures occur.
- Mortality rate in dogs ingesting castor beans is approximately 9%.

PEARLS & CONSIDERATIONS 

COMMENTS

- Severity of signs increases if the seed is chewed open. Ricin is not likely to be released from the seed unless the coat is masticated, broken, or damaged.
- All known or potential ingestions should be considered serious and treated aggressively to avoid serious consequences.
- In humans, ingestion of 1-8 seeds can be lethal; the same may be true for dogs or cats.
- The toxalbumin is one of the most deadly substances known. Lethal dose in mice is 0.025 mg/kg IP and 1 mg/kg PO in humans.
- Latin name *(Ricinus)* means “insect,” since beans resemble some ticks or beetles.

PREVENTION

Keep castor beans out of reach of pets.

EDITOR: SAFDAR A. KHAN

1ST EDITION AUTHOR: SAFDAR A. KHAN

Carpal Ligament Trauma/Breakdown

BASIC INFORMATION

DEFINITION

Carpal trauma includes ligamentous (sprain), fibrocartilaginous (hyperextension), fracture, or shearing injuries.

SYNONYMS

Palmar carpal breakdown, carpal laxity syndrome

EPIDEMIOLOGY

GENETICS & BREED PREDISPOSITION

Racing greyhounds: accessory carpal bone fractures. Carpal laxity syndrome: rapidly growing large/giant breed dogs.

RISK FACTORS

Racing or agility activities; distal forelimb trauma

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Sprains (hyperextension)
- Fractures
- Shearing/degloving wounds
- Coaptation-related injuries, including pressure sores from casts or splints; dermatitis from soiled bandages; and wound infection or dehiscence from old, dirty dressings

HISTORY, CHIEF COMPLAINT

- Forelimb trauma
- Lameness after competition; slowing or drifting wide on racetrack turns

PHYSICAL EXAM FINDINGS

- Lameness
- Carpal swelling
- Open wounds around the carpus
- Pain or crepitation during palpation of the carpus
- Gross instability characterized by plantigrade stance
- Gross instability characterized by “broken over” or flexed carpal stance

ETIOLOGY AND PATHOPHYSIOLOGY

- Track animals racing counterclockwise are predisposed to right-sided injuries (80%).
- In pets, carpal fractures (usually radial carpal bone) are less common than ligament injury.
- In racing animals, fractures usually involve the accessory carpal bone.
- Carpal laxity syndrome: potential ligamentous weakness

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis of carpal injury is based on physical and radiographic examinations.

CARPAL LIGAMENT TRAUMA/BREAKDOWN Lateral view of a mature malamute with a left forelimb lameness due to palmar carpal breakdown after a jump from a deck. Note hyperextension of the left carpus.

DIFFERENTIAL DIAGNOSIS

- Autoimmune polyarthropathy (systemic lupus erythematosus, rheumatoid arthritis)
- Infectious (Lyme borreliosis, rickettsial diseases)

INITIAL DATABASE

- Mediolateral and dorsopalmar radiographic projections of the distal limb (pes and carpus)
- CBC and chemistry panel based on American Society of Anesthesiologists (ASA) patient classification (see p. 1372)
- Electrocardiography and thoracic radiography (if part of massive trauma)

ADVANCED OR CONFIRMATORY TESTING

- Oblique radiographic views to outline nondisplaced fractures
- Stress radiography (mediolateral radiograph with carpus manually forced into hyperextension) for localizing joint instability

TREATMENT

TREATMENT OVERVIEW

The goal of therapy is to reestablish anatomic or functional joint and limb activities:

- Fractures: stabilization and anatomic reduction
- Ligamentous injuries: reestablishment of carpal support with ligament repair or arthrodesis
- Shearing injuries: wound management

ACUTE GENERAL TREATMENT

- Minimally displaced, nonarticular fractures, grade I, and most grade II ligament sprains are externally splinted for 6-8 weeks.
- Luxated joints, intraarticular fractures, and grade III sprains are initially supported in a modified Robert-Jones bandage until definitive surgery.

- Carpal laxity syndrome: soft exercise surfaces, with or without splintage
- Shearing injuries, after initial wound management protocols, are covered and supported until definitive treatment is performed.
    - Gentle lavage using warm saline, lactated Ringer's solution, dilute chlorhexidine solutions of open wounds to reduce gross contamination (patients are sedated and given analgesics).
    - Coverage of tissues with moistened (above solutions) gauze sponges useful in débridement (wet-to-dry-bandages), since they are changed daily.
    - Alternatively, direct application of sugar or honey has been used to reduce infection and promote healing in highly contaminated, traumatic open wounds, but the role of such treatment in the joint space is unclear.
    - Final surgical débridement and joint lavage can be performed during orthopedic stabilization surgery.
    - Wounds with healthy granulation tissue, reduced contamination, and early epithelialization can be closed with sutures or covered with a non-adherent dressing and allowed to heal via second intention.

CHRONIC TREATMENT

- Surgical repairs require 6-12 weeks of external coaptation (e.g., splint, cast, or external fixator) and exercise restriction.
- Radial carpal bone luxation is treated with open joint tissue repair.
- Large radial carpal and accessory carpal bone fractures are treated with lag-screw fixation.
- Small radial carpal and accessory carpal bone fractures are excised and have good outcomes.
- Avulsion fractures are treated with tension band techniques.
- Hyperextension injuries are managed with partial carpal arthrodesis (middle and distal carpal joints) or pancarpal arthrodesis (injuries involving the antebrachial carpal joint).
- Collateral ligament injuries are primarily repaired or replaced with synthetic suture.

POSSIBLE COMPLICATIONS

- Reduction/implant failure
- Delayed or failed arthrodesis
- Wound infection
- Coaptation-related morbidity
- Degenerative joint disease

RECOMMENDED MONITORING

- Lameness evaluation 1-3 months after injury and treatment
- Serial radiographic studies to evaluate fracture healing or progression of arthrodesis

PROGNOSIS AND OUTCOME 

- Good to excellent for noncompeting dogs
- Variable for athletic dogs needing to return to preinjury competition levels
- Severe shearing injuries with neurovascular compromise may necessitate limb amputation.

PEARLS & CONSIDERATIONS 

COMMENTS

- Complete palmar carpal breakdown (grade lll sprain) requires pancarpal arthrodesis.
- Intraarticular fractures, when treated conservatively, rarely heal with osseous bridging, thus leading to degenerative joint disease.
- Partial carpal arthrodesis can promote a return to most preinjury activities.
- In racing greyhounds, treatment of radial carpal or accessory carpal bone fractures with lag-screw fixation (preferred) or fragment excision provides a return to competitive performance.

Carnitine Deficiency

BASIC INFORMATION

DEFINITION

Carnitine is an amino acid derivative. Carnitine deficiency is a relatively uncommon condition characterized by inadequate quantities of L-carnitine in blood, skeletal muscle, and cardiac muscle (systemic carnitine deficiency) or normal to elevated levels of carnitine in blood and low levels in cardiac muscle (myopathic form of carnitine deficiency).

SYNONYMS

Since L-carnitine is the biologically active isomer, the terms *carnitine* and *L-carnitine* are used interchangeably in the clinical setting.

EPIDEMIOLOGY

SPECIES, AGE, SEX

l-carnitine (β-hydroxy-γ-trimethylaminobutyric acid) appears to be a conditionally essential nutrient for dogs and cats. Although not essential under normal circumstances, deficiency can occur in certain cases secondary to decreased carnitine synthesis, decreased dietary intake, intestinal malabsorption, increased renal loss (such as with cystinuria), or membrane transport defects.

GENETICS & BREED PREDISPOSITION

- Cats: none reported
- Dogs: members of isolated families of various breeds, including American cocker spaniels and boxers, may develop carnitine deficiency. Breeds that develop cystinuria or urate urolithiasis may develop carnitine deficiency. Breeds predisposed to ceroid lipofuscinosis may also develop carnitine deficiency.

RISK FACTORS

- Cats: rapid weight loss in obese cats, idiopathic hepatic lipidosis
- Dogs: some dogs with cystinuria are also carnitinuric and develop carnitine deficiency due to excessive renal loss of carnitine. Dogs consuming vegetarian diets or protein-restricted diets that are not supplemented with carnitine may also develop carnitine deficiency.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Cats: idiopathic hepatic lipidosis. No cardiac effects of carnitine deficiency have been identified.
- Dogs: dilated cardiomyopathy (DCM), lipid-storage myopathy, juvenile-onset distal myopathy (rottweilers), ceroid lipofuscinosis (Tibetan terriers), and male infertility

HISTORY, CHIEF COMPLAINT

- Cats: compatible with idiopathic hepatic lipidosis (rapid weight loss in obese cats)
- Dogs: compatible with congestive heart failure (exercise intolerance and weight loss progressing to cough, respiratory distress, and eventually, ascites); compatible with myopathy; compatible with ceroid lipofuscinosis

PHYSICAL EXAM FINDINGS

- Cats: obesity; signs of idiopathic hepatic lipidosis (icterus, hepatomegaly, dehydration)
- Dogs: DCM; variable combinations of tachypnea, dyspnea, tachycardia, and lethargy
- Lipid-storage myopathy; stilted gait and muscle weakness
- Ceroid lipofuscinosis; progressive visual deterioration, behavioral changes, seizures, ataxia, and various degrees of motor and sensory dysfunction

ETIOLOGY AND PATHOPHYSIOLOGY

- Sources of carnitine include endogenous synthesis in the liver from lysine and methionine or dietary intake. Beef and lamb are the best dietary sources of carnitine; plant proteins generally are poor dietary sources of carnitine.
- In the body, 95%-98% of carnitine is stored in skeletal and cardiac muscle. Carnitine is necessary for transport of fatty acids into the mitochondria, the site of ATP generation for cardiac function. The heart obtains 60% of its total energy production from oxidation of long-chain fatty acids; therefore carnitine deficiency can result in cardiac dysfunction.
- Another important function of carnitine is its buffering capacity; prevents buildup of acyl-CoA derivatives in the mitochondria that inhibit oxidative metabolism.
- Dogs: myopathic form of carnitine deficiency occurs in some dogs with DCM and is thought to result from a membrane transport defect. Systemic form of carnitine deficiency can also result in DCM and may result from increased renal loss (such as with cystinuria) or inadequate dietary intake of carnitine or its precursor amino acids (such as with vegetarian or protein-restricted diets). Carnitine deficiency associated with ceroid lipofuscinosis is thought to involve a defect in the carnitine biosynthetic pathway involving e-*N*-trimethyllysine, a precursor for carnitine biosynthesis.
- Cats: association between L-carnitine and idiopathic hepatic lipidosis is less clear but may be related to inadequate synthesis or tissue availability.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis of carnitine deficiency in dogs is predicated on low plasma L-carnitine concentration; however, normal plasma carnitine levels do not rule out the myopathic form of carnitine deficiency where plasma carnitine levels are normal or elevated, but cardiac muscle levels are low.

DIFFERENTIAL DIAGNOSIS

- Cats: other hepatopathies, other influences on hepatic lipidosis
- Dogs: idiopathic DCM and other causes of myocardial failure; lipid storage myopathy and other causes of myopathies

INITIAL DATABASE

Samples for plasma carnitine levels are collected in heparinized (green-top) tubes or a syringe coated with heparin. Immediately place the sample on wet ice and centrifuge within 30 minutes of obtaining the sample; separate plasma from cells and freeze the plasma until it is analyzed. Be careful to avoid contaminating the plasma with cells from the buffy coat, and avoid using a sample that is hemolyzed. Ship sample on dry ice to lab for analysis.

ADVANCED OR CONFIRMATORY TESTING

- Dogs: myopathic carnitine deficiency is estimated to occur in 17%-60% of dogs with DCM. Evaluating carnitine levels in cardiac tissue requires fluoroscopic-guided endomyocardial biopsy, which is currently unavailable to most practices.
- Percutaneous skeletal muscle biopsies can be obtained in patients suspected of having a myopathy.
- Reported reference ranges for carnitine levels in various tissues (see tables).

TREATMENT

TREATMENT OVERVIEW

The therapeutic goal is to restore carnitine homeostasis:

- Cats: improve liver function
- Dogs: improve cardiac or skeletal muscle function

ACUTE GENERAL TREATMENT

- Cats: supportive care for idiopathic hepatic lipidosis
- Dogs: supportive care for congestive heart failure

CHRONIC TREATMENT

- Cats: L-carnitine, 200-500 mg PO per day during enteral nutritional support for idiopathic hepatic lipidosis has been recommended.

- Dogs: L-carnitine, 100-200 mg/kg PO q 8 h has been suggested. Use higher end of dosage range for myopathic carnitine deficiency. Approximately one third of dogs will develop diarrhea while receiving the high-end dose. If this occurs, reduce the dose of carnitine to the highest level the dog will tolerate without developing diarrhea.
- Even if plasma and tissue carnitine levels are unavailable in a patient, it is still strongly recommended to consider carnitine supplementation (plus taurine) in American cocker spaniels, boxers, and dogs with cystine or urate urolithiasis that develop DCM.
- Carnitine is a very safe substance. Most common side effect at high doses is diarrhea.
- It takes 3-4 months before any objective echocardiographic changes may occur, so don't stop prematurely.
- If purchasing carnitine through a health food store, only use products that contain the USP (produced under good manufacturing practices) seal. It can be very expensive to purchase carnitine through health food stores.
- Alternatively, buy carnitine in bulk (1 tsp = 2 grams of carnitine) from Lonza (http://www.carnitine.com/carnitine/en.html). Use the human-grade carnitine.

Feline Values

Feline Values	Plasma Free Carnitine	Plasma Ester Carnitine	Plasma Total Carnitine
Males (n = 9)	3.9-18.3 µmol/L	0-5.8 µmol/L	5.0-22.2 µmol/L
Females (n = 4)	5.0-33.8 µmol/L	0-11.6 µmol/L	5.2-44.4 µmol/L

NCP, Noncollaginous protein.*Reference range from 18 healthy adult beagle dogs.

Canine Values

Canine Values	Free Carnitine	Ester Carnitine	Short-Chain Acylcarnitine	Long-Chain Acylcarnitine	Total Carnitine
Plasma (µmol/L)	9-36	N/A	<7	N/A	12-40
Cardiac muscle (nmol/mg NCP)	3.5-11.5 or 0.94-9.8*	<5.0	0.05-2.7*	0-0.66	4.5-14.0 or 1.78-12.4*
Skeletal muscle (nmol/mg NCP)	2.2-15.4*	N/A	0.1-4.1*	0.05-0.81*	4.3-18.3*

RECOMMENDED MONITORING

- Cats: clinical condition, return to food intake
- Dogs: clinical condition, thoracic radiography, echocardiography

PROGNOSIS AND OUTCOME

- Cats: poor to good (± L-carnitine supplementation) depending on severity of idiopathic hepatic lipidosis and rapidity with which adequate nutritional support occurs
- Dogs: guarded to poor; few dogs with DCM respond to L-carnitine, but those that do have a much better prognosis than those not treated with carnitine. It is especially important to consider carnitine supplementation in American cocker spaniels, boxers, and dogs with cystine or urate urolithiasis that develop DCM. DCM has reversed in a few dogs supplemented with carnitine.
- Prognosis for other conditions associated with carnitine deficiency in dogs (e.g., ceroid lipofuscinosis, lipid storage myopathies) is not known.

PEARLS & CONSIDERATIONS

COMMENTS

In cats, recovery of appetite occurs within days to weeks of provision of L-carnitine and appropriate nutritional management.

CLIENT EDUCATION

Explain the importance of feeding a properly formulated diet.

Cardiotoxic Plants

BASIC INFORMATION

DEFINITION

Toxicosis occurring as a result of ingestion of plants that produce substances harmful to the heart: cardiac glycosides or grayanotoxins.

EPIDEMIOLOGY

SPECIES, AGE, SEX

All ages and breeds are susceptible; dogs are more likely to be involved.

RISK FACTORS

Plants or flower bouquets present in pet's environment. Preexisting cardiac disease may increase risk.

GEOGRAPHY AND SEASONALITY

Toxicosis occurs throughout the year but more likely to occur in spring and summer months (outdoor exposures).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History or evidence of exposure (witnessed ingestion, chewed plant, or plant material present in the vomitus)
- Cardiac glycosides: onset of clinical signs within 2-8 hours of ingestion: salivation, vomiting, lethargy, depression, and ataxia. With severe intoxications, convulsions and death are possible.
- Grayanotoxins: signs occur within 6hours of ingestion: lethargy, salivation, vomiting, signs of abdominal pain, ataxia, lateral recumbency, and seizures are possible.

PHYSICAL EXAM FINDINGS

- Cardiac-glycoside–containing plants: pale mucous membranes, weak pulses, tachypnea, bradycardia, or paroxysmal tachycardias
- Grayanotoxin-containing plants: tachycardia, tachypnea, hyperthermia, vomiting, lethargy, hypotension, and bradycardia; diarrhea is uncommon.

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

- Present in nature, landscaping, house plants, and floral arrangements
- Common cardiac-glycoside–containing plants: *Asclepias* spp. (some): milkweed; *Convallaria majalis*: lily of the valley; *Digitalis purpurea*: foxglove; *Hellebore* spp.; *Kalanchoe* spp.; *Nerium oleander*: oleander; *Thevitia nerifolia*: yellow oleander; *Thevetia peruviana*: yellow oleander
- Common grayanotoxin-containing plants: *Rhododendron* spp.: rhododendron, azalea, rosebay; *Kalmia* spp.: laurels; *Pieris* spp.: Japanese pieris, Mountain pieris; *Leucothoe* spp.: black laurel

Mechanism of Toxicosis:

- Cardiac glycosides:
  - Inhibition of Na^+/K^+-ATPase pump in the myocardial cell
  - Result: decreased intracellular potassium, increased intracellular sodium. Intracellular sodium is exchanged for calcium, raising intracellular calcium levels. In addition, excessive extracellular potassium may depress cardiac contractility.

- Effects noted include: AV block due to progressive interference with cardiac electrical conduction and increased vagal tone. Decrease in normal resting membrane potential. Decreased myocardial cell pacemaker activity, leading (in severe toxicoses) to malignant cardiac arrhythmias (ventricular) or asystole.

- Grayanotoxins: structurally distinct from cardiac glycosides but with a similar mechanism of action. Like cardiac glycosides, they bind to sodium channels, slowing their opening and closing and decreasing their ion selectivity, and therefore produce similar clinical signs. Many cells are affected, especially excitable cells (neurologic, cardiac, muscle cells).

CARDIOTOXIC PLANTS Foxglove plant *(Digitalis purpurea)* is a source of cardiac glycosides such as digitalis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is made based on history of exposure and the presence of gastrointestinal and cardiac signs. Plant material present in pet's environment, vomitus, or lavage fluid may also be helpful in arriving at a diagnosis. Serum digoxin levels are confirmatory (cross-reactivity with cardiac glycosides); turnaround time limits utility in critical cases, but in cases that are less severe, the test is helpful for identifying whether preventive measures need to be taken to avoid reexposure in the future.

DIFFERENTIAL DIAGNOSIS

Toxicologic:

- Bufo toad ingestion
- Digoxin overdose (see online chapter: Digoxin Toxicosis)
- Antiarrhythmic medication ingestion

Spontaneous, nontoxicologic:

- Primary cardiac disease
- Systemic illness causing ventricular arrhythmias
- Gastroenteritis

INITIAL DATABASE

- CBC (no significant changes expected)
- Serum chemistry panel: hyperkalemia possible; *hypo*kalemia markedly worsens the toxic effects (including making the heart refractory to antiarrhythmics such as lidocaine and procainamide) and needs to be treated (see p. 577).
- Electrocardiogram (ECG) to assess cardiovascular status
  - A combination of first- or second-degree AV block together with possibility of exposure to incriminating plant and compatible clinical signs is highly suggestive of the clinical diagnosis of glycoside plant cardiotoxicity.
  - Ventricular or atrial arrhythmias of virtually any type are possible.
  - The most common electrocardiogram (ECG) changes include first-, second-, or even third-degree atrioventricular (AV)

block, ventricular arrhythmias, and ST segment changes.
- Blood pressure (may see hypotension)

ADVANCED OR CONFIRMATORY TESTING

- Serum digoxin levels (cardiac-glyco-side–containing plants). Any detectable amount in a patient not receiving digoxin pharmaceutically confirms the diagnosis. Test can be performed at a local human hospital.
- Presence of oleandrin in gastrointestinal (GI) contents and body fluids can confirm exposure (available in some veterinary diagnostic laboratories).

TREATMENT 

TREATMENT OVERVIEW

Treatment is aimed at management of severe cardiac arrhythmias and systemic disturbances (e.g., dehydration), and early decontamination of the patient (emesis induction and administration of activated charcoal). An intravenous antidote (Digibind) exists for cardiac glycosides but is often cost-prohibitive (see online chapter: Digoxin Toxicosis).

ACUTE GENERAL TREATMENT

- Decontamination of patient:
  - Emesis: see p. 1364
  - Activated charcoal; after emesis or if a few hours have elapsed after exposure; (1-4 g/kg) with a cathartic such as 70% sorbitol (3 mL/kg) PO
- Treat cardiac arrhythmias:
  - Bradyarrhythmias in a normotensive patient: atropine, 0.02-0.04 mg/kg IV, repeat as needed
  - Ventricular arrhythmias (see p. 1165).
  - Digoxin immune Fab (Digibind) may be used for treating refractory cardiac arrhythmias or hyperkalemia in cardiac glycoside toxicosis.
- Supportive care:
  - IV fluids as needed; avoid calcium-containing fluids (e.g., LRS) unless hypocalcemia
  - Correct acid-base status and electrolytes as needed.
  - Control central nervous system signs with benzodiazepine if needed (e.g., diazepam, 0.5-1 mg/kg IV).
  - Control severe vomiting with metoclopramide (0.1-0.4 mg/kg PO, SQ, or IM q 6 h) or maropitant, 1 mg/kg SQ q 24 h or 2 mg/kg PO q 24 h, provided GI obstruction is ruled out.

POSSIBLE COMPLICATIONS

Permanent cardiac damage

RECOMMENDED MONITORING

- ECG, electrolytes, blood pressure, heart rate, and pulse

PROGNOSIS AND OUTCOME 

- Cardiac glycosides: Animals with moderate to severe cardiovascular signs have a guarded prognosis; even with intensive supportive care, serious intoxications may require several days of in-hospital treatment.
- Animals with only GI signs but no subsequent cardiovascular signs have a good prognosis.
- Grayanotoxins: prognosis is generally good with grayanotoxin-containing plants.

PEARLS & CONSIDERATIONS 

COMMENTS

- Domesticated grayanotoxin plants, such as those sold in nurseries, are generally less toxic than their wild counterparts and mainly cause gastrointestinal signs.
- Cardiac glycosides are bitter tasting; however, when leaves dry, sugar is released and the leaves may be more attractive for ingestion.

- Cardiotoxicity of these plants is exclusively arrhythmogenic; structural heart disease (e.g., valve disease) is not caused by these plants.

CLIENT EDUCATION

Client should be made aware of toxic plants in their pet's environment.

1ST EDITION AUTHOR: CAROLINE W. DONALDSON

Cardiomegaly (Radiographic)

BASIC INFORMATION

DEFINITION

Enlargement of the cardiac silhouette relative to the thorax. This is a relatively common radiographic finding and may be due to underlying acquired or congenital cardiac disease.

- Radiographic assessment:
  - Subjective
    - Empirical: based on clinical experience
    - Compare to previous radiographs of same patient or other patient of same breed/conformation
  - Objective
    - Vertebral heart score: sum of long and short axes of cardiac silhouette on lateral view compared to length of thoracic vertebrae, beginning at T4 and continuing caudally
      - Canine normal = 9.7 ± 0.5
      - Feline normal = 7.5 ± 0.3
      - Has not proven to be more accurate than subjective assessment

EPIDEMIOLOGY

GENETICS & BREED PREDISPOSITION

Dog Breeds Predisposed to Heart Disease

Disease	Some Commonly Affected Breeds
Congenital	
Patent ductus arteriosus	Maltese, poodle, keeshond, bichon frise, Pomeranian
Subaortic stenosis (must be severe to cause cardiomegaly)	Newfoundland, bloodhound, boxer, golden retriever, rottweiler
Tricuspid dysplasia	Labrador retriever
Pulmonic stenosis	English bulldog, Scottish terrier, wirehaired fox terrier
Ventricular septal defect	Lakeland terrier, West Highland white terrier
Acquired	
Valvular endocardiosis	Cavalier King Charles spaniel, small breeds
Dilated cardiomyopathy	Doberman pinscher, Irish wolfhound, Great Dane, boxer, Saint Bernard, Afghan hound, Newfoundland, Old English sheepdog
Pericardial effusion	Retrievers, German shepherds, other large breeds (hemangiosarcoma, idiopathic sterile pericarditis); brachycephalic dogs (chemodectomas)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Dyspnea, tachypnea, cough, exercise intolerance, syncope
- May be incidental finding

PHYSICAL EXAM FINDINGS

Cardiac murmur, arrhythmia, tachycardia, muffled heart sounds, and in more advanced cases, increased lung sounds, pulse

alterations, ascites, jugular venous distension

ETIOLOGY AND PATHOPHYSIOLOGY

- Pressure overload: outflow obstruction, hypertension
- Volume overload: valvular insufficiency, cardiomyopathy, shunt
- Pericardial effusion: neoplasia, inflammation, hemorrhage; rarely, infection

Enlarged Chamber	Appearance on Lateral View	Appearance on VD/DV View
Left atrium	Dorsal deviation of left mainstem bronchus	Increase in soft-tissue opacity, causing splaying of the mainstem bronchi
Left ventricle	Dorsal deviation of trachea	Enlargement of apex at 3 to 5 o'clock
Right atrium	Bulge at cranial aspect of cardiac silhouette	Bulge at 9:30 to 11:30 o'clock
Right ventricle	Widening of the cardiac silhouette, increased cardiosternal contact	Rounding and ventricle enlargement at 5 to 8 o'clock "Reverse D" appearance

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Differential diagnosis of cardiomegaly is based on specific cardiac chamber enlargement and the appearance and size of the great vessels and pulmonary vasculature.

- Left-sided cardiomegaly:
  - Valvular disease: mitral insufficiency
  - Cardiomyopathy
    - Dilated (dilated cardiomyopathy, DCM): canine
    - Hypertrophic (hypertrophic cardiomyopathy [HCM]), restrictive: feline
  - Congenital
    - Left-to-right shunts: pulmonary overcirculation
      - Patent ductus arteriosus: ± main pulmonary artery, descending aorta, left auricular bulge
      - Ventricular or atrial septal defect
    - Subaortic stenosis: aortic arch dilation
    - Mitral dysplasia
- Left-sided congestive heart failure:
  - Enlarged left atrium
  - Interstitial to alveolar pulmonary infiltrates; perihilar, caudal distribution
  - In dogs with DCM and in cats, cardiogenic edema may have patchy, diffuse distribution.
  - ± Enlarged pulmonary veins
- Right-sided cardiomegaly:
  - Valvular disease: tricuspid insufficiency
  - Congenital
    - Pulmonic stenosis: main pulmonary artery dilation
    - Tetralogy of Fallot: no main pulmonary artery enlargement, ± pulmonary underperfusion
    - Tricuspid dysplasia: can resemble generalized cardiomegaly, pericardial effusion on radiographs
    - Right-to-left patent ductus arteriosus or ventricular septal defect: heart may be of normal size, ± pulmonary underperfusion, main pulmonary artery, and lobar artery dilation
  - Cor pulmonale
    - Secondary to pulmonary hypertension: main pulmonary artery and lobar artery dilation
    - Example: heartworm disease, pulmonary thromboembolism, chronic pulmonary disease
- Right-sided congestive heart failure:
  - Pleural effusion
  - Enlarged caudal vena cava
  - Hepatomegaly
- Generalized cardiomegaly:
  - Pericardial effusion: globoid appearance; loss of normal heart shape. No enlarged left atrium.
    - Idiopathic

        - Heart base, right atrial/auricular mass
        - Mesothelioma
        - Congestive heart failure
        - Left atrial rupture
        - Peritoneal-pericardial diaphragmatic hernia
    - Dilated cardiomyopathy
    - Mitral and tricuspid insufficiency
        - Individual chamber enlargement, including left atrial enlargement
- Great vessels:
    - Pulmonary trunk dilation: 1 to 2 o'clock on ventrodorsal/dorsoventral (VD/DV) view
        - Pulmonic stenosis, pulmonary hypertension
    - Aortic arch dilation: 11 to 1 o'clock on VD/DV view
        - Aortic stenosis, patent ductus arteriosus. May be normal in geriatric cats.
    - Caudal vena cava enlargement
        - Right-sided congestive heart failure, cardiac tamponade, right atrial obstruction
- Pulmonary vasculature: corresponding pulmonary arteries and veins should be of equal size:
    - Large pulmonary arteries
        - Pulmonary hypertension: heartworm disease, pulmonary thromboembolism, chronic pulmonary disease
    - Large pulmonary veins
        - Venous congestion associated with left atrial enlargement
    - Large pulmonary arteries and veins
        - Left-to-right shunts
    - Small pulmonary arteries and veins
        - Right-to-left shunts, low cardiac output

INITIAL DATABASE

- Right or left lateral and VD or DV thoracic radiographs made during full inspiration
- Electrocardiogram, blood pressure, serum biochemistry profile

ADVANCED TESTING

- Echocardiography
- Nonselective or selective angiography

TREATMENT

TREATMENT OVERVIEW

Treatment is specific to underlying cause. The general goal is to optimize preload and afterload, as well as improve diastolic and systolic cardiac function if abnormal.

ACUTE AND CHRONIC TREATMENT

As required based on underlying cause

PROGNOSIS AND OUTCOME

Variable depending on underlying disease

PEARLS & CONSIDERATIONS

COMMENTS

- Things that mimic cardiomegaly:
    - Chondrodystrophic, shallow-chested patient (especially lateral view)
    - Films made during expiration
    - Excess pericardial fat
    - Patient obliquity

- Things that mimic pulmonary disease:
  - Films made during expiration
  - Underexposure
  - Excess intrathoracic and/or extrathoracic fat
- Positional differences:
  - Cardiac apex is normally rounded and dorsally displaced on left lateral view.
  - Cardiac silhouette is normally more elongated on VD view and more oval in shape on DV view.
  - With pleural effusion, cardiac silhouette is better outlined on VD view.
- Breed/conformation differences:
  - Deep-chested patients: cardiac silhouette more narrow and vertically oriented on lateral projection compared to patients with other chest conformations.
  - Chondrodystrophic, shallow-chested patients: cardiac silhouette appears large relative to thorax. Trachea deviated dorsally on lateral projection (normal).
- Normal geriatric felines:
  - Horizontal orientation of heart
  - Tortuous, prominent aorta
- Cardiomegaly is present in 80% of dogs with hemodynamically significant pericardial effusion (cardiac tamponade); for the remaining 20%, diagnosis depends on physical exam (tachycardia + weak pulse + muffled heart sounds) and echocardiography.

AUTHOR: WENDY D. FIFE

EDITOR: ETIENNE CÔTÉ

Campylobacter Enteritis

BASIC INFORMATION

DEFINITION

Well-recognized diarrheal disease resulting from invasive and toxigenic effects of *Campylobacter* spp. infection

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Most commonly occurs in young animals <6 months old
- Pathogen of dogs, cats, humans, and various wild and domestic animals

RISK FACTORS

- Young age
- Crowded conditions such as kennels, catteries, or animal shelters
- Conditions with poor hygiene and sanitation
- Immunocompetence/immunodeficiency of individual patient
- Concomitant gastrointestinal infections
- History of antibiotic therapy

CONTAGION & ZOONOSIS

- Contagious between humans and numerous animal species
- Commonly spread between animals by fecal-oral route through contaminated food and water sources.
- Humans appear to be more susceptible than dogs or cats to clinical disease.
    - Dogs and cats are a major source of *C. jejuni* infection in people, especially puppies or kittens recently acquired from pet stores or kennels.
    - Other sources of infection to humans include eating raw or undercooked meat, especially poultry.
    - Owners of pets should be warned of the risks and practice good hygiene to minimize risk of zoonosis.

GEOGRAPHY AND SEASONALITY

Appears to be more common in the summer and fall months. In the United States, young cats in the upper Midwest commonly carry *C. upsaliensis*.

ASSOCIATED CONDITIONS & DISORDERS

May be associated with other gastrointestinal infections or parasites:

- Parvovirus
- Coronavirus
- Giardiasis
- Salmonellosis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Most carriers of *Campylobacter* show no clinical signs.
- Clinical disease usually occurs in young dogs and cats.

HISTORY, CHIEF COMPLAINT

- Acute diarrhea ranging from mild to severe, with watery to mucoid diarrhea with or without blood.
- Animals may have tenesmus, possibly vomiting, or inappetence.

- Chronic diarrhea that may be intermittent
- Cholecystitis has been reported in two dogs associated with *C. jejuni*.
- May cause abortion and fetal resorption in the bitch

PHYSICAL EXAM FINDINGS

Acute cases may have fever and/or signs of dehydration.

ETIOLOGY AND PATHOPHYSIOLOGY

- Gram-negative, curved, motile, microaerophilic bacterial rods
- Component of the normal intestinal flora
- Clinical disease depends on number of organisms ingested as well as degree of development of protective antibody
- Disease localizes in jejunum, ileum, cecum, and colon
- Virulence factors, including cytotoxin production, allow organism to invade epithelium.
- Enterotoxin results in secretory diarrhea.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis should be suspected in a young animal with diarrhea and fecal cytologic findings that identify slender, curved rods and leukocytes. Confirmation, which is often undertaken given the risk of contagion and/or zoonosis, requires culture identification or positive PCR.

DIFFERENTIAL DIAGNOSIS

- Viral diarrhea: parvovirus, coronavirus, rotavirus
- Bacterial diarrhea: *Salmonella*, *Clostridium*
- Parasites
- Dietary indiscretion

INITIAL DATABASE

CBC, serum chemistry profile, and urinalysis results usually normal or nonspecific

- Mild hemoconcentration may be seen with dehydration
- Leukocytosis may be seen with invasion of mucosa
- Serum chemistry profile may show elevated total proteins and prerenal azotemia with dehydration

ADVANCED OR CONFIRMATORY TESTING

- Microscopic examination of feces:
  - Evaluation of stained smears of fresh feces for presence of characteristic organisms.
  - Increased numbers of fecal white blood cells should be observed if intestinal inflammation is present.
  - *Campylobacter* may be difficult to distinguish from other similar species, including *Helicobacter*, on cytologic evaluation alone.
  - *Campylobacter* enteritis is difficult to diagnose cytologically, because many dogs have this organism as part of normal flora.
  - Darkfield or phase contrast microscopy if available
- Fecal culture:
  - Requires special *Campylobacter* plates and microaerophilic conditions
  - Samples of fresh feces or rectal swabs can be submitted.
  - Organisms remain viable for 3 days at room temperature and 1 week if refrigerated, but viability is improved with shorter delays.
- Polymerase chain reaction:
  - The most reliable method of definitive identification of *Campylobacter* species
  - Fecal samples should be placed in isopropyl alcohol and are stable for 72 hours.

TREATMENT

TREATMENT OVERVIEW

Treatment for latent carriers should only be performed if an immunocompromised person or animal is in the home and at risk or showing signs of infection. Otherwise, the treatment goal is confined to elimination of clinical signs in animals showing them.

ACUTE GENERAL TREATMENT

- Efficacy of antibiotic therapy in altering course of disease is unknown.
- Erythromycin, 10 to 20 mg/kg PO q 8 h, is the treatment of choice.
- Tetracyclines also have activity against *Campylobacter* (doxycycline, 5 mg/kg PO q 12-24 h).
- Quinolones (e.g., enrofloxacin, 5-10 mg/kg PO q 24 h) thought to be effective, but a high rate of drug resistance may develop.
    - Deleterious effects on joint cartilage are a concern, because many patients are young, growing animals.
    - Marbofloxacin should be considered as an alternative in cats, owing to ocular toxicity of enrofloxacin.
- Chloramphenicol has mixed results.
- Duration of treatment with any of these antibiotics is typically 2-3 weeks.

CHRONIC TREATMENT

May be indicated in carrier animals (treatment for 4-6 months has been reportedly necessary to completely clear the organism).

POSSIBLE COMPLICATIONS

Erythromycin commonly causes vomiting in dogs and cats.

RECOMMENDED MONITORING

- Monitor clinical signs.
- Recheck fecal culture to assess fecal shedding and potential exposure to humans.

PROGNOSIS AND OUTCOME

- Prognosis for recovery is good in the absence of other serious concomitant disease.
- Worse prognosis if underlying immunodeficiency or complicating disease

PEARLS & CONSIDERATIONS

COMMENTS

- May be difficult to attribute *Campylobacter* as cause of diarrhea in dogs and cats, since also part of normal flora
- Latent carriers may need to be treated if potential exposure and transmission to humans is a concern (e.g., immunocompromised persons).
- Lack of response to therapy should prompt investigation into other concurrent intestinal disease or possible antibiotic resistance.

PREVENTION

- Good sanitation and avoidance of overcrowding
- Avoid undercooked meats

TECHNICIAN TIPS

- Care should be taken to avoid any risk of fecal contamination to other hospital patients or staff.

CLIENT EDUCATION

- Owners should be informed that this is a zoonotic disease and humans are very susceptible.
- Good hygiene is essential, especially with a puppy or kitten with diarrhea.

1ST EDITION AUTHOR: CHRISTOPHER J. JONES

Callus/Pressure Sore

BASIC INFORMATION

DEFINITION

- Callus: a thickened, hyperkeratotic, alopecic area of skin over a pressure point
- Pressure sore (decubital ulcer): an area of tissue damage or necrosis concentrated over a bony prominence, resulting from prolonged application of pressure

SYNONYM

Decubital ulcer (pressure sore)

EPIDEMIOLOGY

SPECIES, AGE, SEX

Any patient can develop a callus or pressure sores.

GENETICS & BREED PREDISPOSITION

Large- or giant-breed dogs, because of their size and weight, are disproportionately more commonly affected.

RISK FACTORS

- Animals that are weak or emaciated, as well as those that are recumbent for long periods on hard surfaces, are at a high risk for developing pressure sores.
- Immunosuppressed individuals may be more prone to secondary infections of pressure point lesions.
- Hypothyroid dogs may develop unusually severe calluses or calluses in unusual areas.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Often have a history of prolonged recumbency or sleeping on hard surfaces such as wood, cement, or brick
- Owner may notice progressive lesions over bony prominences. Some owners may not notice sores until they break open, or see the patient further aggravating the lesions by licking them.

PHYSICAL EXAM FINDINGS

- A callus initially appears as a thickened, hyperkeratotic, lichenified, and alopecic area of skin over a bony prominence, commonly affecting the elbows, hocks, and sternum.
- The severity of pressure sores is variable:
    - They can be erythematous to purple in color, with a serous, sanguineous, or purulent discharge. Ulcers with undermined edges are common sequelae.
- Either of these lesions may develop secondary infections with abscessation and draining tracts.

ETIOLOGY AND PATHOPHYSIOLOGY

- A callus is caused by pressure-induced ischemia and inflammation.
- Prolonged pressure compresses capillary circulation, causing tissue damage or necrosis, producing a pressure sore:
    - Grade I lesions affect the epidermis and superficial dermis.
    - Grade II lesions extend to the subcutis. Within 24-48 hours, the ulcer edges become undermined.
    - Grade III lesions extend to the deep fascia.
    - Grade IV lesions involve the underlying bone.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Ulcerated neoplasm
- Infected/necrotic wound as a result of trauma
- Calcinosis circumscripta

INITIAL DATABASE

- A thorough history and physical exam are most important.
  - Diagnosis is generally based on physical location of the lesion(s) over pressure points, typical appearance (see above), and owner's description of the environment and surfaces on which the animal lies.
- Radiographs of the affected area may help to ascertain bony involvement (uncommon).

ADVANCED OR CONFIRMATORY TESTING

- Cytologic examination and culture and susceptibility testing may be indicated for the management of secondary infections.
- Histopathologic evaluation of biopsies can be used for distinguishing infected/necrotic callosities and pressure sores from neoplasms and calcinosis circumscripta.

TREATMENT

TREATMENT OVERVIEW

- Recognition and elimination of the cause(s) is paramount.
- Providing a soft, padded environment may be all that is required to decrease the size of callus lesions and prevent progression.
- Resolving pressure sores and preventing new lesions depend on providing an optimum environment for healing by treating infection and encouraging blood supply to the area.

GENERAL TREATMENT

- Pressure sores should be cleaned daily with an antiseptic solution such as chlorhexidine diluted to 0.05%.
  - With standard 4% chlorhexidine solution, dilute 1 part chlorhexidine to 80 parts water (or 12 mL in 1 L of water) to obtain a 0.05% concentration.
- Various treatments have been suggested to accelerate healing of pressure sores, including wound-healing creams, raw honey, or a topical antibiotic, mupirocin.
- Although systemic antibiotics do not penetrate well, owing to the area of capillary and venous congestion at the base and tissue margins of a pressure sore, coverage is prudent.
  - Cephalexin, 30 mg/kg PO q 12 h for 30 days may be beneficial.
- Grade II-IV pressure sores often require surgical débridement and closure, but not until the patient is ambulatory. Otherwise, the wound may dehisce.
- Physical barriers such as Elizabethan collars may help deter self-trauma to pressure point lesions.

POSSIBLE COMPLICATIONS

- Wound dehiscence after surgery
- Slow healing

PROGNOSIS AND OUTCOME

- Callus lesions can be controlled by attention to home environment and bedding.
- Since the severity of pressure sores varies, severe lesions are accordingly more difficult to manage.
- If the patient recovers from the underlying disease/reason for recumbency quickly, the pressure sore should heal spontaneously, but often slowly.

PEARLS & CONSIDERATIONS

COMMENTS

Prevention of pressure sores is of utmost importance because they can be difficult to manage, prone to infection, and slow to heal.

PREVENTION

- Prevention is vastly superior to any kind of treatment.
- All recumbent patients should be turned frequently and given massage, physiotherapy, and/or hydrotherapy to stimulate blood flow.
- Recumbent animals should be kept on a well-padded surface such as a waterbed, soft egg crate, foam rubber pad, or airbed.

TECHNICIAN TIP

The keys for preventing pressure sores in recumbent patients are “dry and clean, soft, and shift”: bedding should be changed when damp or soiled; well-padded; and the patient's recumbency should be altered periodically (e.g., every 4-6 hours) to avoid extended time spent on the same pressure points.

Calicivirus, Cat

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Common viral disease in domestic and some exotic cats, characterized by upper respiratory signs, oral ulceration, and less commonly arthritis

SYNONYMS

Upper respiratory infection (calicivirus is one possible etiology); limping kitten syndrome; older literature: classification as picornavirus. Virulent systemic feline calicivirus (VS-FCV) is also known as *hemorrhagic fever–like FCV*

EPIDEMIOLOGY

SPECIES, AGE, SEX

- All domestic cats and some exotic feline species are susceptible.
- All ages affected, but susceptibility for typical upper respiratory infection is highest in kittens.
- Adults are more likely to experience the virulent systemic form of infection.
- No gender predilection

RISK FACTORS

- Multiple-cat environments
- Crowding
- Stress
- Poor husbandry
- Coinfection with other respiratory pathogens worsens disease

CONTAGION & ZOONOSIS

FCV is a highly contagious disease of cats. No zoonotic implications are known.

GEOGRAPHY AND SEASONALITY

Worldwide with no seasonality

ASSOCIATED CONDITIONS & DISORDERS

- Lymphocytic-plasmacytic stomatitis and gingivitis linked to chronic carriers
- Frequent coinfection with other upper respiratory pathogens

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Pneumotropic isolates affect primarily the upper, and uncommonly the lower, respiratory tract.
- Rheumatic isolates cause joint pain and lameness in naturally infected kittens.
    - Joint disease also reported after administration of modified-live calicivirus vaccine
- Virulent systemic form may cause more severe clinical signs in adults.
    - Vaccinated cats can be affected.

HISTORY, CHIEF COMPLAINT

- Malaise: lethargy, listlessness
- Inappetence/anorexia
- Ocular signs (see Physical Exam Findings below)

- Sneezing
- Nasal discharge (serous or purulent)
- Drooling
- Reluctance to walk, lameness

PHYSICAL EXAM FINDINGS

Pneumotropic form:

- Conjunctivitis: diffuse, bilateral
- Epiphora
- Blepharospasm
- Chemosis: may be dramatic; entire globe may become hidden behind swollen conjunctiva
- Oculonasal discharge (serous or purulent)
- Fever
- Vesicles or erosions on tongue, palate, nasal planum:
  - Visible during routine examination of mouth
  - Characteristic of calicivirus, but also occurs less commonly from herpesvirus infection and exposure to topical irritants, especially hospital and surgical disinfectants
  - May cause drooling
- Dehydration
- Cough is uncommon

Rheumatic form:

- Fever; temperature often >104°F (>40°C)
- Joint swelling
- Pain
- Myalgia
- Oral ulcers possible
- Kitten/cat may eat well but be reluctant to walk

Virulent systemic form:

- Fever
- Facial and limb edema that may progress to necrosis
- Upper respiratory signs
- Icterus with pancreatitis
- Dyspnea
- Epistaxis and/or hematochezia
- Ulcerations in mouth, face, muzzle, pinna, and extremities
- Pneumonia
- Pericarditis
- Death

ETIOLOGY AND PATHOPHYSIOLOGY

- Infection with FCV, an RNA virus with multiple subtypes of varying degrees of virulence and cross-reactivity, is acquired predominantly via ingestion.
  - Spread by aerosol route less likely
- Replication occurs in oropharyngeal tissues, with spread primarily to epithelium of conjunctiva, nose, and oral cavity, including the tongue and palate.
  - Rapid cytolysis of infected cells ensues.
  - In the virulent systemic form, signs result from vasculitis and development of disseminated intravascular coagulation/systemic inflammatory response syndrome.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- Presumptive diagnosis is primarily based on history, physical examination, and clinical signs. Virus identification must be interpreted carefully; it rarely affects treatment and is mainly of academic interest.

DIFFERENTIAL DIAGNOSIS

- Feline herpesvirus 1:
  - Cough and keratitis more likely with feline herpesvirus infection
  - Oral ulceration less likely with feline herpesvirus infection
- Chlamydiosis
- Mycoplasmosis
- Bordetellosis
- Corneal injury/trauma
- Oral/lingual ulceration accompanied by fever may be caused by licking of surgical and/or hospital disinfectants from feet or fur.

INITIAL DATABASE

- Fluorescein staining of corneas to rule out corneal ulcers/injury
- Feline leukemia/feline immunodeficiency virus tests to rule out underlying immune compromise
- No characteristic findings on CBC, biochemical profile, or urinalysis

ADVANCED OR CONFIRMATORY TESTING

- Viral culture
- Viral identification usually not warranted except in cases of virulent systemic calicivirus infection

TREATMENT

TREATMENT OVERVIEW

Treatment is aimed at controlling pain, maintaining supportive care, treating secondary bacterial infection, and preventing spread to unaffected cats. Therapeutic goals are to maintain hydration and nutrition; provide pain relief for ulcers, joint/muscle pain; and control secondary bacterial infection.

ACUTE GENERAL TREATMENT

- Fluids to maintain hydration
- Syringe feeding if anorexic
- Erythromycin ophthalmic ointment to combat potential secondary *Chlamydia* or *Mycoplasma* infections
- Buprenorphine (0.01-0.03 mg/kg q 8-12 h IM, IV, PO) may be considered for analgesia.
- Sucralfate slurry dribbled on lingual ulcers may be beneficial.
- α-Interferon may inhibit viral replication.

CHRONIC TREATMENT

- Recrudescence of clinical disease is uncommon.
- Cats may be susceptible to infection with new subtypes.

NUTRITION/DIET

Feeding tubes may be required for nutritional support in cases with severe or protracted oral ulceration (see p. 1270).

DRUG INTERACTIONS

Nonsteroidal antiinflammatory drugs and steroids are discouraged, owing to risks and interference with therapeutic benefits of fever and cytokine release.

POSSIBLE COMPLICATIONS

- Interstitial viral pneumonia and/or secondary bacterial pneumonia can be life-threatening complications.
- Oral ulcers and arthritis usually resolve without complication.
- Sudden dyspnea may occur if pneumonia develops.

RECOMMENDED MONITORING

Clinical signs

PROGNOSIS AND OUTCOME

- Prognosis is good for recovery from typical calicivirus infection with supportive care.
- By contrast, a mortality rate of 40% is reported for the virulent systemic form.

PEARLS & CONSIDERATIONS

COMMENTS

- Constant viral mutation within individuals and endemically infected populations may account for extreme variation in virulence between subtypes.
- Recovered cats remain lifelong carriers. Virus is shed continuously from oral cavity, regardless of health status or stress.
- Properly vaccinated cats may become infected with different subtypes.

PREVENTION

- Proper husbandry to prevent cat-to-cat contact and cross-contamination during cleaning and feeding procedures.
- FCV is stable and resistant to many disinfectants, except bleach (sodium hypochlorite) diluted 1 part bleach to 32 parts tap water.
- Proper vaccination at 8-10 weeks, after 12 weeks of age, 1 year later, and every 3 years afterward.

TECHNICIAN TIPS

All cats, especially kittens, seen with signs of upper respiratory tract infection should be considered FCV-infected so that appropriate precautions can be taken to limit spread within the hospital.

CLIENT EDUCATION

- Emphasize proper vaccination
- In catteries, consider immunizing kittens from carrier queen as early as 6 weeks of age.

Calcium Channel Blocker Drug Toxicosis

BASIC INFORMATION

DEFINITION

Calcium channel blocker (CCB) drugs are commonly used for the treatment of hypertension and tachyarrhythmias in human and veterinary medicine. Adverse effects at therapeutic dose or with overdose result in hypotension and bradycardia or tachycardia, causing weakness, ataxia, and inappetence within 30 minutes to 12 hours after ingestion.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Animals of all breeds, ages, and both sexes are susceptible. Exposure is more common in dogs.

RISK FACTORS

- Preexisting renal or cardiovascular disease may predispose to signs.
- Hepatic disease may reduce metabolism and elimination of CCBs.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Sustained/controlled/extended/delayed-release preparations may delay onset of signs (6-12 hours), whereas immediate-release preparations can cause signs within 30 minutes.

HISTORY, CHIEF COMPLAINT

- History of suspected or observed exposure
- Weakness, depression, ataxia, vomiting possible

PHYSICAL EXAM FINDINGS

- Hypotension and bradycardia are common; reflex tachycardia is possible if hypotension predominates (dihydropyridine CCBs).
- Pale mucous membranes
- Hypothermia possible (due to hypotension)
- Depression, ataxia, seizures, or coma possible
- Dyspnea possible (pulmonary edema)

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

- Prescription medication (human or veterinary)
- Dihydropyridine-type CCBs (e.g., amlodipine [Norvasc]) have effects that are confined to vascular smooth muscle. Thus they are used for treating hypertension.
- Nondihydropyridine-type CCBs (benzothiazepines such as diltiazem [Dilacor, Cardizem] or phenylalkylamines such as verapamil [Isoptin, Calan]) have greater potency in cardiac muscle and cardiac nodal tissues than in the vasculature. Thus they are used for treating arrhythmias and cardiomyopathy.

Mechanism of Toxicosis:

- CCBs close L-type calcium channels by binding to their α-subunit. Decreased calcium influx results in vasodilation (dihydropyridine-type) or a decrease in cardiac contractility and electrical impulse conduction at the SA and AV nodes (nondihydropyridine-type).
- CCBs decrease pancreatic insulin secretion, resulting in hyperglycemia.

- CCBs may cause noncardiogenic pulmonary edema (mechanism unknown)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on observation or evidence of ingestion (chewed container) along with physical exam findings of hypotension and/or bradycardia. Confirmation with plasma drug levels is uncommonly performed, and treatment generally should be initiated without such results.

DIFFERENTIAL DIAGNOSIS

- Toxicologic:
  - β-Adrenergic receptor antagonists overdose (propranolol, metoprolol), α2-adrenergic receptor agonists (imidazoline-type decongestants), cardiac glycosides (example: digoxin, some cardiac glycoside containing plants; bufo toad toxicosis), antidepressant toxicosis, organophosphate and carbamate insecticides
- Spontaneous, nontoxicologic:
  - Primary cardiac disease, systemic illness causing hypotension

INITIAL DATABASE

- Blood pressure (see): hypotension
- Electrocardiogram (ECG; see):
  - Sinus bradycardia, AV block with verapamil or diltiazem
  - Sinus tachycardia with dihydropyridines
- Serum chemistry profile: hyperglycemia, hypokalemia, hypophosphatemia, hypomagnesemia possible
- Acid-base status: lactic acidosis possible

ADVANCED OR CONFIRMATORY TESTING

Plasma CCB levels may be measured at a human hospital for confirmation. Therapeutic monitoring to assess response to treatment is not useful, as reference ranges have not been established for animal.

TREATMENT

TREATMENT OVERVIEW

Treatment consists of decontamination (emesis and charcoal administration), stabilizing the cardiovascular system, and maintaining tissue perfusion by maintaining adequate blood pressure during the course of toxicosis. If no clinical signs are present, continuous monitoring in a veterinary facility for 12-24 hours or longer following ingestion is recommended; signs can be delayed, especially with extended release formulations.

ACUTE GENERAL TREATMENT

- Decontamination
  - Emesis with a recent ingestion or in an animal showing no overt signs of toxicosis (see)
  - Activated charcoal: 1-2 g/kg (or labeled dosage) with a cathartic PO following emesis (if performed); repeat half the original dose q 6 h for large ingestions or extended-release preparations.
  - Gastric lavage: if large number of tablets, which can form concretions
  - Enema (see p. 1258): consider if the medication is an extended-release preparation, as significant absorption can occur in colon; 2.5-5 mL/kg of warm tap water or isotonic saline
- Fluid therapy
  - Fluid rate should be guided by blood pressure monitoring; avoid volume overload (iatrogenic pulmonary edema).
- Treatment of hypotension
  - IV crystalloid fluids
  - Hetastarch for persistent hypotension
    - Dogs: 20 mL/kg/d IV; initial 5 mL/kg bolus over 15-30 minutes, followed by CRI of 15 mL/kg/day
    - Cats: 10 mL/kg/d IV
  - Calcium chloride or calcium gluconate for refractory hypotension; monitor continuous ECG, and discontinue if bradycardia worsens.
    - Calcium chloride provides 3 times more calcium per mL than calcium gluconate.

        - Calcium chloride and calcium gluconate are very irritating and can cause tissue necrosis if extravascular; use indwelling catheter.
        - Calcium chloride (10% solution; 27.2 mg Ca/mL): 0.1-0.5 mL/kg slow IV bolus or CRI of 0.01 mL/kg/h (5 mg/kg/h), *or*
        - Calcium gluconate (10% solution; 9.3 mg Ca/mL): 50-150 mg/kg (0.5-1.5 mL/kg) slow IV over 5 minutes to effect or CRI of 5 mg/kg/h (0.05 mL/kg/h).
    - If hypotension persists after crystalloids, hetastarch, and calcium supplementation, dopamine (1-20 mcg/kg/min IV CRI) may be used, provided the patient is volume-expanded/well hydrated.
- Severe bradycardia/AV block:
    - Atropine: 0.02-0.04 mg/kg IV, SQ, or IM; repeat as needed; *or*
    - Isoproterenol: 0.4 mg in 250 mL of D5W, drip slowly IV to effect; *or*
    - Temporary cardiac pacing (see)
- Control seizures (see p. 1009) with diazepam (0.5-1 mg/kg IV) or pentobarbital (3-15 mg/kg IV slowly to effect).
- Supplement potassium in hypokalemic patients when the potassium is below 2.5 mEq/L.
- Oxygen therapy if pulmonary edema occurs

CHRONIC TREATMENT

Some animals may need continued treatment for renal insufficiency.

DRUG INTERACTIONS

- CCBs will increase blood levels of propranolol and digoxin.
- Propranolol, ketoconazole, and itraconazole increase CCB levels by reducing clearance of CCBs.
- Cimetidine will increase bioavailability of CCBs.
- Phenobarbital will increase clearance of CCBs.

POSSIBLE COMPLICATIONS

- Pulmonary edema
- Renal insufficiency due to decreased renal perfusion

RECOMMENDED MONITORING

- Blood pressure
- ECG
- Electrolytes
- Serum chemistry panel, especially renal parameters
- Respiration (rate, lung sounds, pulse oximetry)
- CNS signs

PROGNOSIS AND OUTCOME

- Prognosis is generally good with prompt treatment. Refractory hypotension, severe hyperglycemia, and pulmonary edema may convey a guarded prognosis.
- After recovery, long-term effects are uncommon. Organ dysfunction secondary to sustained hypotension is possible, such as myocardial ischemia or renal failure.

PEARLS & CONSIDERATIONS

COMMENTS

- Many preparations of CCBs are sustained-, controlled-, extended-, or delayed-release medications, which may substantially lengthen the onset and duration of signs.
- Bezoar formation is possible with ingestion of large quantities of sustained/controlled/extended/delayed-release preparations, especially nifedipine.
- Signs of toxicosis can occur at veterinary therapeutic doses of CCBs. These medications have a narrow margin of safety.
- Noncardiogenic pulmonary edema is possible as a toxic effect; fluid overload should be avoided.

PREVENTION

Owners should keep all medications out of reach of pets.

TECHNICIAN TIPS

It is important to know whether CCB involved in the intoxication is regular or extended-release medication.

CLIENT EDUCATION

Owners should be made aware of possible adverse effects when veterinary patients are prescribed CCBs.

AUTHOR: CRISTINE HAYES

EDITOR: SAFDAR KHAN

Calcipotriene/Vitamin D3 Analog Toxicosis

BASIC INFORMATION

DEFINITION

Synthetic vitamin D3 analogs are used topically for treating psoriasis in human and occasionally for treating some skin conditions in dogs and cats. Toxicosis manifests acutely with nonspecific signs of illness and within days may cause kidney disease/renal failure.

SYNONYMS

Calcipotriene, calcipotriol = 1,25 dihydrocholecalciferol (= calcitriol) analog; Tacalcitol = 1,24 dihydrocholecalciferol analog; vitamin D2 = ergocalciferol; vitamin D3 = cholecalciferol. Popular brands (calcipotriene): Dovonex; Taclonex, Dovobet (calcipotriene 0.005% or 50 mcg/g)

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs appear to be very sensitive to toxicosis

RISK FACTORS

- Dogs, especially young dogs, with indiscriminate eating habits
- Patients with chronic kidney disease may be at higher risk for adverse renal effects
- Presence of vitamin D3 analog in pet's environment

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of ingestion of vitamin D3 analog (chewed up tube/capsules) possible
- Anorexia, vomiting, lethargy, diarrhea within 12-24 hours of ingestion
- PU/PD (due to renal failure) within24-72 hours

PHYSICAL EXAM FINDINGS

- Depression, lethargy, and weakness
- Vomiting (hematemesis), diarrhea (melena)
- Signs of dehydration
- Cardiac arrhythmias
- Seizures (usually seen within 1-3 days of ingestion, if at all)

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

- Vitamin D3 analogs are available by prescription as creams, lotions, ointment, and capsules. Toxicosis occurs secondary to acute accidental ingestions by the patient.

Mechanism of Toxicosis:

- Through calcium-binding proteins, vitamin D3 analogs increase the amount of calcium absorbed from the intestines, as well as increasing bone resorption of calcium and renal tubular resorption of calcium.
- The result is hypercalcemia and hyperphosphatemia.
- Unregulated increases in calcium and phosphorus result in soft-tissue mineralization, especially kidneys, myocardium, large blood vessels, and GI tract.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on suspected or confirmed history of exposure to calcipotriene or other vitamin D3 analogs and development of clinical signs including vomiting, anorexia, weakness, and lethargy initially; polydipsia, polyuria, and renal failure >24-72 hours after exposure. Hypercalcemia and hyperphosphatemia are noted in virtually all clinically important cases at first and may normalize while renal values rise (renal damage is due to precipitation of calcium in kidneys, and in certain cases, serum calcium and phosphorus levels may have normalized while azotemia persists), indicating renal failure. A patient with normal serum Ca, P, and renal values 3 or more days after exposure either was not exposed or received a minor exposure.

DIFFERENTIAL DIAGNOSIS

- Rodenticide cholecalciferol ingestion
- Other causes for hypercalcemia (see pp. 553 and 1397) plus hyperphosphatemia include chronic kidney disease, hypoadrenocorticism, lymphoma, perianal adenocarcinoma, multiple myeloma, osteolytic tumors.

INITIAL DATABASE

- CBC and serum biochemical profile (hyperphosphatemia and/or hypercalcemia usually in 12 hours; increased BUN, creatinine within 1-3 days if at all; monitor at least every 24 hours for 3-4 days or longer if abnormalities noted.
- Calcium (mg/dL) phosphorus (mg/dL) product (historically, >70 has suggested greater risk for dystrophic mineralization)
- Urinalysis including specific gravity
- Abdominal and thoracic radiographs +/− ultrasound (dystrophic mineralization)

ADVANCED OR CONFIRMATORY TESTING

Rarely practical during active management of toxicosis

- Increased serum 25-hydroxycholecal-ciferol; no assays available to detect calcipotriene in clinical cases
- Total wet weight calcium may be elevated in kidneys.
- Histopathologic evidence of tissue mineralization (kidneys, aorta, GI mucosa, lungs, heart)

TREATMENT

TREATMENT OVERVIEW

- Immediate treatment of renal failure, cardiac arrhythmias, and seizures as needed
- Prevention of absorption by inducing emesis and administering activated charcoal in promptly presented patient (no clinical signs)
- Promote calciuresis and limit calcium and phosphorus absorption from intestine.
- Inhibit release of calcium and phosphorus from bone.
- Judicious supportive care, notably with intravenous fluids

ACUTE GENERAL TREATMENT

- Prevent absorption: emesis if <4 hours (hydrogen peroxide 3%, 0.25-0.5 mL/kg PO once [dogs] or xylazine hydrochloride, 0.44 mg/kg IM [cats] followed by activated charcoal, 2 g/kg suspended in 10 mL tap water PO; follow label directions for brands) and a cathartic, given q 8 h 24 hours
- Promote calciuresis: saline diuresis using isotonic crystalloids (e.g., 0.9% saline) at 130 mL/kg/d barring cardiovascular contraindications; furosemide, 2.5-4.5 mg/kg PO, IM, or IV q 6-8 h; prednisolone, 1-3 mg/kg PO q 8-12 h
- Inhibit release of calcium and phosphorus from bone (specific antagonist): pamidronate, 1.3-2 mg/kg IV infusion over 2 hours. Repeat in 3-7 days if needed based on persistent hypercalcemia.
- Phosphate binders (e.g., aluminum hydroxide, 10-30 mg/kg PO q 8 h)

CHRONIC TREATMENT

Several days or even weeks of ongoing treatment (including hospitalization) may be needed for treating hypercalcemia, hyperphosphatemia, and renal failure in some cases.

NUTRITION/DIET

Kidney disease dietary therapy (optimized protein, low calcium diet)

POSSIBLE COMPLICATIONS

Calcification of soft tissues—especially in kidneys, lungs, walls of great vessels

RECOMMENDED MONITORING

Follow serum renal, calcium, phosphorus values—initially daily, then weekly until they remain normal without medical support.

PROGNOSIS AND OUTCOME

- Good if treatment is initiated before persistent hypercalcemia, azotemia, and soft-tissue calcification
- Guarded for several months after a patient recovers from hypercalcemia and hyperphosphatemia of several months' duration; calcified plaques in walls of great vessels are intrinsically weaker, can rupture

PEARLS & CONSIDERATIONS

COMMENTS

- Ingestion of 40-60 mcg/kg of calcipotriene or more in dogs can lead to marked hypercalcemia, hyperphosphatemia, renal failure and death.
- Several human supplements contain large amounts of vitamin D, up to 5000 IU (= 0.125 mg).
- 40 IU of vitamin D = 1 mcg or 1 IU of vitamin D3 = 0.025 mcg of cholecalciferol
- The recommended dose of calcitriol for treatment of renal secondary hyperparathyroidism in dogs is 1.65-3.63 ng/kg *(please note it is nanogram not microgram)* PO q 24 h. This corresponds to 0.00165-0.00363 micrograms per kilogram.

PREVENTION

- Prevent pet access to vitamin D3-containing products.
- Store medications in pet-proof cabinets.

TECHNICIAN TIPS

Keep in mind that topical creams/ointments may be potent (contain vitamin D analogs) and can cause life-threatening intoxications. If an owner is using a human skin cream on a pet's skin abrasion, be sure the cream does not contain calcipotriene or other similar compound.

CLIENT EDUCATION

- Maintain information on types of topical medications used in the home.
- Keep a list of all medications in the home, separate from the medications themselves.

Calcinosis Cutis and Calcinosis Circumscripta

BASIC INFORMATION

DEFINITION

- Calcinosis cutis is uncommon and characterized by inappropriate deposition of calcium within the skin. Calcinosis cutis typically denotes a specific form of dystrophic calcification associated with spontaneous or iatrogenic hyperadrenocorticism.
- Calcinosis circumscripta is a localized nodular deposition of calcium in subcutaneous tissue or in other areas such as the tongue, tendons, and ligaments.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Calcinosis cutis develops as a result of another underlying disorder in dogs, most commonly spontaneous or iatrogenic hyperadrenocorticism. It has been reported in three dogs being treated for blastomycosis with amphotericin B, one dog with atypical fungal infection, and another dog with suspected leptospirosis.
- Calcinosis circumscripta is an uncommon disorder found in dogs younger than age 2 years. It is rare in cats.

GENETICS & BREED PREDISPOSITION

Calcinosis circumscripta is typically found in large-breed dogs, with German shepherds being predisposed.

RISK FACTORS

- Increased risk of calcinosis cutis with chronic administration of exogenous corticosteroids
- Calcinosis circumscripta lesions develop at sites of repetitive trauma.

ASSOCIATED CONDITIONS & DISORDERS

- Calcinosis cutis: hypertrophic osteodystrophy and idiopathic polyarthritis

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Calcinosis cutis is classified as dystrophic, metastatic, idiopathic or iatrogenic.

- *Dystrophic calcification* is either localized or generalized. Localized dystrophic calcification occurs as a result of tissue abnormalities or injury. Generalized dystrophic calcification most commonly occurs in dogs with spontaneous or iatrogenic hyperadrenocorticism.
- *Metastatic calcification* is the calcification of normal skin secondary to an underlying abnormality in calcium or phosphorus metabolism. Although rare, canine and feline metastatic calcification has been reported with chronic renal failure and is restricted to the footpads.
- *Idiopathic calcification* occurs in localized (calcinosis circumscripta) or generalized forms. The underlying cause is unknown.
- *Iatrogenic calcinosis cutis* occurs secondary to percutaneous absorption or penetration of calcium-containing products (e.g., calcium chloride). It has been reported in both dogs and cats as a consequence of subcutaneous injections of calcium-containing solution.

HISTORY, CHIEF COMPLAINT

- Dogs affected with calcinosis cutis may present for evaluation of erythematous papules or plaques with gritty surfaces, with or without concurrent pruritus.
- In calcinosis circumscripta, dogs present with a solitary mass over bony prominences or in the oral cavity, particularly the tongue.

PHYSICAL EXAM FINDINGS

- Calcinosis cutis lesions may be found anywhere on the body but typically develop along the dorsum of the trunk, inguinal region, and axillae. Early lesions are erythematous papules that coalesce to form firm, gritty plaques. A chalky white to pink material can be seen through intact epidermis of early nonulcerated lesions. Ulceration and crusting occur during transepidermal elimination of mineralized debris. Lesions can be quite pruritic, leading to extreme self-trauma.
- Calcinosis circumscripta is usually a solitary lesion, but multiple masses are possible. The lesion is a firm, haired to alopecic, well-circumscribed, subcutaneous or deep dermal mass that may ulcerate and discharge a chalky or gritty substance.

ETIOLOGY AND PATHOPHYSIOLOGY

- The pathogenesis of calcinosis cutis and calcinosis circumscripta probably involves abnormally high mitochondrial calcium phosphate levels, resulting in crystal formation and cell death. Calcium salts are deposited along collagen and elastin fibers.

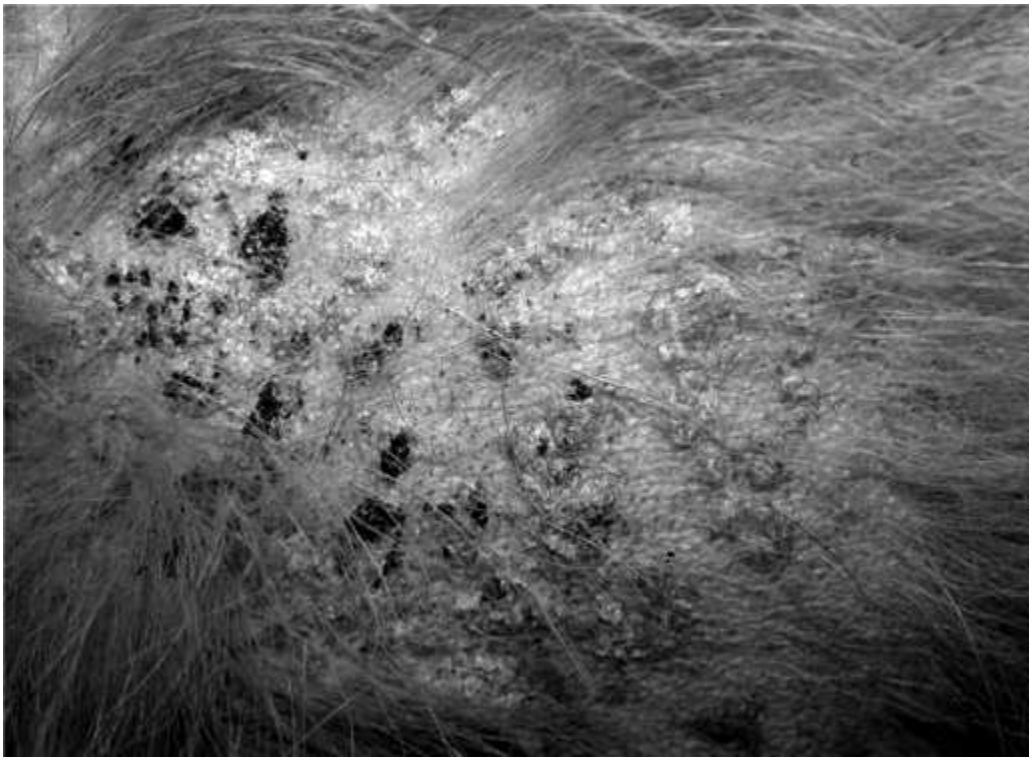
DIAGNOSIS

DIAGNOSTIC OVERVIEW

Physical examination is the cornerstone of diagnosis: calcinosis cutis is suspected when erythematous papules or plaques that may exude a gritty white substance develop in dogs with iatrogenic or spontaneous hyperadrenocorticism. Biopsies are usually performed for confirmation.

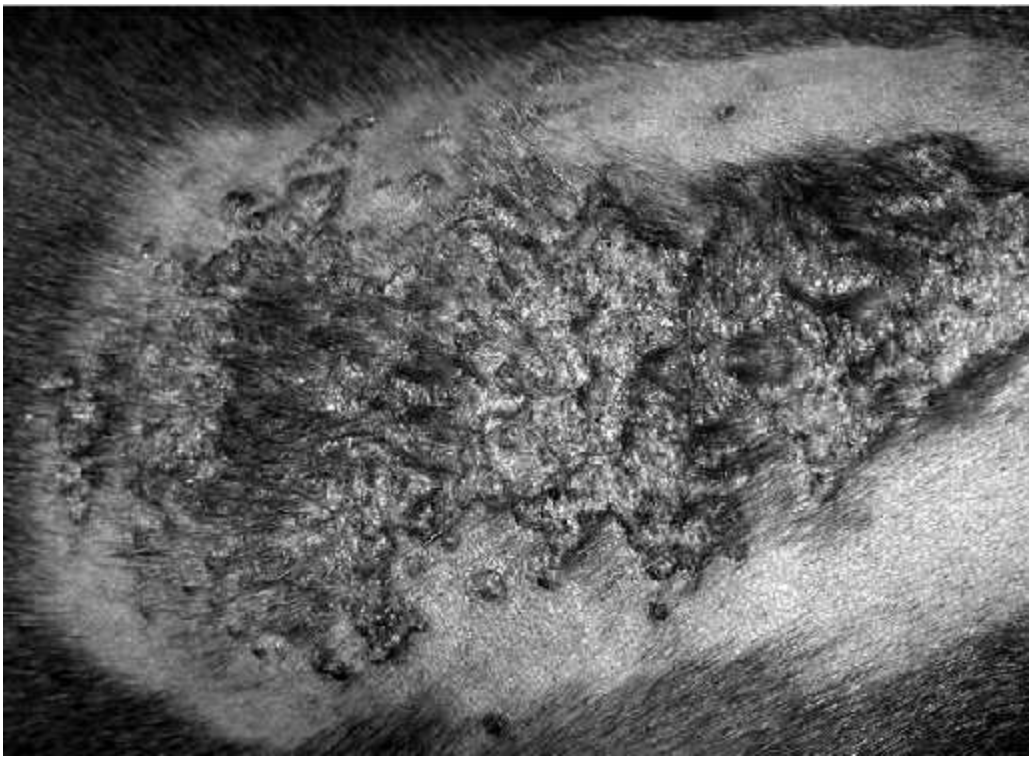
DIFFERENTIAL DIAGNOSIS

- Calcinosis cutis: bacterial pyoderma, deep fungal infection, demodicosis, neoplasia
- Calcinosis circumscripta: neoplasia, foreign body



EARLY LESIONS OF CALCINOSIS CUTIS. Note the crusted, erythematous papules.

(Courtesy Dr. J. Wellington.)



CALCINOSIS CUTIS Calcinosis cutis on dorsal cervical region of a boxer with spontaneous hyperadrenocorticism.

(Courtesy Dr. J. Wellington.)

INITIAL DATABASE

- Cytologic evaluation of exudates: amorphous gritty material
- Skin scrapings: sample has gritty consistency when smeared onto microscope slide
- Routine hematologic and biochemical profile: changes associated with hypercortisolism are usually noted in spontaneous and iatrogenic hyperadrenocorticism cases
- Normal calcium and phosphorus levels are typically found, except in patients with metastatic calcification.

ADVANCED OR CONFIRMATORY TESTING

- Skin punch biopsies and histopathologic analysis: multifocal accumulations of finely or coarsely granular amorphous basophilic debris in deep dermal or subcutaneous tissue encompassed by granulomatous inflammation
- Radiographs: conglomerated calcified mass in skin or subcutis with calcinosis circumscripta

TREATMENT

TREATMENT OVERVIEW

In most patients with calcinosis cutis, lesions slowly resolve spontaneously once the underlying disease is controlled or resolved. Surgical excision is curative for solitary lesions of calcinosis circumscripta.

ACUTE GENERAL TREATMENT

- Discontinue or reduce dosage of systemic corticosteroids.
- Oral antihistamines and bathing with oatmeal-based shampoo may be effective in controlling pruritus associated with calcinosis cutis.

CHRONIC TREATMENT

- Topical dimethyl sulfoxide applied to up to one-third of body each treatment may dissolve the calcium. If lesions are extensive, serum calcium levels should be monitored for hypercalcemia with this therapy.
- Hydrotherapy and frequent bathing with antibacterial shampoo will reduce pruritus and potential for secondary bacterial

infection.

PROGNOSIS AND OUTCOME

- Calcinosis cutis may regress spontaneously without treatment over weeks to months, with resolution or control of the underlying disease.
- Recurrence of calcinosis circumscripta lesions post surgical excision does not occur.

PEARLS & CONSIDERATIONS

COMMENTS

In patients with calcinosis cutis associated with excessive glucocorticoids, lesions increase in size, or new lesions may appear for up to 3 months after discontinuing the steroid or treatment of spontaneous hyperadrenocorticism.

Cachexia, Cardiac

BASIC INFORMATION

DEFINITION

Weight and lean tissue loss commonly associated with congestive heart failure (CHF)

EPIDEMIOLOGY

SPECIES, AGE, SEX

More common in dogs than in cats

RISK FACTORS

More common in right-sided or biventricular than in isolated left-sided CHF but can occur regardless of underlying cause

ASSOCIATED CONDITIONS & DISORDERS

Occurs secondary to CHF

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Cachexia ranges in severity from subtle muscle loss to severe, end-stage muscle wasting.

HISTORY, CHIEF COMPLAINT

Heart failure (see p. 470)

PHYSICAL EXAM FINDINGS

- Loss of lean body mass first noted in epaxial, gluteal, scapular, or temporal muscles; may be subtle initially
- Carefully palpate obese animals and animals with ascites or subcutaneous edema to determine whether muscle loss is present.

ETIOLOGY AND PATHOPHYSIOLOGY

- Cardiac cachexia reduces strength, immune function, and survival.
- Decreased food intake, increased energy requirements, and production of the inflammatory cytokines, tumor necrosis factor (TNF) and interleukin 1 (IL-1)
    - TNF and IL-1 cause anorexia, increased energy requirements, catabolism of lean body mass, myocardial fibrosis, and decreased cardiac contractility (negative inotropy).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

All animals with CHF should be assessed carefully for early signs of muscle loss so that cachexia can be detected at its early stages when intervention is more likely to be successful.

DIFFERENTIAL DIAGNOSIS

Cachexia from other diseases (e.g., cancer, renal failure)

INITIAL DATABASE

- Diet history, including specific types and amounts of food eaten, dietary supplements, treats, and foods used for administering medications
- Evaluation for potential causes of anorexia (e.g., worsening CHF; medication side effects such as azotemia, hyperkalemia, or hypotension; unpalatable diet)

TREATMENT

TREATMENT OVERVIEW

The goals of treating cardiac cachexia are to (1) optimally manage CHF, (2) minimize anorexia, (3) reduce energy requirements, (4) ensure adequate protein intake, and (5) modulate cytokine production.

ACUTE GENERAL TREATMENT

- In acute CHF episodes, avoid diet changes until the patient is home and stabilized on medications.
- To avoid food aversions, introduce new diet gradually when patient is stabilized.

CHRONIC TREATMENT

- Ensure optimal medical therapy for CHF (see p.470).
- Nutritional management is key to the effective chronic treatment of cardiac cachexia (see below).

NUTRITION/DIET

- Tips to minimize anorexia (see p.1377):
  - Reduced sodium diet palatable to individual patient may require diet changes (e.g., dry to canned, or different brand or flavor).
  - Balanced homemade diet formulated by veterinary nutritionist
  - Smaller, more frequent meals
  - Palatability enhancers (cooked meat or low-sodium broth)
  - Fish oil supplementation (see “Modulate cytokine production” below)
- Reduce energy requirements:
  - Optimal management of CHF
  - Exercise restriction
- Ensure adequate protein intake:
  - Avoid protein-restricted diets (e.g., “renal” diets or cardiac diets with <5.1 g/100 kcal protein)
- Modulate cytokine production:
  - Administer one 1-gram fish oil capsule (containing 180 mg eicosapentaenoic acid and 120 mg docosahexaenoic acid) per 5 kg body weight q 24 h.
  - Fish oil should contain vitamin E as an antioxidant, but no other nutrients.
  - Cod liver oil and flaxseed oil should not be used (ineffective).

DRUG INTERACTIONS

Medication side effects can contribute to cachexia by causing anorexia (e.g., digoxin toxicity, azotemia secondary to angiotensin-converting enzyme inhibitor or overzealous diuretic use).

RECOMMENDED MONITORING

- Body weight (be sure to adjust for ascites) and assessment of muscle loss
- Appetite and food intake

PROGNOSIS AND OUTCOME

Prognosis depends on the underlying cardiac disease. However, anorexia is a common contributing factor to an owner's decision for euthanasia.

PEARLS & CONSIDERATIONS

COMMENTS

- Animals with CHF often have variable and cyclical appetites. Reassure owners that this is common, and that they can offer favorite (low-sodium) foods when this occurs. However, anorexia longer than 24-48 hours should trigger reevaluation of CHF and medications.
- Centesis should be performed on anorectic animals with a significant ascites or pleural effusion to reduce fluid accumulation (for comfort).
- Animals with CHF may prefer foods at a particular temperature (e.g., room temperature, warmed, refrigerated, or even frozen).
- Dogs with CHF often prefer sweet tastes, particularly as the disease progresses. Adding items such as maple syrup, fruit-flavored yogurt, or applesauce to the dog's food may improve food intake.

PREVENTION

- None known
- Early detection in more subtle stages
- Minimize by ensuring adequate food intake and optimal therapy for CHF

CLIENT EDUCATION

- Sodium intake:
  - Provide owner-specific instructions regarding foods high in sodium (to be avoided), appropriate dog foods, acceptable low-salt treats, and methods for administering medications.
- Appetite:
  - Provide the owner with suggestions for improving the animal's appetite (see Nutrition/Diet above and).

Cachexia, Cancer-Associated

BASIC INFORMATION

DEFINITION

The term *cancer cachexia* refers to weight loss in an animal or person with underlying neoplastic disease. Classic defining clinical features of the syndrome include severe involuntary weight loss, fatigue, anemia, and progressive depletion of both lean body mass and adipose stores.

SYNONYM

Cancer-associated weight loss

EPIDEMIOLOGY

SPECIES, AGE, SEX

Cancer cachexia has been reported in association with neoplastic disease in many species, including people, cats, and dogs with naturally occurring malignancies, as well as laboratory rodents bearing implanted tumors. Animals of any age and either sex may be affected.

RISK FACTORS

- Advanced clinical stage of neoplastic disease
- Tumors of the upper gastrointestinal tract (esophagus, stomach, and pancreas) in humans
- Lower risk in people with treatment-responsive lymphomas, soft-tissue sarcomas, and breast cancer
- Cancer cachexia is less common in dogs than in people.
- Cats appear to be at greater risk for cancer cachexia than dogs: up to 90% of cats with neoplastic disease experience clinically apparent loss of lean body mass.

ASSOCIATED CONDITIONS & DISORDERS

Cancer cachexia is a form of protein-energy malnutrition, the most common form of malnutrition found in critically ill animals and people. It occurs when protein and energy intake is insufficient to meet requirements. Protein-energy malnutrition is associated with hypoproteinemia, delayed wound healing, immunosuppression, and compromised gastrointestinal, pulmonary, and cardiovascular function. Multiorgan failure and death will be the eventual outcome unless nutritional support is provided and the primary underlying disease process is resolved.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Although weight loss is the primary abnormality in all cats and dogs with cancer cachexia, specific historical findings differ substantially from animal to animal. Weight loss may be mild to profound in severity, ranging from acute to chronic in duration. Weight loss is also superimposed on any clinical signs associated with the underlying neoplastic disease, which vary with the specific diagnosis.

PHYSICAL EXAM FINDINGS

Physical exam findings in animals with cancer cachexia can be divided into two groups: abnormalities related to cancer cachexia, and abnormalities caused by the animal's underlying cancer. The clinical signs associated with cancer cachexia are nonspecific, initially may be subtle, and can easily be overlooked. Findings may include muscle wasting, pallor, weakness, poor haircoat, hepatomegaly, splenomegaly, evidence of chronic infections, and lymphadenopathy. Peripheral edema could be present in severe cases. Physical exam findings related to the underlying malignancy are highly variable and depend on the animal's specific histopathologic diagnosis and stage of disease. No two animals with cancer cachexia have exactly the same presentation.

ETIOLOGY AND PATHOPHYSIOLOGY

- The etiology of cancer cachexia is highly variable and multifactorial.
- There are two major categories of cancer cachexia: primary and secondary.
- Primary cancer cachexia is an incompletely understood paraneoplastic syndrome in which tumor-related changes in host metabolism lead to inefficient use of consumed calories, in turn leading to gradual depletion of lean body mass and adipose stores. No matter how many calories are fed or by what route, host requirements cannot be met.
- Recent studies suggest that primary cancer cachexia may be an inflammatory disorder caused by alterations in proinflammatory mediators such as interleukin (IL)-1 alpha, IL-1 beta, IL-6, tumor necrosis factor alpha (TNF-α), and various eicosanoids.
- Secondary cancer cachexia is caused by one or more of a variety of functional abnormalities that decrease nutrient intake, digestion, or absorption. Examples include the physical presence of tumor within the digestive tract, causing gastrointestinal dysfunction, or side effects of radiotherapy or chemotherapy such as stomatitis, vomiting, and gastroenteritis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Dogs and cats with cancer-associated cachexia have objective evidence of loss of lean body mass and adipose stores as demonstrated by weight loss and a decline in body condition score.

DIFFERENTIAL DIAGNOSIS

Differential diagnoses for weight loss in a cat or dog with cancer:

- Primary cancer cachexia (paraneoplastic abnormalities in energy metabolism)
- Secondary cancer cachexia:
    - Tumor involving the intestinal tract
    - Paraneoplastic syndromes other than cancer cachexia:
        - Hypercalcemia
        - Fever
    - Treatment-related toxicity:
        - Altered taste and smell perception
        - Learned food aversions
        - Stomatitis/mucositis
        - Gastroenteritis
        - Centrally mediated nausea and vomiting
- Concurrent disease:
    - Infection:
        - Bacterial, viral, fungal, oomycotic, or rickettsial
    - Organ dysfunction/failure (i.e., liver, kidney, lung)
    - Diabetes mellitus
    - Hyperthyroidism (cats)
- Inappropriate nutritional management (unsuitable diet, inadequate caloric intake)

INITIAL DATABASE

- Diet history (specific ration fed and quantity consumed, plus all treats, supplements, and medications)
- Body weight and body condition score
- CBC
- Serum biochemistry profile
- Urinalysis
- Chest and abdominal radiographs
- Retroviral screening (cats)
- Serum thyroxine concentration (cats)

ADVANCED OR CONFIRMATORY TESTING

- Thoracic and abdominal ultrasonography
- Cross-sectional imaging (CT, MRI)
- Endoscopy
- Urine culture and sensitivity
- Fine-needle aspiration cytology, impression smears, or tissue biopsy to confirm the presence or absence of neoplastic cells, organisms, or other abnormalities in suspected lesions

TREATMENT

TREATMENT OVERVIEW

The basic goals of therapy in the cat or dog suffering from cancer cachexia are twofold:

- Return the animal to ideal body condition.
- Maintain the animal in ideal body condition long term.

These goals are accomplished by diagnosing and treating the underlying malignancy and providing appropriate nutritional support.

ACUTE GENERAL TREATMENT

- Cancer cachexia is a paraneoplastic syndrome, so eradication of the underlying neoplastic disease is the best treatment. This goal can be met by:
    - Obtaining a rapid and accurate definitive diagnosis of neoplasia, including neoplasm type and clinical stage
    - Initiating timely and effective antineoplastic therapy
- An individualized feeding protocol is instituted concurrently and is based on the animal's nutritional assessment as defined by the minimum database outlined previously.

CHRONIC TREATMENT

Nutritional recommendations are adjusted as necessary based on repeat nutritional assessment, with the goal of maintaining ideal body condition:

- Food intake is increased or decreased as needed in response to changes in body weight and condition.
- Assisted feeding can be used intermittently to maintain nutrient intake.
- The specific ration recommended for an individual animal may change depending on the progression of the underlying neoplastic disease and concurrent conditions.

NUTRITION/DIET

- Components of the feeding protocol for an animal with cancer-associated cachexia must include:
    - Fluid requirement in milliliters per day

    - Energy requirement in kilocalories per day
    - A choice of commercial ration that meets the animal's needs:
        - Calories appropriately distributed among protein, fat, and carbohydrate
        - All necessary nutrients (i.e., vitamins and minerals) present in correct quantities and ratios
    - A method of feeding that will be tolerated by the animal
- No single diet is appropriate for every animal with cancer cachexia, because underlying disease, nutritional status, and nutrient requirements are highly variable from case to case.
    - Rations with ample protein and fat are often recommended for weight-losing cats and dogs with cancer.
    - Individual restriction of protein, fat, or carbohydrate intake may be indicated, depending on preexisting or concurrent conditions such as renal or hepatic insufficiency, pancreatitis, or diabetes mellitus.
- Voluntary intake is the most practical feeding technique, but quantities of food and water consumed must be measured to ensure that requirements are actually met.
- Assisted feeding should be instituted without delay in animals unable to meet their own nutrient requirements.
- Assisted enteral feeding using some type of feeding tube is usually preferred, because it allows nutrients to be metabolized through normal pathways and is more effective in maintaining gut health.
- Fluid deficits and electrolyte or acid-base imbalances should be corrected before any type of assisted feeding is attempted.

POSSIBLE COMPLICATIONS

- Gastrointestinal intolerance
- See online chapter: Refeeding Syndrome

RECOMMENDED MONITORING

- Nutritional assessment, including diet history, body weight, and body condition score, should be repeated at regular intervals.
- Diagnostics are repeated as indicated based on underlying neoplastic disease and nutritional status; this commonly includes CBC, serum biochemistry profile, urinalysis, and imaging studies.

PROGNOSIS AND OUTCOME

- Cancer cachexia has a well-documented negative effect on quality of life and prognosis in people, and its impact is highly likely to be the same in cats and dogs.
- Increased incidence and severity of treatment-related toxicities, lower treatment response rates, shorter remission durations, and shorter survival times should be expected in weight-losing animals when compared to weight-stable animals with the same tumor.

PEARLS & CONSIDERATIONS

COMMENTS

- Several studies now show that many dogs with cancer are actually obese. Indiscriminate use of high-fat diets in these animals will simply promote additional weight gain and its associated health problems. The primary goal of nutritional therapy in any cat or dog with cancer is always to maintain ideal body weight and condition.
- Recent work suggests that cats with cancer are more likely to have weight loss than dogs. However, it is not yet clear if this weight loss is specifically related to the presence of underlying neoplastic disease, or if it is a generic response to critical illness in the cat.

AUTHOR: GLENNA E. MAULDIN

EDITOR: KENNETH M. RASSNICK

Dystocia

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Difficulty in the normal vaginal delivery of a neonate from the uterus

SYNONYM

Ineffective labor

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs > cats, older > younger

GENETICS & BREED PREDISPOSITION

- Brachycephalic breeds have a higher incidence due to fetal head/birth canal size mismatch and a steep angle of the entrance of the maternal pelvic canal from the abdomen.
- Some purebred colonies (assistance-dog colonies) have a higher-than-breed-average incidence of dystocia, suggesting heritability.
- Breed, parity (number of previous litters), and litter size can influence gestational length (determined to be 65 +/− 1 day from the LH surge or the initial rise in progesterone between 1.5-3 ng/mL) by 1-2 days.

RISK FACTORS

- Large litters
- Poor prepartum condition of the dam
- Small litters with oversized fetuses or prolonged gestation
- Breed conformation, obesity, preeclampsia, malnutrition, vaginal canal abnormalities (strictures, vaginal hyperplasia), pelvic abnormalities (healed fractures with reduction in pelvic canal), and abdominal wall defects (hernias) can predispose a dam to dystocia.
- A previous normal caesarean section does not predispose a bitch to dystocia.

ASSOCIATED CONDITIONS & DISORDERS

Hypocalcemia, hypoglycemia, hypovolemia

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Dystocia can be categorized as resulting from maternal causes, fetal causes, or most commonly a combination of maternal and fetal causes.

HISTORY, CHIEF COMPLAINT

- A client's perception that labor is not initiated or progressing as expected, most commonly due to:
  - Time between stages of labor. Stage I labor typically lasts no more than 12-24 hours.
  - Time between sequential deliveries of neonates. Typically, sequential deliveries should be within 1 hour.
- Alternatively, the presence of stillbirths can prompt presentation for dystocia.
- The clinician must quickly obtain a careful reproductive history detailing: ○ Breeding dates
  - Onset of diestrous behavior
  - Any ovulation timing performed
  - Previous dystocia
  - General medical history

PHYSICAL EXAM FINDINGS

- Physical examination may be unremarkable; normal physical exam findings do not rule out dystocia.
- Typically, dams in stage I labor (uterine contractions) or stage II labor (uterine and abdominal contractions) are euthermic, mildly agitated, trembling, mildly hyperpneic, and nesting.
- Variable abnormal physical findings include atypical vulvar discharge (green, malodorous, frankly hemorrhagic), a fetus or fetal membranes in the birth canal (i.e., presence of a fetus caudal to the cervix, which may be palpable over the brim of the pelvis or may be partially protruding out of the vulva), muscle tremors, fatigue, persistent vomiting, and protracted tenesmus (abdominal efforts).
    - Uteroverdin (green vaginal discharge) indicates placental separation and indicates the need for veterinary medical or surgical intervention if fetal delivery is not prompt.
    - Malodorous discharge suggests fetal death and necrosis or metritis.
    - Inappropriately voluminous hemorrhage should prompt evaluation for uterine trauma (surgical exploration) or abnormal placental site coagulation (medical ± surgical evaluation) or a coagulopathy.
- Protracted muscle tremors, vomiting, or marked fatigue suggest metabolic abnormalities (hypoglycemia, hypocalcemia, ketosis) or exhaustion.
- Protracted tenesmus suggests obstruction or uterine inertia.

ETIOLOGY AND PATHOPHYSIOLOGY

- Normal labor proceeds through three stages:
    - Stage I labor: onset and increase in the frequency and strength of uterine contractions. The dam may be restless or agitated. No external contractions are visible.
    - Stage II labor begins when abdominal efforts (tenesmus) coincide with uterine contractions, resulting in the delivery of a neonate through the birth canal.
    - Stage III labor consists of the delivery of the placenta.
    - Dams typically progress through stage I labor in 12-24 hours and alternate between stages II and III until all neonates and placentae are delivered. Placentae normally may be delivered with the neonate or separately.
- Etiology of dystocia: maternal/fetal causes
    - Maternal dystocia: primary or secondary uterine inertia, birth canal or abdominal wall defects (strictures, hernias), severe perivulvar edema, lack of lubrication in the birth canal, uterine torsion or tear, metabolic derangements
    - Fetal dystocia: oversized, malformed (anasarca), malpositioned, malpostured fetus
    - Combined maternal/fetal dystocia: mismatch of birth canal size versus fetal size
    - Caudal presentations in dogs and cats are normal.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A correct diagnosis of dystocia is dependent on taking an accurate history and performing a thorough physical examination in a timely manner.

DIFFERENTIAL DIAGNOSIS

- Normal labor
- Misinformation about gestational length (see p. 909), in which case lack of labor is then normal
    - In the bitch, gestation is normally terminated 64-66 days from the initial rise in progesterone corresponding to the LH surge, or 56-58 days from the first day of diestrus (the first day vaginal cytology is <50% superficial cells). If no ovulation timing was performed, establishing the first day of behavioral diestrus (refusing the male) can provide guidance.
    - Gestational length from the first breeding date can vary from 58-72 days; this makes determination of due dates from breeding dates risky.
    - In the queen, the mean gestation is 65-66 days from breeding.
    - Ultrasound measurements of gestational sac diameter, crown-rump length, body diameter and/or head diameter can be helpful in determining gestational age when ovulation timing data is not available:
- Completion of labor, misinformation about litter size

Formulas to Predict Gestational Age and Days Before Parturition in the Dog and Cat

GESTATIONAL AGE IN THE DOG (+/− 3 DAYS)

Less than 40 days

Gestational age = (6 × Gestational sac diameter) + 20

Gestational age = (3 × Crown-rump length) + 27

Greater than 40 days

Gestational age = (15 × Head diameter) + 20

Gestational age = (7 × Body diameter) + 29

Gestational age = (6 × Head diameter) + (3 × Body diameter) + 30

DAYS BEFORE PARTURITION IN THE DOG

Days before parturition = 65 - Gestational age

GESTATIONAL AGE IN THE CAT (+/− 2 DAYS)

Greater than 40 days

Gestational age = 25 × Head diameter + 3

Gestational age = 11 × Body diameter + 21

DAYS BEFORE PARTURITION IN THE CAT

Days before parturition = 61 - Gestational age

Gestational age (GA) is based on days post luteinizing hormone (LH) surge in the dog and days post breeding in the cat. Gestational sac diameter (GSD), crown-rump length (CRL), head diameter (HD), and body diameter (BD) measurements are in centimeters. Days before parturition (DBP) is based on 65 +/− 1 days post LH surge in the dog and 61 days post breeding in the cat. Data modified from Nyland et al.

INITIAL DATABASE

- Minimally, hematocrit and total protein (mild decreases expected due to dilution), blood glucose (decreased with prolonged labor), serum electrolytes, and ionized calcium (hypocalcemia possible with prolonged labor) should be evaluated. Urine can be checked for ketones (indicating prenatal mal-nourishment).
- Vaginal digital and/or vaginoscopic examination to determine if a vaginal obstruction exists. In the dog, the cervix (assessing for dilation) and cranial vagina (assessing for obstruction) are beyond the reach of the human finger. Abdominal ultrasound or fetal Doppler evaluation to assess fetal viability.
- Abdominal radiograph to evaluate litter size, relative fetal size and position

ADVANCED OR CONFIRMATORY TESTING

Uterine monitoring (tocodynamometry) to assess strength and frequency of contractions.

- Currently, canine and feline uterine monitors are available for short- or long-term lease through Veterinary Perinatal Services Inc. (www.whelpwise.com).
- Tocodynamometry is the only method of confirming uterine inertia.

TREATMENT

TREATMENT OVERVIEW

Therapeutic goals are to:

- Facilitate delivery of viable neonates, with minimal morbidity to the dam.
- Avoid unnecessary surgical intervention via timely diagnosis and medical intervention.
- Differentiate cases requiring surgical versus medical intervention: surgery is warranted if:

- Refractory (unresponsive) uterine inertia
- Fetal distress and suboptimal response to medical management
- Intractable pain in bitch or queen
- Obvious mismatch of fetal-maternal birth canal size
- Birth canal abnormalities such as strictures or pelvic stenosis that cannot be remedied
    - Minimize fetal stress; neonatal death during the first week of life is related to stress during labor and the immediate postpartum period.
    - Avoid fetal or maternal mortality.
    - Preserve the reproductive capacity of a valuable dam.

ACUTE GENERAL TREATMENT

- Supportive: intravenous balanced electrolyte solution with 5% dextrose if appropriate (dam is hypovolemic, dehydrated, or hypoglycemic)
- Calcium: calcium gluconate 10% solution (= 10 g/100 mL solution, or 0.465 mEq Ca^{++}/mL) (Fujisawa Inc., USA).
    - Given SQ at 1 mL/4.5 kg (10 lb) body weight as indicated by the strength of uterine contractions—generally no more frequently than every 4-6 hours during the second stage of labor.
    - Large volumes of calcium gluconate given subcutaneously may cause local irritation; doses >6 mL should be divided.
    - Intravenous use: generally unnecessary unless systemic signs of severe hypocalcemia are present (see p. 576 for signs and intravenous doses).
    - While most dams are eucalcemic, the benefit of calcium administration is still seen, suggesting a cellular or subcellular effect.
- Oxytocin:
    - The administration of oxytocin increases the frequency of uterine contractions, whereas the administration of calcium increases their strength.
    - Oxytocin, 10 USP units/mL (American Pharmaceutical Partners Inc., Los Angeles) is most effective at mini doses, starting with 0.25 units SQ or IM to a maximum dose of 4 units per bitch or queen.
    - The frequency of oxytocin administration is dictated by the labor pattern, and it is generally not given more frequently than every 30-60 minutes.
    - Uterine contractions compromise placental blood flow and cause fetal hypoxia. Excessive contractions (due to uterine hypertonicity, over-dosage of oxytocin, obstruction) can compromise fetal survival. Uterine relaxation between contractions allows normal placental blood flow to resume.
    - Absolute contraindications to oxytocin therapy: fetal obstruction in any part of the uterus or birth canal, uterine torsion, uterine laceration or rupture.
- Persistence of a fetus in the birth canal beyond 5-10 minutes warrants assisted delivery.
    - Placental separation and the potential for fetal hypoxemia are likely.
    - Caution: traction applied to a fetus retained in the birth canal must be very gentle to avoid trauma to the fetus.
    - Traction is only advised if the veterinarian can position his/her fingers around the fetus's shoulders or hips for gentle traction.
    - Lubrication delivered via a red rubber catheter and water-soluble lubricant jelly can be helpful.
    - Elevation of the bitch's forequarters can assist in manipulation of the fetus in the birth canal.

CHRONIC TREATMENT

Medical therapy for dystocia, based on the administration of calcium gluconate and oxytocin, can be directed and tailored based on the results of tocodynamometry.

DRUG INTERACTIONS

Calcium is given before oxytocin in most cases, improving contractile strength before increasing frequency of contractions. The action of oxytocin is improved when given 15 minutes subsequent to calcium.

POSSIBLE COMPLICATIONS

- Hypercalcemia-induced arrhythmias if calcium solution is given intravenously at too rapid a rate.
- Fetal hypoxia secondary to placental compression during uterine contractions induced by parenteral oxytocin administration, particularly if given inappropriately (too early in labor, when fetal obstruction is present, if uterine torsion is present, too frequently, too rapidly) or at excessive doses.
- Uterine rupture, with fetal and maternal morbidity and mortality if ecbolic agents (oxytocin) are given excessively, inappropriately (too early in labor, when fetal obstruction is present, if uterine torsion is present, too frequently, too rapidly) or when the uterine wall is compromised or torn.

RECOMMENDED MONITORING

- Progression of labor with viable neonates delivered
- Using real-time transabdominal ultrasonography, fetal heart rates should be >180 bpm.
- Sustained fetal heart rates <180 bpm are associated with fetal distress.
- Continued uterine monitoring using tocodynamometry, showing continuation and progression of appropriate contractile strength and frequency

PROGNOSIS AND OUTCOME

Fair to good with timely intervention and appropriate monitoring

PEARLS & CONSIDERATIONS

COMMENTS

Obstruction of the birth canal, regardless of cause (fetal malposition, fetal-dam size mismatch, or anatomic defects of dam), must be ruled out by vaginal palpation. It is an indication for caesarean section and an absolute contraindication for treatment with oxytocin.

PREVENTION

- Complete prebreeding evaluation of the bitch, including a vaginal examination
- Prepartum abdominal radiography to estimate fetal number and relative size in comparison to the dam

Dogs and cats of any breed and either sex.

CONTAGION & ZOONOSIS

- Animal-to-animal contagion with certain infectious etiologies
- Public health concern: severely dyspneic dog or cat may bite if distressed/disoriented.

GEOGRAPHY AND SEASONALITY

Dependent on etiology

ASSOCIATED CONDITIONS & DISORDERS

Respiratory stridor, hypoxemia, syncope

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Inspiratory dyspnea: generally caused by upper-airway obstruction
- Inspiratory-expiratory dyspnea, or expiratory dyspnea: generally caused by lower-airway, pulmonary circulatory, pleural, mediastinal, or metabolic problems

HISTORY, CHIEF COMPLAINT

- Dyspnea may be the presenting complaint if severe and/or the owner is observant.
- Nonspecific systemic complaints (anorexia, lethargy; hiding [cats]) may be reported in pets that are more mildly dyspneic or with owners who are less observant.
- Owners may describe excessive abdominal wall excursions (“belly breathing”) as the first manifestation of dyspnea, especially in cats.
- Concurrent complaints, including exercise intolerance, lethargy, and inappetence are common but nonspecific.
- Medical history may be very informative (previous respiratory or systemic problems, current medications, etc.).
- Inciting cause (observed foreign-body inhalation, anticoagulant ingestion few days earlier, etc.) occasionally is reported by the owner.

PHYSICAL EXAM FINDINGS

- Respiratory effort: should be assessed immediately at the beginning of the consultation (e.g., exam room) before the hands-on physical examination increases the respiratory rate in nervous patients.
- Animals with moderate or severe dyspnea often manifest an anxious facial expression, reluctance to lie down, and other signs of discomfort.
- Inspiratory dyspnea
    - Severity varies from mild inspiratory wheeze to extreme gasping actions.

    - The sound of turbulent air at the level of the obstruction may suggest the site of obstruction (e.g., nasal versus tracheal).
    - If nasal obstruction, dyspnea disappears when the animal breathes with the mouth open.
    - Other than potentially severe respiratory distress, animals with upper-airway dyspnea are otherwise generally well: no weight loss, no other physical abnormalities.
- Expiratory or expiratory-inspiratory dyspnea.
    - With lower-airway disease, dyspnea is often accompanied by cough, with or without other general systemic signs (lethargy, anorexia, etc.) or signs more closely related to respiratory disease (e.g., cyanosis).
    - If lower-airway dyspnea is severe, the animal's posture can include abducted elbows, an extended neck, and the canthi of the lips drawn caudally.
    - Cough inducible with tracheal pressure does not indicate whether the problem originates from the upper or lower airway.
- Auscultation
    - Decreased intensity or absence of lung sounds suggests pneumothorax, pleural effusion, intrathoracic mass, or diaphragmatic hernia.
    - Presence of crackles and wheezes is nonspecific.

ETIOLOGY AND PATHOPHYSIOLOGY

- Respiratory center in medulla oblongata and pons is stimulated by ↑CO2, ↑H^+, but not ↓O2.
- Chemoreceptors (carotid bodies, aortic bodies) are stimulated by ↑CO2, ↑H^+, and ↑O2, feeding back to the respiratory center.
- Impulses from the respiratory center activate the intercostal muscles (intercostal nerves, which are branches of thoracic spinal nerves) and diaphragm (phrenic nerves).
- Disturbances in this process can occur at many levels, causing dyspnea.
    - Hypercapnia
    - Acidosis
    - Hypoxemia
    - Physical reduction of lung volume (obesity, diaphragmatic hernia, severe ascites)
    - Respiratory paralysis
    - Airway obstruction
- Causes of dyspnea: pulmonary edema, pleural effusion, upper-airway obstruction (laryngeal paralysis, foreign body, brachycephalic syndrome), pneumonia, chronic sterile bronchitis, pulmonary hypertension, pulmonary thromboembolism, pulmonary hemorrhage, marked ascites, hyperthermia, neuromuscular weakness/paralysis, compensation for metabolic acidosis, anxiety.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The location of an anatomic lesion causing dyspnea may be surmised from the sound of breathing: upper-airway obstructions produce audible turbulence of air on inspiration, and the associated raspy or loud whistling noise is heard to occur close to the mouth (nasal, tracheal, pharyngeal, laryngeal disorders) or in the nasal passages on inspiration. Conversely, lower-airway disorders and metabolic causes for dyspnea typically cause a mixed inspiratory-expiratory dyspnea and no such noise. Thoracic radiographs are the initial diagnostic test of choice.

DIFFERENTIAL DIAGNOSIS

- Panting. Unlike dogs that are panting, dogs with dyspnea are likely to show wide chest excursions, an anxious facial expression, and unwillingness to lie down or rest.
- Reverse sneezing. Loud, inspiratory noises that are sudden in onset and in termination can be abolished by opening the animal's mouth.

INITIAL DATABASE

- Thoracic radiographs: diagnostic test of choice for expiratory or expiratory-inspiratory dyspnea
- Oral/pharyngeal exam (may require sedation) and lateral cervical radiograph if upper-airway dyspnea is suspected
- CBC/serum biochemistry profile/urinalysis: no specific changes; results depend on etiology.
- Serum levels of a cardiac myocyte protein, N-terminal proBNP, are significantly elevated when dogs have dyspnea of cardiac origin (congestive heart failure; median = 24.6 pg/mL) versus of noncardiac origin (median = 2.6 pg/mL) ($P < 0.0001$). This excellent differentiating test is limited by central laboratory availability (not in-house/snap).

ADVANCED OR CONFIRMATORY TESTING

- Arterial blood gas: degree of hypoxemia helps determine intensity of acute treatment.
- Pulse oximetry: results may fluctuate; less invasive than arterial blood sampling.
- Coagulation profile: if rodenticide/pulmonary hemorrhage is suspected.
- Transtracheal wash: for evaluation of mild dyspnea associated with chronic cough.
- Bronchoscopy: for tracheal and bronchial visualization, and retrieval of secretions, tissue samples, foreign bodies.
- Rhinoscopy: if nasal obstruction, discharge, or other physical nasal signs are present.
- Echocardiography: if a cardiac cause is suspected (e.g., cardiomegaly; heart murmur).
- Computed tomography (thorax, nose): especially to identify/characterize mass lesions.

TREATMENT

TREATMENT OVERVIEW

- Control dyspnea immediately if life threatening.
- Address/eliminate underlying cause.

ACUTE GENERAL TREATMENT

- Oxygen supplementation (see p. 1318)
- Specific treatment is highly dependent on underlying cause and is initially based on history, physical findings, and thoracic radiographs. Acute general treatment may include removal of upper-airway foreign body; thoracocentesis; diuretic; tracheostomy; or many others, depending on etiology.

CHRONIC TREATMENT

Depends on underlying cause

POSSIBLE COMPLICATIONS

Uncontrolled dyspnea, producing hypoxemia, cyanosis

RECOMMENDED MONITORING

- Respiratory effort
- Thoracic radiographs
- Arterial blood gases

PROGNOSIS AND OUTCOME

Highly variable, based mainly on severity of dyspnea at presentation and ability to control underlying cause

PEARLS & CONSIDERATIONS

COMMENTS

- Dyspneic patients may be fragile. Simple procedures such as thoracic radiography or thoracocentesis need to be accomplished with the lowest effective degree of restraint in severely dyspneic patients, or else postponed.
- A simple way of establishing whether nasal obstruction is present and if so, which side(s) is/are affected involves simply occluding the nostrils, one at a time, and watching to see if airflow flutters a tuft of a few hairs plucked from the patient's coat and held in front of the nonoccluded nostril.

CLIENT EDUCATION

- At the time of diagnosis, patients are usually in serious or critical condition even if they do not appear to have been very ill.
- The long-term outlook depends on the cause of the labored breathing, and tests are necessary to find what the most likely cause is.

AUTHOR & EDITOR: ETIENNE CÔTÉ

Dysphagia

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Difficulty in swallowing resulting from the inability to prehend, form, and/or move a bolus of food from the mouth into the esophagus

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dependent on underlying cause:

- Young dogs: congenital, foreign objects, facial trauma
- Young cats: congenital, inflammatory polyps
- Older animals: neoplasia

GENETICS & BREED PREDISPOSITIONS

Cricopharyngeal achalasia (toy breeds), myasthenia gravis (Jack Russell and fox terriers, English spaniel, Samoyed, Siamese)

RISK FACTORS

Neuromuscular conditions may have breed predispositions.

CONTAGION & ZOONOSIS

Rabies, especially if the animal's rabies vaccination status is unknown or if has been exposed to a potentially rabid animal

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Oral dysphagia:
  - Modified eating behavior (eating with head tilted to one side and throwing head back while eating) common
  - Mandibular/tongue paralysis, dental disease, masticatory muscle swelling or atrophy, inability to open the mouth, and food packed in the buccal folds without retention of saliva
- Pharyngeal dysphagia:
  - Normal prehension
  - Repeated attempts at swallowing while repeatedly flexing and extending the head and neck, excessive chewing, and gagging
  - Saliva-coated food retained in the buccal folds, diminished gag reflex, and nasal discharge from nasopharyngeal aspiration may exist.
- Cricopharyngeal dysphagia:
  - Repeated, nonproductive efforts to swallow and gag associated with regurgitation immediately after swallowing
  - Normal gag reflex and prehension

HISTORY, CHIEF COMPLAINT

Some or all may be present:

- Ptyalism/hypersalivation, gagging, weight loss, ravenous appetite, repeated attempts at swallowing, swallowing with the head in an abnormal position, coughing, regurgitation, painful swallowing, and occasionally anorexia
- Foreign bodies cause acute-onset dysphagia.
- Pharyngeal dysphagia may be chronic and intermittent.

ETIOLOGY AND PATHOPHYSIOLOGY

- Anatomic or mechanical lesions:
  - Pharyngeal inflammation (trauma, abscess, eosinophilic granuloma)
  - Retropharyngeal lymphadenopathy/neoplasia
  - Pharyngeal/retropharyngeal foreign body
  - Salivary mucocele
  - Temporomandibular joint disorders (luxation, fracture, craniomandibular osteopathy)
  - Mandibular fracture
  - Cleft palate
- Pain due to dental disease, trauma, stomatitis, glossitis, and pharyngeal inflammation
- Neuromuscular disorders (trigeminal neuropathy, lingual paralysis)
- Masticatory myositis
- Pharyngeal weakness/paresis/paralysis:
  - Infectious polymyositis (toxoplasmosis, neosporosis)
  - Immune-mediated polymyositis
  - Muscular dystrophy
  - Polyneuropathies
  - Myoneural junction disorders (myasthenia gravis, tick paralysis, botulism)
- Rabies can cause dysphagia by affecting both the brainstem and peripheral nerves.
- Other brainstem disorders

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Dysphagia is a nonspecific chief complaint; thorough oral exam and observation of the patient's attempts to eat food are indicated to determine whether the problem is one of oral, pharyngeal, or cricopharyngeal dysphagia. Further tests are then selected accordingly.

DIFFERENTIAL DIAGNOSIS

- Vomiting
- Regurgitation

INITIAL DATABASE

- CBC: inflammatory conditions can cause leukocytosis, sometimes with a left shift.
- Urinalysis:
  - Usually normal
  - Isosthenuria can be associated with kidney disease.
- Biochemistry: elevated serum creatine phosphokinase activity with muscular disorders

ADVANCED OR CONFIRMATORY TESTING

- Other laboratory tests:
  - Type 2M-muscle antibody serology for masticatory myositis
  - Acetylcholinesterase receptor antibody test for acquired myasthenia gravis
  - Antinuclear antibody test for immune-mediated diseases
- Imaging:
  - Survey radiographs of the skull and neck, with attention to the mandibles, temporomandibular joint, teeth, pharyngeal and retropharyngeal area, and position of the hyoid apparatus
  - Ultrasonography of the pharynx may be useful with mass lesions and for obtaining ultrasound-guided biopsy specimens.
  - Fluoroscopy to evaluate pharyngeal movement in patients with suspected pharyngeal or cricopharyngeal dysphagia (see p. 1205)
  - CT or MRI for suspected intracranial mass
- Other diagnostic procedures:
  - Biopsy of a mass lesion
  - Pharyngoscopy
  - Electromyography of the pharyngeal musculature to confirm the presence of a neuromuscular disorder
  - Repetitive nerve stimulation and edrophonium chloride test for suspected myasthenia gravis (suboptimal)
  - Cerebrospinal fluid analysis

TREATMENT

THERAPEUTIC OVERVIEW

- Determine underlying cause.
- Direct primary treatment at the underlying cause.
- Nutritional balance to maintain optimal body condition

NUTRITION/DIET

- Nutritional support:
  - Care taken to avoid aspiration when feeding orally
  - Animals with oral dysphagia may be able to swallow if a bolus of food is placed in the caudal pharynx; other animals may find a gruel that can be lapped easier to swallow.
  - Elevating the head and neck may make swallowing easier for animals with pharyngeal or cricopharyngeal dysphagia and help prevent aspiration of food.
- If nutritional requirements cannot be met by oral feeding, an esophagostomy or gastrostomy tube may be necessary (see p. 1267,p. 1270).
- Surgical excision of a mass lesion
- Foreign-body removal
- Cricopharyngeal myotomy may benefit patients with cricopharyngeal dysphagia, but a correct diagnosis is essential; cricopharyngeal myotomy will exacerbate dysphagia with oropharyngeal dysphagia.

POSSIBLE COMPLICATIONS

Aspiration pneumonia is a common complication.

RECOMMENDED MONITORING

- Daily for signs of aspiration pneumonia
- Body condition and hydration status daily
- If oral nutrition does not meet requirements, use esophagostomy/gastrostomy tube feeding.

PROGNOSIS AND OUTCOME

Dependent on the cause and the associated complication of aspiration pneumonia

PEARLS & CONSIDERATIONS

COMMENTS

- Uncommon problem
- Dysphagia is not a diagnosis but a clinical sign

CLIENT EDUCATION

Monitor for aspiration pneumonia

AUTHOR: REMO LOBETTI

EDITOR: ETIENNE CÔTÉ

Dysautonomia

BASIC INFORMATION

DEFINITION

Dysautonomia is characterized by a degeneration of the autonomic ganglia, with failure of parasympathetic and sympathetic function in multiple organs.

SYNONYMS

Key-Gaskell syndrome, pure autonomic failure, pandysautonomia, autonomic neuropathy

EPIDEMIOLOGY

SPECIES, AGE, SEX

- In the United States, dogs are most commonly affected; occasional feline cases. In the United Kingdom, horses are most commonly affected.
- Any age animal may be affected, but dysautonomia most commonly affects young adult dogs (median age 18 months).

RISK FACTORS

Free-roaming, rural dogs are at higher risk.

CONTAGION & ZOONOSIS

- Except for rare reports of multiple dogs in a household affected, no evidence of contagion
- No evidence of zoonosis

GEOGRAPHY AND SEASONALITY

- In the United States, the greatest concentration of dysautonomia centers around the borders between Missouri, Kansas, and Oklahoma. Cases are also seen in the northern Colorado and southern Wyoming front range, with occasional cases elsewhere in the country.
- The disease is most common in the late winter/early spring, with the incidence dropping off during the summer months.

ASSOCIATED CONDITIONS & DISORDERS

Autonomic failure can be a part of a more diffuse peripheral neuropathy or neuromuscular junction disorder.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Different combinations of organ failure may be seen.
- Dogs will sometimes present in the early stage of disease with only one obvious sign (e.g. dilated pupils or gastrointestinal [GI] atony). Other signs rapidly develop, allowing a diagnosis of dysautonomia.

HISTORY, CHIEF COMPLAINT

Acute disease: most cases <5-14 days duration

- Most common complaint is GI disturbance: vomiting/regurgitation and diarrhea; some animals instead are constipated.
- Dysuria
- Photophobia, dilated pupils, or third eyelid elevation
- Coughing
- Nasal discharge
- Weight loss

PHYSICAL EXAM FINDINGS

- Diminished anal sphincter tone
- Dry eyes and mucous membranes, with normal hydration; crusty nose
- Midrange or dilated pupils with no pupillary light reflex but normal vision
- Elevated third eyelid, enophthalmos, and ptosis
- Distended, easily expressed bladder
- Abdominal discomfort
- Heart rate and blood pressure are usually at the low end of normal range.
- Nasal discharge or crackles on lung auscultation if secondary rhinitis or aspiration pneumonia
- Cachexia can be dramatic even in relatively short-duration disease.

ETIOLOGY AND PATHOPHYSIOLOGY

- Histologically there is loss of neurons in the autonomic ganglia, with little inflammation.
- Cause is unknown, but toxic and immune-mediated hypotheses are being investigated.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- To establish the diagnosis, it is necessary to document autonomic failure in multiple organs, without significant deficits in sensory or motor function. Not all patients show all clinical signs.
- Dysautonomia can mimic other diseases in the early stages when only one or two functions are affected.

DIFFERENTIAL DIAGNOSIS

- The most dramatic signs reflect parasympathetic loss, so anticholinergic toxicosis needs to be ruled out.
- Other differentials would be determined by the specific organ most prominently affected.
    - GI: gastroenteritis, GI foreign body, metabolic causes, idiopathic mega-esophagus, focal myasthenia gravis
    - Dry eyes and mucous membranes: dehydration, keratoconjunctivitis sicca (eyes only)
    - Dilated pupils: intraocular or retro-bulbar disease
    - Photophobia: corneal ulcer or anterior uveitis
    - Elevated third eyelid, enophthalmos and ptosis: any cause of Horner's syndrome, especially retrobulbar, mediastinal, or middle ear disease
    - Dysuria: urinary tract infection, disease affecting sacral spinal cord, cauda equina, or pelvic nerves
    - Loss of anal sphincter tone: disease affecting sacral spinal cord, cauda equina, or pudendal nerves
    - Respiratory: any cause of pneumonia or rhinitis

INITIAL DATABASE

- CBC, serum biochemistry panel, urinalysis: unremarkable
- Radiographs may reveal evidence of ileus, distended bladder, megaesophagus, and/or aspiration pneumonia.
- Abdominal ultrasound or barium series may show lack of intestinal motility.
- Ocular pilocarpine test will rule out anticholinergic toxicity in animals with dilated pupils:
    - Place 2-3 drops of 0.05% pilocarpine (1% diluted 1:20 with saline or eye flush) in one eye.
    - Compare pupil size every 15 minutes for up to one hour.
    - Pupil should constrict in dysautonomia; anticholinergic toxicity or normal pupil would not respond.
- Atropine test: does not rule out anticholinergic toxicity but documents cardiac involvement.
    - Measure heart rate before and after IV atropine.
    - Rate should increase in normal animal; may not change in dysautonomia.

ADVANCED OR CONFIRMATORY TESTING

Diagnosis can be confirmed histopathologically by cell loss and gliosis in autonomic ganglia. The celiacomesenteric ganglia can be found surrounding the origin of the cranial mesenteric artery from the aorta, and there are usually autonomic ganglia in the periadrenal tissues.

TREATMENT

TREATMENT OVERVIEW

Since the cause is unknown, treatment is supportive and thus dictated by the signs shown.

ACUTE AND CHRONIC TREATMENT

- Prokinetic drugs (metoclopramide or cisapride)
- Eye lubrication
- Humidification of air
- Manually express the bladder. Low-dose bethanechol may help bladder contraction but may cause increased vomiting.
- Antibiotics for secondary infections

NUTRITION/DIET

- Support nutrition and hydration
  - IV fluids
  - PEG tube may be of value, but if complete GI atony TPN may be necessary (see p. 1270 and p. 1322).

DRUG INTERACTIONS

Animals with dysautonomia develop supersensitivity to direct-acting cholinergic or adrenergic drugs, as evidenced by the ocular pilocarpine test. Therefore any of these drugs should be used cautiously beginning at about 10% of the normally used dose and escalating the dose as needed.

POSSIBLE COMPLICATIONS

Aspiration pneumonia can occur at any time in animals that are vomiting or regurgitating.

PROGNOSIS AND OUTCOME

- Prognosis is grave, with 70%-90% fatality
- Animals either die of aspiration pneumonia or are euthanized because of poor quality of life.
- Occasionally an animal will recover but may have permanent dysfunction of one or more organs.

PEARLS & CONSIDERATIONS

TECHNICIAN TIPS

Supportive care is the cornerstone of these patients' treatment, particularly when the disease is advanced. Technicians involved in their care should be proficient in ophthalmic treatments, elevated feedings for megaesophagus, and management of urinary retention, among other skills.

CLIENT EDUCATION

Because the cause is unknown, it is difficult to provide clients with firm recommendations for preventing future occurrences. Dogs in the same household do not appear to be at greater risk.

AUTHOR: DENNIS P. O'BRIEN

EDITOR: CURTIS DEWEY

Drug Eruption

BASIC INFORMATION

DEFINITION

Development of cutaneous or mucocutaneous lesions following drug administration (topical, oral, or injectable). The lesions may be limited to the cutaneous/mucocutaneous areas or may be part of a systemic reaction. These uncommon reactions can be either predictable (pharmacologic) or unpredictable (idiosyncratic).

SYNONYM

Cutaneous adverse drug reaction (CADR)

EPIDEMIOLOGY

SPECIES, AGE, SEX

The incidence of drug eruptions in dogs and cats has been reported as 2% and 1.6%, respectively. It is likely that many cases of drug reaction, by their subtlety, go unreported.

GENETICS AND BREED PREDISPOSITION

No clear breed predisposition

RISK FACTORS

The number of drugs administered, a concomitant infection suppressing the immune system, or other immunosuppressive state might increase the risk of developing a CADR.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of drug administration
- The chief complaint may be variable because of the wide spectrum of clinical signs.
- Depending whether the reaction is predictable or not, it can occur following the first treatment or as the result of several days to years of drug administration (see below).

PHYSICAL EXAM FINDINGS

Several clinical presentations have been described:

- Erythroderma/exfoliative dermatitis: localized or diffuse erythema that can lead to scales, crusts, and alopecia
- Urticaria/angioedema: edematous papules and wheals; variable erythema and pruritus
- Autoimmune diseases (pemphigus, bullous pemphigoid, systemic lupus erythematosus): clinical presentation varies from pustules and crusts to vesicles, bullae, and ulcers depending on the autoimmune dermatosis mimicked.
- Erythema multiforme (EM)/toxic epidermal necrolysis (TEN): group of diseases manifested by an acute reaction pattern of skin and mucous membranes; EM characterized by erythematous maculopapules and flat or raised annular or polycyclic lesions, with minimal epidermal detachment; TEN involves widespread erythema, blistering, and severe epidermal detachment (see online chapter: Erythema Multiforme and Toxic Epidermal Necrolysis).
- Fixed reactions: well-demarcated erythematous lesions sometimes associated with blistering and necrosis
- Macules and papules: usually erythematous; pruritic or not
- Pruritus: localized or widespread, can lead to self-induced lesions
- Injection-site reactions: local reaction characterized by alopecia, inflammation, necrosis, or ulceration
- Vasculitis: purpura, necrosis, and punctate ulcers, especially localized over extremities, pressure points, and oral mucosa

ETIOLOGY AND PATHOPHYSIOLOGY

- Although some drugs are more frequently associated with drug reactions, all kinds of drugs are at risk to cause a CADR.
- CADR may be immediate after first administration or after weeks to months of administration without prior apparent reaction.
- The predictable (pharmacologic) reactions are related to the pharmacologic actions of the drugs and thus more common. They are associated to the dose, the pharmacologic side effects/toxicity or drug interactions, and reversed when the drugs are discontinued.
- The unpredictable (idiosyncratic) reactions are usually considered immunologically mediated. They can also be associated with individual genetic differences in the metabolism of drugs, leading to inappropriate generation or accumulation of toxic metabolites (e.g., MDR1 gene mutation in collie and other herding breeds; see p. 706). These reactions (cutaneous and/or systemic) are often serious and potentially fatal.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The key elements necessary for identifying a CADR are a thorough history, including drug administration and appropriate timing for the development of skin eruptions, a lack of alternative explanations for the lesions, and dechallenge, with resolution of skin lesions within 1-2 weeks. Rechallenging with the suspected drug confirms the diagnosis but is generally not recommended.

DIFFERENTIAL DIAGNOSIS

- Erythroderma/exfoliative dermatitis: epitheliotropic lymphoma
- Urticaria/angioedema; macules/papules; pruritus: hypersensitivity disorders, ectoparasitosis, superficial bacterial or fungal infection, and mast cell tumor
- Autoimmune skin diseases: spontaneous autoimmune disease not related to drugs, which is more common
- EM/TEN: superficial and deep infection (bacterial and fungal), urticaria, autoimmune skin diseases, burns, ulcerative stomatitis, and epitheliotropic lymphoma
- Fixed reactions: contact dermatitis, hypersensitivity disorders, pyoderma, and fungal infection
- Injection-site reactions: traction alopecia, hypersensitivity disorders, pyoderma, dermatophytosis, alopecia areata, and neoplasia
- Vasculitis: urticaria, autoimmune skin diseases, EM/TEN, disseminated intravascular coagulation, coagulopathy, frostbite, and neoplasia

INITIAL DATABASE

- History of drug administration before onset of skin lesions
- Routine dermatologic diagnostics should be performed as appropriate (skin scrapings, skin cytology, skin biopsy, fungal culture) based on differential diagnosis.
- Although a wide range of dermatohistopathologic patterns exists in CADR, it is recommended to perform skin biopsies in order to confirm the diagnosis or eliminate differential diagnoses.

ADVANCED OR CONFIRMATORY TESTING

- Suspected vasculitis: rickettsial titers, if other clinical signs suggestive of rickettsial diseases are present
- Suspected systemic lupus erythematosus: antinuclear antibody test
- Cats: feline immunodeficiency virus (FIV)/feline leukemia virus (FeLV) serology, if considered appropriate based on clinical signs

TREATMENT

TREATMENT OVERVIEW

- Stop the pharmacologic or immunologic reactions causing the drug eruption.
- Prevent secondary skin infection if the cutaneous barrier is ruptured.
- Supportive care is important when the animal is debilitated.

GENERAL TREATMENT

- Discontinue use of the offending medication.
- Supportive care as needed, including fluid therapy, nutritional support, analgesics, antipruritic therapy, or wound care. Depending on the clinical presentation, corticosteroids may be used (controversial).

PROGNOSIS AND OUTCOME

Good, except if internal organs are affected or if there is extensive epidermal necrosis

PEARLS & CONSIDERATIONS

COMMENTS

- Lesions can persist for days to weeks after discontinuing the medication.
- Hospitalization may be indicated.
- Consider short-term glucocorticoid or immunosuppressive therapy if severe pruritus or immune-mediated dermatosis exists and concurrent infection is absent.
- Immunomodulatory therapy can be beneficial in EM/TEN, injection-site reactions, or vasculitis.
- Avoid future use of the offending medication or chemically related drugs.

AUTHOR: FRÉDÉRIC SAUVÉ

EDITOR: MANON PARADIS

Drowning

BASIC INFORMATION

DEFINITION

Potentially fatal disorder characterized by asphyxia and possibly dysfunction of multiple organ systems due to submersion in a liquid medium (typically water)

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats of either sex and any age

RISK FACTORS

Preexisting disorders (orthopedic injury, neurologic dysfunction, visual deficits, respiratory abnormality) can predispose an incapacitated patient to fall into water or become submerged during aquatic activity.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Fresh water versus salt water aspiration

HISTORY, CHIEF COMPLAINT

There is almost always a known submersion incident. If possible, it is helpful to obtain information regarding factors that have been reported to influence prognosis in human medicine.

- Circumstances surrounding submersion (severe internal injuries worsen prognosis)
- Duration of submersion (prognosis worsens with increased time)
- Tonicity and temperature of the water (prognosis better with fresh/ice water)
- Apnea after rescue (spontaneous breathing improves prognosis)
- Immediate neurologic condition after rescue (poor condition may worsen prognosis)

PHYSICAL EXAM FINDINGS

Variable depending on severity. May include wet fur, collapse, dyspnea, tachypnea, tachycardia, bradycardia, cyanosis, hypoperfusion, hypothermia, increased bronchovesicular breath sounds, or cardiac or respiratory arrest.

ETIOLOGY AND PATHOPHYSIOLOGY

- Pulmonary, fresh water: affects the surface-tension properties of pulmonary surfactant (surfactant washout), leading to alveolar instability, the possibility of noncardiogenic pulmonary edema, and altered ventilation/perfusion ratio. Because of the relative hypotonicity of fresh water, aspirated fluid is generally quickly absorbed into the circulation. If enough fluid is absorbed, hyponatremia causes hemolysis.
- Pulmonary, sea water: elicits fluid influx into the pulmonary parenchyma (osmotic gradient) and alveolar flooding; volume may be so great as to cause hypovolemia.
- Hepatocellular: hepatic ischemia as a result of hypoxia and compromised cardiovascular function causes direct hepatic injury and lobar necrosis.
- Hematologic dysfunction: hypoxemia, vascular stasis, and acid-base disturbances predispose animals to development of disseminated intravascular coagulation.
- Acute kidney injury: renal hypoxia contributes to tubular cell death.
- Cardiovascular effects: elevated systemic and pulmonary vascular resistance, cardiac arrhythmias, and cardiac arrest are primarily due to hypoxemia. They are positively related to the length of anoxic insult and negatively related to the effects of hypothermia and effectiveness of resuscitation in humans.
- Neurologic effects: ischemia leads to an elevation in extracellular central nervous system tissue glutamate concentration,

which is thought to be directly related to neuronal damage. Both cerebral ischemia and hypoxia can lead to irreversible neurologic dysfunction.
- In all, 90% of drowning victims aspirate fluid into the lungs; in 10%, drowning is associated with laryngospasm and inhalation against a closed glottis, causing noncardiogenic pulmonary edema without aspiration of water.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Known history of recent submersion is generally sufficient to make the diagnosis. Involvement of other organ systems such as hepatocellular, hematologic, cardiovascular, renal, and neurologic systems can be common.

INITIAL DATABASE

- Arterial blood gas analysis (hypoxemia variable with degree of aspiration/noncardiogenic pulmonary edema; metabolic acidosis possible and appears detrimental to prognosis)
- Pulse oximetry: low Spo2
- Electrocardiogram: ventricular arrhythmias
- CBC (usually unremarkable)
- Serum chemistry (increased liver enzymes, possibly hypoproteinemia or azotemia)
- Urinalysis (usually unremarkable)
- Thoracic radiographs (pulmonary infiltrates of varying location and type)
- Blood pressure (monitor for hypotension)

ADVANCED OR CONFIRMATORY TESTING

Bronchoalveolar lavage or transtracheal wash is indicated if warranted by clinical suspicion of pulmonary infection; not required for diagnosis of drowning.

TREATMENT

TREATMENT OVERVIEW

- Improve ventilation (goal: PaCO2 = 30-40 mm Hg or less)
- Maintain appropriate intravascular volume and tissue perfusion (*mean* arterial blood pressure >60-80 mm Hg, central venous pressure = 2-5 cm H2O, urine production >1-2 mL/kg/h)
- Ensure adequate blood oxygen saturation (Spo2 > 92%, Pao2 > 80 mm Hg [room air])
- Correct electrolyte imbalances or severe acidosis (e.g., if pH < 7.1)
- Referral for therapeutic ventilation may be warranted early in the course of disease and should be considered in those animals with severe respiratory distress (SpO2 < 92%, Pao2 < 80 mm Hg) despite oxygen supplementation.

ACUTE GENERAL TREATMENT

- Regain spontaneous ventilation and circulation (see p. 1223).
- Oxygen supplementation (see p. 1318).
- IV fluid administration as indicated.
- Mechanical ventilation with positive end expiratory pressure where indicated (see p. 1362).
- Abdominal thrust or gravitational drainage offers *no* advantage and may increase complications such as regurgitation and aspiration and delaying adequate treatment.
- Antibiotic therapy is not indicated unless clinical and radiographic evidence of pulmonary infection. Ongoing antibiotic use should be based on culture and sensitivity results.
- Corticosteroid therapy was once suggested but has failed to demonstrate any therapeutic advantage in large studies and may predispose patients to infection.

POSSIBLE COMPLICATIONS

- In addition to being risk factors that led to the incident, preexisting problems such as respiratory disease, heart disease, or seizure disorders should be identified; they may complicate resuscitation.
- Infrequently, grossly contaminated water can cause lower-airway obstruction (particulate matter) or pulmonary infection.
- Uncommonly, renal function can become compromised due to decreased renal perfusion, hypoxemia, or severe

hemoglobinuria.
- Cerebral hypoxia, cerebral hypoperfusion, or carbon dioxide narcosis can cause varying degrees of neurologic impairment but are rarely permanent.

RECOMMENDED MONITORING

- Thoracic auscultation
- Respiratory rate and effort
- Arterial blood gas analysis
- Urine output
- Serial neurologic evaluation and modified Glasgow Coma Score designation (see p. 235)
- Hematocrit, electrolyte and pH imbalances
- Electrocardiogram

PROGNOSIS AND OUTCOME

- Most near-drowning animals are markedly improved within 24 hours. Failure to rapidly improve is associated with a grave prognosis, as is persistent hypoxemia.
- By extrapolation from human medicine, the need for CPR on presentation, blood pH < 7.0, and apnea or coma are poor prognostic indicators.
- Similar to human beings, submersion for >25 minutes, resuscitation for >25 minutes, cardiac arrest at time of presentation, and lack of return of purposeful movements within 24 hours of the incident are associated with severe neurologic deficits or death.

PEARLS & CONSIDERATIONS

COMMENTS

Abdominal thrust and gravitational pull (suspended upside down) offer no benefits and may increase complications such as regurgitation, aspiration, and delayed resuscitation.

PREVENTION

- Outdoor supervision
- Avoidance of swimming by dogs with disorders causing episodic lack of control (seizures, syncope)
- Precautionary poolside safety measures such as pool covers and gated pool areas
- Boating safety measures: flotation devices; keeping animals in boat cabin, on boat floor, or away from railings
- Avoid semifrozen lakes, ponds, or rivers

TECHNICIAN TIPS

- Early placement of an arterial catheter may allow for rapid, accurate interpretation of pulmonary gas exchange, since intermittent SpO2 can require the oxygen cage to be open for longer periods of time, can be difficult to interpret in a panting animal, and does not give information pertaining to changes in acid-base status or PaCO2.
- A urinary catheter and closed collection set allows for frequent, accurate calculation of urine output and may aide in nursing care.
- Many dogs presented on emergency for near-drowning have visual, neurologic, musculoskeletal, or other deficits that existed previously and predisposed them to the incident. It is useful and important to be aware of these preexisting deficits when monitoring recovery so as to avoid misinterpreting the long-standing condition as a complication of near-drowning.

Draining Tracts, Cutaneous

BASIC INFORMATION

DEFINITION

A tract that connects an area of subcutaneous or deeper soft-tissue inflammation to the skin surface

SYNONYMS

Fistulous tract, sinus tract

EPIDEMIOLOGY

SPECIES, AGE, SEX

Variable depending on etiology

RISK FACTORS

- Penetrating injuries, chronic exposure of the skin to trauma or moisture, wound contamination, contact with infected individuals, immunodeficiency syndromes

CONTAGION & ZOONOSIS

Pathogens with zoonotic potential include: *Nocardia*, *Blastomyces*, *Sporothrix*, and *Leishmania* among others.

GEOGRAPHY AND SEASONALITY

In warm, dry climates: grass awns as penetrating foreign bodies

ASSOCIATED CONDITIONS & DISORDERS

- Frequently associated with cutaneous nodular disease
- May be associated with additional systemic signs depending upon the etiology

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

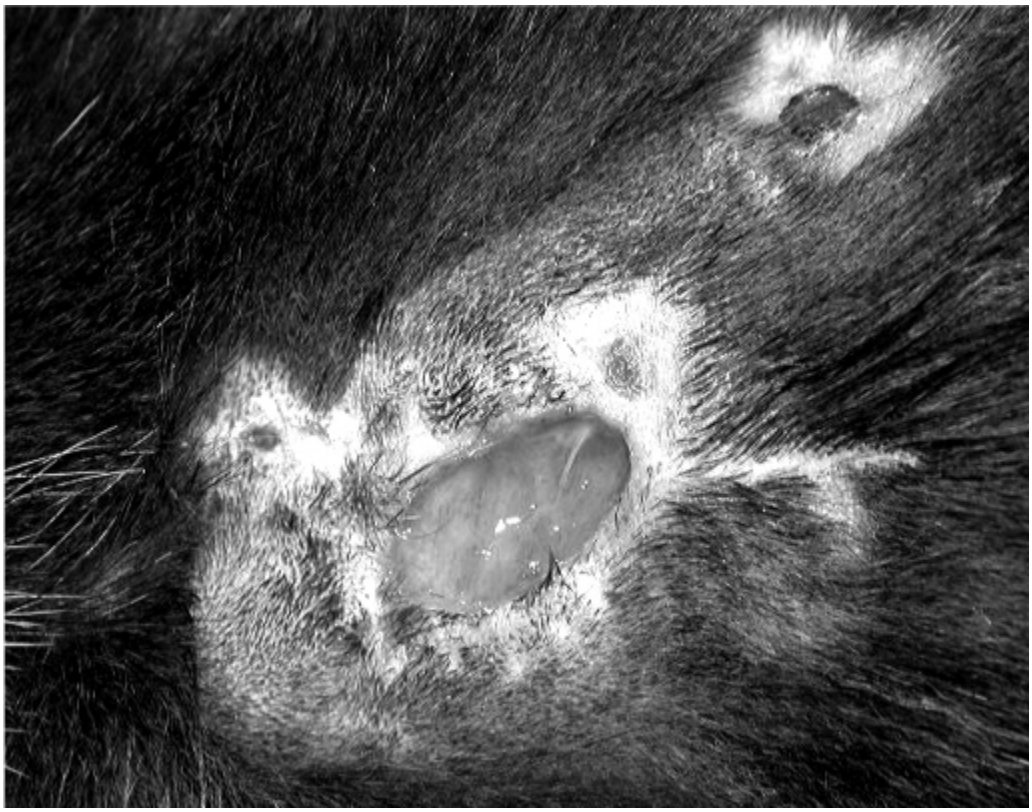
- Infectious
- Noninfectious
- Neoplastic

HISTORY, CHIEF COMPLAINT

There may be a history of a previous penetrating injury, typically associated with infectious causes. For all three forms/subtypes, a common complaint is of a nonhealing cutaneous wound that may fail to respond to antimicrobial therapy.

PHYSICAL EXAM FINDINGS

- Lesions may be solitary or multiple.
- Draining tracts are often associated with cutaneous nodules (fungal or bacterial granuloma, idiopathic sterile pyogranuloma/granuloma, sterile nodular panniculitis)
- Lesions may or may not be painful.
- Exudate from the tracts may be serous, serosanguineous, or purulent. Tissue granules may be found within the exudate (e.g., actinomycosis, actinobacillosis, nocardiosis, and bacterial pseudomycetoma).



DRAINING TRACTS, CUTANEOUS Draining tract in a cat with panniculitis due to nocardiosis.

(Courtesy Dr. Andrew Lowe.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Infectious causes are often the result of direct inoculation of the organism into the subcutaneous tissue via penetrating injury. A major exception is the systemic mycoses (histoplasmosis, blastomycosis, coccidioidomycosis, cryptococcosis), which are acquired mainly through inhalation and only very rarely through direct inoculation. Immunosuppressive diseases may increase the risk of infection or colonization with opportunistic pathogens.
    - Bacterial (including feline subcutaneous abscesses, actinomycotic infections *[Actinomyces, Nocardia], Streptomyces griseus*, *Dermatophilus congolensis*, actinobacillosis, mycobacteria, deep bacterial infections and bacterial pseudomycetoma)
    - Fungal (as above, plus zygomycosis, pythiosis, sporotrichosis, and dermatophytic pseudomycetoma)
    - Parasitic (including leishmaniasis, neosporosis, *Cuterebra*, dracunculiasis, and cutaneous dirofilariasis)
- Noninfectious:
    - Foreign bodies (although secondary bacterial infection is virtually inevitable)
    - Immune-mediated (sterile nodular panniculitis, systemic lupus erythematosus, perianal furunculosis, drug eruption)
    - Xanthomatosis
    - Neoplasia

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A draining cutaneous tract is a readily visible but nonspecific clinical sign for which the underlying cause must be determined. Additional testing, usually beginning with cytologic evaluation of exudate, is almost always necessary. Further tests are then indicated based upon the cytologic results.

DIFFERENTIAL DIAGNOSIS

Persistent exudation of fluid from subcutaneous or deeper tissues through an opening in the skin is characteristic of a draining tract. Few differential diagnoses exist; hemorrhage and serum exudation from a superficial wound should be easily differentiated by nature of fluid and depth of wound.

INITIAL DATABASE

A thorough diagnostic approach is indicated with draining tracts: all of the following diagnostic tests are indicated for a complete evaluation.

- Cytologic evaluation: as well as the exudate, any tissue granules present should be crushed between two slides and examined. Fine-needle aspirates of nodules or impression smears of biopsy samples may also prove useful (Diff-Quik followed by acid-fast and periodic acid–Schiff staining). If samples are submitted to an outside laboratory, be sure to send unstained slides, and advise the lab of differential diagnoses being considered.
- Diagnostic imaging/radiographs: may help identify foreign bodies or diseases with systemic manifestations, such as pulmonary involvement with blastomycosis, or underlying bony lesions (e.g., osteomyelitis, neoplasia)
- Culture and sensitivity: bacterial (aerobic and anaerobic), fungal, and mycobacterial cultures should be considered in cases of persistent draining tracts. Culture of the superficial exudate will likely not reflect the true, deeper disease process. Samples of deep tissue should be obtained by biopsy for culture. Many of the potential pathogens are difficult to successfully culture (false-negative results). Notify the lab as to which differentials are being considered so appropriate sampling, transport, and culture procedures are performed (many organisms are highly infectious to humans under laboratory conditions).
- Histopathologic evaluation: obtain multiple specimens from both open and closed lesions. Wedge or elliptical biopsies provide a better yield for deep subcutaneous lesions than punch biopsies. Special stains may be required for positive identification (notify pathologist of differential diagnoses).
- A lack of organisms on cytologic and histopathologic evaluation and culture, if performed correctly, may indicate a noninfectious etiology.
- Routine CBC, serum biochemistry profile, urinalysis: nonspecific

ADVANCED OR CONFIRMATORY TESTING

- Serologic testing: a fourfold rise in antibody titer from samples taken 3 weeks apart may help confirm some mycoses (e.g., cryptococcosis, blastomycosis, *Pythium*).
- Urine *Blastomyces* antigen test: blastomycosis (see 138)
- Fundic examination
- Antinuclear antibody (see p. 1070)

TREATMENT

TREATMENT OVERVIEW

Treatment varies widely, depending on the etiology; more specific treatment information may be sought once this is determined.

ACUTE GENERAL TREATMENT

- In general, an inciting cause (e.g., foreign body, neoplasm) should always be identified and, if present, should be removed for an optimal outcome/potential for cure.
- Lavage and débridement of the lesions in combination with appropriate antimicrobial therapy based on culture and sensitivity are indicated for infectious etiologies.
- Noninfectious etiologies (e.g., sterile nodular panniculitis, perianal fistulae) may respond to immunosuppressive doses of glucocorticoids and other immunosuppressive therapies (e.g., cyclosporine).

PROGNOSIS AND OUTCOME

Variable depending on etiology

PEARLS & CONSIDERATIONS

COMMENTS

- Patients with chronic or recurrent infectious draining tracts should be evaluated for underlying immunosuppressive diseases or persistent local/focal abnormalities (foreign body, neoplasm, etc.).
- Only after infectious agents have been completely ruled out and a definitive diagnosis has been reached should treatment be considered for noninfectious diseases that respond to glucocorticoid therapy.

TECHNICIAN TIPS

- Patients with draining tracts should be handled with gloves, and contact with exudates should be minimized until a definitive etiology is determined (zoonosis risk).

AUTHOR: ANDREW LOWE

EDITOR: MANON PARADIS

Dracunculus insignis Infection

BASIC INFORMATION

DEFINITION

Rare parasitic infection of dogs

SYNONYMS

Canine guinea-worm, canine dracunculiasis

EPIDEMIOLOGY

SPECIES, AGE, SEX

Infects dogs (any wild carnivore and member of the Canidae family). Also recovered from raccoons and mink (reservoir hosts).

GENETICS & BREED PREDISPOSITION

Sporting breeds of dogs are predisposed.

RISK FACTORS

Hunting/foraging and drinking water from freshwater environments (inhabited by aquatic crustaceans ["water fleas"], intermediate hosts belonging to genus *Cyclops*).

CONTAGION & ZOONOSIS

Although they have their own species of this parasite *(Dracunculus medinensis),* humans are not susceptible to infection with this canine parasite.

GEOGRAPHY AND SEASONALITY

Found in definitive hosts throughout North America. No seasonality.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- One or more blisterlike cutaneous swellings/nonhealing ulcers. Often on the extremities or ventral abdomen.
- Some owners may notice the characteristic protruding end of the female worm in the lesion.

PHYSICAL EXAM FINDINGS

- Ulcerative nodules or abscesses can be found on the skin of the limbs, head, and abdomen.
- The worm typically protrudes from the ulcerated lesion, making it easily visible to the owner and/or veterinarian.
- Lesions may be painful or pruritic.
- The dog may or may not be febrile.
- The veterinarian should exercise caution and not pull or attempt to manually extract the worm. The female worm's body is extremely fragile and subject to breakage.

ETIOLOGY AND PATHOPHYSIOLOGY

- The adult worm may be up to 100 cm (3 feet) in length.
- This is an unusual parasite in that the female possesses no vulva to allow exit of her offspring.
- The female worm lives in the subcutaneous connective tissues of the dog's extremities, producing a large cutaneous swelling that eventually develops into a nonhealing ulcer. From this ulcer, the female worm extrudes her anterior end.
- Whenever the female worm makes contact with water, her uterus will prolapse through her anterior, releasing a mass of

first-stage larvae into the water. These larvae are 500-750 mm in length with unique, characteristic long tails. The larvae are ingested by the intermediate host, a copepod aquatic crustacean (water flea) usually belonging to the genus *Cyclops;* eventually, larvae develop into infective third-stage larvae.
- Dogs become infected by drinking the water containing the *Cyclops* harboring the infective larvae.
- In approximately 1 year, the ingested larvae mature to adult parasites. Male and female worms copulate. The female eventually migrates to the extremities, where she produces the nodule which eventually will develop into a cutaneous ulcer in the dog.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Suspicion of dracunculiasis is first raised with the appearance of a cutaneous ulcer and is greatly heightened if a fine, threadlike structure is seen protruding from the lesion. Confirmation is simple, using a test tube full of cold water, a centrifuge, and a microscope.

DIFFERENTIAL DIAGNOSIS

- In heartworm-endemic areas (or with appropriate travel history), this nematode may be confused with a single aberrant (erratic) adult *Dirofilaria immitis*, which can be found in a variety of ectopic sites throughout a dog's body. These “lost” adult heartworms may produce subcutaneous nodules or abscesses, but adult heartworms usually do not protrude from the lesion.
- Foreign bodies within the skin which may produce nonhealing ulcerous lesions; however, these lesions usually do not resemble a protruding female worm.

INITIAL DATABASE

- CBC and serum chemistry profile: unremarkable
- Impression smears of the lesion may reveal inflammatory cells and first-stage larvae.

ADVANCED OR CONFIRMATORY TESTING

With the worm still embedded in tissues and protruding from the nonhealing ulcer, the protruding (anterior) end of the worm should be dipped into a test tube containing cool water to elicit release of a mass of first-stage larvae into the water; a cloudy discharge (containing microscopic larvae) may be observed. The test tube should be centrifuged and the water supernatant collected off. The larvae may be found in the sediment at the bottom of the test tube. Microscopic examination of the sediment will reveal the first-stage larvae (500-750 mm in length) with their characteristic long tails.

TREATMENT

TREATMENT OVERVIEW

- Manually extract the adult female parasite from the ulcerous lesion.
- Careful surgical intervention with blunt dissection is recommended.

ACUTE GENERAL TREATMENT

- Do not attempt to pull on the worm; it is entwined within the subcutis and prone to breaking. Surgical extraction using blunt dissection is recommended. Some antiinflammatory drugs may ease removal.
- There is no effective medical treatment; surgical extraction is recommended. Possible experimental treatments include:
  - Niridazole, 12.5 mg/kg PO q 12 h for 10 days, *or*
  - Thiabendazole, 50 mg/kg PO q 24 h for 2 to 3 days
- Multiple infections in a single ulcerative lesion do not occur. Once the sole female is removed, healing should take place quickly.

CHRONIC TREATMENT

As needed for dermatologic complications:

- Secondary bacterial infection
- Cellulitis

- Culture and sensitivity of skin lesion with appropriate antimicrobial therapy

BEHAVIOR/EXERCISE

- The "old school"/Old World therapy of removing *D. medinensis* in humans is to tie the worm to a small stick and gradually roll the worm up over the course of a few days or weeks. Dogs are not likely to tolerate this therapy.
- Depending on the location of the lesion, an Elizabethan collar may be indicated.

***DRACUNCULUS INSIGNIS* INFECTION** Third stage larvae of *Dracunculus insignis* (500-750 mcm in length). Note the characteristic long tail of each larva.

POSSIBLE COMPLICATIONS

Breaking the friable body of the female worm in situ and not being able to recover the remnants of the parasite

RECOMMENDED MONITORING

Visual assessment of the healing process of the lesion

PROGNOSIS AND OUTCOME

Excellent prognosis if the parasite is surgically extracted and no portions remain in situ.

PEARLS & CONSIDERATIONS

COMMENTS

- These worms are singular in their appearance in ulcerated skin lesions.
- Although this nematode is extremely rare, it is easy to diagnose. Blunt dissection of tissues and manual extraction of the worm without breakage are paramount.
- *D. insignis* is closely related to the human scourge, *D. medinensis*, the human guinea-worm, the "serpent on the stick," or the serpent of the Staff of Aesculapius, the symbol of the medical profession.

PREVENTION

Prevent dogs from roaming and coming into contact with freshwater aquatic environments containing *Cyclops* species harboring

infective larvae of *D. insignis.*

TECHNICIAN TIPS

The use of a compound microscope to detect the presence of the unique first-stage larvae with their characteristic long tails is the key to diagnosis.

CLIENT EDUCATION

Dogs should never be allowed to roam freely, thus avoiding contact with infested water.

AUTHOR: CHARLES HENDRIX

EDITOR: DOUGLASS MACINTIRE

Distichiasis/Ectopic Cilia/Trichiasis

BASIC INFORMATION

DEFINITION

- Distichiasis: common condition represented by the presence of an additional row of adventitious lashes on the eyelid margin arising from the meibomian glands, in addition to the normal eyelashes emerging from the usual peripheral eyelid margin
- Ectopic cilia: well-recognized condition consisting of aberrant individual eyelashes that arise from the meibomian glands and grow through the palpebral conjunctiva toward the globe
- Trichiasis: common condition associated with normal eyelid/facial hair that is directed toward and contacts the conjunctiva or cornea

DISTICHIASIS/ECTOPIC CILIA/TRICHIASIS Distichiasis in a dog. Note the numerous long, aberrant hairs along the upper and lower eyelid margins and arising from the meibomian gland ducts *(arrows).* These hairs were an incidental finding and caused no clinical signs, so no treatment was warranted.

SYNONYMS

Aberrant cilia, “abnormal eyelashes,” distichia

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Common in dogs, rare in cats
- Most often in young dogs, but can occur at any age

GENETICS & BREED PREDISPOSITION

- *Distichiasis:* any breed, but common in American and English cocker spaniels, miniature long-haired dachshund, English bulldog, golden retriever, Cavalier King Charles spaniel, Pekingese, toy and miniature poodles, Yorkshire terrier, and Shetland sheepdog
- *Ectopic cilia:* any breed, but common in boxers
- *Trichiasis:*
    - Congenital trichiasis: English cocker spaniel and small breed dogs such as brachycephalic breeds with prominent

facial folds (e.g., Pekingese, pug)
- Acquired trichiasis: breeds with redundant dorsal skin folds (English bulldog, shar-pei, chow chow, bloodhound, Saint Bernard)

ASSOCIATED CONDITIONS & DISORDERS

- Conjunctivitis (see p. 239)
- Ulcerative keratitis (see Corneal Ulceration, p. 250)
- Nonulcerative keratitis (see Corneal Pigmentation, p. 246; Corneal Vascularization, p. 254)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- *Distichiasis:*
  - Generally does not produce clinical signs; most cases are clinically silent.
  - Epiphora and blepharospasm may be seen if ocular irritation is present.
- *Ectopic cilia:*
  - Acute onset of signs of ocular pain, such as severe blepharospasm and epiphora
- *Trichiasis:*
  - Signs of ocular irritation, such as blepharospasm and epiphora

PHYSICAL EXAM FINDINGS

- *Distichiasis:*
  - Single to multiple cilia along eyelid margin (incidental finding [see figure])
  - Epiphora, mild conjunctivitis, and nonulcerative keratitis are seen if cilia are causing ocular irritation; blepharospasm, ulcerative keratitis, +/− entropion (secondary/spastic) in severe cases.
- *Ectopic cilia:*
  - Most common at the 12 o'clock position (center of upper eyelid)
  - Emerge through the palpebral conjunctiva 4-6 mm posterior (caudal) to the eyelid margin
  - Magnification is needed to identify the cilia.
  - Acute blepharospasm and epiphora are typical; focal signs of nonulcerative and ulcerative keratitis often present (in a vertical pattern that follows the path of eyelid movement).
- *Trichiasis:*
  - Congenital trichiasis: The cilia or hair that contact the cornea occur on the lateral two-thirds of the upper eyelid.
  - Medial canthal trichiasis: The hairs that contact the cornea arise along the medial eyelid margin and in the area of the caruncle (aberrant dermis at the medial canthus and present on the conjunctiva).
  - Trichiasis is a common consequence of agenesis of the lateral two-thirds of the upper eyelid in cats.
  - Signs of ocular irritation, such as epiphora, if mild
  - Keratitis (ulcerative and nonulcerative) if severe

ETIOLOGY AND PATHOPHYSIOLOGY

- Meibomian glands without cilia may spontaneously develop distichiasis or ectopic cilia if the glands become metaplastic.
- *Distichiasis:*
  - Cilia originate from the meibomian glands, develop from metaplastic meibomian glands, and arise secondary to chronic inflammation (meibomitis); acquired condition.
  - May or may not contact cornea
- *Ectopic cilia:*
  - Cilia originate from the meibomian glands and emerge through the palpebral conjunctiva.
  - Always contact cornea
  - Can occur at any time in the animal's life
- *Trichiasis:*
  - Normal hairs that are abnormally directed toward the eye
  - Congenital trichiasis of the upper eyelid can be bilateral or unilateral.
  - Acquired trichiasis develops secondary to ptosis associated with redundant skin folds (see Genetics & Breed Predisposition).
  - Acquired trichiasis develops secondary to loss of muscle tone in older dogs.
  - Associated with entropion, prominent nasal folds, and medial canthal hairs (eyelids and caruncle)

DIAGNOSIS

OVERVIEW STATEMENT

Ocular disease associated with distichiasis is suspected based on the presence of conjunctivitis or ulcerative and/or nonulcerative keratitis. It is confirmed when adventitious lashes are seen to originate from the meibomian glands (no magnification necessary for most clinicians).

Ocular irritation related to ectopic cilia is suspected based on acute blepharospasm and epiphora with signs of focal ulcerative and/or nonulcerative keratitis; confirmation requires magnification to identify cilia emerging from the palpebral conjunctiva.

Ocular disease associated with trichiasis is suspected when conjunctivitis or ulcerative and/or nonulcerative keratitis is present and when normal eyelid/facial hair is directed toward and contacts the conjunctiva or cornea.

DIFFERENTIAL DIAGNOSIS

- Trichomegaly (excessively long eyelashes)
- Other causes of blepharospasm, including corneal ulceration, conjunctivitis, uveitis, epiphora
- Entropion

INITIAL DATABASE

Complete ophthalmic examination (see p. 1313) including:

- Schirmer tear test (normal >15 mm after 1 minute in dogs, variable in cats)
- Fluorescein dye application
- Intraocular pressure (normal: 10-25 mm Hg)
- Examination of the eyelid margin and palpebral conjunctiva with magnification and a good light source
- Examination of the cornea

ADVANCED OR CONFIRMATORY TESTING

Magnification 5 to 10× is often needed to visualize ectopic cilia.

TREATMENT

TREATMENT OVERVIEW

Treatment goals are to eliminate ocular irritation; to determine if distichiasis, trichiasis, or ectopic cilia are responsible for clinical signs of ocular disease; and to remove the offending cilia or direct the cilia away from the globe. The presence of distichiasis and/or trichiasis without signs of ocular irritation does not require treatment.

ACUTE GENERAL TREATMENT

- *Distichiasis:*
  - Usually does not produce clinical signs; no treatment required
  - Hairs regrow within 4-5 weeks with mechanical epilation/plucking.
  - If clinical signs are present, consider surgical treatment:
    - Before removal, expression of the meibomian glands pushes hidden hairs from the glands.
    - Cryotherapy along the palpebral surface of the meibomian glands using a double freeze/thaw cycle is effective treatment for a large number of distichia in a patient.
    - Electrolysis is useful for single or a low number of cilia; procedure is tedious, and excessive current may cause tissue damage.
    - Carbon dioxide laser removal is tedious and can predispose to excessive tissue damage.
    - Resection from the conjunctival surface effective for single or multiple cilia
    - Eyelid-splitting techniques are not recommended because of the potential for postoperative eyelid deformities and regrowth of hairs.
- *Ectopic cilia:*
  - Typically produce clinical signs; therefore treated surgically
  - En-bloc resection of aberrant cilia, including associated conjunctiva and underlying meibomian gland
  - Surgical removal usually successful, but regrowth can occur.
- *Trichiasis:*
  - If minor ocular irritation, conservative management may be effective:
    - Clipping hairs short to prevent ocular contact
  - Variable surgical therapies depending on location of trichiasis:

- Many procedures complex; consider referral to veterinary ophthalmologist.
- Medial canthal trichiasis may be corrected by permanent medial canthoplasty (pocket technique or Wyman technique) or cryotherapy.
- Nasal fold trichiasis may require resection of prominent nasal skin folds.
- Trichiasis associated with ptosis (drooping of the upper eyelid) may be corrected by a Stades procedure.
- Trichiasis associated with redundant dorsal skin folds may be corrected by extensive removal of tissue or by the use of anchoring sutures to the periosteum.
- Trichiasis associated with eyelid agenesis in cats may be corrected by cryotherapy until kitten is old enough for permanent surgery (e.g., rotational flap).

CHRONIC TREATMENT

If recurrence, repeat treatment may be required

POSSIBLE COMPLICATIONS

- The most common complication to correction of distichiasis, ectopic cilia, and trichiasis is recurrence.
- Postoperative eyelid scarring ± entropion

RECOMMENDED MONITORING

Have owner monitor animal for signs of recurrent ocular irritation postoperatively; may indicate regrowth of offending hair(s).

PROGNOSIS AND OUTCOME

Generally good prognosis, but recurrence is possible regardless of treatment.

PEARLS & CONSIDERATIONS

COMMENTS

- Distichiasis and trichiasis are among the most common eyelid abnormalities.
- Goal is not simply to diagnose distichiasis or trichiasis, but to determine if the abnormal hair(s) is/are causing ocular irritation, as this determination will help decide whether treatment is necessary.
- Keratitis that presents in a vertical pattern that follows the path of eyelid movement should raise the suspicion of an ectopic cilium in the upper eyelid.
- Magnification commonly is needed to identify ectopic cilia, and without a magnifying glass or loupe, the diagnosis should not be ruled out based on absence of visualization.
- Ectopic cilia and hairs causing distichiasis will regrow within 4-5 weeks with mechanical epilation/plucking.
- No single treatment guarantees permanent resolution of distichia, ectopic cilia, or trichiasis.

PREVENTION

Avoid breeding affected or closely related dogs.

CLIENT EDUCATION

- Presence of distichiasis or trichiasis does not indicate disease.
- Animals with distichiasis, ectopic cilia, or trichiasis are monitored for signs of ocular irritation.
- Recurrence is possible regardless of treatment.

AUTHOR: PHILLIP A. MOORE

EDITOR: CHERYL L. CULLEN

Distemper, Canine

BASIC INFORMATION

DEFINITION

Viral disease principally of young dogs and caused by a morbillivirus of the family Paramyxoviridae. Clinical disease includes mild to severe systemic illness with high morbidity and variable mortality (mortality often related to central nervous system [CNS] infection).

SYNONYMS

Distemper, hardpad disease

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs, especially urban or suburban dogs between 3 and 6 months of age
- Other susceptible species include additional members of the order Canidae (coyote, dingo, wolf, fox), ferrets, mink, skunk, raccoon, panda, and select members of the order Felidae (lion, cheetah, jaguar, margay, ocelot).

GENETICS & BREED PREDISPOSITION

More common, with higher mortality rates, in dolichocephalic breeds versus brachycephalic breeds

RISK FACTORS

Inadequate vaccination, exposure to animals with clinical or subclinical disease, transplacental transmission, and exposure of vaccinated but immunocompromised animals to an infected animal

CONTAGION & ZOONOSIS

Highly contagious (aerosol route most common) between infected, shedding individuals and susceptible individuals. Not considered zoonotic.

ASSOCIATED CONDITIONS & DISORDERS

- Hyperkeratosis of the footpads (hardpad disease)
- Ocular signs (anterior uveitis, optic neuritis, retinal degeneration, keratoconjunctivitis) can develop with systemic disease or as a sequela.
- Postencephalitic epilepsy
- Myoclonus
- Persistent anosmia (loss of sense of smell) possible in recovered patients

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Subclinical to mild disease is probably most common, but systemic/generalized form is the most recognized.
- Generalized distemper: manifests initially as a respiratory infection followed by gastrointestinal (GI) signs and often CNS signs; CNS signs may manifest concomitant with or after resolution of respiratory and GI signs.
- Old-dog encephalitis (ODE) likely results from an inflammatory reaction associated with persistent canine distemper virus infection of the CNS gray matter. Clinical signs can include ataxia, compulsive movements such as head pressing or continual pacing, and uncoordinated hypermetric gait. Systemic signs are not associated with this form.
- Inclusion-body polioencephalitis is a variant of the disease, can occur after vaccination, and only manifests as a CNS disease. The pathogenesis is similar to ODE.

HISTORY, CHIEF COMPLAINT

With the generalized form of the disease, initial presentation typically includes one or more of the following: lethargy, ocular and nasal discharge (serous or mucopurulent), cough, inappetence, vomiting, diarrhea. A patient with a more advanced form of the disease often has a history of neurologic signs (seizures, ataxia, etc.).

PHYSICAL EXAM FINDINGS

- Systemic disease: as above; fever, ocular signs (keratitis, conjunctivitis, uveitis), loud breath sounds on auscultation, dehydration, cachexia, poor haircoat. Dental abnormalities in dogs that survive neonatal infections (dental enamel hypoplasia, tooth impaction, oligodontia).
- Neurologic disease: signs indicative of encephalitis or encephalomyelitis (seizures, vestibular signs, cerebellar signs/hypermetria, paresis). Seizures are commonly manifested as “chewing-gum” seizures (vigorous repetitive opening and closing of the mouth) but can also be generalized. Hyperesthesia attributable to viral meningitis is uncommon. Myoclonus (rhythmic twitching of the head, neck, or one or more limbs) occurs as the disease progresses and is very suggestive of canine distemper. Optic neuritis and chorioretinitis can be observed.
- Systemic and neurologic signs are not always present at the same time. More often, neurologic disease occurs 1-3 weeks after recovery from systemic signs, but the two forms can coincide. Rarely, the neurologic signs will occur weeks to months later.

ETIOLOGY AND PATHOPHYSIOLOGY

- Certain strains of canine distemper virus (CDV) are more virulent and neurotropic; Snyder Hill strain is associated with polioencephalomyelitis; A75/17 and R252 strains are associated with CNS demyelination.
- Shedding of the virus begins by the seventh day after infection and may continue for up to 90 days.
- Shedding is primarily aerosol, but virus can also be recovered from urine, feces, nasal and ocular secretions, and skin.
- After initial exposure, CDV replicates in the upper-respiratory epithelium tissue macrophages. These cells are carried by the local lymphatics to the tonsils and retropharyngeal and bronchial lymph nodes. Here, the virus multiplies and disseminates systemically in mononuclear cells, creating an initial fever and leukopenia 3-6 days after exposure. Lymphopenia is associated with viral damage to both T and B lymphocytes.
- Viremia occurs by the ninth day post infection as the virus spreads hema-togenously to epithelial tissues and the CNS. Occurrence of viremia depends on host humoral and cell-mediated immunity. Infection of epithelial tissue correlates with shedding of the virus and occurs through all epithelial secretions, even in animals with subclinical infections.
    - Dogs with adequate humoral and cell-mediated immunity clear the virus by day 14.
    - Dogs with an intermediate level of immunity have infection of the epithelial tissues by day 14. Clinical signs that develop eventually resolve if the antibody titer increases and the virus is cleared from most tissues. Some virus may persist in footpads and CNS.
    - In dogs with poor immunity, virus spreads to many tissues by day 14, including skin, endocrine glands, exocrine glands, and epithelial cells of the intestinal tract, the respiratory system, and the genitourinary tract.
- Clinical signs are usually severe; secondary bacterial infections are common (although this advances morbidity, studies indicate it does not increase mortality).
- CNS infection occurs hematogenously. CDV enters the CNS through meningeal perivascular spaces, the choroid plexus, and the ventricular ependymal cells. Acute CDV encephalomyelitis occurs early in the course of the disease of young and immune-deficient dogs, causing a polioencephalomyelitis.
- Full recovery from CDV infection in young animals is uncommon, but likely produces lifelong immunity.
- Transplacental infections can result in abortions or stillbirths. Puppies that survive transplacental infections can develop neurologic signs by 6 weeks of age and often have lifelong immunodeficiency.
- Some dogs will continue to shed the virus for up to 2 months after infection.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

A presumptive diagnosis in a young, unvaccinated dog is made based on presentation of clinical signs that include oculonasal discharge, vomiting, and/or diarrhea with or without a recent onset of neurologic signs. Older dogs can initially present with signs consistent with infectious tracheobronchitis. Clinical confirmation typically comes from a blood sample submitted for immunofluorescent antibody testing of white blood cells, or anti-CDV antibody titers in cerebrospinal fluid (CSF).

DIFFERENTIAL DIAGNOSIS

- Canine infectious tracheobronchitis
- Canine parvoviral enteritis
- Other CNS diseases of young dogs

INITIAL DATABASE

- CBC can reveal an absolute lymphopenia; rarely, CDV inclusions are identified in lymphocytes, monocytes, neutrophils, or erythrocytes.
- Serum biochemistry profile and urinalysis are variable and not definitive for CDV.
- Thoracic radiographs: interstitial pattern in early phases; evidence of bronchopneumonia in later stages with secondary bacterial infection

ADVANCED OR CONFIRMATORY TESTING

- Serum antibody testing: elevated serum IgM titers in unvaccinated dogs confirm recent exposure or current infection.
- CSF
  - Elevated CSF protein and lymphocytic pleocytosis are typical.
  - Presence of CSF antibody titers to CDV are confirmatory when there is no blood contamination of the sample.
  - With potential blood contamination of the CSF sample, paired samples of CSF and serum are tested for CDV and canine parvovirus (CPV) antibody titers; since CPV does not cross the blood-brain barrier, a CDV/CPV ratio that is higher in CSF than in blood suggests CDV infection.
  - Severely immunosuppressed patients or those with the noninflammatory demyelinating form of CDV may have normal CSF, often with low CSF protein (<5 mg/dL).
- Fluorescent antibody testing
  - Cytologic smears from buffy coat, tonsillar or conjunctival epithelial scrapings, CSF, bone marrow, urine sediment
  - More rewarding on conjunctival scrapings early in course of the disease
- PCR test for CDV: whole blood, serum, CSF
- Postmortem testing: immunofluorescent techniques for frozen samples of tonsils, lymph nodes, GI epithelium, spleen, urinary bladder, brain

TREATMENT

TREATMENT OVERVIEW

Affected animals are treated with supportive care, antibiotics to control secondary bacterial infection, and anticonvulsants to control seizures. No medication is known to eradicate the virus.

ACUTE GENERAL TREATMENT

- Broad-spectrum antibiotics (parentally initially) such as ampicillin, 22 mg/kg IV q 8 h, and enrofloxacin (not in growing puppies), 5 mg/kg diluted 1:1 in saline and given slowly IV q 12 h for secondary bacterial infections
- Nebulization and coupage if pneumonia apparent radiographically
- Antidiarrheals (e.g., loperamide, 0.1-0.2 mg/kg PO up to q 8 h), antiemetics (e.g., dolasetron, 0.3-0.6 mg/kg IV or SQ q 12-24 h; or metoclopramide, 0.2-0.4 mg/kg SQ q 8 h), and GI protectants (e.g., omeprazole, 0.7 mg/kg PO q 24 h) as needed for GI signs
- IV fluid resuscitation to correct dehydration and electrolyte disturbances
- Diazepam or midazolam if acute seizure control is needed (0.5 mg/kg IV or 1 mg/kg per rectum PRN up to 4 times in 2 hours)
- Isolation: patients are in an infectious phase of the disease and contagious.

CHRONIC TREATMENT

- Anticonvulsant therapy (phenobarbital, 2-4 mg/kg PO q 12 h; or leve-tiracetam, 20 mg/kg PO q 8 h) for seizure control. Sodium valproate (60-100 mg/kg PO q 8 h) can be considered in early stages of myoclonus but is ineffective in later stages.
- The use of corticosteroids is controversial. Antiinflammatory doses are considered useful to combat optic neuritis. Immune-suppressive doses are sometimes advocated for acute inflammatory CDV encephalitis in older dogs without systemic disease. Corticosteroids are advocated in the treatment of ODE and vaccine-induced CDV. Corticosteroid doses should be tapered to the lowest effective dose and are *contraindicated* in the presence of systemic disease with mucosal (respiratory, ocular, GI) signs and any evidence of secondary bacterial infections.

POSSIBLE COMPLICATIONS

- Recovery from systemic signs of the disease may precede development of neurologic signs weeks to months later.
- A possible link has been noted between rheumatoid arthritis and CDV.

PROGNOSIS AND OUTCOME

- Development of CNS signs is the most important negative prognostic factor.
- Dogs with adequate immunity do not develop clinical signs, and they clear the virus within 14 days post infection. The incidence of late-onset CNS signs in these dogs is low.
- Dogs with inadequate immunity develop mild to severe systemic signs and frequently develop CNS signs.

PEARLS & CONSIDERATIONS

COMMENTS

- CDV has a worldwide distribution and most commonly affects puppies and young, unvaccinated adults. Unvaccinated puppies exposed to an infected dog in the waiting room of a veterinary hospital should be vaccinated at that time and usually develop sufficient immunity before the virulent virus produces systemic signs.
- Weimaraners may have an unusual susceptibility to vaccination (see below).

PREVENTION

- Routine vaccination with a modified live canine distemper (ML-CDV) vaccine is indicated in puppies (every 3-4 weeks beginning at 6 weeks and ending at 16 weeks). A booster vaccine is given 1 year later and then periodically (every 3 years).
- Vaccination usually confers adequate immunity. Immunocompromised dogs or dogs exposed to a large amount of highly virulent CDV strain can still develop disease.
- Vaccine-induced infections are very rare and only produce CNS signs.
- Complications from the vaccine can occur but are also rare. Complications can include hypertrophic osteodystrophy (HOD) and juvenile cellulitis. Clinical signs usually develop within 10 days of vaccination (range 4-21 days) and have been associated with all ML-CDV vaccine strains. Weimaraners are the most frequently affected breed, and some evidence suggests there are familial tendencies. A corticosteroid-responsive neutrophilic meningitis/arteritis has also been described in this breed in association with ML-CDV vaccination. The use of a recombinant CDV vaccine in young Weimaraners instead of ML-CDV is suggested to reduce the risk of such complications. Additional vaccinations in Weimaraners after 1 year of age have not shown the same problems.
- Recombinant CDV vaccines are currently available and showed comparable efficacy to ML-CDV vaccines in initial studies.

TECHNICIAN TIPS

- Affected dogs should be isolated from other hospitalized patients, and gowns and gloves should be worn by personnel when handling these patients to prevent transmission of disease to other dogs.
- Transmission via fomites can be devastating; be sure that nebulization equipment and other objects are thoroughly disinfected before and after each use.

CLIENT EDUCATION

- Vaccination of young dogs is essential.
- Dogs with CDV infections should be isolated from healthy dogs for at least 2 weeks after cessation of signs in survivors. Some dogs will continue to shed the virus for up to 2 months after infection.
- In the environment, CDV is very sensitive to UV light, heat, and drying.

EDITOR: DOUGLASS K. MACINTIRE

1ST EDITION AUTHOR: JODI D. SMITH

Disseminated Intravascular Coagulation

BASIC INFORMATION

DEFINITION

An acquired syndrome of coagulation system dysregulation in which coagulation is abnormally and inappropriately activated, resulting in widespread deposition of fibrin in the microvasculature. Depletion of platelets and coagulation factors then causes bleeding in a subset of patients with disseminated intravascular coagulation (DIC).

SYNONYM

Dysfibrinogen syndrome

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs of any age and either sex; rarely identified in cats

RISK FACTORS

Primary disorders that initiate DIC: neoplasia, sepsis, polytrauma, shock, multiple organ dysfunction syndrome, gastric dilation-volvulus, severe inflammatory and immune reactions (pancreatitis, immune hemolysis, envenomation), liver failure

ASSOCIATED CONDITIONS & DISORDERS

DIC always develops secondary to an underlying or primary disease process (see Risk Factors above).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute DIC: associated with fulminant diseases (e.g., sepsis, anaphylaxis, heatstroke, pancreatitis, envenomation)
- Chronic DIC: develops secondary to solid tumors and hematopoietic neoplasia; common in dogs with hemangiosarcoma

HISTORY, CHIEF COMPLAINT

Typically reflects the primary disease (see above); signs of DIC are nonspecific and to most owners, indistinguishable from signs of the underlying disorder.

PHYSICAL EXAM FINDINGS

Variable, depending on primary disease and extent of thrombosis/factor depletion. None, one, or several of the following may be apparent:

- Collapse, pale mucous membranes, tachycardia, tachypnea, diffuse bruising (ecchymoses), melena, icterus

ETIOLOGY AND PATHOPHYSIOLOGY

- Two major pathways initiate DIC:
  - Systemic inflammatory response accompanied by cytokine activation and coagulation cascade activation (e.g., sepsis, polytrauma)
  - Release or exposure of procoagulant stimuli into the vascular space initiates widespread activation of coagulation (e.g., hemangiosarcoma, mammary carcinoma).
- Systemic fibrin deposition is insufficiently balanced by opposing anticoagulant mechanisms.
  - Antithrombin depletion from consumption, degradation, and suppressed synthesis
  - Protein C system: downregulated by proinflammatory cytokines
- Fibrinolysis is concomitantly suppressed.

- High plasminogen activator inhibitor levels impair fibrinolysis.
- Subsequent depletion of coagulation factors, including consumption of platelets, develops in some patients.
- Local thrombosis contributes to acidosis, ischemia, and tissue necrosis, which can perpetuate the syndrome.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

No single laboratory test is diagnostic for DIC. Early diagnosis of the thrombotic phase of DIC is especially challenging and requires an elevated index of clinical suspicion. The presence of nonspecific physical exam abnormalities (see above), especially together with a documented recent (hours/days) decrease in platelet count and/or altered coagulation parameters in a patient with a recognized risk factor, should alert the clinician to the possibility of DIC. The suspicion is further increased if signs of hemorrhage are present, but at the hemorrhagic stage, DIC is more likely advanced and more difficult to treat effectively.

DIFFERENTIAL DIAGNOSIS

- Hemorrhagic DIC:
  - Anticoagulant rodenticide exposure
  - Severe thrombocytopenia
  - Inherited or acquired platelet dysfunction
  - Dextran or hetastarch administration (prolonged clotting times)
  - Liver failure
- Thrombotic DIC: organ failure or pulmonary thromboembolism (PTE) due to cardiac disease, heartworm disease, tumor emboli, or “hypercoagulability” associated with antithrombin loss

INITIAL DATABASE

- CBC, platelet count, blood smear evaluation
  - Thrombocytopenia
  - Schistocytosis (fragmented red blood cells) from shredding effect of intravascular fibrin strands
- Serum biochemistry profile, urinalysis: evidence of underlying disease; effects of thromboembolism (e.g., renal, hepatic)
- Chest and abdominal radiographs: evidence of underlying disease and/or thromboembolism, hemorrhage
- Coagulation testing (prothrombin time [PT], activated partial thromboplastin times [APTT], fibrinogen [hypofibrinogenemia])
- D-dimer or fibrin/fibrinogen degradation product (FDP) concentration: typically increased in DIC
- Antithrombin III activity: typically decreased in DIC

TREATMENT

TREATMENT OVERVIEW

DIC can be thought of as a secondary complicating factor of other serious disorders. Therefore treatment involves two parallel approaches: control of hemo-static abnormalities (thromboembolism or hemorrhage, whichever is predominant) and control or reversal of the underlying disorder.

ACUTE GENERAL TREATMENT

- Always treat the primary condition.
- Support adequate perfusion with intravenous fluids as needed.
- Supplemental oxygen therapy if indicated (e.g., pulmonary disease including PTE)
- Red blood cell transfusion or polymerized hemoglobin solution: considered in anemia cases (see p. 1347).
- Fresh-frozen plasma (FFP) transfusion if fibrinogen and clotting factor depletion cause overt signs of hemorrhage, or if fibrinogen-deficient patients require surgery (see p. 1347). High volume and repeated doses of FFP may be needed (10-15 mL/kg IV q 8-12 h).
- Heparin (either unfractionated or low-molecular-weight heparin) should be considered in cases with signs of dyspnea due to PTE or organ failure due to thrombosis.
  - “Regular” unfractionated heparin (UFH): 100-200 U/kg SQ q 8 h, or 15-25 U/kg/h IV continuous rate infusion
  - Low-molecular-weight heparin: dalteparin (Fragmin), 100 IU/kg SQ q 12 h; or enoxaparin (Lovenox), 1-1.5 mg/kg SQ q 12 h.

CHRONIC TREATMENT

DIC is always a sequela, and chronic treatment should be directed toward the primary condition.

DRUG INTERACTIONS

Avoid heparin, hetastarch, and dextrans when prolonged clotting times due to severe factor and fibrinogen depletion or severe thrombocytopenia are present.

POSSIBLE COMPLICATIONS

- PTE
- Thromboembolism to other organs (e.g., renal, brain, hindlimb, hepatoportal)
- Hemorrhage into other organs, leading to organ dysfunction

RECOMMENDED MONITORING

- Serial platelet counts and coagulation times
- Monitor organ function and tissue oxygenation.
- If heparin treatment: closely monitor to detect signs of hemorrhage, falling platelet count, or excessive prolongation of in vitro clotting time (UFH therapy).
- A target prolongation of APTT to 1.5 to 2 times patient baseline is considered evidence of UFH high-dose anticoagulant effect.
- UFH and low-molecular-weight heparins can be monitored based on their inhibition of Factor Xa. In human studies, the target range of anti-Xa activity for UFH = 0.3-0.7 U/mL (UFH) and for low-molecular-weight heparin = 0.5-1 U/mL.

PROGNOSIS AND OUTCOME

- Guarded because diagnosis is often reached late (inadequate suspicion), syndrome is challenging to treat (both thromboembolic and hemorrhagic phases exist), and a primary disorder is concurrent. Prognosis depends primarily on the underlying condition and the extent of thromboembolic/hemorrhagic sequelae if any.

PEARLS & CONSIDERATIONS

COMMENTS

- The development of DIC contributes to the morbidity and mortality of the primary disease.
- Treating DIC becomes less rewarding late in the disease process.
- Having an early suspicion that DIC may develop is important for selecting appropriate tests to document and monitor the syndrome.

PREVENTION

The critical factors in preventing or ameliorating DIC are specific and aggressive correction of the primary disease process.

CLIENT EDUCATION

Development of DIC represents a severe complication of many different systemic diseases.

1ST EDITION COAUTHOR: MARJORY B. BROOKS

Disorientation/Confusion

BASIC INFORMATION

DEFINITION

An inappropriate state of confusion with respect to time and/or place and/or identity

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats, any age or gender

GENETICS AND BREED PREDISPOSITION

- Cats and dogs that are predisposed (brachycephalic and dome-headed breeds) to congenital hydrocephalus may be disoriented and confused.
- Inherited inborn errors of metabolism (e.g., various lysosomal storage diseases)
- Breeds predisposed to various diseases resulting in metabolic derangements (e.g., portosystemic shunts resulting in hepatic encephalopathy)
- Breeds of animals predisposed to epilepsy (i.e., disorientation/confusion during the postictal period)

RISK FACTORS

- Old age: canine and feline cognitive dysfunction syndrome (see p. 225)
- Access to psychoactive drugs or potentially neurotoxic substances
- Preexisting liver or kidney disease, diabetes mellitus, hypothyroidism, or other diseases causing osmotic, electrolyte, and/or acid-base disturbances

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- External trauma
- Ingestion of toxic substance with central nervous system effects
- Barring history or suggestion of observed trauma or intoxication, owners may describe any combination of the following signs:
  - Not responding to being called by name
  - Wandering aimlessly
  - Behaving unaware or “forgetful” of surroundings or of owner/family members
  - Urinating or defecating in inappropriate places
  - Not behaving in anticipatory manner with regard to daily routines (e.g., not being excited to being fed at usual time)
- Clear, concise description of primarycomplaint and ask questions pertaining to:
  - Vision or hearing changes
  - Potential access to toxins or psycho-tropic drugs
  - Signs associated with metabolic disturbances (e.g., alterations in thirst, appetite, gastrointestinal/urologic behaviors)
  - History of recent trauma
  - History of seizures (animals can be disoriented during the postictal period).

PHYSICAL EXAM FINDINGS

- Physical examination findings depend on the etiology (see specific diseases).
- For accurate treatment and prognosis, it is important to identify whether the cause of the disorientation is of:
  - Primary brain origin (e.g., canine or feline cognitive dysfunction syndrome, congenital hydrocephalus, brain neoplasia)
  - Secondary to some other cause (e.g., trauma, various metabolic encephalopathies, various toxicities)
  - Resulting from visual impairment: may note mydriasis in normal ambient lighting (see p. 141)
  - Resulting from hearing impairment
  - Benign behavioral origin

ETIOLOGY AND PATHOPHYSIOLOGY

- Disorientation can result when a disease affects the cerebrum.
- Exact pathophysiologic explanation of altered frontal and temporal lobe function varies with each disease but may include:
  - Alterations in neuronal metabolism (e.g., hypoglycemia, hypothyroidism, hypocalcemia)
  - Accumulation of neurotoxic substances (e.g., hepatic encephalopathy)
  - Chronic oxidative stress in the brain, leading to neurodegeneration (e.g., canine and feline cognitive dysfunction syndrome)
  - Alterations in brain neurotransmitters (e.g., hepatic encephalopathy, epilepsy)
  - Alterations in neuronal excitability (e.g., electrolyte disturbances)
  - Direct mechanical damage (head trauma)
- Animals can become disoriented despite normal cerebral function when they are blind and/or deaf (see pp.141 and 280).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The history and physical exam provide essential clues to investigate this nonspecific chief complaint. A neurologic examination is indicated in all cases, as are routine laboratory tests to investigate metabolic causes.

DIFFERENTIAL DIAGNOSIS

- See Etiology and Pathophysiology above for differentiation of specific inciting causes.
- Differential diagnosis for disorientation:
  - Stereotypic behavior
  - Complex partial seizure
  - Absence seizure

INITIAL DATABASE

- Age of onset
- Complete neurologic examination (see p. 1311)
- Complete ophthalmic examination (see p. 1313)
- CBC, serum biochemistry, urinalysis (1) to determine any underlying systemic condition and (2) as preanesthetic workup (if needed).
- NOTE: Diagnosis of age-related cognitive dysfunction is a diagnosis of exclusion in elderly patients; therefore, one should first consider other diseases resulting in disorientation.

ADVANCED OR CONFIRMATORY TESTING

- Brainstem auditory evoked response testing; rule out deafness.
- Scotopic and photopic maze testing/obstacle course: vision
- Electroretinogram: retinal function
- CT or MRI of brain
- Cerebrospinal fluid cytologic with biochemical ± serologic assessment
- Clinical laboratory diagnostic tests for various endocrinopathies, for liver function, toxicology screen, etc.

TREATMENT

TREATMENT OVERVIEW

Treat the underlying cause of disorientation when possible.

ACUTE GENERAL TREATMENT

Acute treatment varies according to the etiology (see specific etiology).

CHRONIC TREATMENT

Animals with incurable disorientation (e.g., age-related cognitive dysfunction) may need special care including:

- Being confined within a yard or home (e.g., to prevent wandering away and getting lost)
- Taking animal outside to urinate/defecate more frequently (dogs, if dog is inappropriately urinating/defecating in the house)

PROGNOSIS AND OUTCOME

Prognosis depends on the etiology.

PEARLS & CONSIDERATIONS

COMMENTS

- Up to 75% of dogs 7 years or older will demonstrate at least one clinical sign consistent with canine cognitive dysfunction syndrome.
- Animals with clinical signs of disorientation related to vision or hearing loss will commonly adapt to their surroundings and have a good quality of life, provided they are not used for tasks requiring these senses and if their home environment does not change drastically (e.g., moving furniture in new places frequently).

AUTHOR: AUBREY A. WEBB

EDITOR: ETIENNE CÔTÉ

Diskospondylitis

BASIC INFORMATION

DEFINITION

An inflammation/infection of the intervertebral disk and the adjacent end plates and vertebral bodies. Bacterial cause (usually *Staphylococcus*) is most common; occasionally, it is due to the fungal organism *Aspergillus*.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Most commonly seen in medium- to giant-breed male dogs (males outnumber females 2:1).
- Any age dog can be affected, but one large retrospective study found that older dogs were overrepresented, with the highest risk for dogs >10 years of age.
- Purebred dogs may be predisposed, especially Great Danes.
- Has also been seen in small-breed dogs as well as in cats.

GENETICS & BREED PREDISPOSITION

German shepherds are overrepresented for fungal diskospondylitis.

CONTAGION & ZOONOSIS

Diskospondylitis caused by *Brucella canis* carries the possibility of zoonosis.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Variable clinical presentation
- Most dogs show progressive clinical signs over several weeks, but some dogs develop clinical signs acutely.
- Clinical signs are often nonspecific (fever, anorexia, weight loss, lethargy, depression) but usually include spinal hyperpathia.

PHYSICAL EXAM FINDINGS

- General physical and neurologic examination findings (see p. 1311) vary depending on the location, severity, and secondary effects of the infection.
- Patients examined early in the course of the disease often show only signs of spinal hyperpathia without paraparesis.
- Later, patients may have more severe spinal hyperpathia with varying degrees of paraparesis.
- Occasionally, patients present with an acute onset of back pain with associated ambulatory or nonambulatory paraparesis/paraplegia.

ETIOLOGY AND PATHOPHYSIOLOGY

- Some dogs that develop diskospondylitis may have underlying immune compromise.
- Infectious organisms may gain access to the disk space and vertebrae via several mechanisms.
    - Hematogenous spread of bacteria or fungi: the most common mechanism, although the primary source of infection is not always found.
        - The urinary tract is the most likely source of infection.
        - Other sources, although rare, are bacterial endocarditis and dental disease.
    - Foreign-body migration: most commonly a grass awn. Plant materials have barbed ends that allow them to migrate through tissues (via inhalation and migration through the lungs or diaphragm, ingestion and subsequent penetration through the bowel wall, or transcutaneous penetration), carrying bacteria to the disk space.
    - Iatrogenic: infection may develop after spinal surgery or paravertebral injection.
    - Bacterial organisms that are involved are usually coagulase-positive *Staphylococcus* organisms *(S. pseud-intermedius*, *S. aureus.)* Other bacterial pathogens include *Streptococcus* species, *Brucella canis*, and *Escherichia coli*. Less frequently isolated bacteria are *Pasteurella*, *Proteus*, *Corynebacterium*, *Actinomyces*, *Nocardia*,

Bacteroides, and *Mycobacterium* species.
- Fungal organisms include *Aspergillus* and *Paecilomyces* species.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Radiographs are the most useful diagnostic tool. Changes first appear 2-4 weeks after the onset of clinical signs.

DIFFERENTIAL DIAGNOSIS

Radiographically, diskospondylitis must be distinguished from spondylosis deformans and spinal neoplasia:

- Spondylosis and sclerosis are common both in spondylosis deformans and diskospondylitis, but vertebral endplate lysis is seen only in diskospondylitis.
- Typically, in spinal neoplasia the lytic lesion is confined to a single vertebra, whereas in diskospondylitis, the lysis is associated with adjacent vertebrae.

INITIAL DATABASE

- CBC, serum biochemistry panel: typically unremarkable
  - Leukocytosis may be seen if there are concurrent systemic abnormalities (e.g., pyometra, prostatic abscess, endocarditis).
- Urinalysis reveals bacterial cystitis in up to 40% of cases.
  - The same organism is occasionally identified in both urine and blood cultures.
- Blood cultures should be obtained whenever possible.
- Cerebrospinal fluid is typically normal.
- *Brucella* titers may be positive. Because of the zoonotic potential, this titer should be performed in all sexually intact patients suspected of having diskospondylitis.
- Radiographs are the most useful diagnostic tool. Changes first appear 2-4 weeks after the onset of clinical signs.
  - Collapse of the disk space
  - Proliferative bony changes adjacent to the intervertebral disk space
  - Sclerosis at the bony margins
  - The first radiographic signs are usually a collapsed intervertebral disk space, with or without subtle vertebral endplate erosion.
  - With more chronic infections, the bone becomes more sclerotic, and ventral spur formation occurs. This is often accompanied by marked osteolysis and inflammatory new bone formation.
  - Multiple sites of involvement are found in approximately 40% of cases.
  - The most common site for diskospondylitis is L7/S1.

ADVANCED OR CONFIRMATORY TESTING

- The most sensitive procedure for identifying infectious organisms associated with diskospondylitis is culture of surgically obtained tissue. Samples can be taken at the time of surgery (if indicated for decompression), but otherwise it is an invasive diagnostic tool.
- Fluoroscopically guided percutaneous disk aspiration has been shown to be useful in obtaining a positive culture in approximately 75% of cases.
- Myelography and MRI are useful tools to identify spinal cord compression. The vertebral endplates often demonstrate strong contrast enhancement with MRI.

TREATMENT

TREATMENT OVERVIEW

Successful treatment of diskospondylitis depends on long-term antibiotic therapy.

ACUTE AND CHRONIC TREATMENT

- When a specific causative agent is not identified, empirical treatment with antibiotics is warranted. The most common causative bacteria are coagulase-positive *Staphylococcus* spp., which are generally sensitive to first-generation

cephalosporins or β-lactamase-resistant penicillins.

- Antibiotic treatment usually results in improvement of spinal hyperesthesia within 4-5 days. If there is no improvement within 7-10 days of starting antibiotics, the case should be reevaluated (if not already done, consider blood or urine culture, fungal titers, aspiration of the lesion, etc.).
- Antibiotic therapy should be continued for at least 6 weeks after clinical and radiographic improvement is seen. Specifically, antibiotic therapy should be continued until there is no additional or persistent bony lysis, which is considered a radiographic sign of progression of the disease. In most cases, antibiotic therapy is prolonged and may easily be required for a year from onset of therapy.
- With positive *Brucella* test results, options include antibiotic treatment, with strict control of exposure to other dogs, or euthanasia (see Brucellosis, Dog, p. 162).
- Limited success is seen using itraconazole in fungal diskospondylitis.
- Surgical treatment: based on imaging studies and clinical signs (e.g., vertebral instability or spinal cord compression associated with neurologic deficits); spinal cord decompression via a dorsal or hemilaminectomy may be indicated.

Organisms That Cause Diskospondylitis and Recommended Antibiotics (Pending Culture and Sensitivity)

Organism	Antibiotic	Dosage
Staphylococcus species	Cephalexin	22 mg/kg PO q 8 h
	Amoxicillin-clavulanate	13.75 mg/kg PO q 12 h
Streptococcus species	Amoxicillin	22 mg/kg PO q 12 h
Brucella canis	Enrofloxacin	5 mg/kg PO q 12 h
	Doxycycline	25 mg/kg PO q 12 h
Escherichia coli	Enrofloxacin	5 mg/kg PO q 12 h (dog)
	Cephalexin	22 mg/kg PO q 12 h
	Amoxicillin-clavulanate	13.75 mg/kg PO q 12 h
Actinomyces species	Penicillin G	100,000 U/kg IM, SC q 6 h
Aspergillus species	Itraconazole	5 mg/kg PO q 12 h

BEHAVIOR/EXERCISE

Exercise restriction is recommended for these patients to keep them comfortable and lessen the risk of trauma to the spine.

RECOMMENDED MONITORING

- In addition to clinical signs, radiographs should be monitored during the healing phase.
  - The radiographic signs of healing diskospondylitis lesions are disappearance of the lytic focus and its replacement by bridging or fusion of involved vertebrae.
- In young dogs (<1 year), radiographic improvement parallels clinical improvement and includes minimal additional bony lysis along with increased sclerosis and bridging.
- In older dogs, there is a lag of 3-9 weeks between the time of clinical improvement and the appearance of radiographic characteristics of recovery.
  - During the lag period, radiographic findings are consistent with progression of disease, showing increased bony lysis without additional sclerosis or bridging. The bony lysis is likely secondary to bone being resorbed at the site of the lesion before new bone formation can occur.

PROGNOSIS AND OUTCOME

- The prognosis is variable and depends mainly on the severity of neurologic deficits and the causative agent.
  - Patients with only spinal hyperpathia and no neurologic deficits have an excellent prognosis.
  - As the severity of the neurologic signs worsens, so does the prognosis.
- Prognosis is also based on response to treatment and is less favorable when the animal does not respond to medical management. In such cases, a different antibiotic may be considered or a disk/bone culture can be performed to rule out fungal disease and identify an organism.
- Fungal diskospondylitis carries a grave prognosis.

- Patients who require surgery carry a guarded prognosis that worsens with the degree of spinal instability.

PEARLS & CONSIDERATIONS

COMMENTS

Approximately 56% of dogs with diskospondylitis have associated spinal cord compression. In the majority of these dogs (76%), the compression is caused by soft tissue (i.e., proliferation of the annulus secondary to instability, steatitis) rather than subluxation (20%).

Discolored Urine

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Urine that is any other color besides yellow or amber; most often caused by the presence of blood, hemoglobin, myoglobin, or bilirubin

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dependent on underlying cause

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Owner may note discolored urine with no other clinical signs.
- Signs may relate to primary cause. For example:
  - Pollakiuria, dysuria, stranguria associated with lower urinary tract disease
  - Weakness, collapse, pallor associated with severe hemolysis
  - Weakness or pain associated with severe muscle damage

PHYSICAL EXAM FINDINGS

- Lower urinary tract disease:
  - Vaginal disease (infection, inflammation, mass)
    - Vaginal discharge
    - Vaginal mass
    - Vulvar abnormalities
  - Prostatomegaly
  - Thickened, abnormal urethra
  - Distended bladder
- Hemolysis:
  - Pallor
  - Tachycardia
  - Weakness, collapse
  - Splenomegaly
- Muscle damage:
  - Weakness
  - Signs of pain
  - Signs of blunt trauma or prolonged recumbency
- Icterus:
  - Yellow mucous membranes, sclera, skin

ETIOLOGY AND PATHOPHYSIOLOGY

- Yellow, dark yellow
  - Normal
- Red, pink, red/brown, orange
  - Hematuria
  - Hemoglobinuria
  - Myoglobinuria
- Orange/yellow
  - Very concentrated normal urine
  - Excess urobilin
  - Bilirubin

- Yellow/brown, green/brown
  - Bile pigments
- Brown to black
  - Methemoglobin
  - Myoglobin
  - Bile pigments
- Colorless
  - Very dilute urine

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A comprehensive urinalysis is the most important step to help determine the source of discolored urine. Evaluation of urine color as compared to serum color also helps narrow the differential diagnosis list.

DIFFERENTIAL DIAGNOSIS

- Dark yellow/orange
  - Normal
  - Prehepatic icterus (extravascular hemolytic anemia)
  - Hepatic icterus:
    - Dogs/cats: hepatic neoplasia, toxin-induced hepatopathy
    - Dogs: idiopathic or breed-associated hepatitis
    - Cats: hepatic lipidosis, cholangitis/cholangiohepatitis
  - Posthepatic icterus (biliary disease, pancreatic disease, duodenal disease)
- Red, pink, red/brown, orange
  - Urinary tract infection
  - Idiopathic cystitis/feline lower urinary tract signs (FLUTS [cats])
  - Urolithiasis
  - Urethritis
  - Prostatitis, prostatic neoplasia
  - Vaginitis
  - Intravascular hemolytic anemia
  - Hemoglobin transfusion
  - Neoplasia (e.g., transitional cell carcinoma, renal carcinoma, others)
  - Coagulopathy
  - Trauma
  - Estrus
- Brown to black
  - Trauma
  - Heinz body hemolysis-inducing toxins:
    - Zinc
    - Copper
    - Onions, garlic, broccoli
    - Drugs (acetaminophen, methylene blue)
- Colorless
  - Normal
  - Fluid therapy/overhydration
  - See Polyuria/Polydipsia, 902:
    - Diabetes mellitus
    - Diabetes insipidus
    - Diuretics
    - Hepatic diseases
    - Hyperthyroidism
    - Hypoadrenocorticism
    - Hypokalemia
    - Pyometra
    - Renal failure
    - Glucocorticoid excess (hyperadrenocorticism, iatrogenic)
    - Psychogenic polydipsia

INITIAL DATABASE

- CBC
  - Anemia
- Serum biochemistry profile
  - Metabolic diseases (see Polyuria/Polydipsia above)
  - Evaluate color of serum:
    - Clear: consider myoglobin.
    - Pink: hemolysis
    - Yellow: icterus
- Urinalysis
  - Comparing free-catch to cystocentesis sample often aids in localization:
    - Discoloration of urine in both samples suggests a systemic, renal, ureteral, or urinary bladder disorder.
    - Discoloration of free-catch urine but normal-color cystocentesis urine suggests a urethral, uterine, prostatic, testicular, preputial, vulvar, or vaginal problem.
    - Discoloration of cystocentesis urine with a normal-color free-catch sample suggests erroneous switching of the samples or other error.
  - Hematuria:
    - Cystitis
    - Urolithiasis
    - Urethritis
    - Neoplasia
    - Prostatitis/prostatic abscess
    - Prostatic neoplasia
    - Bladder neoplasia
    - Trauma
    - Estrus
    - Idiopathic renal hematuria
  - Pyuria:
    - Cystitis, pyelonephritis
    - Inflammation, sterile (idiopathic cystitis/FLUTS)
    - Neoplasia
  - Hemoglobinuria: hemolysis
  - Myoglobinuria: muscle damage
- Urine culture and sensitivity
- Abdominal radiographs
  - Calculi
  - Mass effect
  - Prostatomegaly
  - Metal in gastrointestinal tract (e.g., zinc)
  - Enlargement/mineralization of sublumbar lymph nodes, suggesting prostatic or urinary bladder neoplasia
- Abdominal ultrasound
  - Renal disease (pyelonephritis, mass, diffuse infiltration, other)
  - Bladder wall tumor (transitional cell carcinoma, other)
  - Prostatic disease
  - Urolithiasis
  - Sublumbar lymphadenopathy
  - Other neoplasia/abnormality contributing to hemolysis
- Sedated vaginal examination
  - Mass
  - Inflammation/infection
  - Conformational abnormality

ADVANCED OR CONFIRMATORY TESTING

As dictated by findings for the individual case:

- Laboratory testing
  - Vaginal smear
  - Urine protein/creatinine ratio
  - Ejaculate examination
  - Fine-needle aspirate
- Imaging
  - Excretory urogram
  - Double contrast cystogram
  - Contrast vaginogram
- Biopsy

- Cystoscopy
- Exploratory laparotomy (virtually always replaced by less invasive means unless laparotomy is also therapeutic [e.g., urolith removal])

TREATMENT

TREATMENT OVERVIEW

- Correct underlying cause based on accurate diagnosis.
- Most life-threatening situations evaluated/addressed first

PROGNOSIS AND OUTCOME

Varies based on underlying cause

PEARLS & CONSIDERATIONS

- Physical examination and minimum laboratory work (CBC, serum biochemistry profile, urinalysis) essential to help quickly narrow the differential list.
- Comparison of urine color to plasma color and free-catch versus cystocentesis urine samples are simple but vital steps for narrowing the differential diagnosis list.
- Basic imaging (abdominal radiographs and ultrasound) can rule in or rule out many common causes of discolored urine.
- Color is not an indication of urine concentration; urinalysis with specific gravity is indicated for differentiation from pathologic conditions.
- Bilirubin conjugation and excretion is normal in the dog but not the cat; therefore trace or mild bilirubinuria in dogs may be normal and is not necessarily indicative of hepatobiliary or hemolytic disease.

TECHNICIAN TIPS

- Note color of urine before and after centrifugation.
- If red urine clears after centrifugation, the problem is hematuria. Hemoglobin and myoglobin stay in suspension, so urine color will not change with centrifugation.

Disaster Working Dog Management and Health

BASIC INFORMATION

DEFINITION

Working dogs are highly trained for a specific task or tasks by an individual or organization for the purpose of assistance in a disaster, emergency, or disaster prevention. The nature of their work exposes them to environmental and physical risks less commonly encountered by pet dogs.

SYNONYMS

Accelerant-detection dog, bomb sniffer, drug-detection dog, search and rescue dog (Urban Search and Rescue [USAR]), cadaver dog, dual-purpose dog (does patrol and some type of detection work), explosives-detection dog, military working dog (MWD), patrol dog, guard dog

EPIDEMIOLOGY

SPECIES, AGE, SEX

Primarily young adult male dogs (2-8 years old)

GENETICS & BREED PREDISPOSITION

German shepherd, Labrador retriever, Belgian malinois, other breeds or crossbreeds

RISK FACTORS

- Physical safety of working and training environment, risk of exposure, environmental conditions
- Specific risk factors include long hours; stressful environment; oral, dermal, and respiratory exposure to toxins; hazardous footing; work low to the ground and in inaccessible areas, risking exposure to pockets of toxins/gases not apparent to handlers.
- Weapons of mass destruction, chemicals (chemical agent or toxic industrial chemical), biologics, nuclear and radiologics, incendiaries and explosives

CONTAGION & ZOONOSIS

- Agents of bioterrorism, foreign animal diseases, biological weapons of mass destruction
- Infectious agents: *Leptospira,* rabies, other endemic infectious agents (tickborne, geologically specific agents, others), ectoparasites and endoparasites

GEOGRAPHY AND SEASONALITY

Consider effects of weather conditions, especially temperature extremes, on working dogs. Consider geographic location and local environmental conditions such as dust, mold, sand, floodwater, toxic plants, and the like as inhaled, ocular, dermal, or ingestion risks.

ASSOCIATED CONDITIONS & DISORDERS

Nutritional (dehydration, diet change, or anorexia when working), stress related (gastric dilatation/volvulus, anorexia/adipsia, “burnout”)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Environmental concerns, foot problems, trauma, explosives, toxins, lacrimators, pharmaceuticals and illicit drugs, weapons of mass destruction (biological, chemical, radiologic)

HISTORY, CHIEF COMPLAINT

- Known exposure
- Inability to work or perform task
- General signs of illness that may include vocalizing, hypersalivation, lameness, ocular signs, nasal discharge, sneezing, diarrhea, vomiting, poor or no appetite, manifestations of anaphylaxis, ataxia, depression, hyperactivity, cough, weakness, petechiae, hemorrhage, collapse, central nervous system depression, collapse, muscle tremors, polyuria/polydipsia, seizure, coma

PHYSICAL EXAM FINDINGS

- Variable, based on exact disorder
- Most commonly, abnormalities include dehydration, heat or cold stress, exhaustion, and foot disorders.
- Signs of toxin exposure may include coughing, choking or gasping for air; red eyes and gums, tearing, salivation; miotic or mydriatic pupils; nausea, ptyalism, emesis or diarrhea (+/- hemorrhagic), fatigue; disorientation, muscle twitching, seizures, paralysis, involuntary urination or defection.
- May be none initially (chronic, organ involvement, carcinogenic)

ETIOLOGY AND PATHOPHYSIOLOGY

- Environmental: dehydration, heat stroke, hypothermia, inadequate nutrition, inadequate conditioning, drowning, choking, plant toxins, moldy food (tremorgenic mycotoxins), zootoxins
- Foot problems: laceration, abrasion, torn nail(s), contact dermatitis
- Trauma: fracture, laceration, abrasion, projectiles, blunt trauma, crushing injury, sprain, strain
- Explosives: cyclonite (C-4); 2,4,6-trinitrotoluene (TNT); pentaerythritol tetranitrate, dynamite (nitroglycerin + stabilizing agent), nitrates, smokeless powders, chlorates, nitromethane, triacetone triperoxide
- Toxins: ethylene glycol; rodenticides; herbicides; insecticides; toxic agents released at disaster site (gas, smoke, particulates, liquids, solids) such as hydrocarbons, polychlorinated biphenyls, hazardous metals, asbestos, gases (hydrogen cyanide, hydrogen sulfide, Freon, halogenated gases, carbon monoxide), soaps/detergents/acids/alkalis, propylene glycol, phenol, alcohols
- Lacrimators: oleoresin capsicum (pepper spray), *o*-chlorobenzylidene malononitrile, 1-chloroacetophenone (mace), dibenzoxazepine
- Illicit/legal drugs/supplements: marijuana, cocaine, amphetamines, opiates, phencyclidine, prescription medications, over-the-counter medications; herbal preparations and supplements
- Routes of exposure: dermal, inhalation, ocular, or ingestion. Swallowing of inhaled large-particulate (2-5 mcg) material moved to the oropharynx by mucociliary apparatus.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of disaster working dog health or management problems is based upon the handler's chief complaint, the signs exhibited by the dog, and the possible or known risk factors in the working environment.

DIFFERENTIAL DIAGNOSIS

Varies with presentation, history, and physical exam findings

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis: common abnormalities include evidence of renal failure (azotemia + isosthenuria) from toxins, evidence of hepatopathy from trauma, thrombocytopenia and coagulopathy from heat stroke, calcium oxalate monohydrate crystalluria with ethylene glycol toxicosis, cylindruria (urinary casts) with renal trauma/toxin/heat stroke.
- Lactate level for dogs presenting in shock, acute abdomen, or circulatory compromise
- Arterial blood gas and/or pulse oximetry
    - Oxygen saturation (SpO_2) low with near-drowning, noncardiogenic pulmonary edema (shock, seizure, trauma)
    - Note for carbon monoxide poisoning (combustion of gasoline, fire/smoke): pulse oximetry cannot evaluate the true severity of hypoxemia because of its inability to differentiate between oxygenated hemoglobin and carboxyhemoglobin.
- Arterial blood pressure: for diagnosis and monitoring of hypotension in hypovolemic shock, or identification of hypertension with some intoxications
- Electrocardiogram: sinus tachycardia with some intoxications; ventricular arrhythmias with hypoxemia, myocarditis, ischemic events, heat stroke
- Radiographs as appropriate for trauma, respiratory signs, neurologic signs, gastrointestinal signs

- Ultrasound for suspected cardiac or pulmonary signs or gastrointestinal disorders

ADVANCED OR CONFIRMATORY TESTING

- Ethylene glycol test, coagulation profiles, infectious disease titers, cultures
- Specific diagnostic tests exist, but availability varies. Tests available include heavy metals, cholinesterase, polychlorinated biphenyl (PCBs), carboxyhemoglobin (CO poisoning), anticoagulants, pharmaceutical and illicit drugs, mycotoxins.
- Obtain and store preexposure blood.
- Necropsy for unexplained death, and consider for any working dog.

TREATMENT

TREATMENT OVERVIEW

- Treatment consists of appropriate therapy for the signs presented in the field and referral to veterinary hospital as appropriate and as available (on-site veterinary team, local practitioner or 24-hour emergency and/or specialty hospital). Therapeutic goals are to stabilize the patient, decontamination if necessary, decrease ongoing exposure and absorption, and the institution of appropriate supportive care.

ACUTE GENERAL TREATMENT

- Stabilize the patient:
  - General emergency medicine and stabilization of vital signs and specific derangements with appropriate cardiovascular and respiratory support
  - Control hemorrhage, shock.
  - Control dyspnea, oxygen therapy, move to fresh air.
  - Control seizures, tremors.
  - Control pain.
- Decrease ongoing exposure and absorption:
  - Induce vomiting, gastric lavage (exceptions include corrosive agents, hydrocarbons, PCBs, soaps and detergents [cationic agents], acids and alkalis, phenol).
  - Administer water or milk orally for dilution (useful for corrosive agents, soaps, detergents, acids and alkalis, explosives [C-4, nitrates, nitromethane]).
  - Activated charcoal ± saline cathartic or sorbitol for noncorrosive agents (minimally effective for some heavy metals or short-chain solvents, hydrocarbons, soaps and detergents, acids and alkalis, ethylene glycol)
  - Gastrointestinal protectants
  - Decontamination:
    - Using copious amounts of water and liquid dish detergent (rinse, wash, rinse—cycle 3 times); ocular and nasal flushing using water or saline (consider teaching working canine to sneeze when young); washing, brushing or clipping hair in feet if buildup of debris or concrete dust. Clip affected haired areas to facilitate removal. Body temperature of the patient must be monitored to avoid hypothermia.
    - Human Safety and Personal Protective Equipment (PPE): basic guidelines include gloves, protective eyewear and footwear, respiratory protection (i.e., N-96 particulate respirators), and durable clothing. Training ahead of time and continual monitoring and assessment of safety risks to modify the PPE as appropriate are paramount for human and canine safety.
    - Powders: use care brushing, as it may aerosolize; wipe only.
    - CAUTION: some hazardous materials become reactive when exposed to water. Alternate decontamination methods may include application of baking powder or flour then physical removal by wiping, brushing, or combing.
    - Caked on contamination: may need to try to scrape off or break down with mineral oil (for petroleum-based products) or mechanics' handwashing products.
    - Eye ointments: avoid, as they may absorb contaminant and worsen corneal damage.
    - Bleach: 0.5% hypochlorite rinse followed by routine soap-and-water decontamination protocol for blister agents (vesicants) or flood water exposure
    - Phenol exposure: (human PPE is a MUST). Use paper/disposable towels to blot fur and skin prior to washing.
    - Eye flush: 15 minutes required for exposure to blister agents, blood, or metabolic agents (0.9% saline or tepid clean water)
- Supportive care:
  - Fluid therapy: diuresis to help promote removal of agents that are primarily excreted renally and to address shock, dehydration, and metabolic derangements.
  - Treat dehydration, hypothermia/hyperthermia, stress colitis, hemorrhagic gastroenteritis, and hemorrhagic cystitis. Recognize metabolic differences between human and canine sensitivity to contaminants (can be more, the same, or

less). Sensitivity is also dependent upon such factors as health, conditioning, age, and concentration and length of exposure to contaminants. Treat appropriately based upon the patient's signs, test results, and response to treatment.

BEHAVIOR/EXERCISE

- Kenneling (housing, husbandry, and/or transportation) influences physical and psychological welfare. Long-term stress can result in poor training and working ability, behavioral and physiologic changes. Caretakers are advised to take positive steps to ensure the highest degree of welfare, with benefits from providing for all the animal needs; should include environmental enrichment (i.e., feeding devices).

CHRONIC TREATMENT

As indicated for specific case

DRUG INTERACTIONS AND CONTRAINDICATIONS

As indicated for individual treatments

POSSIBLE COMPLICATIONS

As indicated for individual case

RECOMMENDED MONITORING

- As indicated:
  - Monitoring may improve mentation and demeanor.
  - Temperature: during decontamination procedures and/or shock, to help prevent hypothermia
  - Hydration, electrolytes, hematocrit/total solids, blood glucose, blood urea nitrogen, urine production and serial urinalyses
  - Pain
- May be lifelong if injury or exposure leads to permanent lesions
- Baseline (yearly or biannually) blood work: CBC, serum biochemistry profile, heartworm antigen test, urinalysis, and thyroid profile. Consider infectious disease screening as appropriate for location: Lyme disease, ehrlichiosis, bartonellosis, leishmaniasis, foreign animal diseases, etc.
- Necropsy is advised for working animals to aid in monitoring and for future health and prevention strategies for other working dogs.

PROGNOSIS AND OUTCOME

Prognosis depends on source, speed of identification of inciting cause, and speed of appropriate decontamination, emergency, and supportive care. Prognosis improves with proper prevention, awareness, and monitoring work site for potential concerns.

PEARLS & CONSIDERATIONS

COMMENTS

- Important resources:
  - Center for Disease Control: www.cdc.gov
  - National Veterinary Response Teams (NVRT), part of the National Disaster Medical System (NDMS), Department of Health and Human Services: www.ndms.dhhs.gov/; www.hhs.gov/emergency/
  - American Veterinary Medical Association: www.avma.org
  - Veterinary Medical Assistance Team: www.VMAT.org
  - American Society for the Prevention of Cruelty to Animals, Animal Poison Control Center: www.ASPCA.org; 1-888-426-4435
  - Material Safety Data Sheet (MSDS)
  - Emergency Response Guidebook (U.S. Department of Transportation): www.labelmaster.com/ERG/
- Most common problems are conjunctival irritation, respiratory tract problems, decreased appetite, dehydration, exhaustion, cuts, and foot/pad disorders.
- Health problems should be treated with the highest standards of veterinary care. Chronic diseases (e.g., allergies, degenerative joint disease, epilepsy, cardiopulmonary disease, gastrointestinal diseases) may benefit from treatment by a specialist and/or by complementary therapies such as acupuncture, massage, physical rehabilitation, supplements, and

nutrition.
- Proper nutrition, housing, welfare, and adequate exercise/training are extremely important for working dogs and can affect behavior, willingness to work, scent-detecting ability, and ability to work long hours. Keep in mind safety of food and water sources.
- Handler physical and mental health must be appropriate to complement the teamwork needed.
- Handling and training should include obedience, crate training, restraint, and muzzling to aid in situations where working dog is injured, contaminated, or needs veterinary care. Also helpful are routine handling of the mouth, feet, brushing, bathing, clipping or shaving, rinsing of eyes, and teaching to sneeze. Positive reinforcement training in these areas could be lifesaving in an emergent situation, especially if the handler is unable to accompany the working dog.
- Person(s) providing treatment should utilize proper PPE, including gloves, eye protection, mask, apron, and so forth. Disasters with mass casualties may include human contamination as potential risk (human immunodeficiency virus, hepatitis, etc.). Dogs may carry infectious-disease agents, endo- or ectoparasites, zoonotic diseases, or topical chemicals.
- Knowledge of chronic medications' effects on work (i.e., prednisone may affect odor detection) and interactions with toxicants (i.e., hydrocarbons and certain medications) is important.

PREVENTION

- Heat Index guidelines are not established but should be considered. Rest and hydration at least every 30-60 minutes. (FEMA guidelines are equal rest time for every 20-45 minutes of work.) Cooling by convection and evaporation as means of heat dissipation (tepid water soak of body; not extremities, not ice [causes peripheral vasoconstriction], not alcohol). Fluids (subcutaneous by site veterinarian) before work in stressful environments are not likely to be beneficial.
- Working dogs should be in top health, conditioning, and have excellent nutrition to work at their best ability and without distraction.
- Ample time for play and rest and recovery from stressful work situations is essential.
- Routine veterinary preventive health care is paramount, with appropriate vaccinations for anticipated infectious diseases.
- Acclimation of dogs to personal protective devices such as goggles and foot protection before field work is important. Masks may not be appropriate, owing to panting and need for olfactory sense.
- Decontamination procedures including bathing and ocular and nasal flushing are particularly important in disaster situations. Dogs should be accustomed to bathing and trained for mass-decontamination procedures; may include muzzle (prevent drinking of decontamination effluent), crate or kennel for decontamination protocol, separation from handler, and handling by people in full PPE (such as level A or B suits).
- Regular cleaning during work of nose, muzzle, and body to prevent licking (including licking the nose, where material may collect on the nasal planum) and ingestion. Baby wipes could be used periodically, flush eyes regularly.
- Knowledge of the type of agent(s) at the scene, and regular reevaluation. Try to keep in well-ventilated area and upwind +/- upgrade area.
- Prevent drinking unknown sources by keeping well hydrated. Consider home water source or bottled water, electrolyte solutions, and/or flavoring of the water, which may encourage drinking.
- Prevent ingestion by using basket-type muzzle.
- Reflective safety vest
- Canine floatation device
- Appropriate holding/traveling area environment: fans/air conditioning or heat, water for cooling and bottled drinking water and/or electrolyte solution, crate, good footing/bedding while traveling or at staging area. Consider vehicle alarm for excessive vehicle temperatures.

TECHNICIAN TIPS

- Working dogs can be aggressive, fearful, or highly stressed! Communication with the handler is essential (if available), and many times their presence and restraint assistance is helpful, even if not routine handling protocol. Safety is critical—your own, the canine, and the safety of other people assisting.
- Working dogs are very often used to being muzzled, and the handlers do not associate this with a stigma as civilian owners may do. Use muzzles often for safety. Request chemical restraint as appropriate.
- PPE: always wear gloves and assume contamination or zoonotic threat (see Acute General Treatment above); decrease ongoing exposure and absorption; focus on decontamination, human safety, and personal protection.
- Training: work in hospital to set up disaster plan, train/volunteer with local and national groups for disaster veterinary medicine (see Client Education below).
- Save samples from working dogs in case needed for further diagnostics (blood, urine, fur, vomitus, feces, food/water, etc). If animal dies, save for necropsy.

CLIENT EDUCATION

- Search out veterinary and disaster assistance in advance: National Veterinary Response Teams (NVRT)—federal resource, Department of Health and Human Services, National Disaster Medical System [NDMS]); Veterinary Medical Assistance Teams (VMAT), part of American Veterinary Medical Association (AVMA); State and County Animal Response Teams; local Veterinary Medical Association and veterinary emergency hospital; Society for the Prevention of Cruelty to Animals (SPCA);

Office of Emergency Preparedness, State and County Emergency Management Resources.

- Employer should have access for handlers to ASPCA—Animal Poison Control Center (1-888-426-4435) with credit card on file or account established. Handlers should have phone number at all times.
- PPE for handler and dog. Keep extra supply of working-dog equipment; may be difficult to decontaminate and need to be discarded.
- Training in first aid procedures and kits: include bandaging and splint materials, sterile saline for flushing eyes and wounds, apomorphine and/or hydrogen peroxide for inducing vomiting, activated charcoal with a cathartic, resuscitator bag and mask (canine oxygen masks available such as for fire department use), stethoscope, thermometer, ophthalmic ointment, booties, moist toilettes, liquid dish soap for decontamination of skin and coat, towels for drying, water supply.
- Knowledge of normal vital signs and physical exam findings
- Canine field cardiopulmonary cerebral resuscitation
- Obtain or locate ample source of safe water for hydration and decontamination. Be sure food is stored safely, and avoid contamination.
- Knowledge of possible risks in animal's line of work: define ahead of time or search out site Safety Officer or official site disaster veterinarian.
- Save vomitus, urine, and/or feces if dog is not acting normally: may be diagnostic. Save sample of material or liquid the animal ingested or drank. (Keep sample bags or sterile plastic sample containers in vehicle or jump-pack.) Save water and food sample.
- Long-term health of disaster working dogs does not appear to be significantly compromised by their work (i.e., response to 9/11 terrorist attacks), although working dogs may have evidence of inhaled matter in pulmonary tissues (presence of anthracotic pigments or refractile particulate material).
- If working dog dies, save body in cool area for necropsy as soon as possible at a veterinary teaching hospital, military pathologist, or as available to the site. (Cooling could include refrigeration unit, ice bags, or wrapping in blankets to prevent deterioration of tissues for analysis.) Do not freeze.

AUTHOR: POLLY A. FLECKENSTEIN

EDITOR: ETIENNE CÔTÉ

Dilated Cardiomyopathy

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A primary myocardial disease characterized by impaired systolic function (pump failure) of one or both ventricles, leading to cardiac enlargement and potentially congestive heart failure, arrhythmias, or both. Diastolic dysfunction may also be observed.

SYNONYMS

Congestive/dilatative cardiomyopathy (obsolete), DCM

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs:
  - Adult-onset disease (4-10 years) except in Portuguese water dogs and toy Manchester terriers (juvenile; weeks/months of age)
  - Male > female
- Cats:
  - 2-20 years (mean, 9.8 ± 4.4 years)
  - Male > female

GENETICS & BREED PREDISPOSITION

- Dogs:
  - Large/giant-breed dogs overrepresented (Doberman pinscher, Irish wolfhound, Great Dane, Scottish deerhound, boxer, Afghan hound, Old English sheepdog, dalmatian).
  - Variety of spaniel breeds (English, American cocker spaniels; others)
  - Irish wolfhounds, Newfoundlands, Doberman pinschers, boxers: autosomal dominant trait. Portuguese water dogs: autosomal recessive trait (suspected).
- Cats: Abyssinian, Burmese, and Siamese overrepresented

RISK FACTORS

- Taurine deficiency in cats (common cause of DCM in cats, mainly before 1987)
- Dalmatians fed a low-protein diet
- Spaniel, retriever breeds: taurine deficiency

GEOGRAPHY AND SEASONALITY

Chagas' disease–associated DCM (southern United States): clinical presentation is indistinguishable from idiopathic dilated cardiomyopathy.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Occult DCM: earliest level. Overtly healthy dog with systolic dysfunction on echocardiography, ventricular arrhythmias, or both.
- Congestive heart failure (CHF)
- Cardiac arrhythmias: atrial fibrillation (especially giant breeds), ventricular arrhythmias (boxers, Doberman pinschers)
- Sudden cardiac death.

HISTORY, CHIEF COMPLAINT

- Occult DCM: by definition, without clinical signs (screening exam or incidental finding)

- CHF: any combination of tachypnea, coughing, restlessness, abdominal distension, lethargy, inappetence, respiratory distress
- Cardiac arrhythmias: syncope, collapse, lethargy, precipitation of CHF

PHYSICAL EXAM FINDINGS

- Some or all of the following are commonly observed: weakness, depression, tachypnea, respiratory distress, weight loss/advanced cachexia, cardiogenic shock due to decreased arterial blood pressure, soft grade 1-3/6 systolic left and/or right apical murmur, S3 or summation gallops, arrhythmia.
  - Right-sided CHF: jugular pulse/distension, muffled heart and ventral lung sounds with pleural effusion, hepatomegaly due to congestion (± ascites)
  - Left-sided CHF: pulmonary crackles/rales, muffled lung sounds with pleural effusion (cats)
- Hypokinetic femoral pulses; pulse deficits with premature beats or atrial fibrillation
- Subcutaneous pitting edema is rare; large/giant breeds almost exclusively.

ETIOLOGY AND PATHOPHYSIOLOGY

- Proposed etiologies for idiopathic DCM include viral infection, nutritional deficiency, immune-mediated, micro-vascular hyperreactivity, and a variety of genetic disorders.
- Deficiency in calstabin-2 implicates this cytoskeletal protein abnormality as a cause of DCM in Dobermans.
- Before clinical signs, onset of myocardial failure leads to reduced cardiac output followed by activation of various neurohormone and cytokine pathways to support blood pressure. This leads to short-term stability but long-term further myocardial damage.
- Very rare cases due to infection (parvoviral, protozoal) or toxicity (doxorubicin, radiation)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is suspected—especially in predisposed breeds—if respiratory distress is noted with a gallop sound and/or systolic murmur over the mitral area and/or with arrhythmias (atrial fibrillation, premature ventricular complexes). Suspicion is heightened if radiographs suggest left atrial enlargement, pulmonary vein enlargement and/or pulmonary edema. The final diagnosis is reached with echocardiography. Diagnosis of occult (clinically inapparent) DCM requires echocardiography, 24-hour ECG recordings, or both. Blood-based markers of heart disease are currently in testing and might have a role in the future with diagnosis or prognosis of DCM.

DIFFERENTIAL DIAGNOSIS

- Clinical:
  - Primary respiratory disease, noncardiogenic pulmonary edema, pleural space disorders (pneumothorax, noncardiogenic effusions), heartworm disease, myxomatous valvular heart disease, infectious endocarditis or myocarditis, cardiac tumors and pericardial effusion, diaphragmatic hernia, pulmonary hemorrhage, airway obstruction (laryngeal paralysis, tumor, foreign body, collapsing trachea), congenital heart disease
- Radiographic:
  - Pericardial effusion, peritoneopericardial diaphragmatic hernia, myxomatous valvular heart disease and other causes of chronic cardiac volume overload (arteriovenous fistula: rare), congenital heart disease, other pleural effusions
- Echocardiographic:
  - Myocardial failure due to advanced or end-stage valvular disease (myxomatous valvular heart disease) or shunts (patent ductus arteriosus, fistulas, septal defects). Subnormal fractional shortening (FS)% may be normal in many healthy individuals; check left ventricle (LV) diameter, E-point to septal separation, or even premature ventricular complexes on ECG/Holter for support of DCM. Less common: myocarditis, ischemic cardiomyopathy, acute systemic hypertension.

INITIAL DATABASE

- Thoracic radiography: generalized cardiomegaly and signs of CHF (left-sided: interstitial or alveolar pulmonary edema [dogs, cats] and/or pleural effusion [cats]), (right-sided: pleural effusion, enlarged caudal vena cava, hepatomegaly, ascites [much more common in dogs]). Occult DCM: often unremarkable (poor screening tool), although left atrial and/or left ventricular enlargement may be noted.
- ECG: sinus tachycardia, possibly with atrial or ventricular premature complexes; atrial fibrillation; ventricular tachycardia, especially in boxers and Doberman pinschers; prolonged and/or increased voltage QRS complexes suggestive of LV enlargement; low-voltage QRS complexes with pleural or pericardial effusion.
- Routine hematologic tests and urinalysis: usually normal. Exceptions:

  - Severe DCM: prerenal azotemia, elevated alanine aminotransferase; hyponatremia and hypochloremia, if noted with CHF, confer a poorer prognosis because they indicate free water retention.
  - Concurrent disease
  - Result of therapy for heart failure (hypokalemia, metabolic alkalosis, prerenal azotemia)
- Effusion analysis: usually modified transudate (nucleated cell count< 2500/mcL, total protein < 4.0 g/dL); chylous effusion possible in cats

ADVANCED OR CONFIRMATORY TESTING

- Echocardiography: ventricular and atrial dilation, reduced myocardial systolic function (reduced left ventricular FS% and ejection fraction), increased E-point septal separation. Doppler studies often confirm mitral and tricuspid regurgitation, low-velocity transaortic flow, diastolic ventricular dysfunction, and possibly pulmonary hypertension (if severe left-sided heart failure).
- Taurine concentrations: deficiency if <40-50 nmol/mL (plasma) or <250 nmol/mL (whole blood). Taurine assays require special handling (green-top tube or myocardium only; frozen)
- Histopathologic study: lesions include absence of inflammation, myocyte loss, attenuated wavy fibers, and increased myocardial fibrosis.

TREATMENT

TREATMENT OVERVIEW

Treatment mainly consists of medications to relieve signs of congestive heart failure, and antiarrhythmics in cases with rapid atrial fibrillation or life-threatening ventricular arrhythmias. Other goals should focus on improved quality of life (e.g., appetite, exercise capacity). Treatment of “occult” (clinically inapparent) DCM remains controversial and may or may not help.

ACUTE GENERAL TREATMENT

In cases of severe cardiogenic pulmonary edema: see Heart Failure, Acute, p. 468 .

- Minimize stress (e.g., keep cats separated from canine patients).
- Oxygen supplementation
- Furosemide: Dogs—2-6 mg/kg IV or IM initial dose, then 1-2 mg/kg q 2-3 h as needed for resolution of pulmonary edema, then q 8-12 h for the first 3 days. Cats—1-4 mg/kg parenterally q 4-12 h as needed; duration of effect around 1-2 hours.
- Thoracocentesis if large-volume pleural effusion (therapeutic, diagnostic). Moderate to severe pleural effusion does not respond rapidly to diuretics, and in acute situations, it should be physically removed via centesis (see p. 1338)
- 2% nitroglycerin paste applied topically: 1” q 8 h (dog); 0.25” q 8 h (cat)
- Life-threatening arrhythmias (see pp. 1165 and)
- Sodium nitroprusside (dogs): effective for treating critical cardiogenic pulmonary edema but requires constant-rate infusion, protection from light, and careful monitoring. Start at 2 mcg/kg/min IV and titrate upward. Mean blood pressure must remain > 70 mm Hg. Maximum = 10 mcg/kg/min.
- Dobutamine (if severe heart failure or cardiogenic shock; ECG monitoring needed):
  - Dogs: start at 2.5-5 mcg/kg/min, titrate upwards q 30-60 min in 2.5 mcg/kg/min IV increments until heart rate increases by > 10% or PVCs develop/become more frequent. Maximum infusion rate 15 mg/kg/min IV.
  - Cats: >2.5 mcg/kg/min not recommended and should be used with extreme caution

CHRONIC TREATMENT

- Thoracocentesis and abdominocentesis as needed
- Diuretics (as needed to control edema):
  - Furosemide: Dogs—1-4 mg/kg PO q 8-24 h. Cats—1-2 mg/kg PO q 8-24 h.
  - For chronic treatment of CHF where fluid retention is refractory to furosemide alone, add:
    - Spironolactone (dogs, cats), 1-2 mg/kg q 12-24 h PO; *and/or*
    - Hydrochlorothiazide (dogs, cats), 2-4 mg/kg q 12 h PO (alternative use: BID q 48 h [q 12 h alternating one day on, one day off] to start, and monitor renal values more closely once adding this diuretic to furosemide)
- ACE inhibitors:
  - Enalapril: dogs, 0.5 mg/kg q 12-24 h PO; cats, 0.5 mg/kg q 24 h PO; *or*
  - Benazepril: dogs, 0.5 mg/kg q 12-24 h PO; cats, 0.25-0.5 mg/kg q 24 h PO; *or*
  - Lisinopril: dogs, 0.5 mg/kg q 24 h PO
- Digoxin: Dogs—0.003 mg/kg q 12 h PO (a dose preferred by author [other publications usually have a higher dose] that usually doesn't yield digoxin toxicosis and results in 70%-75% of dogs reaching therapeutic levels). Cats—0.01 mg/kg or ¼ of a 0.125 mg tablet PO q 48 h.

- Pimobendan: dogs, 0.2-0.3 mg/kg q 12 h PO for heart failure
  - Novel therapy (use after careful consideration of benefits and risks).
- Beta-blockers blunt cardiotoxic effects of sympathetic nervous system; however, heart failure must be well controlled first, and dose begun low and up-titrated slowly (days to weeks) with careful monitoring. Options include:
  - Carvedilol: dogs, up to 0.5 mg/kg q 12 h PO (start with ¼ dose initially)
  - Metoprolol: dogs and cats, up to 1 mg/kg q 8 h PO (start with ¼ dose initially)
  - Atenolol: dogs and cats, up to 1 mg/kg q 12 h PO (start with ¼ to ½ dose initially)
- Arrhythmias
  - In atrial fibrillation, slowing of ventricular response rate in DCM is achieved with digoxin and/or diltiazem (1-1.5 mg/kg PO q 8 h). If necessary, atenolol or carvedilol can be used instead of diltiazem. Use of atenolol or carvedilol in this situation should be done carefully, owing to their pronounced effect on contractility; consultation with a cardiologist might be warranted.
  - Serious ventricular arrhythmias are managed with identification and treatment of underlying causes (e.g., hypoxemia from pulmonary edema); if rapid or causing clinical signs, these must be controlled (see p. 1165).

NUTRITION/DIET

Diet: if CHF has occurred and is now controlled:

- Keep patient eating with adequate level of protein intake.
- Eliminate high-salt snacks.
- Sodium-restricted commercial diets such as Purina CV or Hills H/D (not at the expense of good appetite) or balanced home-cooked low-sodium diets
- Taurine: recommended in all cats (250 mg/cat PO q 12 h) with DCM until demonstrated that patient is unresponsive to taurine; dose in dogs is 500 mg/dog PO q 12 h.
- Omega-3 fatty acids may improve appetite and reduce cachexia (EPA, 30-40 mg/kg q 24 h; DHA, 20-25 mg/kg PO q 24 h).
- Consider L-carnitine (110 mg/kg PO q 12 h) in boxers and American cocker spaniels not responding to taurine.

BEHAVIOR/EXERCISE

- Absolute rest during treatment of CHF or life-threatening arrhythmias
- Once congestive heart failure is resolved, slowly increase activity back to normal; quality of life is important. Ask owner to use common sense (e.g., if patient is tired, take break from activity; if normally fetches the ball 100 times, consider 10 times now).

DRUG INTERACTIONS

- Quinidine, verapamil: will increase serum digoxin level (risk of toxicosis)
- Hypokalemia, hypercalcemia, renal dysfunction, and hypothyroidism predispose to digitalis intoxication (therefore, decrease dose of digoxin).

POSSIBLE COMPLICATIONS

- Sudden death due to arrhythmias (especially uncontrolled ventricular tachycardia)
- Renal insufficiency due to low cardiac output, medical treatment; however, mild to moderate azotemia (without associated clinical signs) is expected with diuretic treatment.
- Iatrogenic complications due to medical treatment (hypokalemia, azotemia, other electrolyte abnormalities)

RECOMMENDED MONITORING

- Monitor 7-10 days after discharge, then as needed (e.g., q 1-4 mon, barring decompensation): physical examination, thoracic radiographs, ECG, serum renal and electrolyte profile.
- Holter/event monitors, echocardiography, other: if significant or unexpected change in patient's condition
- Serum digoxin levels 1 week (dogs) or 2 weeks (cats) after start of therapy (therapeutic range = 0.8-1.8 ng/mL) taken 6-8 hours post pill.
- Renal/electrolyte panel 5-7 days after starting angiotensin-converting enzyme inhibitors
- Repeat echocardiogram in 3-6 months after initiating taurine supplementation to determine response to therapy.

PROGNOSIS AND OUTCOME

- Overall, death usually occurs 3-24 months after diagnosis.
- Paroxysmal ventricular tachycardia and atrial fibrillation are probable markers of shorter survival.
- Plasma cardiac Tn-I > 0.20 ng/mL is suggestive of shorter survival time.

- Prognosis is influenced by treatment, time of diagnosis, and client compliance.
- Prognosis generally worse in Portuguese water dogs and Doberman pinschers than in other breeds, but some Dobermans live months to years after diagnosis.
- Prognosis in Irish wolfhounds with DCM is fair; lifespan virtually unaffected.
- In cats with DCM not due to taurine deficiency, the prognosis is usually grave.

PEARLS & CONSIDERATIONS

COMMENTS

- Most dogs have left atrial enlargement, pulmonary venous enlargement, and perihilar/caudodorsal pulmonary edema if pulmonary infiltrates are cardiogenic, whereas cats usually have atrial enlargement with variable edema location and pulmonary vein enlargement.
- Low echocardiographic LV FS% is not pathognomonic for DCM; many normal hearts contract more in apical-to-basilar direction, and this motion is not accounted for by the FS%.
- Most small-breed dogs more likely to have chronic mitral valve endocardiosis > collapsing trachea > primary respiratory disease > DCM causing similar clinical presentation.
- DCM in cats is rare, hypertrophic cardiomyopathy is common; the opposite is true in dogs.

CLIENT EDUCATION

Monitor for signs associated with progression of disease (coughing [dogs], open-mouth breathing [cats], respiratory changes, lethargy, collapse) and adverse side effects of medications (vomiting, diarrhea, anorexia).

TECHNICIAN TIPS

- Unlike most hospitalized cases, heart failure patients do not need fluids because they are hypervolemic (“drowning in their own fluids”); an exception is low-dose fluids used for delivery of IV heart medications.
- Heart patients generally need to be stress free as possible (e.g., avoid cats mixing with dogs, avoid having inexperienced technician draw blood).
- One of the best and simplest ways to monitor the heart patient is to monitor respiratory rate per minute instead of physically handling these patients.

Digoxin Toxicosis

BASIC INFORMATION

DEFINITION

Clinical signs caused by excessive administration of, or individual intolerance to, normal doses of digoxin

SYNONYMS

Digitalis poisoning, digoxin intoxication. Digoxin and digitalis are used interchangeably; other digitalis derivatives, such as digitoxin, are no longer used clinically.

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats of any age, either sex

GENETICS & BREED PREDISPOSITION

Doberman pinschers appear predisposed.

RISK FACTORS

- Renal failure
- Hypovolemia, dehydration
- Hypokalemia
- Concurrent administration of drugs that increase serum digoxin levels: diazepam, erythromycin, quinidine, tetracycline, verapamil
- Obesity (if digoxin is dosed on total body weight rather than lean body weight)
- Intravenous digoxin
- MDR-1 gene mutant

ASSOCIATED CONDITIONS & DISORDERS

Underlying heart disease prompting digoxin treatment

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Systemic signs
- Cardiac arrhythmias

HISTORY, CHIEF COMPLAINT

- Hallmarks of digoxin toxicosis: lethargy, anorexia, vomiting, and diarrhea, together or individually
- May be intermittent in mild cases
- Severe toxicosis: refractory vomiting, tenesmus, collapse, death
- Except for massive overdoses, digoxin treatment needs to have been underway for >24 hours (and usually weeks) to produce signs of toxicosis.
- Most commonly, patients are receiving digoxin as part of long-term cardiac treatment. Much less commonly, digoxin toxicosis occurs from a pet's consuming plants or human medication.

PHYSICAL EXAM FINDINGS

- Lethargy, dehydration
- Physical findings attributable to underlying heart disease

- Digoxin toxicosis can also produce virtually any cardiac arrhythmia.
  - Bradycardia or tachycardia on examination

ETIOLOGY AND PATHOPHYSIOLOGY

- Digoxin is a cardiac glycoside drug derived from the foxglove plant.
  - It is absorbed slowly (6-8 hours to peak serum concentration with oral tablets in dogs; faster with elixir) and is mainly excreted renally (>60%).
- The half-life is long: 14-56 hours (dogs), 30-173 hours (cats).
- Therefore, when intoxication occurs, it more often is a cumulative process (chronic treatment).
- Acute overdoses are amenable to activated charcoal administration for several hours after ingestion.
- All cardiac glycosides (therapeutic, e.g., digoxin, digitoxin [historic]; or botanical, e.g., foxglove, oleander) act on the sodium/potassium/adenosine triphosphate pump of mammalian cells to increase intracellular Na^{+} and Ca^{2+} concentrations.
- Cardiovascular, neurologic, and gastrointestinal effects are responsible for clinical signs.
- With digoxin toxicosis, systemic clinical signs precede or occur concurrently with cardiac arrhythmias.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is strongly suspected on the basis of medication history and clinical signs. Initial testing offers supportive evidence, but the diagnosis is often established based on resolution of clinical signs when the drug is stopped.

DIFFERENTIAL DIAGNOSIS

- Primary gastrointestinal disease
- Uremia/renal failure
- Cardiac arrhythmias of primary cardiac or systemic origin

INITIAL DATABASE

- Serum biochemistry profile, urinalysis:
  - Evidence of chronic kidney disease or hypokalemia increases likelihood of intoxication.
  - Concurrent treatment with diuretics may cause azotemia and isosthenuria.
  - Generally if azotemia is severe (blood urea nitrogen > 80 mg/dL and creatinine > 3 mg/dL), some degree of reduced renal function is expected, and digoxin elimination is likely reduced, predisposing to toxicosis.
- Electrocardiogram (ECG):
  - First-degree atrioventricular (AV) block (see p. 120): early ECG manifestation of digoxin toxicosis
  - Higher degrees of AV block, premature atrial or ventricular complexes common

ADVANCED OR CONFIRMATORY TESTING

- Serum digoxin concentration: confirmation (retrospective)
  - Therapeutic level: 0.8-2.0 ng/mL
  - >2-3 ng/mL with clinical signs: digoxin toxicosis
  - Turnaround time of test limits immediate usefulness, but some local human hospitals may provide stat service.
- Evaluations of renal/central nervous/gastrointestinal systems: as dictated by clinical signs

TREATMENT

TREATMENT OVERVIEW

- Acute overdoses: prevent digoxin assimilation.
- All cases: reduce serum digoxin concentration.

ACUTE GENERAL TREATMENT

- Acute overdoses (uncommon): activated charcoal and supportive care (see Etiology and Pathophysiology above)
- Toxicosis in dogs receiving normal digoxin doses chronically: the cornerstone of treatment is discontinuation of the drug.
  - Treatment may be restarted 48 hours later at half the dose after signs of toxicosis have resolved.

- Intravenous fluid therapy: judicious if patient has cardiac disease
- Potassium supplementation in hypokalemic patients: essential, since hypokalemia may potentiate arrhythmias
- Ventricular antiarrhythmics if rapid ventricular arrhythmias (see p. 1165)
- Treatment for supraventricular arrhythmias if very rapid (see p. 111).
- Soluble antidigoxin antibodies may be administered in severely ill patients.
    - Number of vials (38 mg each) given slowly IV = serum digoxin level [ng/mL] × body weight (kg)/100
    - For example, 2 vials slow IV, single dose for a 35-lb (16-kg) dog with serum digoxin level 12 ng/mL
    - Very costly ($500 per vial)

RECOMMENDED MONITORING

Monitoring serum concentrations is secondary to monitoring of clinical signs alone.

PROGNOSIS AND OUTCOME

- Dependent on dose, elimination (renal function, hydration), extent of signs, and response to treatment
- Severe digoxin intoxication can be fatal.

PEARLS & CONSIDERATIONS

COMMENTS

- Differentiation between digoxin toxicosis and an unrelated problem (e.g., primary GI disturbance, renal failure, other) may be challenging.
- It is virtually always preferable to assume that digoxin toxicosis exists and discontinue the drug and use other cardiac drugs (e.g., beta-blockers, inotropes) as replacements if necessary while evaluation of the other differential diagnoses takes place; response to discontinuation helps confirm toxicosis retrospectively.

PREVENTION

Early detection of clinical signs of toxicosis by owners, and if signs occur, discontinuation of the drug, monitoring, and supportive care

AUTHOR & EDITOR: ETIENNE CÔTÉ

Dietary Intolerance

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Adverse reactions to an ingested food or food additive due to nonimmunologic mechanisms (common)

SYNONYMS

Adverse reaction to food, food intolerance, lactose intolerance

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats: no age or gender predilection

RISK FACTORS

- Food contaminated with microorganisms or their toxic metabolites
- Specific foods (onions, chocolate)
- Toxic food preservatives (e.g., propylene glycol in cats)
- Preformed vasoactive amines (e.g., histamine) in food such as fish
- Dairy products
- Dietary indiscretion (gluttony, pica, ingestion of indigestible materials)

ASSOCIATED CONDITIONS & DISORDERS

- Dietary hypersensitivity
- Inflammatory bowel disease

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Vomiting, diarrhea, intermittent abdominal pain, abdominal distension, soft feces, excessive flatulence, increased frequency of defecation

PHYSICAL EXAM FINDINGS

Diarrhea (small or large bowel), vomiting, abdominal distension, urticaria, angioedema

ETIOLOGY AND PATHOPHYSIOLOGY

- Food poisoning:
  - Eating foods (e.g., through scavenging, improperly cooked homemade foods, raw diets, contaminated moist or dry commercial foods [e.g., aflatoxin]) that are contaminated with bacteria, fungal toxins, or other toxins that cause an immediate gastrointestinal (GI) response (see p. 434)
- Idiosyncratic adverse reactions to food additives:
  - Examples include food colorings (azo or non-azo dyes), certain preservatives and emulsifying agents, thickeners or stabilizers (e.g., seaweed extracts, seed gums)
  - Occur infrequently and unpredictably in individuals, and are not apparently dose related
  - Histaminergic reactions mediated by type 1 (mast cell mediated) or 2 (receptors for gastric acid release in the stomach) histamine receptors
- Pharmacologic reactions to vasoactive amines (e.g., histamine) found in food
- Carbohydrate intolerance (lactase deficiency):
  - Mediated by lack of carbohydrate digestion (lactose intolerance) due to mucosal disease or lack of enzyme activity —either congenital or acquired

- A true allergic reaction to proteins in milk (e.g., bovine IgG) can mimic carbohydrate intolerance.
- Which of these types of reactions are causing the problem is rarely defined and not clinically relevant.

- Dietary indiscretion:
  - Typically defined as the consumption of unusual or spoiled foods (as can occur with scavenging or raiding the garbage can), the consumption of too much food (gluttony), or pica (eating nonfood substances such as hair, rocks, bones, etc.)
  - The insult occurring in the GI tract varies with the type of indiscretion observed, and thus no consistent clinical presentation is recognized.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Food intolerance is suspected on the basis of acute vomiting and/or diarrhea, often but not always occurring as a result of acute dietary alterations; confirmatory diagnosis is often retrospective, with resolution of clinical signs as a result of proper diet. In contrast to dietary hypersensitivity (food allergy), the response to the change in food is more rapid (few days to 2 weeks) with dietary intolerance. Therefore, if no response occurs during this time frame, the diagnosis of intolerance should be questioned.

DIFFERENTIAL DIAGNOSIS

- Any chronic disorder affecting the GI tract (e.g., hypoadrenocorticism, protein-losing enteropathy, infiltrative disease)
- Inflammatory bowel disease
- GI neoplasia
- Chronic parasitism
- Food hypersensitivity

INITIAL DATABASE

- CBC: nonspecific and usually normal
- Serum biochemistry profile: nonspecific and usually normal
- Urinalysis: nonspecific
- Fecal flotations to rule out parasitic causes of vomiting/diarrhea

ADVANCED OR CONFIRMATORY TESTING

- Proper nutrition/elimination food trial
- Further testing generally unnecessary for the primary diagnosis; used for identifying other disorders with similar signs or for identifying inciting causes (differential diagnosis)
- Abdominal radiography and ultrasonography: used for ruling out the other causes of vomiting and diarrhea for which imaging modalities are diagnostic (e.g., intestinal obstruction, intestinal mass)
- Endoscopy with biopsy and histopathologic evaluation of GI mucosa: mucosa may be normal or show increases in lamina propria lymphocytes or plasma cells, but inflammatory changes seen in dogs or cats with food intolerance are generally less profound than found in those with IBD or other diseases of the mucosa.

TREATMENT

TREATMENT OVERVIEW

Avoid exposure to food toxins, dairy products, certain carbohydrates, and dietary sources of vasoactive amines (e.g., certain types of fish). Control episodes of dietary indiscretion.

ACUTE GENERAL TREATMENT

- Nonspecific supportive care based on clinical signs (e.g., parenteral fluid administration for dehydration)
- Perform an elimination food trial (in general, a shorter trial of 7-10 days is all that is required to result in the resolution of the signs of dietary intolerance).
- Clinical signs of GI disease usually resolve within a few days on the new diet that does not contain the offending substance.

NUTRITION/DIET

- Maintain strict avoidance of offending foods or ingredients (e.g., dairy products).
- Find an acceptable commercial or homemade food for long-term maintenance.
- Control episodes of gluttony, pica, or ingestion of indigestible materials.

POSSIBLE COMPLICATIONS

Certain types of food poisoning can cause serious and life-threatening disease.

PROGNOSIS AND OUTCOME

Good prognosis if offending foods or ingredients are eliminated from the diet

PEARLS & CONSIDERATIONS

COMMENTS

In instances of recurrent food intolerance (versus one-time events), use of a food diary by the animal owner is important to monitor clinical response and compliance.

TECHNICIAN TIPS

Gradual transition to a new food is critical for a pet with health problems and may be the single most important thing you can do to help a pet accept a new food. Mix more of the new food with less of the old food over a period of at least 7 days. An alternative method for transitioning, especially for cats, is to offer the new food side by side with the old food in identical dishes, instead of mixing them both in the same dish.

CLIENT EDUCATION

Human food sources, snacks, treats, and food for other animals in the household (e.g., dog having access to cat food) can be a problem.

AUTHOR: PHILIP ROUDEBUSH

EDITOR: DEBRA L. ZORAN

Diarrhea, Chronic

BASIC INFORMATION

DEFINITION

An increase in frequency of defecation, stool fluidity, and/or fecal volume (increased water content or fecal solids) that is persistent (more than 2-3 weeks) or episodic.

EPIDEMIOLOGY

CONTAGION & ZOONOSIS

Potentially zoonotic organisms; see Diarrhea, Acute, p. 303.

GEOGRAPHY AND SEASONALITY

See Diarrhea, Acute, p. 303.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Small-intestinal (SI) diarrhea versus large-intestinal (LI) diarrhea or both

- Further segregated into diseases caused by maldigestion or malabsorption
- Malabsorption further segregated into nonprotein-losing versus protein-losing disease

Clinical Signs of Small-Intestinal Versus Large-Intestinal Diarrhea

Characteristic	Small Intestine	Large Intestine
Feces		
Mucus	Uncommon	Common
Hematochezia (fresh blood in/on feces)	Absent	Often present
Melena (digested blood in feces)	± Present	Absent
Volume	Often increased	Normal to decreased (due to increased frequency)
Quality	Nearly formed to watery (“cowpile”); ± undigested food/fat; possibly malodorous	Loose to semisolid
Shape	Variable (dependent upon amount of water present)	Normal or narrowed
Steatorrhea (undigested fat in feces)	Present with maldigestive or malabsorptive disorders	Absent
Defecation		
Frequency	Normal to mildly increased (2-4 times/d)	Greatly increased (4-10 times/d)
Dyschezia (inability to defecate without straining or signs of pain)	Absent	Dogs: frequent. Cats: less common.

Characteristic	Small Intestine	Large Intestine
Tenesmus (straining)	Absent	Dogs: common. Cats: less common; rule out stranguria.
Urgency	Less common, unless severe acute enteritis	Frequent
Associated Signs		
Weight loss	Common	Uncommon. Possible with severe chronic colitis, diffuse neoplasia, histoplasmosis, pythiosis.
Vomiting	Possible	May be seen, especially with acute colitis (30%). Possible before onset of abnormal stools.
Appetite	Usually normal; may be ↑ or ↓ in bowel infiltration/inflammation depending on severity of lesion	Normal to decreased if severe disease (neoplasia, histoplasmosis)
Halitosis	± Present (maldigestion/malabsorption)	Absent
Borborygmus	Possible	Absent
Flatulence	Possible	Common
Fecal incontinence	Rare	Possible
"Scooting" or chewing of perianal area	Absent	Possible with proctitis

HISTORY, CHIEF COMPLAINT

- Typical: persistent indoor fecal incontinence and/or loose stool
- Age, when/where the pet was acquired, vaccination and dietary history, environment, recent medications, and presence or absence of recent stressful episode (recent move, changes in family routine, etc.) help identify trigger factors.
- Differentiate SI diarrhea from LI (see table).

PHYSICAL EXAM FINDINGS

- Hydration status
- Depression/weakness/lethargy
- Emaciation: malnutrition, chronic malabsorption, protein-losing enteropathy
- Dull hair coat: malabsorption (fatty acids, protein, vitamins)
- Fever: inflammation, infection, neoplasia
- Edema, ascites, decreased lung/heart sounds (pleural effusion): protein-losing enteropathy
- Pale mucous membranes: chronic GI blood loss, anemia of chronic illness/inflammation
- Abdominal palpation may reveal a mass (foreign body, neoplasm, granuloma, abscess, mesenteric lymph-adenopathy), thickened bowel loops (inflammation, neoplastic infiltration), "aggregated" bowel loops (mass, peritoneal adhesions), "sausage-shaped" intestinal loop (chronic, intermittent intussusception), evidence of pain (inflammation, obstruction, ischemia, gas distension), gas/fluid distension (diarrhea, obstruction [mass], ileus)
- Rectal palpation (mandatory unless intractably painful): mass (polyp, neoplasm, granuloma), circumferential narrowing (stricture, spasm, neoplasm), irregular mucosal texture (colitis, neoplasm, perineal fistula)

ETIOLOGY AND PATHOPHYSIOLOGY

- Small intestine
  - Decreased fluid and electrolyte absorption
  - Incomplete nutrient absorption (fats, carbohydrates)
  - Increased fluid and electrolyte secretion
- Large intestine
  - Decreased fluid and electrolyte absorption
  - Secretion of fluid and electrolytes
  - Failure of reservoir function

CAUSES OF CHRONIC SMALL- AND LARGE-INTESTINAL DIARRHEA

- Parasites causing SI: *Isospora*, hookworms, roundworms
- Parasites causing LI: Whipworms *(Trichuris vulpis),* amoebiasis, *Balantidium coli*.
  - *Giardia* may be SI and/or LI.
- Dietary intolerance and dietary allergies may be SI and/or LI.
- Inflammatory bowel disease (IBD): lymphocytic-plasmacytic, eosinophilic, granulomatous enteritis may be SI and/or LI. Hypereosinophilic syndrome (cats primarily), neutrophilic (suppurative/purulent) enteritis and breed-specific (shar-pei, basenji, soft-coated Wheaten terrier) tend to cause SI. Chronic ulcerative colitis and histiocytic ulcerative colitis (primarily boxers) are most often LI.
- Neoplasia (lymphoma, adenocarcinoma, leiomyoma/leiomyosarcoma, mast cell tumour): SI and/or LI
- Infectious organisms causing:
  - SI signs: *Cryptosporidia parvum*
  - LI signs: salmonellosis, yersiniosis, *Bacillus piliformis*, pythiosis, protothecosis and *Tritrichomonas foetus* in cats
  - Both SI and LI: campylobacteriosis, *Clostridia* spp., histoplasmosis, feline leukemia virus (FeLV), feline immunodeficiency virus (FIV) and feline infectious peritonitis (FIP)
- Chronic small intestinal bacterial overgrowth (SIBO) in dogs may occur secondary to idiopathic antibiotic responsive enteritis or tylosin-responsive diarrhea. It may be idiopathic or occur secondary to diseases such as an immunoglobulin A deficiency, exocrine pancreatic insufficiency (EPI), a partial obstruction (chronic intussusception) or blind loops of bowel, or disease causing abnormal motility and thereby clearance of organisms, as well as a gastric acid deficiency.
- Villous atrophy (idiopathic, gastrinoma, gluten-sensitive enteropathy) causes SI diarrhea.
- Endocrine causes such as hyperthyroidism (cats) and hypoadrenocorticism may cause SI and/or LI diarrhea.
- Protein-losing enteropathy such as intestinal lymphangiectasia is primarily SI in nature.
- Any of the preceding disorders can cause protein-losing enteropathy, depending upon disease progression and severity.
- Maldigestive diseases (EPI, lactase deficiency [especially cats]) cause SI signs.
- Functional disorder (irritable bowel syndrome [IBS]) is a diagnosis by exclusion and causes LI diarrhea.
- Other: chronic active pancreatitis (cats and dogs) causes SI signs (lethargy, agitation/abdominal discomfort, vomiting, +/− diarrhea).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The list of causes of chronic diarrhea is exhaustive, hence the extreme importance of obtaining a thorough history from the client and considering the pet's environment prior to embarking on a battery of tests that may be unwarranted. Every animal with chronic large-bowel or mixed diarrhea should have a rectal exam and a direct smear performed. Fecal examinations should always be performed on *fresh* samples.

DIFFERENTIAL DIAGNOSIS

See Etiology and Pathophysiology above.

INITIAL DATABASE

- Fecal examinations
  - Cytology (fresh saline smears): ova, larvae, certain bacteria, protozoa *(Giardia, T. foetus, Entamoeba*, *Balantidium coli).*
  - *Campylobacter* fecal cytology alone not sufficient in making a diagnosis, as many are nonpathogenic.
  - Flotation
  - Gram stain
  - Zinc sulfate centrifugal flotation (*Giardia* cysts)
  - ELISA: *Giardia*-specific antigen
  - Iodine stain: enhances visualization of *Giardia* trophozoites, stops motion of organism and cysts (stain light brown).
- CBC: to assess hydration status (PCV/TS), presence of leukocytosis (inflammation, infection, stress), eosinophilia (eosinophilic IBD, endoparasitism), lymphopenia (lymphangiectasia), anemia (chronic GI blood loss, anemia of chronic illness/inflammation, nutrient malabsorption), thrombocytosis with microcytic, hypochromic anemia (iron deficiency)
  - Absence of a stress leukogram: hypoadrenocorticism
- Serum biochemical profile: hypoproteinemia (hypoalbuminemia, +/− hypoglobulinemia), elevated BUN (prerenal azotemia, GI bleeding, high-protein diet), elevated liver enzyme activities (primary hepatic disease, reactive hepatopathy, pancreatitis, or primary GI tract disease with portal bacterial translocation), hypocholesterolemia (lymphangiectasia, hepatopathy)
- Urinalysis to assess specific gravity (renal function [renal versus prerenal azotemia]), proteinuria
- Cats: serum thyroxine concentration (>6 years old), FeLV/FIV

ADVANCED OR CONFIRMATORY TESTING

- Abdominal radiographs: survey and/or contrast radiography
- Abdominal ultrasonography: mass lesion, thickened bowel loops, loss of detail of the layers of GI wall, evaluation of other abdominal organs
- Adrenocorticotropic hormone stimulation test (hypoadrenocorticism)
- Fecal cultures (*E. coli*, *Salmonella* spp., *C. jejuni*, *Clostridium* spp., *Y. enterocolitica*). Efficacy in determining true infection is controversial; many of these bacteria are commensal organisms, and their presence in feces does not necessarily correlate with disease.
- *T. foetus*: culture of feces using the InPouch TF (BioMed Diagnostics, White City, OR)—young cats from cattery or shelter
- *C. perfringens* fecal endospore enumeration (unreliable and not recommended)
- *C. perfringens* enterotoxin: caution, discordant results amongst detection methods
- Recommendations for *C. perfringens*: ELISA for enterotoxin combined with PCR for the enterotoxin gene
- *C. difficile:* test for the enzyme glutamate dehydrogenase (GDH; constitutively produced), available as a commercial kit. If positive on fecal culture or positive detection of GDH enzyme, further testing for enterotoxin A and B recommended. PCR of toxin genes should be interpreted with caution (no difference in toxigenic *C. difficile* shedding by diarrheic dogs versus nondiarrheic dogs).
- *Campylobacter:* PCR; positive PCR result requires further testing techniques such as sequencing of the 16S rDNA gene, etc.
- *Cryptosporidium:* fecal ELISA test
- *Salmonella:* positive PCR samples should be cultured followed by sero-typing of suspected colonies.
- Occult blood: chronic blood loss; meat-based diet may cause false positives with some kits.
- Trypsin-like immunoreactivity (TLI) test: EPI (species-specific test)
- Serum cobalamin (vitamin B12), folate
  - Folate: depends on jejunum's absorptive function (proximal SI)
  - Cobalamin: depends on pancreatic intrinsic factor secretion and absorption in ileum (distal SI)
  - ↓Folate and ↓cobalamin: diffuse malabsorptive disease
  - ↓Cobalamin, ↑folate: antibiotic-responsive enteritis/SIBO
  - TLI, cobalamin, and folate often run together.
- Species-specific pancreatic lipase immunoreactivity (PLI) test (spec CPL/cPLI, fPLI) for the diagnosis of chronic active pancreatitis
- If presence of hypoproteinemia and hypoalbuminemia, further diagnostics required to identify origin of loss; kidneys (urine protein/creatinine ratio if proteinuria noted on dipstick), liver (serum bile acids), or GI (fecal alpha-protease inhibitor)
- Serologic titers (histoplasmosis)
- Endoscopy: gastroduodenoscopy and colonoscopy indicated to determine extent of disease
- Exploratory laparotomy: full-thickness biopsies (biopsy even if no gross lesions)
- Molecular techniques (PCR, RT-PCR): increasing commercial availability (results highly dependent on laboratory's quality control)
- Empirical therapy may be elected because of client's financial constraints: probiotics, anthelmintics, antimicrobials (metronidazole, tylosin, enrofloxacin), dietary trials, antiinflammatories/immunomodulators.

TREATMENT

TREATMENT OVERVIEW

The goal of therapy is to treat the underlying cause of the diarrhea.

ACUTE GENERAL TREATMENT

- Low-fat, highly digestible low-fiber diets (low-fat cottage cheese, tofu, rice, potatoes)
- Small, frequent meals (3-6/d)
- High-fiber diets (colitis)
- Empirical treatment: anthelmintics (fenbendazole) or metronidazole, even with negative tests

CHRONIC TREATMENT

- Dependent on underlying cause; see specific disorders for details.
- Deworming medications
- Antimicrobials (see p. 303 and specific organism)
- Immunosuppressive agents such as prednisone/prednisolone/budesonide (use minimum effective dose), cyclosporine, azathioprine (not in cats), chlorambucil
  - Possible immunomodulating/antiinflammatory activities, such as metronidazole and tylosin
- Antiinflammatories (sulfasalazine/olsalazine/mesalamine)

- Adjunctive therapy: cobalamin supplementation and probiotics
- Antifungal agents (histoplasmosis)

NUTRITION/DIET

- Dietary modifications such as feeding a novel protein source or a hydrolyzed protein for a trial period (minimum 3 to 4 weeks). All other foods and antigen sources (treats, flavored medications) must be eliminated during this time.

POSSIBLE COMPLICATIONS

- Immunosuppressive therapy (azathioprine, chlorambucil): myelosuppression
- 5-aminosalicylates: keratoconjunctivitis sicca
- Iatrogenic hyperadrenocorticism with chronic glucocorticoid use, therefore use minimum effective dose
- Excessive protein loss: edema/cavity effusions
- Buccal mucosal irritation: pancreatic enzyme supplementation (EPI)

PROGNOSIS AND OUTCOME

- Dependent on underlying cause, response to treatment, owner compliance, and interindividual variation
- Guarded: histoplasmosis, protothecosis, pythiosis, yersiniosis, regional granulomatous enterocolitis, FIP
- Poor to guarded: basenji, shar-pei, soft-coated Wheaten terrier–associated IBD, villous atrophy (clinical signs often persist despite treatment), feline hypereosinophilic syndrome
- Fair: histiocytic ulcerative colitis (lifetime therapy needed, difficult to control)
- Fair to good: antibiotic-responsive enteritis/SIBO, depending on underlying cause. Some require frequent or continuous treatment; others have prolonged remission with one course of antibiotics. FeLV/FIV (when secondary infections controlled).
- Fair to excellent: IBD (realistic expectation: maintenance of remission/control of relapses, rather than cure)
- Good: dietary intolerance/food allergy, giardiasis, salmonellosis (although mortality rate can be high [hospitalized, young, immune-compromised]), campylobacteriosis, *Clostridium* spp. (although fatalities reported)
- Good to excellent: hyperthyroidism, EPI (continual treatment), hypoadrenocorticism (lifelong treatment), hook-worms/roundworms/whipworms
- Lymphangiectasia: unpredictable. Remission in some (months to years), cachexia, cavity effusions, intractable diarrhea in others with inability to control protein loss.
- Neoplasia: dependent on tumor type

RECOMMENDED MONITORING

- Body weight, serum protein and albumin concentrations, frequent CBCs if using immunosuppressive agents
- Schirmer tear test (sulfasalazine, TMS)

PEARLS & CONSIDERATIONS

COMMENTS

During diagnostic procedures (laparotomy, laparoscopy or endoscopy), it is vital to always obtain biopsies, even if tissues appear grossly normal.

TECHNICIAN TIPS

Proper hygiene is of paramount importance to avoid promoting contagion and to prevent zoonoses (handwashing between pets, gloves when cleaning a patient with diarrhea, never placing food in laboratory area where fecal analyses are performed).

CLIENT EDUCATION

Some of the preceding diseases can be frustrating to treat (waxing and waning nature). Inform owner at time of diagnosis: avoids unrealistic expectations/disappointment.

EDITOR: ETIENNE CÔTÉ

Diarrhea, Acute

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- An increase in frequency of defecation, stool fluidity, and/or fecal volume (increased water content or fecal solids) that is sudden in onset and of short duration (<2 weeks).

EPIDEMIOLOGY

RISK FACTORS

- Environment: overcrowding, poor sanitation, immune compromise (infectious)
- Unsupervised activity (dietary indiscretion), stress (increased shedding of infectious organisms), close contact, animals from large geographic areas as associated with dog/cat shows (greater exposure to variety of pathogens)
- Raw diets: salmonellosis, *Escherichia coli* infection (young or immune-compromised patients)

CONTAGION & ZOONOSIS

- Potential zoonoses: *Ancylostoma caninum* (cutaneous larval migrans), *Balantidium coli, Campylobacter* spp., *Clostridium difficile, Cryptosporidium parvum, Echinococcus* spp., *Entamoeba histolytica, E. coli, Giardia lamblia, Pentatrichomonas hominis, Salmonella* spp., *Shigella* spp., *Toxocara* spp. (visceral and ocular larval migrans), *Toxoplasma gondii, Yersinia enterocolitica*
- Species-specific viral infections: feline leukemia virus (FeLV)/feline immunodeficiency virus (FIV)/feline infectious peritonitis (FIP)/feline panleukopenia (cat to cat); canine parvovirus (dog to dog)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Small or large intestine, or combination.

HISTORY, CHIEF COMPLAINT

- Typical reasons for presentation include owner observation of a new onset of indoor fecal incontinence and/or loose stool.
- Duration of clinical signs/course
- When/where the pet was acquired, vaccination history, dietary history, and environment, recent medications, and presence or absence of recent stressful episode (recent move, changes in family routine, etc.) help identify trigger factors. Differentiate small-intestinal diarrhea from large (see table in Diarrhea, Chronic, p. 305).

PHYSICAL EXAM FINDINGS

- Mentation: depression and dehydration make infections or intoxications more likely.
- Mucous membrane color
  - Brick red/injected: rule out sepsis, hemorrhagic gastroenteritis.
  - Pallor: hypoperfusion/shock/pain versus anemia due to gastrointestinal (GI) blood loss
- Hydration (caveat: nauseated animal may have slimy mucous membranes despite dehydration).
- Signs of shock, sepsis (fever/subnormal temperature, tachycardia [less consistent in cats], tachypnea, cool extremities [variable])
- Posture: possible “dog-praying” position/arched back (sign of abdominal pain).
- Abdominal palpation:
  - Lymphadenopathy (neoplasia, inflammation, infection)
  - Thickened bowel (inflammatory, neoplastic infiltration)
  - Fluid- or gas-filled bowel
  - Intussusception (sausage shape), especially in puppies with viral gastroenteritis or parasitism
  - Evidence of pain
  - Urinary bladder (urine production with respect to hydration status and renal function)
  - Abdominal mass (obstruction, foreign body)

- Perineum: perineal hernia and anal sac disorders may mimic signs of large-bowel disease.
- Rectal palpation; with large bowel diarrhea, the following signs are possible:
  - Pain/increased mucosal sensitivity
  - Palpable foreign material
  - Hematochezia
- Cats: palpate for thyroid nodule (hyperthyroidism).
- Observe animal defecating (tenesmus, signs of pain, character of feces)

ETIOLOGY AND PATHOPHYSIOLOGY

- Abnormality of transmucosal movement of water and solute:
  - Osmotic (decreased solute absorption)
  - Secretory (hypersecretion of ions)
  - Exudative (increased permeability)
  - Abnormal motility
- More than one mechanism possible, depending on underlying cause

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The list of causes of acute diarrhea is extensive, but it can be narrowed substantially based on a thorough history that includes information on the pet's environment and diet. Fecal examinations are indicated in all cases and should be performed on fresh samples. Further diagnostic testing is warranted in acute diarrhea cases if the patient shows signs of being systemically ill, if a zoonotic concern exists, if the history or physical exam reveals abnormalities that suggest a nontransient cause, or if follow-up reveals that a prolonged course is occurring (becomes chronic diarrhea rather than acute). Otherwise, a large proportion of acute diarrhea cases in dogs and cats is self-resolving and does not warrant testing beyond a fecal exam.

DIFFERENTIAL DIAGNOSIS

- Diet (food intolerance/allergy, poor-quality food, abrupt diet change, dietary indiscretion/toxin ingestion [mycotoxins, spoiled foods], overeating)
- Parasites (helminths [hookworms—*Ancylostoma/Uncinaria* spp.; whipworms—*Trichuris vulpis;* ascarids/roundworms —*Toxocara* spp., *Strongyloides* spp.], cestodes, trematodes, *Trichinella* spp., protozoa [*Isospora* spp.—coccidiosis; *Giardia* spp; *Cryptosporidium* spp.; *Pentatrichomonas/Tritrichomonas foetus; Balantidium coli; Entamoeba histolytica; Neorickettsia helminthoeca [salmon poisoning]*)
- Bacteria (*Campylobacter jejuni*, *Clostridium* spp. *[perfringens, difficile, upsaliensis], E. coli*, *Salmonella* spp., *Yersinia enterocolitica*, *Shigella* spp., *Bacillus piliformis*, antibiotic-responsive diarrhea/Enterobacteriaceae)
- Viral (astrovirus, coronaviruses, canine distemper virus, canine parvovirus, FeLV/FIV [secondary infections], feline parvovirus/panleukopenia, rotavirus)
- Other infectious (*Histoplasma capsulatum;* pythiosis/lagenidiosis; protothecosis)
- Heavy metals/organophosphates
- Drugs (several classes and types, notably: antibiotics, antineoplastics, anthelmintics, nonsteroidal antiinflammatory drugs, digoxin, lactulose)
- Hemorrhagic gastroenteritis (HGE)
- Intestinal foreign body
- Intussusception (especially puppies with viral gastroenteritis)
- Intestinal volvulus
- Irritable bowel syndrome
- Lymphangiectasia
- Neoplasia (lymphoma [most common], adenocarcinoma)
- Extraintestinal causes (acute pancreatitis, hypoadrenocorticism, hepatobiliary disease, renal disease, diabetes mellitus, exocrine pancreatic insufficiency, hyperthyroidism [cats])

INITIAL DATABASE

- Fecal examinations: basic
  - Cytology (fresh saline smears): ova, larvae, certain bacteria, protozoa (*Giardia, T. foetus, Entamoeba* spp., *Balantidium coli*)
  - Flotation
- CBC (if depressed, dehydrated, pyrexic):
  - Leukocytosis: rule out inflammatory, infection, stress.

  - Leukopenia (often seen with parvovirus, panleukopenia).
  - Elevated packed cell volume (PCV)/total solids (TS): rule out dehydration.
  - Elevated PCV without concomitant elevation in TS: rule out hemorrhagic gastroenteritis.
  - Absence of stress leukogram suggestive of hypoadrenocorticism
- Serum biochemical profile:
  - Decreased electrolytes: gastrointestinal (GI) tract loss
  - Hyperkalemia/hyponatremia: hypoadrenocorticism. Do not rule out hypoadrenocorticism based on normal serum electrolyte concentrations (atypical hypoadrenocorticism).
  - Hypoglycemia: sepsis (any age), anorexia, heavy parasitism (patients < 6 months old)
  - Elevated liver enzyme activities: rule out hepatic disease, pancreatitis, or primary GI tract disease with portal bacterial translocation.
- Urinalysis: specific gravity (renal versus prerenal azotemia), bilirubinuria in cats consistent with hepatic disease
- Serum thyroxine concentration (older cats—hyperthyroidism)
- Parvoviral fecal antigen test (ELISA)
- Abdominal radiographs, contrast radiography and/or ultrasonography, depending on history and physical exam (history of dietary indiscretion; mass, pain or “sausage-shaped” bowel loop on abdominal palpation)

ADVANCED OR CONFIRMATORY TESTING

As dictated by clinical suspicion based on history, exam, and initial diagnostic tests

TREATMENT

TREATMENT OVERVIEW

Many cases of acute diarrhea in otherwise normal dogs and cats are transient and self-resolving. If a diagnosis of benign acute diarrhea due to a spontaneous and temporary disorder such as dietary indiscretion has been established, then no treatment or simply palliative treatment for comfort (e.g., with antidiarrheal medications) are good options. However, in some individuals, acute diarrhea produces signs of volume depletion/dehydration, or is associated with disorders that are not likely to be self-resolving or may cause contagion or zoonosis. The goal of treatment in such cases is to correct any volume deficits with parenteral fluid therapy and eliminate the cause if one has been identified through diagnostic testing. Finally, to prevent infectious transmission to other patients or hospital personnel, it is important to have an established hospital protocol when dealing with such patients.

ACUTE GENERAL TREATMENT

See Colitis, Acute p. 227

DRUG INTERACTIONS AND CONTRAINDICATIONS

- Prochlorperazine and chlorpromazine may precipitate seizures in animals with a history of seizure activity.
- Metoclopramide and maropitant should not be used if an obstruction is suspected.
- Metronidazole: risk of neurotoxicity at higher dosages

POSSIBLE COMPLICATIONS

- Further/ongoing dehydration
- Severe mucosal damage: pyrexia, secondary sepsis/endotoxemia
- Development of intussusception/other intestinal accident

RECOMMENDED MONITORING

Adjusted based on physical examination

PROGNOSIS AND OUTCOME

- Dietary indiscretion: often benign and self-resolving
- Parasitic diseases generally good response to treatment, barring obstruction
- Infectious causes, intoxications, mechanical/functional obstruction, HGE, acute pancreatitis, hepatitis, renal disease, hypoadrenocorticism: potentially life-threatening

PEARLS & CONSIDERATIONS

COMMENTS

- Advanced diagnostic evaluation may not be necessary in a patient with first-time acute diarrhea when that patient is otherwise stable and well. However, if diarrhea fails to respond to treatment within 24-48 hours, or if deterioration occurs at any time, further diagnostic testing and treatment are warranted.
- Establish a hospital infectious protocol aimed at preventing contagion (quarantine as needed, parasite control, good sanitation habits, impervious flooring in kennels/dog runs).
- Routine deworming of bitches and puppies (every 2 weeks) decreases transmission.
- Routine antibiotic use in uncomplicated diarrhea is discouraged (alters GI flora, promotes antibiotic resistance).

TECHNICIAN TIPS

- Help establish a hospital infectious protocol and implement it upon admission of a patient with a suspicion of contagion.
- Proper hygiene is vital to avoid contagion and zoonoses (handwashing between patients, gloves when cleaning a patient with diarrhea, never placing human or animal food in laboratory area where fecal analyses are performed).

CLIENT EDUCATION

- Pets are occasionally reservoirs for human infection, so proper hygiene is essential: frequent handwashing, regular cleaning of pet's food bowls, bedding, and litterbox (cats).
- Feeding of raw diets is discouraged (risk of transmission of zoonotic pathogens (*E. coli.*, *Salmonella* spp.).

AUTHOR: LISA CARIOTO

EDITOR: ETIENNE CÔTÉ

Diaphragmatic Hernia

BASIC INFORMATION

DEFINITION

Disruption of the continuity of the diaphragm such that abdominal organs can shift into the thoracic cavity.

SYNONYM

Pleuroperitoneal hernia. (Note: peritoneopericardial diaphragmatic hernias are covered separately; see p. 864 .)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Both dogs and cats
- Congenital pleuroperitoneal hernias are rarely reported, since many affected animals die soon after birth.
- Traumatic: commonly in male dogs 1-3 years old

RISK FACTORS

Trauma is the most common cause of diaphragmatic hernia.

ASSOCIATED CONDITIONS & DISORDERS

- Incarceration, obstruction, and strangulation of abdominal viscera
- Hepatic venous stasis, biliary tract obstruction, icterus, and ascites secondary to liver herniation
- Pleural effusion, hemothorax, chylothorax, bile pleuritis, and pneumothorax can complicate hernias.
- Musculoskeletal or neurologic abnormalities secondary to trauma

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Congenital pleuroperitoneal hernia
  - Animals are dead at birth or die soon after with severe respiratory deficiency.
- Traumatic diaphragmatic hernia
  - Clinical course can be acute or chronic.

HISTORY, CHIEF COMPLAINT

- Acute:
  - History of trauma
  - Shock
  - Respiratory distress
  - Pale or cyanotic mucous membranes
- Chronic:
  - Dyspnea or tachypnea
  - Exercise intolerance
  - Anorexia
  - Depression
  - Vomiting
  - Dysphagia
  - Diarrhea
  - Constipation
  - Weight loss
  - Difficulty in lying down
  - Abdominal distension

- Some animals can be clinically normal, and the hernia is an incidental (typically radiographic) finding.

PHYSICAL EXAM FINDINGS

- Signs of hypovolemic shock
- Dyspnea and/or tachypnea
- Pale or cyanotic mucous membranes
- Tachycardia
- Cardiac arrhythmias
- Muffled heart and lung sounds on thoracic auscultation
- Borborygmi on thoracic auscultation
- Hyporesonance on chest wall percussion (pleural effusion)
- Hyperresonance on chest wall percussion (gastric tympany)
- Tucked-up or empty appearance of the abdomen
- Abdominal distention with fluid wave if ascites

ETIOLOGY AND PATHOPHYSIOLOGY

- Congenital:
  - Defect in the dorsolateral part of the diaphragm
  - The intermediate part of the left lumbar muscle of the crus may be absent, or the defect may be more extensive with both crura and parts of the central tendon missing.
- Traumatic:
  - Direct:
    - Thoracoabdominal stab and gunshot wounds
    - Iatrogenic injury during thoracocentesis
  - Indirect:
    - Primarily motor vehicle accidents, but other blunt abdominal trauma can cause diaphragmatic hernia.
    - An abrupt increase in intraabdominal pressure with the glottis open results in a large pleuroperitoneal pressure gradient.
      - This pressure gradient causes the diaphragm to tear at its weakest points, which are usually the muscular portions.
      - The location and size of the tear are dependent on the position of the animal on impact and the location of the viscera.
      - Viscera malpositioned in the thoracic cavity can suffer ischemic injury from alterations in blood flow.
      - Venous congestion of entrapped liver lobes can lead to pleural or abdominal effusion.
    - Clinical signs reflect respiratory dysfunction secondary to loss of diaphragmatic integrity, pleural effusion, or displacement of pulmonary parenchyma.
    - Clinical signs may also reflect dysfunction of displaced abdominal viscera.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

The diagnosis is usually established by demonstrating a loss of diaphragmatic integrity by thoracic or abdominal imaging (plain and contrast radiography, abdominal ultrasonography), particularly in patients with a history of pleural space disease following trauma.

DIFFERENTIAL DIAGNOSIS

- Peritoneopericardial diaphragmatic hernia (see p. 864)
- Other causes of pleural or peritoneal effusion
- Pneumothorax
- Pneumonia
- Other causes of abdominal distension or ascites

INITIAL DATABASE

- CBC, biochemistry panel, urinalysis: variable results depending on time of presentation, severity of clinical signs, and organs displaced into the thorax
- Thoracic radiographs may show:
  - Loss of the diaphragmatic line
  - Loss of cardiac silhouette

    - Dorsal displacement of lung fields
    - Pleural effusion
    - Presence of gas (stomach or intestines) in the thoracic cavity
- Thoracocentesis may be necessary for diagnostic thoracic radiographs (if large-volume pleural effusion).
- Abdominal radiographs may show absence or cranial displacement of normal abdominal viscera.

ADVANCED OR CONFIRMATORY TESTING

- Ultrasonography may demonstrate a rent in the diaphragm, the organs herniating through it, or viscera in abnormal positions.
- Positive contrast celiography may demonstrate contrast medium in the pleural cavity, absence of a normal liver lobe outline, and incomplete visualization of the abdominal surface of the diaphragm.
- Contrast radiography of the intestinal tract may show barium-filled stomach or intestine in the thoracic cavity.
- In some animals, the diagnosis is confirmed during exploratory surgery.

TREATMENT 

TREATMENT OVERVIEW

- Stabilize patient.
- Resolve respiratory distress.
- Return the abdominal organs to the abdominal cavity.
- Repair the diaphragmatic defect.

ACUTE GENERAL TREATMENT

- Oxygen administered via face mask, nasal cannula, or oxygen cage (see p. 1318)
- Fluid therapy as needed to stabilize cardiovascular status (particularly for acute trauma patients)
- Thoracocentesis if needed (see p. 1338)
- Position the patient in sternal recumbency with the head elevated above the rear limbs (forelimbs elevated) if tolerated.

CHRONIC TREATMENT

Surgical treatment:

- Diaphragmatic hernias are often repaired through a midline celiotomy. A median sternotomy may be required for additional exposure.
- Return the abdominal organs to the abdominal cavity.
    - The diaphragmatic defect can be enlarged if necessary to reposition organs that have become swollen/congested or that have developed adhesions.
- Close the diaphragmatic defect via standard herniorrhaphy, abdominal flaps, porcine small intestinal submucosal patches (Vet BioSIS), or synthetic material (Silastic sheeting).
- Remove air and fluid from the pleural cavity after closing the diaphragmatic defect.
- Explore the entire abdominal cavity for associated injuries if traumatic etiology.

POSSIBLE COMPLICATIONS

- Reexpansion pulmonary edema can follow rapid lung reexpansion.
- Hypoventilation or hypoxia due to pain, pneumothorax, hemothorax, or tight bandages

RECOMMENDED MONITORING

- Vital signs
- Respiratory patterns
- Pain

PROGNOSIS AND OUTCOME 

Prognosis is good if the animal survives the early postoperative period (12 to 24 hours).

PEARLS & CONSIDERATIONS

COMMENTS

- Findings on physical examination maybe normal in some animals.
  - Diaphragmatic hernias are occasionally discovered as incidental findings in patients evaluated for other reasons.
- The radiographic diagnosis of diaphragmatic hernia can be surprisingly difficult in some cases.
  - Ultrasonography may be more useful in making the diagnosis, especially if moderate to severe pleural effusion is present.
- Surgery should be delayed until the patient's condition has stabilized.
- Perform surgery as soon as possible if the stomach has herniated into the thoracic cavity.

PREVENTION

Routine use of leashes to avoid hit-by-car injuries

TECHNICIAN TIPS

Materials for thoracocentesis to evacuate pleural fluid just after anesthetic induction to better stabilize the patient while prepping for surgery include: 22-G over-the-needle catheter or butterfly needle, three-way stop cock, extension set, syringe, and collection bowl (see p. 1338). Extra towels or something to prop/elevate the cranial half of the body while prepping may help move abdominal contents out of the thoracic cavity and improve respiratory function.

CLIENT EDUCATION

Patients with diaphragmatic hernia usually have a history of trauma, but failure to perform radiographic examination of the thorax often results in delayed diagnosis.

AUTHOR: MICHAEL B. MISON

EDITOR: RANCE K. SELLON

Diabetic Ketoacidosis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Diabetic ketoacidosis (DKA) is a lifethreatening metabolic disorder caused by insulin deficiency and/or insulin resistance that leads to excess hepatic production of ketoacids and progressively worsening metabolic acidosis, hyperosmolality, serum electrolyte derangements, and systemic signs of illness.

EPIDEMIOLOGY

See Diabetes Mellitus, p. (297)

CLINICAL PRESENTATION

HISTORY/CHIEF COMPLAINT

The history and physical examination findings are variable because of the progressive nature of DKA and the variable time between the onset of DKA and owner recognition of a problem. The classic clinical signs of diabetes (i.e., polyuria, polydipsia, polyphagia, weight loss) develop initially, followed by systemic signs of illness (lethargy, anorexia, vomiting) as ketonemia and metabolic acidosis develop and worsen. Underlying illness that precipitates DKA (e.g., pancreatitis, infection) also contributes to the clinical picture. The time interval from onset of diabetes to onset of DKA is unpredictable, but once ketoacidosis develops, severe illness usually becomes evident within days.

PHYSICAL EXAM FINDINGS

Findings are variable for reasons discussed above. Common physical exam findings in addition to those found in nonketotic diabetic dogs and cats (see p. ((() include dehydration, depression, weakness, tachypnea, and sometimes a strong odor of acetone on the breath. Slow, deep breathing (i.e., Kussmaul's respiration) may be observed in animals with severe metabolic acidosis. Such signs as vomiting and abdominal pain are common because of the common concurrent occurrence of pancreatitis.

ETIOLOGY AND PATHOPHYSIOLOGY

- Synthesis of ketone bodies (i.e., acetoacetic acid, β-hydroxybutyric acid, and acetone) requires mobilization of free fatty acids (FFAs) from triglycerides stored in adipose tissue and a shift in hepatic metabolism from fat synthesis to fat oxidation and ketogenesis.
- Accelerated production of ketones occurs as a result of insulin deficiency, insulin resistance, and increased production of diabetogenic hormones, most notably glucagon.
- Insulin deficiency “allows” lipolysis to increase, thus increasing the availability of FFAs to the liver and in turn promoting ketogenesis.
- Insulin deficiency may be absolute or relative; that is, DKA may develop in some diabetic dogs and cats despite daily injections of insulin.
- Increased concentrations of diabetogenic hormones (glucagon, epinephrine, cortisol, growth hormone) combined with concurrent illness and an altered metabolic milieu (e.g., increased concentrations of plasma FFAs and amino acids, metabolic acidosis) cause insulin resistance and stimulate lipolysis, ketogenesis, and gluconeogenesis, which worsen hyperglycemia and promote ketonemia.
- Progressive accumulation of ketones in the blood overwhelms the body's buffering system, causing metabolic acidosis, and surpasses the renal tubular threshold for complete resorption, causing ketonuria.
- Ketonuria contributes to the osmotic diuresis caused by glycosuria and enhances excretion of solutes (e.g., sodium, potassium, magnesium).
- Excessive renal loss of water and electrolytes combined with fluid loss secondary to vomiting leads to volume contraction, an underperfusion of tissues, and development of prerenal azotemia.
- Progressively worsening hyperglycemia combined with urinary losses of water leads to hyperosmolality, a shift of water out of cells, and marked cellular dehydration.
- The severe metabolic consequences of DKA, which include severe metabolic acidosis, hyperosmolality, obligatory osmotic diuresis, dehydration, and electrolyte derangements, quickly become life-threatening.
- Severe hyperglycemia with concurrent hyperosmolality and lack of ketonemia or ketonuria is characteristic of the hyperosmolar nonketotic diabetic syndrome. The pathogenesis of this disorder is similar to DKA; however, it is believed that insulin capacity in the body is sufficient to inhibit ketogenesis but not hyperglycemia.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- The diagnosis of diabetes mellitus requires appropriate clinical signs and documentation of persistent fasting hyperglycemia and glycosuria. The concurrent documentation of ketonuria or ketonemia establishes the diagnosis of diabetic ketosis (DK), and documentation of metabolic acidosis establishes the diagnosis of DKA.
- Commonly used urine reagent strips do not detect β-hydroxybutyrate. If ketonuria is not noted but DKA is suspected, blood can be tested for acetoacetic acid and acetone using Acetest tablets (Ames Division, Miles Laboratories, Elkhart, Ind.) or for β-hydroxybutyrate using a benchtop or handheld chemistry analyzer.

INITIAL DATABASE

- The laboratory evaluation of a healthy dog or cat with ketosis is similar to the nonketotic diabetic.
- The laboratory evaluation of sick dogs and cats with DKA should include a CBC, serum biochemical profile, serum electrolytes, arterial acid-base evaluation, and urinalysis with bacterial culture and sensitivity.
- Additional data such as radiographs, abdominal ultrasound, or further clinical pathologic studies may be needed, depending on results of the history, physical examination, and nature of concurrent illnesses. Approximately 70% of dogs with DKA will have a concurrent illness.
- Typical findings in DKA include severe hyperglycemia, metabolic acidosis, hyperosmolality, hyponatremia, hypokalemia, hypochloremia, prerenal azotemia, increased liver enzyme activities, hypercholesterolemia, and urinary tract infection. Alterations associated with concurrent pancreatitis are also common.

TREATMENT

TREATMENT OVERVIEW

- Treatment of DKA requires intensive fluid therapy and insulin administration to correct existing metabolic misbalance and stop ketogenesis. Supportive care, close monitoring, and treatment of concurrent illness are required for successful treatment. Referral to a veterinary specialist should be considered for the treatment and management of severe cases or if 24-hour monitoring is unavailable.
- Provide adequate amounts of insulin to maintain the blood glucose concentration between 150 and 300 mg/dL (8.4-16.7 mmol/L).
- Restore water and electrolyte losses and maintain hydration and normal serum electrolyte concentrations.
- Correct metabolic acidosis.
- Identify and treat concurrent illness.
- Provide dextrose or food as needed to avoid hypoglycemia.
- Avoid overly aggressive therapy; slowly correct abnormalities over 24-48 hours.

TREATMENT

- For “healthy”-appearing dogs and cats with DK, short-acting regular insulin can be administered SQ q 8 h until ketonuria resolves. The patient should be fed a third of its daily caloric intake at the time of each insulin injection. The insulin dose should be adjusted based on blood glucose concentrations. Longer-acting insulin preparations can be administered once DK has resolved.
- Treatment for systemically ill dogs and cats with DKA includes intravenous fluids with appropriate supplements, regular (crystalline) insulin, bicarbonate, dextrose, and ancillary therapy, depending on concurrent illness.
    - Initial type of fluid depends on serum electrolyte concentrations. If not known, use 0.9% saline solution at a rate sufficient to correct dehydration over 12-24 hours; adjust based on hydration status, urine output, and persistence of fluid losses.
    - Potassium supplementation in fluids depends on serum potassium concentration; if unknown, initially add 40 mEq KCl to each liter of fluids.
    - Phosphate supplementation in fluids is indicated if serum phosphorus concentration <1.5 mg/dL (0.48 mmol/L) or hemolytic anemia develops; initial IV infusion rate is 0.01-0.03 mmol/kg/h in calciumfree fluids (e.g., 0.9% saline).
    - Dextrose supplementation in fluids is indicated when blood glucose approaches or falls below 250 mg/dL (13.9 mmol/L); initially add dextrose to make 5% solution. As insulin administration must be continued to resolve the ketosis, dextrose should be used to maintain the blood glucose concentration between 150-250 mg/dL (8.4-13.9 mmol/L).
    - Magnesium supplementation is not indicated unless persistent lethargy, anorexia, weakness, or refractory hypokalemia or hypocalcemia is encountered after 24-48 hours of fluid and insulin therapy, and hypomagnesemia is documented.
    - Bicarbonate supplementation is rarely indicated; adequate fluid therapy restores renal excretion of ketoacids, thus

lowering their concentration in blood. If serum bicarbonate is still <12 mEq/L (total venous CO2 <12 mmol/L) after several hours of fluid therapy, a onetime dose of bicarbonate can be given. The dose is based on the formula: mEq $HCO3^-$ = body weight (kg) × 0.4 × (12 - animal's serum [$HCO3^-$]) × 0.5; if animal's $HCO3^-$ or total co2 concentration is unknown, use 10 in place of (12 - animal's $HCO3^-$). Add to IV fluids and give over 6 hours; do not give as bolus infusion. Only re-treat if plasma bicarbonate concentration remains <12 mEq/L after 6 hours of $NaHCO3^-$ therapy.

- Begin insulin therapy 2-6 hours after initiating fluid therapy. If serum potassium level is normal, begin insulin treatment as described below. If hypokalemia is present, decrease insulin dose by 50% during the initial 2-3 hours, and provide adequate potassium supplementation.
  - Regular insulin is administered using one of two techniques:
    - For the intermittent IM technique, the initial insulin dosage is 0.2 U/kg IM, then 0.1 U/kg IM hourly; switch to regular insulin SQ every 6-8 hours once blood glucose approaches 250 mg/dL (13.9 mmol/L), and add dextrose to IV fluids as discussed above.
    - For the low-dose IV infusion technique, the initial insulin infusion rate is 0.05 U/kg/h (cat) or 0.1 U/kg/h (dog), diluted in 0.9% saline and administered via infusion or syringe pump as a continuousrate infusion (CRI) in a line separate from that used for fluid therapy. Adjust infusion rate based on hourly blood glucose measurements; as blood glucose level decreases and approaches 250 mg/dL (13.9 mmol/L), add dextrose to IV fluids as discussed above. The insulin administration rate may need to be adjusted when dextrose is added to the IV fluids.
  - The goal of insulin treatment is a gradual decline in blood glucose concentration, preferably 50-75 mg/dL/h (2.8-4.2 mmol/L/h).
  - Switch to longer-acting insulin preparations once the patient is nonketotic and eating (see p. 297).

POSSIBLE COMPLICATIONS

- Complications result from overzealous treatment, inadequate patient monitoring, inadequate fluid replacement, and failure to reevaluate biochemical parameters in a timely manner.
- Common complications include hypokalemia, hypoglycemia, hypernatremia, hemolytic anemia induced by hypophosphatemia, and neurologic signs secondary to cerebral edema.
- Slow correction of abnormalities over 24-48 hours will minimize complications.

RECOMMENDED MONITORING

- Blood glucose measurement every 1-2 hours initially; as blood glucose level decreases in response to treatment, adjust insulin therapy and begin dextrose infusion when approaches 250 mg/dL (13.9 mmol/L).
- Hydration status, respiration, pulse every 2-4 hours; adjust fluids accordingly.
- Serum electrolyte and total venous co2 concentrations every 6-12 hours; adjust fluid and bicarbonate therapy accordingly.
- Urine output, glycosuria, ketonuria every 2-4 hours; adjust fluid therapy accordingly.
- Daily body weight, packed cell volume, temperature, blood pressure
- Additional monitoring, depending on concurrent disease

PROGNOSIS AND OUTCOME

The prognosis for successful treatment of DKA is dependent in part on the severity of the metabolic derangements at the time DKA is diagnosed, underlying illnesses that precipitated DKA, and complications that develop during treatment. Close supervision and monitoring are imperative for a successful outcome. With optimal in-hospital treatment (intensive care), the rate of survival to discharge is approximately 70%.

PEARLS & CONSIDERATIONS

Anecdotally, addition of hydrogen peroxide to urine has been thought to convert β-hydroxybutyrate to acetoacetate, thus reacting with ketone reagent squares on urine dipsticks. However, the required concentration of β-hydroxybutyrate for this reaction to proceed is very high, and clinically such patients also have very high acetoacetate concentrations. Therefore the concept, while sound, is not clinically useful.

Diabetes Mellitus

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Diabetes mellitus is a complex metabolic disorder caused by decreased production of insulin by the pancreatic β cells and/or decreased insulin utilization by peripheral tissues.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Diabetes mellitus typically occurs in older dogs and cats.
- Peak prevalence: dogs, 7-9 years, with 70% older than 7 years; cats, 9-11 years
- Juvenile-onset diabetes: dogs and cats <1 year of age; uncommon
- In dogs, females are affected twice as frequently as males. In cats, diabetes occurs predominately in neutered males.

GENETICS & BREED PREDISPOSITION

- The role of genetics remains to be determined. Genetic predispositions for diabetes have been suggested by familial associations in dogs and by pedigree analysis of keeshonden.
- Dog breeds at increased risk: Australian terrier, bichon frise, Cairn terrier, fox terrier, keeshond, miniature and standard poodle, Samoyed, miniature and standard schnauzer, spitz
- There is no clear-cut breed predisposition in cats, although Burmese cats are overrepresented in Australia.

RISK FACTORS

- Obesity
- Recurring pancreatitis
- Diestrus in the older intact female dog
- Diseases causing insulin resistance, most notably hyperadrenocorticism and acromegaly
- Insulin-antagonistic drugs, most notably glucocorticoids and progestagens

ASSOCIATED CONDITIONS & DISORDERS

- Renal insufficiency
- Hyperlipidemia
- Systemic hypertension
- Bacterial infections Cataracts and blindness (dogs)
- Peripheral neuropathy causing weakness and plantigrade stance (cats)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Insulin-dependent diabetes mellitus is present in 99% of dogs and 50%-70% of cats at the time diabetes is diagnosed. It is characterized by an absolute deficiency of insulin and mandatory need for insulin injections to control clinical signs of the disease. Historically, “type 1 diabetes.”
- Non–insulin-dependent diabetes mellitus is present in approximately 30% of cats at the time diabetes is diagnosed and it is characterized by a reduced population of pancreatic β cells and potential for clinical response to weight loss, diet, oral hypoglycemic drugs, and correction of concurrent insulin-antagonistic disease or drugs. Historically, “type 2 diabetes.”
- Transient or subclinical diabetes is present in approximately 20% of cats and is characterized by resolution of the clinical diabetic state weeks to months after initiating insulin treatment. Overt diabetes may or may not recur in the future.

HISTORY, CHIEF COMPLAINT

- Polydipsia, polyuria, polyphagia, and weight loss in virtually all diabetics
- Additional clinical signs can include:

- Lethargy
- Poor body condition
- Blindness from cataracts (dogs)
- Lack of grooming behavior, poor haircoat (cats)
- Decreased jumping ability, rear limb weakness, or development of a plantigrade posture (cats)

PHYSICAL EXAM FINDINGS

There are no specific physical exam findings. Body weight ranges from obese to thin. Lethargy is variable. A dry, lusterless haircoat and scales from hyperkeratosis; hepatomegaly from hepatic lipidosis; lenticular changes consistent with cataract formation (dogs); and impaired ability to jump, weakness in the rear limbs, ataxia, or a plantigrade posture from peripheral neuropathy (cats) may be identified.

ETIOLOGY AND PATHOPHYSIOLOGY

- The etiology of diabetes is multifactorial and involves a combination of genetic predisposition, environmental factors, insulin resistance, and decreased numbers of functioning β cells.
- Decreased numbers of β cells typically result from destruction secondary to vacuolar degeneration, islet amyloidosis (cats), immune destruction (dogs), hyperfunction-induced apoptosis (cats), pancreatitis, or congenital islet hypoplasia.
- Insulin deficiency causes decreased tissue utilization of glucose, amino acids, and fatty acids; accelerated hepatic glycogenolysis and gluconeogenesis; and accumulation of glucose in the circulation, causing hyperglycemia.
- Progressively worsening hyperglycemia leads to glycosuria, which creates an osmotic diuresis, causing polyuria. Compensatory polydipsia prevents dehydration as long as there is free access to water.
- The diminished peripheral tissue utilization of glucose and amino acids results in weight loss.
- Insulin deficiency results in failure of the satiety center to inhibit the feeding center in the hypothalamus, causing polyphagia.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is based on the presence of appropriate clinical signs (i.e., polyuria, polydipsia, polyphagia, weight loss), and documentation of persistent fasting hyperglycemia (blood glucose >200 mg/dL [11 mmol/L]) and persistent glycosuria.

INITIAL DATABASE

A thorough diagnostic evaluation is indicated to identify any disease that might be causing or contributing to the diabetic state, that may result from the diabetic state, or that may force modification of therapy.

- CBC: typically normal
- Common serum biochemical profile findings: hyperglycemia, hypercholesterolemia, and increased serum alanine aminotransferase and alkaline phosphatase activities.
- Common urinalysis findings: specific gravity >1.025, glycosuria, findings consistent with concurrent bacterial urinary tract infection (see p. 1596). Bacterial culture of urine is recommended in all diabetic patients irrespective of urinalysis results. Ketonuria establishes a diagnosis of diabetic ketosis or ketoacidosis.
- Findings on abdominal ultrasound may include hepatomegaly, changes suggesting pancreatitis, and bilateral adrenomegaly or an adrenal mass if concurrent hyperadrenocorticism is present.
- Additional diagnostic tests to consider include serum thyroxine concentration in an older diabetic cat, serum pancreatic lipase immunoreactivity for pancreatitis, serum progesterone concentration in an intact female diabetic dog.

DIFFERENTIAL DIAGNOSES

- Polyphagia (see pp. 899,)
- Polyuria/polydipsia (see pp. 902, p. 1419, p. 1420,p. 1585)
- Weight loss (see p. 1181 ,p. 1436)

TREATMENT

TREATMENT OVERVIEW

- The primary goal is elimination of owner-observed clinical signs and maintenance of a healthy, active pet while avoiding

clinical signs of hypoglycemia.
- Stable body weight once obesity is corrected
- Avoidance of chronic complications of diabetes mellitus, most notably recurring ketosis, clinical signs of poor control of glycemia (e.g., lethargy, weight loss, poor body condition), cataracts (dogs), and clinical signs of peripheral neuropathy (cats)

TREATMENT 

- For dogs, recombinant human or pork-source NPH or Lente insulin at an initial dosage of 0.25 U/kg SQ q 12 h
- For cats:
  - Glargine insulin at starting dose of no more than 3 U/cat SQ q12 h if blood glucose is >360 mg/dL (>20 mmol/L). Close monitoring of blood glucose is required; dose reduction is expected in the first 7 days. If close monitoring is not possible, it is safer to start with 1 U/cat SQ q12 h.
  - Alternatively, recombinant human or pork-source Lente or beef/porksource PZI insulin can be used at an initial dose of 1 unit per cat SQ q 12 h.
- Keep daily exercise fairly consistent for dogs.
- Identify and treat concurrent disorders that interfere with insulin effectiveness.
- Treatment with the oral sulfonylurea, glipizide, may be considered in diabetic cats when the owner refuses to administer insulin, if ketonuria and peripheral neuropathy are not identified, and if the cat is relatively healthy.
- Treatment of DKA: see p. 299

NUTRITION/DIET

- Adjust dietary caloric intake to correct or prevent obesity.
- Divide total daily caloric intake in half, and offer at the time of each insulin injection. Consumption may be immediate or intermittent throughout the 12-hour period, depending on eating habits of the dog or cat. Some cats may prefer to “graze” throughout the day.
- For maintenance in dogs, increase fiber content of the diet unless concurrent disease or adverse effects dictate otherwise. Amount of fiber depends on fiber type: insoluble fiber should be >10%, soluble fiber should be 4%-8%, and mixtures of soluble and insoluble fiber should be >8% of diet on dry-matter basis.
- In cats, restrict carbohydrate content of diet, ideally to 15% or less of metabolizable energy. Fiber content of the diet can also be increased as described for dogs.

POSSIBLE COMPLICATIONS

Insulin-induced hypoglycemia, diabetic ketoacidosis

RECOMMENDED MONITORING

- Initially, monitor clinical response and blood glucose concentrations weekly until diabetic control is attained, defined as resolution of clinical signs and blood glucose concentrations ranging between 100 and 300 mg/dL (5.5 and 16.7 mmol/L) during the 12 hours after insulin administration.
- With instruction, some clients may be able to obtain blood glucose curve results for their pet via home monitoring. However, any adjustments in insulin dose should only be done in consultation with the veterinarian.
- Monitor history, physical examination, body weight, and serum fructosamine concentration every 3-6 months once diabetes is controlled.
- Evaluate multiple blood glucose concentrations during the 12 hours after insulin administration if diabetic control is lost (i.e., return of clinical signs, abnormalities identified on physical examination, or progressive loss of body weight). Adjust insulin therapy accordingly.

TECHNICIAN TIPS

- Minimize stress to the patient.
- Perform blood sampling for glucose measurements in a quiet room, and have all equipment ready before taking the patient out of a cage for venipuncture.

PROGNOSIS AND OUTCOME 

- Prognosis depends on owner commitment to treating the disorder, ease of glycemic regulation, presence and reversibility of concurrent disorders, and avoidance of chronic complications associated with the diabetic state.
- Mean survival time for diabetic dogs and cats is approximately 3 years from time of diagnosis, although diabetic dogs and cats that survive the first 6 months can easily maintain a good quality of life for longer than 5 years with proper care.

Diabetes Insipidus

BASIC INFORMATION

DEFINITION

Well-recognized disorder of insufficient antidiuretic hormone (ADH) secretion (central diabetes insipidus) or action (nephrogenic diabetes insipidus) resulting in inadequate urine-concentrating ability.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Affects both dogs and cats
- No breed, gender, or age predilection

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Central diabetes insipidus (CDI): hypothalamus/pituitary gland disorder
- Nephrogenic diabetes insipidus (NDI): renal disorder

HISTORY, CHIEF COMPLAINT

- Polyuria, polydipsia, loss of house training, perceived urinary incontinence
- Stupor, disorientation, ataxia, and seizures may be reported if an underlying neurologic disorder is present.

PHYSICAL EXAM FINDINGS

- Usually normal
- Dehydration may be noted if the animal has not had free access to water.
- Neurologic abnormalities (e.g., stupor, disorientation, ataxia) may be seen in CDI cases with underlying hypothalamic/pituitary lesions, or as a consequence of severe hypernatremia from hypertonic dehydration.

ETIOLOGY AND PATHOPHYSIOLOGY

- Normal daily water consumption: <70 mL/kg/d for dogs (higher in dogs <4 kg); <250 mL/d for the average-sized cat
- ADH is released by the neurohypophysis (segments of hypothalamus and posterior pituitary gland) in response to increased plasma osmolality, and to a lesser degree to reduced blood volume.
- ADH binds to receptors at the renal distal tubules and collecting ducts and allows water to be resorbed from the lumen of the duct into the renal interstitium, resulting in concentrated urine. Water resorption is also dependent on the osmotic gradient of the renal interstitium.
- CDI results from a lack of hypothalamic production of ADH secondary to cerebral trauma, cranial neoplasia (primary or metastatic), or hypothalamic/pituitary cysts. Those animals without a discernable underlying cause are classified as having idiopathic CDI.
- NDI results from a reduced capacity of ADH to bind to its renal receptors and exert its renal actions. Interference with the binding capacity of ADH can be secondary to *Escherichia coli* endotoxins (pyometra, pyelonephritis), hypercalcemia, hypokalemia, hyperaldosteronism, and hyperadrenocorticism.
- Congenital NDI and congenital CDI are very rare.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnostic approach to diabetes insipidus is directed at ruling out metabolic and other endocrine causes of polyuria/polydipsia, using a CBC, serum biochemistry profile, urinalysis, urine culture, and test(s) for adrenal gland disorders. Once other differentials are

excluded, differentiation of CDI from NDI or psychogenic polydipsia requires a modified water deprivation test or trial therapy with exogenous ADH.

DIFFERENTIAL DIAGNOSIS

Other causes of polyuria/polydipsia, including chronic renal disease, diabetes mellitus, hyperadrenocorticism, hypercalcemia, hyperthyroidism, hypoadrenocorticism, hypokalemia, liver disease, primary hyperaldosteronism (rare), primary renal glycosuria (rare), psychogenic polydipsia, pyelonephritis, and pyometra (see p. 902).

INITIAL DATABASE

- CBC: usually normal; mild hemoconcentration may be present if the animal is dehydrated.
- Serum biochemical profile
- Urea may be decreased due to increased renal loss, or mildly increased in dehydrated patients.
- Mild hyponatremia or hypokalemia occasionally seen
- Urinalysis: usually hyposthenuria (urine specific gravity <1.008) but can concentrate up to 1.015 in cases with partial ADH deficiency
- Other tests to rule out causes of secondary NDI usually include urine culture, abdominal ultrasound, and testing for hyperadrenocorticism (see p. 548).

ADVANCED OR CONFIRMATORY TESTING

- Endogenous creatinine clearance testing or nuclear scintigraphy to estimate glomerular filtration rate: considered if persistent isosthenuria is present, to rule out renal insufficiency.
- Random plasma osmolality:
  - A large overlap can occur between results from patients with a primary polyuric disorder (e.g., CDI or NDI) and a primary polydipsic disorder (i.e., psychogenic polydipsia).
  - Plasma osmolality <280 mOsm/kg is suggestive of psychogenic polydipsia.
  - Plasma osmolality >280 mOsm/kg can be seen with CDI, NDI, or psychogenic polydipsia.
- Modified water deprivation test:
  - Used for differentiating between diabetes insipidus and psychogenic polydipsia
  - Causes of secondary NDI should be ruled out before performing this test.
  - Should not be performed if renal disease or dehydration is present.
  - The patient must be monitored throughout the test.
  - Procedure:
    - Slowly decrease the patient's water intake to 70-100 mL/kg/d over 3-5 days before starting the test to help correct any secondary renal medullary solute washout.
    - Fast the patient for 12 hours before the test.
    - At the start of water deprivation, empty the patient's bladder, and determine the patient's weight, blood urea nitrogen (BUN) (via an Azostick is sufficient), urine specific gravity (USG), and urine osmolality (if readily available).
    - Withhold water and monitor clinical demeanor, weight (after emptying bladder), and USG (± urine osmolality) q 1 h. Assess BUN every few hours.
    - This portion of the test is stopped when 3% of the body weight has been lost, USG increases to >1.030, azotemia occurs, or the pet becomes clinically dehydrated or depressed.
    - If 3% of the body weight has been lost, urine concentration is <1.030, and the pet is still clinically normal, administer ADH (aqueous vasopressin: 0.55 U/kg IM to a maximum of 5 U) and reassess USG at 30, 60, and 120 minutes.
    - Slowly reintroduce water when the test is completed.
  - Interpretation:
    - USG in patients with psychogenic polydipsia should slowly increase to >1.030 with water deprivation alone.
    - Patients with complete CDI will show little or no increase in urine concentration (still <1.015-1.020) with fluid loss of 3%-5% of body weight, but will then show a >50% increase in USG after ADH administration.
    - Patients with partial CDI will show little increase in urine concentration by the time they have lost 3%-5% of body weight but will show an increase in USG of >15% but <50% after ADH administration.
    - Patients with NDI will show little increase in USG even with ADH administration.
  - Possible complications of the test: hypernatremia/hypertonic dehydration (irritability, weakness, ataxia, stupor, coma)
- CT or MRI of the brain can be used to image a potential underlying cranial mass in older patients with CDI.

TREATMENT

TREATMENT OVERVIEW

Therapy is aimed at improving patient and owner quality of life through reduction or resolution of polyuria and polydipsia. Treatment is expected to be lifelong unless an underlying cause can be identified and resolved.

ACUTE GENERAL TREATMENT

None generally required

CHRONIC TREATMENT

- Exogenous ADH administration (desmopressin acetate [DDAVP]: either as tablets [0.1 mg/dog PO q 8 h or 0.025-0.05 mg/cat q 8-12 h; increase dose if no response within 1 week] or intranasal drops administered into the conjunctival sac [1-4 drops/patient q 12 h]) is the treatment of choice for CDI. Patients with NDI are unresponsive to DDAVP therapy.
- Thiazide diuretics can be used in cases of primary NDI or partial CDI to reduce total body sodium concentrations, thereby increasing renal sodium and water resorption and reducing urine volume. Chlorothiazide (20-40 mg/kg PO q 12 h) or hydrochlorothiazide (1-2 mg/kg PO q 12 h) should be used in conjunction with a low-sodium diet.
- Chlorpropamide is an oral hypoglycemic agent that potentiates renal ADH action and may be useful in cases of partial CDI. Doses of 10-40 mg/kg PO q 24 h have been suggested, but clinical responses in cats and dogs have been variable.
- If the polyuria/polydipsia is not disruptive to the owners, and the animal has free access to water, therapy for CDI or NDI may not be required.

NUTRITION/DIET

A sodium-restricted diet alone may be useful at reducing urine volume in patients with CDI and NDI.

DRUG INTERACTIONS

Chlorpropamide may enhance the antidiuretic effects of desmopressin and displaces nonsteroidal antiinflammatory drugs, warfarin, and many others from circulating protein-binding sites, elevating their serum levels.

POSSIBLE COMPLICATIONS

- Cellular overhydration can theoretically occur in patients that consume large volumes of water shortly after receiving DDAVP, owing to a decreased ability to excrete the free water once DDAVP reaches therapeutic effect. Neurologic signs (ataxia, depression, tremors) can occur as a consequence of cerebral edema. It is recommended that pets not have free access to water immediately after each dose.
- Conjunctival irritation is occasionally seen with conjunctival administration of DDAVP but is usually mild.
- Thiazide diuretics may cause hypokalemia and, if given to a patient with primary polydipsia, could lead to cellular overhydration due to decreased free water excretion.
- Hypoglycemia is the most common complication of chlorpropamide therapy.

RECOMMENDED MONITORING

- Clinical response should be monitored in those patients receiving DDAVP therapy.
- Serum electrolytes should be periodically monitored if thiazide diuretics are used, as should blood glucose levels if chlorpropamide is used.

PROGNOSIS AND OUTCOME

- In patients with congenital or idiopathic CDI, clinical signs generally resolve completely with DDAVP therapy, and patients can have a normal life expectancy. The expense of DDAVP therapy, however, can make lifelong treatment not feasible for some pet owners.
- CDI secondary to an underlying cranial tumor has a very guarded prognosis, as progressive neurologic signs often develop in the ensuing months.
- The polyuria/polydipsia of primary NDI is often difficult to manage medically and therefore is associated with a guarded prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- Response to exogenous DDAVP therapy can be used as a less arduous and less hazardous alternative to the water deprivation test to diagnose CDI, once the differential diagnosis has been narrowed down to CDI, NDI, or psychogenic polydipsia. Daily water consumption and USG should be measured before the administration of DDAVP and after a 5- to 7-day course of exogenous therapy. A marked reduction in water consumption and increase in urine concentrating ability occurs in patients with CDI. Patients with NDI or psychogenic polydipsia do not have a clinical response to DDAVP.
- Hyperadrenocorticism is a likely differential in a patient that initially responds to exogenous DDAVP therapy but later has recurrence of polyuria and polydipsia.

TECHNICIAN TIP

- The water deprivation test requires extremely diligent hourly monitoring for the entire duration of the test, without which there is a risk of rapidly progressive life-threatening dehydration in these patients.

CLIENT EDUCATION

Patients with diabetes insipidus must always have free access to water.

AUTHOR: SARAH L. NAIDOO

EDITOR: SHERRI IHLE

Dermatophytosis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Dermatophytosis is a well-recognized contagious infection of the skin, hair, and/or claw with one of several species of superficial fungi (i.e., dermatophytes).

SYNONYMS

Ringworm; tinea (Latin term used by physicians)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Any animal species may contract dermatophytosis, though it is particularly important in cats. It is most commonly a disease of young animals, owing to immaturity of their defense mechanisms.
    - In dogs, the incidence is low. Circular, scaling patches in dogs are more likely to be superficial staphylococcal pyoderma or demodicosis rather than dermatophytosis.
    - In cats, the incidence is higher; it tends to be underdiagnosed in part because of the polymorphic nature of lesions.

GENETICS & BREED PREDISPOSITION

Some breeds or lines of long-haired cats (Persians, Himalayans) appear to be predisposed to infection; some individuals of these breeds are more difficult to treat effectively.

RISK FACTORS

- Any condition that results in debilitation or immunocompromise can serve as a predisposing factor. Examples include cancer, immunosuppressive therapy, metabolic disease.
- Incidence is higher with inadequate husbandry conditions (some shelters, catteries, pet stores, stray/feral cat populations), where high population density, stress (pregnancy, lactation), poor nutrition, concurrent parasitisms, viral infections, and other diseases may make dermatophytosis endemic.

CONTAGION & ZOONOSIS

Dermatophytosis is a contagious zoonotic disease. Humans, dogs, and cats exposed to an infected animal are at risk. Transmission occurs by direct contact, contact with contaminated fomites (carpeting, bedding, grooming implements) or with infected soil. Unaffected animals in the household may serve as “fomites” by innocently transporting spores on their haircoats, though such individuals are actually not infected and should not be termed “carriers.” Fungal spores remain viable for years under ideal conditions.

GEOGRAPHY AND SEASONALITY

Incidence is higher in warmer tropical or subtropical geographic regions, particularly in locales with large stray cat populations.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Beyond the typical grossly visible superficial infection, other forms include:
    - *Subclinical infection:* some infected cats have subtle hair loss and scaling, even appearing grossly normal (particularly if long-haired). These normal-appearing yet infected cats pose a special risk in multianimal facilities, where their unaffected appearance may lead to lack of treatment.
    - *Kerion:* an uncommon, overly exuberant immunologic/inflammatory response to the organism leads to thickened plaquelike to smooth, nodular growths or masses.
    - *Mycetoma or pseudomycetoma:* rare formation of pyogranulomatous draining nodules as a result of deeper extension

of the infection in an immunocompromised host.

HISTORY, CHIEF COMPLAINT

Often a young patient, sometimes from a multianimal environment, presenting with one or more patchy areas of alopecia, scaling, or poor haircoat. There may be a history of contagion to the owner.

PHYSICAL EXAM FINDINGS

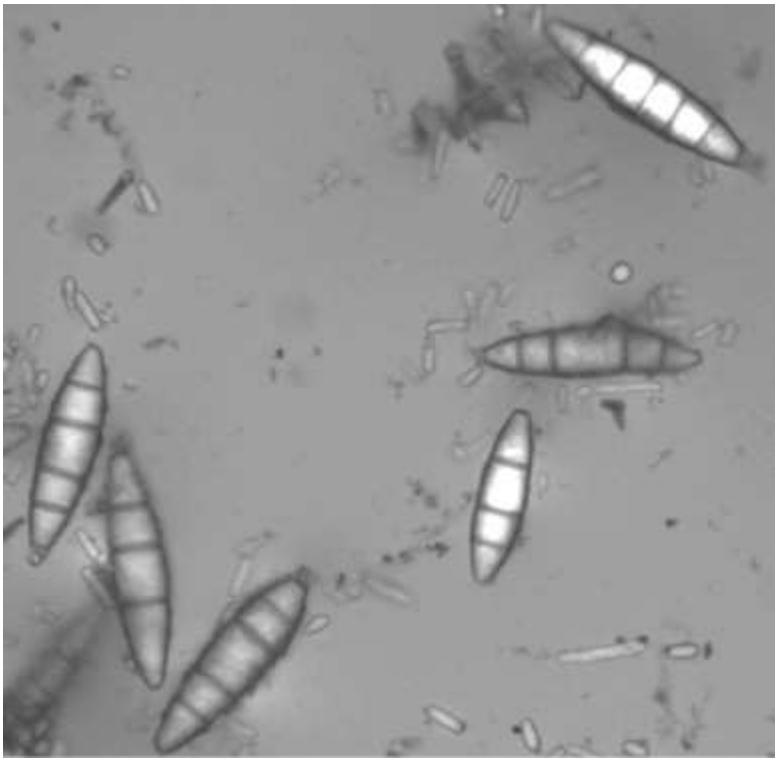
- The classical appearance is focal or multifocal areas of alopecia and scaling or crusting of varying severity, most commonly occurring on the face and forelimbs. The lesions can be circular or ringlike, or more diffuse, and are associated with variable degrees of inflammation and pruritus.
- In cats, dermatophytosis creates an especially large range of clinical signs, including (less commonly) miliary dermatitis, chin acne, or generalized scaling.
- Uncommonly, follicular infection and rupture may produce a pustular appearance.
- Uncommonly, infections on the facial and nasal areas may produce severe alopecia, crusting, weeping, and inflammation that clinically and histologically resemble pemphigus.

DERMATOPHYTOSIS Macroconidia of *Microsporum canis*.

(Copyright Dr. Manon Paradis.)

ETIOLOGY AND PATHOPHYSIOLOGY

- In order of prevalence, causative fungal species include *Microsporum canis*, *Microsporum gypseum*, and the *Trichophyton* group (the latter also known as *Arthroderma*). Feline infections with *M. gypseum* and *Trichophyton* appear to be on the rise, especially in animal shelters; other species such as *M. persicolor* are reported rarely.
- Under usual circumstances, dermatophytes live in nonviable, cornified tissue (superficial epidermis, actively growing hairs, nails); invasion into living tissue implies a compromised host.
- The presence of the fungus alone will not necessarily result in infection. Whether infection ensues depends on host factors (youth, debility, genetics) ; host immunity (natural and acquired); husbandry (stress, nutrition, concurrent disease); number of spores; trauma to the skin (as with scratching); and presence of occlusive conditions on the skin.
- In most normal individuals, after infection, cell-mediated immunity develops against the fungus, eventually resulting in spontaneous cure (typically 12-20 weeks). Animals that fail to develop the appropriate immune response may remain persistently infected until treated.



DERMATOPHYTOSIS Macroconidia of *Microsporum gypseum*.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is suspected based upon history and clinical signs and confirmed with the gold standard of fungal culture; other diagnostic tests are helpful but not reliable.

DIFFERENTIAL DIAGNOSIS

- In dogs, superficial staphylococcal pyoderma and demodicosis have a similar clinical appearance and are more common; therefore, these disorders should be suspected first.
- In cats, miliary dermatitis due to other causes such as flea allergy, mite infestation, or other allergy should be considered, as well as other causes of generalized scaling and pruritus.

INITIAL DATABASE

Following initial clinical suspicion, the following tests can be used to help confirm infection:

- *Trichogram:* the finding of ectothrix spores and/or hyphal elements within hair shafts upon microscopic examination; difficult and insensitive.
    - Hairs are plucked from the edges of lesions and wet mounted in 10% potassium hydroxide or chlorphenolac clearing solution. Plucking fluorescing hairs (see below) may increase the chances of finding spores. This technique is insensitive, requires considerable experience to avoid artifact, and is not recommended for routine use.
- *Wood's lamp*: about 50% of strains of *M. canis* will fluoresce a bright "apple green" color upon exposure to UV light of wavelength 320-400 nm; a reasonable screen but not dependable.
    - This technique is inexact and prone to misinterpretation, because many strains of *M. canis* (and other dermatophyte species) do not fluoresce. Other materials such as keratin scale and topical products may fluoresce, leading to false-positive results.
    - Fluorescence is due to a fungal metabolite produced only when the organism is growing on hair shaft material. A true positive thus appears as bright green fluorescence along the length of the *hairs only*, never in scale, claw, or culture.
    - It is helpful to allow the lamp to warm up for 5 minutes before use to produce maximum fluorescence. Suspected fluorescing hairs should *always* be examined microscopically and/or cultured to confirm the presence of a

dermatophyte.
    - A Wood's lamp is a useful aid to monitor infection status in an animal shelter experiencing endemic infection, if the infection is with a fluorescing strain.
- *Fungal culture:* a highly reliable method if done properly. Requires some skill and experience; therefore submission to a reference laboratory is a valid consideration.
    - To collect a sample for culture, the toothbrush technique is preferred. A new inexpensive toothbrush is vigorously combed over the lesions (or all parts of the haircoat if lesions are not obvious or cat appears “normal”) for 2-3 minutes; wrap in plastic and submit.
    - In-clinic cultures can be carried out using dermatophyte test medium (DTM), available in several formats (vial, round, or square plate). All are equally useful, though the plate formats are easier to inoculate. Some plate formats include a separate compartment with a different medium (Sabouraud's dextrose agar or rapid sporulation medium), which is marginally useful in practice. To inoculate the medium, touch all sides of the toothbrush bristles lightly onto the DTM multiple times.
    - Cover plates, but do not seal with tape. Incubate at warm room temperature (ideally, 28°C/80°F); light conditions do not matter. Growth occurs typically within 7-14 days, though plates are kept for 21 days before deeming them negative.
    - Examine the plates *daily* for growth. Look for a white to off-white, fluffy to powdery colony, with a red color change in the medium *at the same time* that the colony is first visible. Dermatophyte colonies are never black, grey, green, or multicolored.
    - DTM is not infallible. All fungi will eventually cause a red color change; some nonpathogenic saprophytes cause rapid color change. Thus, suspect colonies must be examined microscopically for confirmation: brush a strip of clear cellophane tape over the colony, and mount the tape sticky side down onto a drop of lactophenol cotton blue stain (or methylene blue) on a microscope slide. Examine at 100× to 400× total magnification for typical appearance of dermatophyte macroconidia (see figures). The appearance of these macroconidia varies with fungal species; consult a reference text.
    - When working with an infected multianimal facility, it is convenient to sample each cat with a separate toothbrush and place each in a separate zip-lock plastic bag labeled with identification information.

ADVANCED OR CONFIRMATORY TESTING

Skin biopsy: dermatophytes may be visible on histopathologic examination of skin biopsy specimens, though they are sometimes difficult to find; a negative result does not preclude dermatophytosis. Advising the pathologist that dermatophytosis is suspected will prompt special stains to facilitate identification of fungal elements.

TREATMENT

TREATMENT OVERVIEW

Treatment is strongly advised to accelerate recovery and help minimize spread. The best treatment protocol combines 3 elements: topical, systemic, and environmental treatment. All treatments are continued until clinical (and preferably, mycologic) cure is effected, typically 8-16 weeks.

ACUTE GENERAL TREATMENT

- Topical therapy: kills infective material on the haircoat, but by itself may not speed resolution. Whole-body treatment (dip or rinse) is greatly preferred to spot treatment, which will miss areas of active infection. Any of the following whole-body treatments is recommended and applied twice weekly:
    - Lime-sulfur solution, 1/16 dilution (8 oz in 1 gal water; 30 mL in 480 mL water); do not rinse. Towel dry. In some countries, agricultural products are used. They are labeled 23% calcium polysulfide or 23% sulfur sulfide, which is equivalent to 76.9% lime sulfur solution. Therefore, the same dilution (1/16) is required to obtain a ~5 % solution.
    - Enilconazole topical solution, 0.2% (dilute per label instructions); in cats, prevent grooming with Elizabethan collar until dry.
    - Chlorhexidine + miconazole or chlorhexidine + ketoconazole shampoo or rinse (rinse preferred, use per label instructions).
    - Products based on chlorhexidine or miconazole alone are less effective and not recommended.
- Systemic therapy: shortens the disease course in each animal:
    - Itraconazole is the systemic drug of choice for cats; cost limits its use in dogs. Administer 5-10 mg/kg PO q 24 h for 7 days, then stop drug for 7 days, then treat again for 7 days, then stop for 7 days, then treat for a final 7 days. This week-on/week-off “pulse regimen” saves cost and is effective because the drug accumulates in hair and skin tissue. Animals unresponsive to this protocol may benefit from use of 10 mg/kg PO daily without pulse dosing.
    - Ketoconazole is a reasonable and often inexpensive choice for dogs (5-10 mg/kg PO q 24 h) but should not be used in cats because of frequent hepatotoxicity in this species.
    - Fluconazole may be less effective than other drugs but is rarely hepatotoxic. Administer to dogs or cats at 5-10 mg/kg

PO q 24 h.
    - Terbinafine is much less studied and may have adverse effects, but use is increasing owing to the recent appearance of inexpensive generic formulations. For cats, administer 30-40 mg/kg PO q 24 h; malaise and elevated ALT may occur in up to a third of animals. Terbinafine has been successful in some cats initially unresponsive to azole therapy; unstudied for use in canine dermatophytosis.
    - Griseofulvin: microsize formulation, 25 mg/kg/d (cats); 50-100 mg/kg/d (dogs). Ultramicrosize in PEG base formulation, 5-10 mg/kg/d (cats); 10-30 mg/kg/d (dogs). Teratogenic; do not administer to pregnant animals. Idiosyncratic myelosuppression may be seen in cats, especially those positive for FeLV or FIV.
    - Lufenuron, despite early reports to the contrary, is not effective in treatment or prevention of dermatophytosis in cats.
- Environmental treatment: helps prevent recurrence and spread to other individuals in the household. Effective disinfectants include diluted chlorine laundry bleach (final concentration 0.05% sodium hypochlorite; consult label, but this is most often 1/100 dilution); enilconazole environmental products are effective in countries where licensed. Other disinfectants labeled as effective against dermatophytes often have limited or no effectiveness under field conditions.
    - Typical household with one or a few cats: disinfection not critical; vacuum thoroughly, wipe down hard surfaces with disinfectant if possible.
    - Multianimal facility: *critical* to disinfect entire premises monthly during eradication efforts; see further reading below.
- Treatment of *kerion* is as listed above; *mycetoma* or *pseudomycetoma* require very long-term systemic treatment often combined with surgical debulking.

RECOMMENDED MONITORING

- Fungal culture: repeat after 2 months of treatment, then once monthly until culture is negative twice.
- Serum ALT: once monthly for all cats receiving terbinafine
- CBC: for all cats receiving griseofulvin; after 2 weeks of treatment, then once monthly.

PROGNOSIS AND OUTCOME

- Prognosis for most cases is good, except in immunocompromised animals.
- Especially in long-haired cats, a few animals require more intensive treatment and may take several years to resolve completely.

PEARLS & CONSIDERATIONS

COMMENTS

- Clipping of haircoat: necessity is controversial; it facilitates treatment but is unnecessary in most household situations.
- Eradication of dermatophytosis from an animal shelter or cattery is possible, but expensive and time consuming. Consult references (below and online) for detailed protocols.

TECHNICIAN TIPS

- Remember the potential both for zoonosis and contagion. Basic hygiene (gloves, handwashing) is important to prevent spread.
- Dermatophytosis is common in cats and often does not produce the classic “ring” lesion, whereas it is uncommon in dogs. Appropriate precautions should be implemented accordingly.

CLIENT EDUCATION

Clients should always be advised of the zoonotic nature of this disease, and prompted to seek medical advice if they have concerns or develop lesions.

EDITOR: MANON PARADIS

Dermatomyositis

BASIC INFORMATION

DEFINITION

Familial canine dermatomyositis is a hereditary, idiopathic inflammatory skin disease producing alopecia, erosions, and crusting, predominantly over bony prominences, tip of the tail, and pinnae in collies and Shetland sheepdogs. Histologically, myositis and vasculitis may be noted as the disease progresses. Acquired dermatomyositis may be rarely noted in other breeds.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: primarily young dogs (<6 months old). The full extent of the disease is usually noted by 1 year. Number of lesions and severity usually decreases from then on.
- Cats: do not appear to get dermatomyositis.

GENETICS & BREED PREDISPOSITION

- Dermatomyositis is classically overrepresented in collies and Shetland sheepdogs, Beauceron shepherds, and their crossbreeds.
- Acquired dermatomyositis has been reported in Welsh corgis, Lakeland terriers, chow chows, German shepherds, Kuvasz, and Australian cattle dogs but has an unproven familial basis.

RISK FACTORS

Mechanical trauma and sunlight (UV) and reproductive stress (estrus, parturition, lactation) may worsen the lesions.

ASSOCIATED CONDITIONS & DISORDERS

Myositis and muscle atrophy may lead to dysphagia, megaesophagus with subsequent aspiration pneumonia, skeletal muscle weakness, and lameness.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Owner generally presents a young collie or Shetland sheepdog puppy with skin lesions over bony prominences, face, pinnae, and tip of the tail.
- Puppies may be painful or inappetent, the latter being directly related to the degree of myositis affecting pharyngeal muscles.

PHYSICAL EXAM FINDINGS

- Clinical signs wax and wane and vary from minor skin lesions (papules/rarely vesicles) to severe ulceration of the skin, with a generalized debilitating myositis affecting the head and distal limbs.
- Skin lesions are generally characterized by erosion and crusting around the eyes, on the bridge of the nose, lips, ear, bony prominences (elbows, hocks, digits), and the tail tip. Vesicles are occasionally noted.
- Pruritus is not normally present unless complicated by another condition such as pyoderma.
- Some dogs present with onychodystrophy (abnormal claw formation). Ulcers of the footpads are rarely noted.
- Healing may lead to scarring alopecia.
- Megaesophagus and aspiration pneumonia are occasionally noted.
- Stunted growth, lameness, and muscle wasting may occur as the disease progresses.
- Littermates may be affected to different degrees.

ETIOLOGY AND PATHOPHYSIOLOGY

- The condition is thought to be associated with a hereditary autosomal dominant trait of variable expression in affected collies and Shetland sheepdogs (chromosome 35 in the Shetland sheepdog).

- Most researchers believe the condition has an immune-mediated or autoimmune basis, although others have suggested that a viral or environmental trigger could be important.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A young collie or Shetland sheepdog presenting with facial, ear, and tail tip alopecia and erosion is strongly suggestive of dermatomyositis. This clinical picture should prompt clinician to perform a skin biopsy. Electrodiagnostic testing and muscle biopsy are used when signs of muscle dysfunction predominate (no skin lesions).

DIFFERENTIAL DIAGNOSIS

- Demodicosis
- Dermatophytosis
- Bacterial folliculitis
- *Malassezia* dermatitis
- Discoid lupus erythematosus
- Vasculitis

INITIAL DATABASE

- Skin cytologic preparations: no abnormal findings
- Skin scraping to rule out demodicosis
- Skin biopsy for histopathologic evaluation (may be nondiagnostic in mild cases). Characteristic hydropic degeneration in the basal cell layer, with a mild perivascular to interstitial dermatitis. Follicular atrophy may be noted in chronic lesions. Vasculitis is occasionally noted.
- CBC, serum biochemistry profile, urinalysis: usually within normal limits

ADVANCED OR CONFIRMATORY TESTING

- Electromyograms (see online chapter: Electromyography) are abnormal in cases with subclinical or clinical myositis.
- Muscle biopsy (see p. 1305) reveals myofibrillar degeneration and atrophy, with accumulations of mixed inflammatory cells.
- Neurologic examination is usually normal.

TREATMENT

TREATMENT OVERVIEW

The therapeutic goal is to minimize scarring of facial skin and debilitating myositis. Specific approaches vary, with some dermatologists using several drugs initially and tapering, while others begin with one or two and increase if needed.

ACUTE AND CHRONIC GENERAL TREATMENT

- Therapeutic options include the following drugs, which may be used alone or in combination, depending on the severity of the disease:
  - Pentoxifylline, 15-25 mg/kg PO q 8-12 h
  - Tetracycline and niacinamide *(adult dogs only):* given for minimum 3 months, weaning down based on a favorable response
    - >10 kg: 500 mg of each drug PO q 8 h
    - <10 kg: 250 mg of each drug PO q 8 h
- Vitamin E, 400-800 IU per day PO for minimum 1-2 months
- Omega-3 EFA (Derm Caps)
- Also used often, though with consideration given to risk of side effects (especially prednisone) and cost (cyclosporine):
  - Prednisone, 1-2 mg/kg PO q 12-24 h, weaning down to an alternate-day regimen based on a favorable response.
  - Cyclosporine (Atopica, Neoral): 5 mg/kg PO q 12-24 h
- Supportive care should be considered for all cases and can include controlling secondary infection with appropriate therapy and avoiding mechanical trauma to the face (avoid “gentle leaders”–type muzzle collars), aggressive bathing, or harsh shampoos.
- Soften dry foods and raise bowls to minimize dysphagia.

- Avoid intense sunlight.

POSSIBLE COMPLICATIONS

- Chronic prednisone use can cause iatrogenic hyperadrenocorticism and immune suppression.
- Pentoxifylline can cause gastric irritation, elevated coagulation times, and nervous irritability.
- Cyclosporine: diarrhea, vomiting, anorexia, gingival hyperplasia, and gingivitis are possible. Monitor for tumors.

RECOMMENDED MONITORING

Cyclosporine: check trough cyclosporine levels if adverse reactions are noted, particularly in collies; many are homozygous mutant for the ABCB1 (MDR1) gene, which may cause a marked increase in cyclosporine blood level (see p. 706).

PROGNOSIS AND OUTCOME

Prognosis is variable depending on severity. Mild cases may resolve without further problems, although scarring of the skin may be noted. Dogs with more severe skin lesions may be prone to recurrent skin problems. Cases with severe myositis have a poor prognosis for long-term survival.

PEARLS & CONSIDERATIONS

COMMENTS

- Facial skin lesions in a young Sheltie or collie are very evocative of demodicosis, whereas involvement of the tip of the tail and pinnae is much more suggestive of dermatomyositis.
- The waxing and waning nature of lesions renders evaluation of the efficacy of different drugs very difficult.

PREVENTION

- Do not breed affected individuals.
- Minimize exposure to UV light for affected individuals.

CLIENT EDUCATION

Affected individuals will likely require a higher level of skin care than unaffected dogs.

EDITOR: MANON PARADIS

1ST EDITION AUTHOR: JAN A. HALL

†Deceased

Demodicosis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Demodicosis is a common inflammatory disease associated with an increase in the number of *Demodex* mites found on the skin.

SYNONYM

Demodectic mange

EPIDEMIOLOGY

SPECIES, AGE, SEX

- *Demodex canis* mites are present in small numbers on the skin of most healthy dogs. Transmission occurs from bitch to pups within 3 days of birth.
- Juvenile demodicosis is often first noted by 3-6 months of age.
- Adult-onset demodicosis usually occurs in middle-aged to old dogs and is associated with internal disease and immunosuppression.

GENETICS & BREED PREDISPOSITION

- Dogs affected with juvenile-onset generalized demodicosis, their siblings, and their parents should not be bred; hereditary predisposition is likely.
- Purebred dogs are predisposed for juvenile-onset demodicosis; overrepresented dog breeds may include short-coated dogs such as American Staffordshire terriers, boxers, pit bull terriers, and shar peis.

RISK FACTORS

Poorly characterized immunologic factors influenced by genetics. Concurrent immunosuppressive diseases, states, or treatments.

CONTAGION & ZOONOSIS

Canine demodicosis not considered contagious to immunocompetent animals. *Demodex gatoi*, however, is transmissible to normal in-contact cats.

GEOGRAPHY AND SEASONALITY

D. gatoi is common in the southeastern United States but very rare in many other parts of North America.

ASSOCIATED CONDITIONS & DISORDERS

Canine demodicosis is very frequently complicated by pyoderma.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Canine:

- Juvenile demodicosis: *D. canis* (usually <18 months of age)
  - Localized: one to several small areas of alopecia, most commonly on face and forelegs
  - Generalized: entire body region, complete involvement of two or more feet, or more than six lesions. Often more severe skin lesions and secondary pyoderma.
- Adult-onset demodicosis: *D. canis* (usually >4 years of age)
  - Usually generalized
- Other:

- *Demodex injai:* large follicular mite, often present in low numbers and associated with pruritus and greasy skin on the dorsal trunk of terriers, particularly West Highland white terriers and fox terriers
- A short-bodied *Demodex* mite (tentatively named *D. cornei* because of its likely residence in the stratum corneum) is reported to coinfect the skin of some dogs with *D. canis*.

Feline:

- *Demodex cati:* often associated with immunosuppressive disease, may also cause ceruminous otitis externa
- *D. gatoi:* pruritic, contagious

HISTORY, CHIEF COMPLAINT

- Chief complaint is typically hair loss, but may be pruritus or other skin lesions.
- Pruritus may be absent in canine demodicosis but is very common if secondary pyoderma is present.
- Pruritus is a major feature of *D. gatoi* infestation in cats and of *D. injai* infestation in dogs.
- Malaise may accompany severe cases of generalized canine demodicosis, likely due to severe secondary pyoderma.
- In adult-onset demodicosis, signs caused by underlying disease (e.g., hyperadrenocorticism) or history of immunosuppressive treatment may be present.

PHYSICAL EXAM FINDINGS

Canine:

- Localized demodicosis: several small areas of patchy alopecia, mild erythema, scaling, and variable hyperpigmentation on the face or forelimbs.
- Generalized demodicosis: lesions may be similar but are usually more severe and extensive and complicated by pyoderma. Comedones, papules, pustules, follicular casts, plaques, crusts, edema, and deep folliculitis/furunculosis are common. Peripheral lymphadenopathy, pain, pruritus, and malaise may also be present. In adult-onset cases, physical changes associated with underlying disease (e.g., hyperadrenocorticism, neoplasia) may be found.
- *D. injai:* greasy skin and pruritus on dorsal trunk

Feline:

- *D. cati:* patchy alopecia or ceruminous otitis
- *D. gatoi:* excoriations, symmetrical self-induced alopecia

ETIOLOGY AND PATHOPHYSIOLOGY

- The immune system defect in demodicosis is still poorly understood (likely a mite-specific deficiency in T-lymphocyte function).
- In adult dogs, changes in the immune system relating to internal systemic disease or drug therapy allow the mites to proliferate. Previous corticosteroid administration is a common cause. Less common are spontaneous hyperadrenocorticism, hypothyroidism, concurrent parasites, and neoplasia.
- Poor nutrition, estrus, parturition, and stress also contribute.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

In most cases, canine demodicosis is a straightforward diagnosis, so long as skin scrapings are not overlooked. Diagnostic cornerstones are the presence of cutaneous lesions and associated mites demonstrated on skin scrapings. Al though *D. canis* is a normal skin inhabitant, it is rare to find mites unless there is overgrowth.

DIFFERENTIAL DIAGNOSIS

Uncomplicated demodicosis resembles many other skin disorders, which emphasizes the value of skin scrapings.

Dogs:

- Bacterial folliculitis
- Dermatophytosis

- Dermatomyositis
- Pemphigus foliaceus and other immune-mediated diseases
- Sebaceous adenitis

Cats:

- Hypersensitivity disorders and other ectoparasites *(D. gatoi)*
- Psychogenic (symmetrical) alopecia *(D. gatoi)*
- Dermatophytosis *(D. cati)*

INITIAL DATABASE

- Deep skin scrapings from at least three sites for most species of *Demodex* mites.
    - Skin should be squeezed to express mites from the hair follicles immediately before and/or during scraping, and scraping should continue until mild capillary bleeding is seen.
    - A subjective assessment of mite numbers (0-4+) and the proportion of live mites as well as juvenile mites is important for baseline and subsequent monitoring of therapy.
- In sensitive areas, a trichogram (forceful hair pluck) can reveal the mites but is generally less rewarding than skin scrapings.
- If trichography is negative, skin scrapings should be collected using sedation.

ADVANCED OR CONFIRMATORY TESTING

- Skin biopsies may be needed to find mites when extensive scarring is present (particularly with pedal involvement). Always scrape before collecting biopsies, as histopathologic evaluation usually is not necessary to diagnose this disease.
- Adult-onset demodicosis cases warrant a full diagnostic workup for internal disease as deemed appropriate, including CBC, chemistry profile, urinalysis, imaging, screening tests for endocrinopathies, and FeLV/FIV evaluation in cats.
- In cats suspected of *D. gatoi* infestation, mites are easy to miss owing to removal by licking. If broad superficial skin scrapings, acetate tape preparations, and fecal flotation are negative, a series of weekly lime sulfur dips is used in endemic areas.

DEMODICOSIS Pododemodicosis can resemble many other conditions. Skin scrapings and trichograms should be collected in dogs of any age presenting with pedal lesions.

TREATMENT

TREATMENT OVERVIEW

- Generalized demodicosis requires miticidal therapy and can be a challenging condition to treat.
- Most cases of localized demodicosis will resolve spontaneously as the immune system matures.
- Treatment for underlying or concurrent disease, or discontinuation of immunosuppressive therapy in adult patients.
- Concurrent pyoderma must be treated, and this component of therapy is often most important in restoring normal skin appearance.
- A "cure" means that there is no relapse within 1 year.

ACUTE AND CHRONIC TREATMENT

- Localized demodicosis does not require treatment; topical antimicrobial agents such as benzoyl peroxide gel or mupirocin may be used.
- Therapy for generalized canine demodicosis requires several months and commitment on the part of the owner. All treatments should continue until two consecutive sets of skin scrapings are negative, or for at least 1 month beyond a set of negative skin scrapings.
- Response to therapy is monitored by clinical improvement and monthly skin scrapings.

Options include:

- Amitraz dips:
  - Used in dogs
  - Approved for canine demodicosis, but side effects and the risk to the handler are of concern (see Possible Complications)
  - Labeled for use as a 0.025% dip every 14 days in dogs >4 months of age
  - Increasing the concentration and frequency is associated with a higher success rate.
  - Environmental Protection Agency (EPA)-registered pesticide, so a violation of U.S. federal law to use it in a manner inconsistent with labeling
  - In very small dogs, treat only half the body at a time to minimize the risk of side effects.
  - Clip long-haired dogs and shampoo all dogs (benzoyl peroxide) prior to dipping
- Oral ivermectin (e.g., 10 mg/mL bovine injectable solution):
  - Used off-label in dogs
  - Best studied of the oral treatments
  - Effective at 0.3-0.6 mg/kg PO q 24 h
  - Incrementally increase to full dose over 7-10 days
  - Contraindicated in certain dogs (see Possible Complications)
- Oral milbemycin (oral monthly heartworm preventative):
  - Used off-label in dogs
  - Acceptable alternative at 0.5-2 mg/kg PO q 24 h; greater success at higher end of dose
  - Must be used with caution in certain dogs (see Possible Complications)
- Oral moxidectin (e.g., 10 mg/mL bovine injectable solution):
  - Used off-label in dogs
  - Effective at 0.4 mg/kg PO q 24 h
  - Same contraindications as ivermectin (see Possible Complications)
- Injectable doramectin (e.g., 10 mg/mL bovine/swine injectable solution)
  - Used to a limited degree off-label in dogs and cats (for *D. cati*)
  - Dosed at 0.6 mg/kg SQ once weekly
  - Same contraindications as ivermectin (see Possible Complications)
- Topical metaflumizone and amitraz (ProMeris)
  - Labeled in the United States for dogs with demodicosis
  - Promising results in preliminary studies
  - Monthly topical application (EPA-registered pesticide, so adhere to label)
- Topical imidacloprid and moxidectin (Advantage Multi, Advocate)
  - Labeled for dogs with demodicosis in several countries (not United States)
  - Studies suggest that monthly topical application (as labeled) is insufficient.
- Lime sulfur dips
  - Weekly for 4-6 weeks; treatment of choice for *D. gatoi* infestation and also used for *D. cati*
- Pyoderma may be a substantial secondary problem in dogs; antibiotic therapy should be continued until hair is regrowing.
- In adult-onset cases, strive for control of the underlying disease.

POSSIBLE COMPLICATIONS

- Macrocyclic lactones (ivermectin, oral moxidectin, doramectin, milbemycin [see p. 625]): monitor carefully for neurotoxicity, and educate clients about potential signs. All patients should be heartworm negative. Oral ivermectin and moxidectin can be started at a low dose (e.g., 1/10 of intended volume) and incrementally increased over 7-10 days to avoid the most severe side effects. Listed doses of oral ivermectin, moxidectin, and injectable doramectin should not be used in dogs homozygous for the MDR-1 mutation. However, these patients may tolerate topical moxidectin (Advantage Multi, Advocate) at labelled doses and may tolerate low-dose oral milbemycin (0.5 mg/kg PO q 24 hr, use with caution). See MDR1 Mutation (p. 706).
- Chronic toxicosis (several weeks into therapy) is generally less severe and not associated with MDR-1 mutations.
- Macrocyclic lactone toxicity can be induced in normal dogs by coadministration with p-glycoprotein inhibitors such as ketoconazole and cyclosporine. Coadministration of spinosad is also contraindicated.
- Side effects of amitraz are due to its monoamine oxidase (MAO) inhibitor or alpha-2 adrenergic agonist properties. They include sedation, depression, bradycardia, pruritus, vomiting/diarrhea, and hyperglycemia (avoid in diabetics). Atipamezole can be used as an antidote at 50 mcg/kg IM. Coadministration of MAO inhibitors, including some sedatives, antidepressants, and deprenyl, should be avoided. The dip must be applied in a well-ventilated area using gloves and should be avoided by people with Parkinson's disease, diabetes, respiratory disease, or those taking interacting medications.

RECOMMENDED MONITORING

Skin scrapings are performed every 2-4 weeks during therapy. At this time, score the approximate numbers of mites, the proportion of live mites, the proportion of adults versus immature mites, and the numbers of eggs. Adjust therapy if parameters are not improving.

PROGNOSIS AND OUTCOME

- For most cases of localized juvenile demodicosis, the prognosis is excellent. The prognosis for generalized juvenile cases is good, but a small proportion cannot be cured and require long-term treatment.
- In all cases of adult-onset demodicosis, the prognosis is guarded.

PEARLS & CONSIDERATIONS

COMMENTS

- MDR-1 (ABCB1) testing is available from the Washington State University College of Veterinary Medicine Clinical Pharmacology Laboratory (www.vetmed.wsu.edu/depts-VCPL/test.aspx).
- Remember hair plucks (trichography) as an alternate way of looking for *Demodex* in dogs.
- Scrape greasy terriers, even if alopecia is not a feature, to look for *D. injai*.
- Do not discontinue antibiotic therapy prematurely.
- In *D. gatoi*–endemic areas, weekly lime sulfur dips are part of the workup for pruritic cats.
- *D. canis* mites are usually easy to find, so skin scrapings should be part of the workup of most dermatology patients. Do not miss this important step.

TECHNICIAN TIPS

- For a skin scraping to be considered negative, it must demonstrate no mites whatsoever. Finding dead mites, or just mite segments, is still a positive scraping.
- When assessing skin scrapings, methodically scan the entire slide.
- *Demodex* mite eggs are fusiform (spindle- or lemon-shaped) and are important to note, as they indicate an actively reproducing population.
- Counsel owners on risks of therapy to their pets (all treatments) and themselves (amitraz dips).

Dehydration

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Dehydration occurs when fluid losses (sensible loss [renal] and insensible loss [normally daily gastrointestinal, respiratory]) exceed fluid intake.

SYNONYMS

Decreased circulating blood volume, negative fluid balance

EPIDEMIOLOGY

SPECIES, AGE, SEX

All animals are susceptible to dehydration, depending on the underlying disease process. Due to a high body surface area–to-volume ratio, smaller animals (<10 kg) are more prone to dehydration.

RISK FACTORS

- Diseases and toxins that affect appetite, decreased water ingestion, decreased renal and intestinal conservation of water, and poor vascular integrity predispose to dehydration.
- Infectious diseases such as parvoviral enteritis and coccidiosis; metabolic disturbances resulting from diseases, such as renal failure or hypoadrenocorticism; endocrinopathies such as diabetes mellitus or insipidus; intoxications with substances such as ethylene glycol; and any cause of decreased water and food intake can all result in dehydration.

CONTAGION & ZOONOSIS

Some of the diseases that cause dehydration (such as parvoviral enteritis and leptospirosis) can be contagious to other pets and/or have zoonotic potential.

GEOGRAPHY AND SEASONALITY

- Hotter weather in the summer may make a sick animal become dehydrated more rapidly.
- Frozen water bowls in the winter may cause pets to become dehydrated.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Hypertonic dehydration, isotonic dehydration, hypotonic dehydration

HISTORY, CHIEF COMPLAINT

Anorexia, vomiting, diarrhea, lethargy, weakness, panting

PHYSICAL EXAM FINDINGS

Lethargy, dry/tacky mucous membranes, tachycardia, poor pulse quality, skin tenting, sunken eyes/enophthalmos, and weight loss. The approximate level of dehydration is estimated based on the following physical exam findings: 5% = dry/tacky mucous membranes; 6%-8% = dry mucous membranes and delayed skin tent test, 10%-12% = the patient is in hypovolemic shock, and signs include all of the above plus bilaterally symmetric enophthalmos, tachycardia (dogs), weakness, slow capillary refill time, poor pulse, and lethargy or obtundation.

ETIOLOGY AND PATHOPHYSIOLOGY

Etiology:

- Lack of intake; no access to water
- Gastroenteritis (clostridial, parvoviral, parasitic, foreign body-induced, obstruction-induced)
- Renal failure (acute, chronic)
- Endocrine disease (hypoadrenocorticism, diabetes mellitus or insipidus)
- Intoxication (ethylene glycol, salt water ingestion, or any other toxin that causes vomiting, diarrhea, or renal failure)

Mechanism:

Regardless of cause, dehydration results in a decrease in circulating blood volume, which directly affects perfusion and oxygen delivery to essential tissues/organs. Mild cases may be clinically insignificant, but in moderate or severe dehydration, the metabolic processes in hypoperfused tissues must then rely on anaerobic pathways to produce adenosine triphosphate, which is a less efficient process. Furthermore, a byproduct of anaerobic metabolic pathways is lactic acid, which accumulates in states of decreased perfusion and results in metabolic acidosis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Since dehydration is unlikely to be a primary problem, a diagnostic search for an underlying cause or syndrome is always warranted. Many of the possible causes of dehydration can be ruled out simply with history and physical examination.

DIFFERENTIAL DIAGNOSIS

- Skin tent: old age, thin/emaciated body condition (false increase), obesity (false decrease)
- Tacky mucous membranes: may occur in healthy individuals

INITIAL DATABASE

CBC, serum biochemical profile, urinalysis, fecal exam

ADVANCED OR CONFIRMATORY TESTING

Urine/fecal culture, thoracic and abdominal radiographs, abdominal ultrasound, adrenocorticotropic hormone stimulation testing, ethylene glycol testing, parvoviral fecal antigen testing, *Giardia* antigen testing gastrointestinal barium series—all as dictated by initial diagnostic information and case evolution.

TREATMENT

TREATMENT OVERVIEW

- Fluid replacement
- Correction of electrolyte abnormalities
- Treatment of underlying disease

ACUTE GENERAL TREATMENT

- Fluid replacement with an isotonic crystalloid such as lactated Ringer's solution, Normosol-R, or 0.9% sodium chloride
- Maintenance rate and dehydration replacement must be calculated.
- Dehydration volume is delivered over 24-48 hours and is added to maintenance rates.
- Maintenance rate = 40 mL/kg/24 hours for large dogs (>10 kg), 60 mL/kg/24 hours for cats and small dogs (<10 kg)
- Dehydration replacement volume (mL) = % dehydration as a decimal (e.g., 10% is 0.1) × body weight in kg × 1000
- Adjustment of fluid rate and frequent, close monitoring of respiratory rate and comfort if heart disease, renal disease, or systemic hypertension is present
- Electrolyte replacement:
    - Do not supplement potassium at a rate of >0.5 mEq/kg/h.
    - Do not raise or lower serum sodium at a rate of >1 mEq/L/h.

NUTRITION/DIET

If vomiting has resolved, gradual access to water for oral intake is recommended.

CHRONIC TREATMENT

Depends on underlying disease process

DRUG INTERACTIONS

Do not add sodium bicarbonate to calcium-containing fluids (precipitation reaction).

POSSIBLE COMPLICATIONS

Overhydration: pulmonary edema, pleural or peritoneal effusion, hemodilution, cerebral edema, peripheral edema. Monitor more closely if heart or renal disease; consider colloidal therapy (plasma, albumin, hetastarch) if hypoalbuminemia is present.

RECOMMENDED MONITORING

Body weight, urine output, heart rate, pulse quality, capillary refill time, skin turgor, blood pressure, packed cell volume/total solids, blood urea nitrogen, creatinine

PROGNOSIS AND OUTCOME

Prognosis is good if the underlying disease process is identified and can be corrected.

PEARLS & CONSIDERATIONS

COMMENTS

Recheck electrolyte (sodium, potassium, chloride, and phosphorus) imbalances and acid-base status frequently (every 4-8 hours) during the first 24 hours of therapy to ensure treatment goals are being achieved. Body weight and urine output are among the easiest and most accurate ways to gauge the level of hydration.

PREVENTION

See specific disease information.

TECHNICIAN TIP

Assessing hydration status by skin turgor alone can be misleading, especially in cachectic patients, as the decreased fat content in their subcutaneous tissues will make them appear dehydrated no matter what their hydration status is. The conjunctival mucous membranes are often most reliable (barring ocular disease) because oral mucous membranes are prone to drying (open-mouth breathing/panting in dogs) or coating with mucus (vomiting).

CLIENT EDUCATION

Anorexic animals or those vomiting and having diarrhea (especially very young or very old) can become dehydrated quickly and should be examined by a veterinarian as soon as possible.

AUTHOR: ADAM J. REISS

EDITOR: ETIENNE CÔTÉ

Degenerative Myelopathy

Additional Images Available on Website

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Canine degenerative myelopathy is an inherited degenerative disease, most severely affecting the thoracolumbar spinal cord.

SYNONYMS

Canine degenerative radiculomyelopathy, German shepherd dog myelopathy

EPIDEMIOLOGY

SPECIES, AGE, SEX

Canine; age usually 8 years or older; mean age 9 years

GENETICS & BREED PREDISPOSITION

- Presumed autosomal recessive with a mutation discovered in the canine superoxide dismutase 1 *(SOD1)* gene
- The genetic mutation is similar to some forms of human amyotrophic lateral sclerosis (Lou Gehrig's disease)
- Breed predisposition: purebred dogs—German shepherd, Pembroke and Cardigan Welsh corgi, standard poodle, Rhodesian ridgeback, collie, boxer, Chesapeake Bay retriever, Irish setter, Bernese Mountain dog, mixed breed, wire fox terrier, Kerry blue terrier

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Progressive weakness of pelvic limbs
- Initially, affected dogs will drag nails and show pelvic limb ataxia.
- Difficulty jumping
- The disease results in a progressive paraparesis to paraplegia over 6-12 months from time of suspected diagnosis.
- If signs are allowed to progress, the thoracic limbs will eventually become affected.

PHYSICAL EXAM FINDINGS

- Pelvic limb tremors
- Asymmetric truncal general proprioceptive (GP) ataxia to severe paraparesis and paraplegia
- Upper motor neuron spastic paraparesis (long stride length)
- Postural reaction deficits (e.g., toe dragging, absent conscious proprioception)
- Spinal reflexes present or exaggerated
- Patellar reflex may be decreased to absent
- Variable presence of crossed extensor reflex in pelvic limbs
- Disuse muscle atrophy of pelvic limbs which progresses to neurogenic muscle atrophy
- Absence of paraspinal hyperesthesia
- Urinary and fecal incontinence in later disease stage
- If euthanasia is delayed, the clinical signs will ascend, causing flaccid tetra-paresis and other lower motor neuron signs.
- Dogs at end stage may also have swallowing and respiratory dysfunction.

ETIOLOGY AND PATHOPHYSIOLOGY

- The etiology of degenerative myelopathy is a genetic mutation in the superoxide dismutase 1 *(SOD1)* gene, resulting in a toxic gain of function (the mutation results in misfolding of *SOD1*, causing abnormal accumulations of aggregates in the neuron).
- Dogs homozygous for the mutation are at risk for development of degenerative myelopathy.
- Neuropathologic lesion distribution in the CNS involves axons and myelin in all funiculi of the spinal cord; most severe in the dorsal funiculus and dorsal portion of the lateral funiculus of the thoracolumbar spinal cord.

- Neurons in degenerative myelopathy–affected dogs contain cytoplasmic aggregates that stain with anti-*SOD1* antibodies.
- Some studies have shown degenerative changes in some neurons of the brainstem.
- Peripheral nerves show nerve fiber loss reflective of axonal degeneration and secondary demyelination.
- Muscle specimens show excessive variability in myofiber size, with large and small groups of atrophic fibers.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis of degenerative myelopathy is based on exclusion of other disorders that mimic it. The genetic test may assist with interpretation of clinical signs and diagnostic testing toward a presumptive diagnosis of degenerative myelopathy.

DIFFERENTIAL DIAGNOSIS

Other spinal cord disorders mimic signs of degenerative myelopathy:

- Intervertebral disk disease: Hansen type II
- Inflammatory disease of the spinal cord: myelitis
- Spinal cord neoplasia
- Degenerative lumbosacral stenosis
- Hip dysplasia
- Other coexisting orthopedic diseases

INITIAL DATABASE

- Neurologic examination (see p. 1311).
  - See Physical Exam Findings above for clinical findings.
    - Nonpainful progressive myelopathy
  - Neuroanatomic localization: initial disease stage—upper motor neuron signs (T3 to L3 spinal cord segments); later disease stage involves lower motor neuron signs to the pelvic limbs; end stage—generalized lower motor neuron signs.
- Clinical pathologic tests: generally unremarkable
- Thoracic radiography
  - Screening for metastatic neoplasia (central nervous system neoplasia differential diagnosis)
- Genetic testing
  - Dogs that test homozygous for the mutation are AT RISK for developing degenerative myelopathy. Not all dogs that test AT RISK will develop degenerative myelopathy
  - A direct mutation test for a susceptibility gene is offered. For recessive diseases, the results are expressed as follows:
    - Normal—homozygous for the normal gene
    - Carrier—heterozygous with one copy of the normal and mutated gene
    - AT RISK—homozygous for the mutated gene

ADVANCED OR CONFIRMATORY TESTING

- Clinical working diagnosis is based on ruling out other diseases that cause progressive myelopathy.
- Cerebrospinal fluid analysis: may show increased protein concentration.
- Electrophysiologic testing
  - Electromyography and nerve conduction studies (see p. 1253)
  - Used for ruling out other neuropathic disorders
  - In later disease stage, dogs with degenerative myelopathy will show evidence of axonopathy.
- Survey spinal radiography
- Myelography: no evidence of a compressive myelopathy
- Advanced imaging: no evidence of a compressive myelopathy
  - CT combined with myelography
  - MRI
- Definitive diagnosis is only ever determined postmortem by histopathologic examination of the spinal cord.

TREATMENT

TREATMENT OVERVIEW

There are no proven effective therapies for degenerative myelopathy. Supportive and palliative care are provided to maintain quality of life.

ACUTE AND CHRONIC TREATMENT

Exercise, vitamin supplementation (B12, E, and C), and protease inhibitors (aminocaproic acid) have been advocated as potential therapies. Disclaimer: Although the following drugs have been recommended as supplements in dogs with degenerative myelopathy, efficacy still remains to be proven.

- Aminocaproic acid (500 mg/dog; 15 mg/kg PO q 8 h)
- Vitamin E (1000-2000 IU/dog PO q 24 h)
- Vitamin B12 (100-200 mcg/dog PO q 24 h)
- Encourage exercise and physical rehabilitation to slow onset of disuse muscle atrophy
- Assistive walking devices enable ambulation support and may improve quality of life.
- Monitor for urinary and fecal incontinence:
    - Basic nursing care and hygiene if incontinence occurs, to prevent the onset of urine scald, infected decubital ulcers, or similar skin lesions
- When patient becomes nonambulatory, keep on a well-padded surface.

POSSIBLE COMPLICATIONS

- Urinary tract infections
- Decubital ulcer formation (see p. 174)

RECOMMENDED MONITORING

- Monitor for secondary urinary tract infection
- Monitor for proper nursing care

PROGNOSIS AND OUTCOME

- Long-term prognosis is considered poor.
- Dogs often lose their ability to ambulate in the pelvic within 6-12 months from time of diagnosis.
- The disease eventually will progress to affect the thoracic limbs.
- Owners of large-breed dogs often will elect for euthanasia when their dog needs ambulatory assistance.

PEARLS & CONSIDERATIONS

COMMENTS

- Lack of paraspinal hyperesthesia is a key clinical feature of degenerative myelopathy.
- A suspected diagnosis is based on exclusion of other spinal cord disorders.

TECHNICIAN TIPS

- Physical rehabilitation (see p. 1329) using light exercise may improve the patient's quality of life.
- The patient will need to be closely monitored for urine scald and decubitus ulceration when the disease progresses to lower motor neuron involvement.

CLIENT EDUCATION

- Meticulous nursing care is essential in the recumbent patient.
    - Keep patient clean and dry to prevent urine scald.
    - Keep patient on a protective surface (optimize padding, traction, and ease of cleaning).
- A sling with wheels or a cart may assist with patient mobility.
- Physical therapy using range-of-motion and isometric exercises will help maintain joint flexibility and muscle strength (see p. 1329).

Decongestant Toxicosis

BASIC INFORMATION

DEFINITION

Common decongestants are pseudoephedrine, ephedrine, phenylephrine, and imidazoline derivatives (oxymetazoline, naphazoline, tetrahydrozoline, xylometazoline). They are active ingredients in over-the-counter (OTC) human medications used for the treatment of cold, flu, sinusitis, and allergies. Toxicosis from other active ingredients is discussed separately ().

EPIDEMIOLOGY

SPECIES, AGE, SEX

All species, breeds, and both sexes are susceptible; dogs are more likely to be involved, based on their predilection for dietary indiscretion.

RISK FACTORS

Preexisting cardiac disease, systemic hypertension, and seizure disorders may exacerbate signs of toxicosis.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Direct observation or indirect evidence of exposure
- Pseudoephedrine: rapid onset (within 15-30 minutes with immediate release products; 3-6 hours with extended-release medications) of agitation, hyperactivity, restlessness, panting, mydriasis, shaking, circling or head bobbing
- Phenylephrine: less likely to result in clinical effects, owing to enterohepatic degradation by monoamine oxidases and resultant poor bioavailability (38%) and lack of norepinephrine release (hyperactivity, pacing, shaking)
- Imidazoline decongestants: rapid onset (within 60 minutes; not expected after 3-4 hours) of vomiting, weakness, collapse

PHYSICAL EXAM FINDINGS

- Pseudoephedrine/phenylephrine: as above, plus injected mucous membranes, hyperthermia, tachycardia or reflex bradycardia; less commonly lethargy and staring
- Phenylephrine: as above, plus tachycardia, mydriasis
- Imidazoline: weakness, lethargy, bradycardia, hypotension, prolonged capillary refill time; less commonly hypertension, panting, nervousness, hyperactivity, and shaking

ETIOLOGY AND PATHOPHYSIOLOGY

Source:

- Toxicosis can occur either when animals accidentally ingest OTC medications or are mistakenly given the medication.
- Decongestants stimulate alpha-adrenergic receptors, resulting in vasoconstriction of arterioles in the nasal passages, thus improving air flow.
    - Pseudoephedrine, ephedrine (stereoisomer), ma huang (a herbal form of ephedra). Pseudoephedrine is available as a hydrochloride or sulfate salt. It is found as a single ingredient (30-mg or 60-mg regular pill), or extended-release (120 mg as 12-hour pill or 240 mg as 24-hour pill) or as a liquid (varying concentration). It is more commonly available in combination with other ingredients (cough suppressants, antihistamines, acetaminophen, ibuprofen). Common brand names of products that contain pseudoephedrine include Sudafed, Afrin, Tylenol, Vicks, Alka-Seltzer, and Contac.
    - Phenylephrine is available for oral use (mostly 5- to 15-mg tablets), nasal sprays (0.25%-1%), or eye drops (0.1%). It is available in combination with other medications (antihistamines, cough suppressants, pain killers).
    - Imidazoline decongestant examples are oxymetazoline, tetrahydrozoline, naphazoline, and xylometazoline. These are available as nasal and ophthalmic solutions of varying concentrations (0.01%-0.1%).

Mechanism of Toxicosis:

- Adverse effects are dose-dependent and reflect excessive stimulation of the adrenergic nervous system.
- With pseudoephedrine, the release of norepinephrine increases the potential for central nervous system stimulation. Ingestion of >3 mg/kg in an otherwise healthy dog typically warrants decontamination of the patient and close monitoring.
- With imidazoline decongestants, overdoses cause excess stimulation of central alpha-2 receptors, which results in hypotension. The margin of safety is very narrow with these agents, with ingestion of even a small amount potentially resulting in toxicosis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is suspected based on a combination of evidence of exposure along with presence of consistent signs. OTC urine drug-test kits can detect pseudoephedrine, or it can be detected in plasma at a diagnostic laboratory (can help determine exposure).

DIFFERENTIAL DIAGNOSIS

Toxicologic:

- Pseudoephedrine/ephedrine/phenylephrine: amphetamines, antihistamines, cocaine, metaldehyde, methylxanthines, phenylpropanolamine, strychnine
- Imidazoline: alcohols, amitraz, barbiturates, benzodiazepines, calcium channel blockers, clonidine, essential oils, medetomidine, xylazine

Spontaneous, nontoxicologic:

- Pseudoephedrine/phenylephrine: pheochromocytoma, renal disease, intracranial disease
- Imidazoline: hypoadrenocorticism, advanced cardiovascular disease/cardiogenic shock, sepsis, hypovolemic shock, trauma

INITIAL DATABASE

- CBC
- Serum biochemistry profile
- Arterial blood pressure
- ECG (heart rate and rhythm)
- Body temperature

ADVANCED OR CONFIRMATORY TESTING

Urine drug screening with OTC test kit (optional)

TREATMENT

TREATMENT OVERVIEW

Treatment is indicated based on clinical suspicion (history and physical examination), without urine test confirmation. Treatment may consist of patient decontamination alone (emesis and administration of activated charcoal) if clinical signs are absent, or decontamination and management of cardiovascular and CNS aberrations and thermoregulation if clinical signs are present.

ACUTE GENERAL TREATMENT

- Decontamination of patient:
  - Pseudoephedrine/ephedrine/phenylephrine:
    - Induction of emesis (see p. 1364) with 3% hydrogen peroxide, 2 mL/kg PO 1-2 times to effect, maximum of 45 mL; useful only in asymptomatic animals within 1 hour of ingestion of immediate-release products and within a couple of hours of extended-release products.
    - Activated charcoal (1-2 g/kg granules or 6.6-11 mL/kg of 10% solution with sorbitol or other cathartic PO). Repeat (3.3-5.5 mL/kg without cathartic PO) once 6-8 hours after initial administration if extended-release decongestant.
    - Acidification of urine (use only if facility to run blood gases available): ammonium chloride, 50 mg/kg PO q 6 h; or ascorbic acid, 30 mg/kg PO q 8 h to promote excretion (ion trapping).

        - Control CNS excitation (note: phenothiazines are drugs of choice for controlling CNS excitation: acepromazine, 0.02-0.05 mg/kg IV, IM, repeat as needed; useful for mild hypertension and CNS stimulatory signs; or chlorpromazine, 0.5-1 mg/kg IV.
        - Control tachycardia: propranolol, 0.02-0.04 mg/kg IV, repeat in 4-8 hours; or use esmolol, 0.2-0.5 mg/kg IV or 25-200 mcg/kg/min IV as constant rate infusion.
    - Imidazoline decongestants:
        - Due to the rapid onset of signs after imidazoline decongestant ingestion, emesis and charcoal are generally not recommended.
- Specific treatment:
    - Imidazoline decongestants:
        - Atipamezole (50 mcg/kg IM to effect for hypotension); may be repeated as needed for life-threatening hypotension and bradycardia. A quarter to a third of the dose may be given IV for rapid effect, and the remainder IM.
        - Yohimbine: 0.1 mg/kg IV; repeat in 2-3 hours if needed. Use if atipamezole is not available.
- Supportive care for all decongestant exposures:
    - Intravenous fluid therapy
    - Thermoregulation: cool fluids, external cooling measures as needed
    - Keep the patient calm and reduce external stimuli (quiet surroundings).

DRUG INTERACTIONS

- Diazepam: paradoxical response (when given at high doses or when given too fast) may add to stimulatory signs from pseudoephedrine/ephedrine/phenylephrine.
- Propranolol: contraindicated if systemic hypertension is present (beta-2 blockade in vessels may cause vasoconstriction and worsen the hypertension).
- Atropine: contraindicated for reflex bradycardia due to hypertension.

POSSIBLE COMPLICATIONS

- Disseminated intravascular coagulation (DIC) due to hyperthermia
- Permanent brain damage from prolonged stimulation
- Renal failure from systemic hypo- or hypertension and/or rhabdomyolysis

RECOMMENDED MONITORING

- Heart rate/rhythm
- Blood pressure
- Body temperature
- Mentation
- Serum biochemistry profile, including electrolytes
- Acid-base status if acidifying urine

PROGNOSIS AND OUTCOME

Generally favorable with prompt presentation and appropriate care. Presence of head bobbing, circling, or DIC carries a poor prognosis. Pseudoephedrine exposures exceeding 10 mg/kg are potentially lethal without treatment.

PEARLS & CONSIDERATIONS

COMMENTS

- The use and availability of pseudoephedrine in several U.S. states has been restricted because of alleged use of this medication in illegal amphetamine synthesis. Pseudoephedrine is being replaced by phenylephrine.
- Other agents (nonsteroidal antiinflammatory drugs [p. 768], antihistamines [p. 87], cough suppressants) may also cause toxicosis if a combination product was ingested; be sure to monitor for signs and treat accordingly.
- The signs of pseudoephedrine toxicosis are very similar to amphetamine toxicosis in dogs.
- Several weight-loss OTC products contain varying levels of ma huang, a natural source of ephedrine.

TECHNICIAN TIPS

The over-the-counter availability of these medications may give owners the wrong impression that they are harmless. Any casual mention by an owner of this type of medication is worth discussing with the veterinarian, especially if physical signs compatible with toxicosis are present.

PREVENTION

- Keep medications out of animal's reach.
- Awareness of where pets roam when unsupervised
- Never administer OTC medications to pets without consulting a veterinarian.

CLIENT EDUCATION

- Need to control or monitor pet's environment
- Location of nearest veterinary hospital at any time of day or night

Deciduous Teeth, Persistent (“Retained”)

BASIC INFORMATION

DEFINITION

Deciduous teeth that failed to exfoliate

SYNONYM

Retained deciduous teeth: *retained* refers to failure to erupt (emerge through the gingival surface); *persistent* is more accurate because it refers to failure to exfoliate (cause shedding of the deciduous tooth).

EPIDEMIOLOGY

Dogs and cats. Permanent dentition eruption schedules dictate when a deciduous tooth is considered persistent (use table cautiously; breed and individual variation can be significant [±1 to 2 months]):

GENETICS & BREED PREDISPOSITION

High prevalence in toy dog breeds (Yorkshire terriers, miniature poodles, Pomeranians) suggests inheritance. Recent advances in the understanding of eruption and exfoliation suggest familial and/or genetic influence.

Permanent Dentition Eruption Times in the Dog and Cat

	Dog	Cat
Incisors	3-5 months	3-4 months
Canines	4-6 months	4-5 months
Premolars	4-6 months	4-6 months
Molars	5-7 months	4-5 months

ASSOCIATED CONDITIONS & DISORDERS

As a result of persistence of deciduous teeth:

- Periodontal disease
- Malocclusion
- Malposition, retarded eruption, impaction of permanent teeth
- Palatal/labial trauma

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

Teeth appear too numerous or are angled abnormally. A large percentage of persistent deciduous teeth are found on physical examination of adolescent dogs and cats presented for neutering.

PHYSICAL EXAM FINDINGS

A narrower deciduous tooth is observed alongside an erupting or fully erupted permanent tooth. The deciduous canine and incisor teeth are most commonly affected, though persistent deciduous premolars do occur (there are no deciduous molars or first premolars).

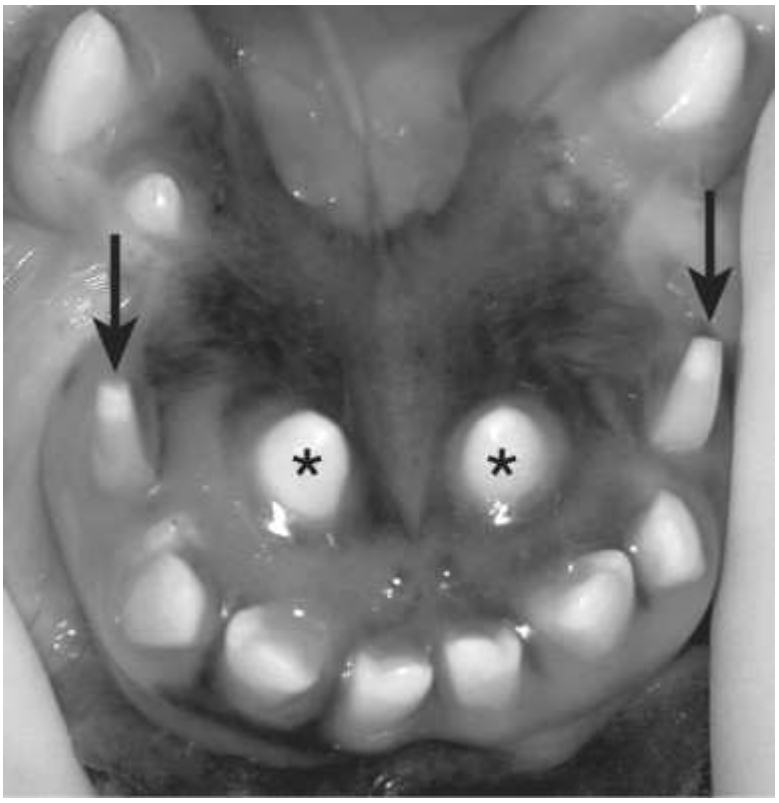
ETIOLOGY AND PATHOPHYSIOLOGY

- Commonly reported causes:
  - Lack of permanent successors
  - Dentoalveolar ankylosis of deciduous teeth
  - Failure of the erupting permanent crown to apply pressure to the deciduous tooth root
  - Hormonal abnormalities affecting growth or metabolism
- Pathophysiologically important information includes:
  - Persistent deciduous teeth may result in malpositioned permanent teeth.
  - Permanent mandibular incisors, canines, and premolars erupt lingual (i.e., toward the tongue) to persistent deciduous teeth; lingually deviated permanent mandibular canine teeth may cause palatal trauma.
  - Permanent maxillary incisors and premolars erupt palatal (i.e., toward the palate) to persistent deciduous teeth.
  - Permanent maxillary fourth premolars erupt buccal/labial (i.e., toward the cheek/lip) and distal (i.e., away from the midline of the dental arch) to persistent deciduous teeth.
  - Permanent maxillary canine teeth erupt mesial (i.e., toward the midline of the dental arch) to persistent deciduous teeth.
  - Food, debris, plaque, and calculus accumulating on and between deciduous and permanent teeth may cause periodontal disease even in young animals.

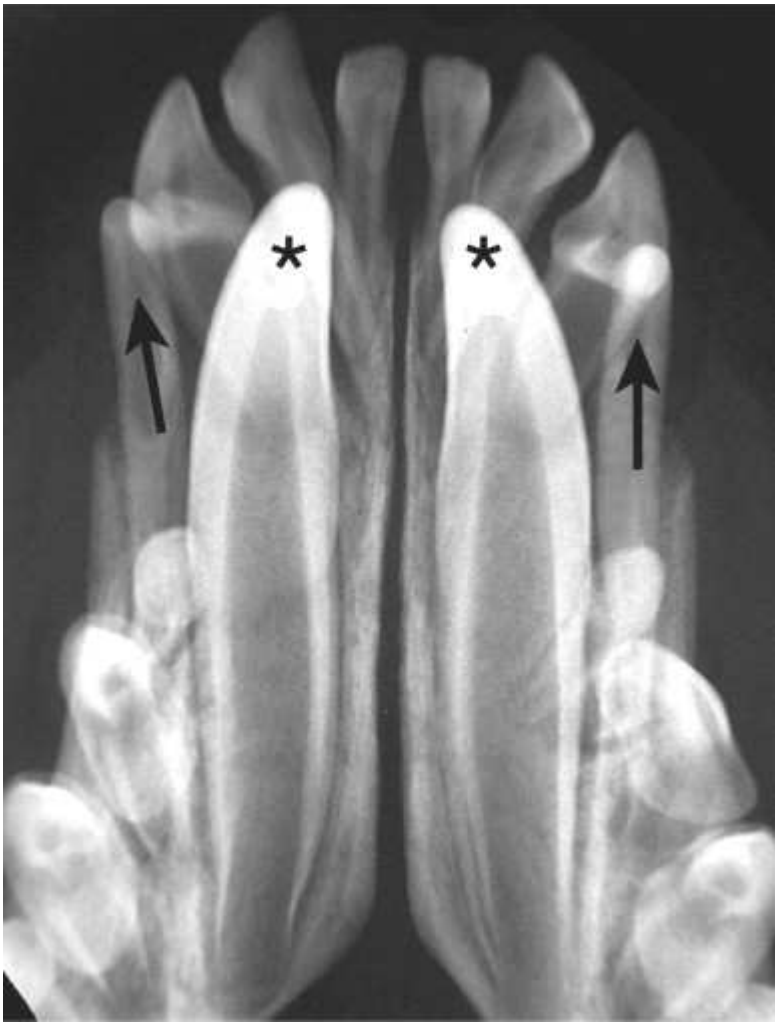
DIAGNOSIS

DIAGNOSTIC OVERVIEW

Physical exam is highly suggestive; presence of a deciduous tooth in a dog or cat with otherwise permanent dentition. Dental radiography is indicated prior to intervention.



DECIDUOUS TEETH, PERSISTENT (“RETAINED”) Bilateral persistent deciduous mandibular canine teeth in a dog *(arrows)*, causing permanent canines *(asterisks)* to be displaced lingually.



DECIDUOUS TEETH, PERSISTENT (“RETAINED”) Radiograph of lower jaw of same dog. Persistent deciduous canine teeth *(arrows)* block normal eruption pathway of permanent successors *(asterisks)*. Radiograph arranged in labial mounting; rostral is toward top of image, patient's left is on right of image.

DIFFERENTIAL DIAGNOSIS

- Missing, malformed, malpositioned or unerupted permanent tooth
- Supernumerary permanent tooth
- Malocclusion

INITIAL DATABASE

- CBC, serum chemistry panel, urinalysis: preoperative, generally unremarkable
- Full-mouth dental radiographs: evaluate root structures, confirm and document presence of healthy permanent teeth.

ADVANCED OR CONFIRMATORY TESTING

Hormone levels if metabolic/endocrine disease is suspected

TREATMENT

TREATMENT OVERVIEW

Extraction is indicated in virtually all cases (exception: no equivalent permanent tooth) to alleviate dental crowding, soft-tissue trauma, and/or dental interlock; prevent periodontal disease; prevent malpositioning of permanent teeth and malocclusion; and

correct existing malocclusion.

ACUTE GENERAL TREATMENT

- No treatment is needed for uncrowded, healthy persistent deciduous teeth that have no permanent counterpart.
- Extraction of all other persistent deciduous teeth is advised.
- Closed and open extraction techniques are acceptable, depending on tooth to be extracted and degree of root resorption.
    - Closed extraction for mobile teeth
    - Open extraction via creation of a mucoperiosteal flap and alveolar bone removal for solid teeth with complete root structures
    - Slow, steady pressure with a dental elevator is key for inducing periodontal ligament fatigue and successful extraction.
    - Be sure to keep all instrumentation away from the erupting permanent tooth.
- Extraction sites should be closed using rapidly absorbable synthetic suture material while avoiding placing sutures directly over an erupting tooth.
- Postoperative dental radiographs are recommended to ensure complete extraction, evaluate surrounding structures for damage, and provide documentation.
- Antibiotics are not usually necessary post extraction.
- Pain management: intraoperative nerve block (0.5% bupivacaine hydrochloride, 0.2 to 0.3 mL near middle mental, inferior alveolar, infraorbital or maxillary nerve) followed by oral nonsteroidal antiinflammatory medication (e.g., carprofen, 2 mg/kg PO q 12 h) for 2-3 days postoperatively.

POSSIBLE COMPLICATIONS

- Root fracture and retained root tips, leading to infection of the permanent tooth
- Retarded eruption, malpositioning, and/or mechanical damage to the permanent tooth
- Accidental extraction of permanent tooth

RECOMMENDED MONITORING

- Examination in 1-2 weeks to evaluate extraction sites
- Examination in 4-6 weeks to evaluate occlusion if necessary; if abnormalities persist, therapeutic recommendations are offered.

PROGNOSIS AND OUTCOME

Excellent for regional healing and reduction of risk of periodontal disease

PEARLS & CONSIDERATIONS

COMMENTS

- Early extraction (5-7 months of age) of persistent deciduous teeth is key to success.
- Deciduous teeth have a thin dentinal layer and long, spindly roots. They are difficult to extract and break easily. The first rule is to *go slow!*

PREVENTION

Selective breeding

TECHNICIAN TIPS

- One tooth in one place at one time is the general rule of thumb.
- If deciduous and permanent teeth of the same type are occupying the same space, the deciduous tooth is persistent.

CLIENT EDUCATION

Genetic counseling

Deafness

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- *Deafness* is the inability to hear.
- *Sensorineural deafness* results from an abnormality in the inner ear and/or vestibulocochlear nerve and/or the auditory pathways in the brain.
- *Conduction deafness* results from a lesion in the outer ear and/or tympanum and/or middle ear.

SYNONYM

Hearing loss

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats; any age, either gender

GENETICS & BREED PREDISPOSITION

- Congenital, inherited, sensorineural deafness is associated with coat and iris color.
  - Cats with white haircoats and blue irides are commonly affected by congenital deafness.
  - Dog breeds with white, spotted, merle, or dapple haircoats are predisposed to congenital deafness.
- Inherited sensorineural deafness is also seen in breeds not related to white, spotted, merle, or dapple coat colors (e.g., Doberman pinscher).
- Breeds with presumed inherited conditions involving the conduction portion of the ear (external and middle ears) are predisposed to developing hearing loss (e.g., Cavalier King Charles spaniels with secretory otitis media (see p. 807).

RISK FACTORS

- Genotype: white, piebald, extreme piebald, or merle genes
- Old age
- Repeated exposure to loud noises
- Breeds of cats or dogs susceptible to otitis externa and/or otitis media
- Exposure to high dosages of systemic ototoxic drugs, such as aminoglycosides, erythromycin, loop diuretics, cisplatin, nitrogen mustard, or topical chlorhexidine antiseptic. Topical drugs are potentially more ototoxic if the tympanum is not intact.

ASSOCIATED CONDITIONS & DISORDERS

- Otitis externa and/or media
- External or middle ear canal neoplasia
- Nasopharyngeal polyps (cats)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Described as:

- Congenital or adult-onset
- Inherited or noninherited
- Sensorineural or conduction deafness

HISTORY, CHIEF COMPLAINT

- Animals with bilateral congenital or adult-onset deafness:
  - Overly aggressive with other puppies in a litter (congenital deafness)
  - Nonresponsive to auditory stimuli (particular frequencies and/or magnitudes)

- Difficult to obedience train, or the adult animal becomes unresponsive to auditory commands to which it was previously responsive
- Tendency to startle when approached from a position out of visual field
- Increased tendency to sleep
- Not aroused from sleep with auditory stimuli

- Diagnosis of unilateral deafness is not possible with behavioral markers alone; electrodiagnostic evaluation is required to establish a diagnosis of unilateral deafness.

PHYSICAL EXAM FINDINGS

- Animals with normal hearing may not respond to loud sounds in the clinical setting; behavioral response to auditory stimuli is unreliable for evaluating deafness.
- Animals with peripheral sensorineural deafness typically have no abnormal physical examination findings.
- Animals with acquired conduction deafness may have one or all of the following clinical signs:
  - Abnormal aural examination
  - Head tilt
  - Facial droop
  - Horner's syndrome
  - Head shaking
  - Signs of pain upon manipulation of the ears
- Animals with deafness resulting from diseases affecting the vestibulocochlear nerve or central components of the auditory pathways will typically demonstrate other concurrent abnormal neurologic signs.

ETIOLOGY AND PATHOPHYSIOLOGY

- Acquired conduction deafness resulting from otitis externa/media
  - Impaired conduction of sound waves to the tympanic membrane from hyperplasia and exuberant cerumen production or the presence of pus in the external ear canal
  - Impaired transduction of sound waves to the otic ossicles due to stiffened, fibrotic, or ruptured tympanic membrane
  - Impaired mechanoelectrical transduction due to sclerosis of otic ossicles
- Acquired conduction deafness from external or middle ear masses
  - Obstruction of sound waves to the tympanic membrane
  - Destruction of middle ear structures
- Presbycusis (senile deafness)
  - Degeneration of the neural components of the inner ear
  - ± Stiffening of the tympanic membrane
  - ± Ankylosis of the otic ossicles
- Loud noise exposure
  - Damage to inner ear hair cells and/or ossicles and/or tympanic membrane
- Congenital hereditary deafness associated with coat color
  - Associated with coat-color genes
  - Abnormal migration of neural crest cells (precursor to melanocytes) to the inner ear (thought to provide nourishment to inner ear); associated with sacculocochlear-type degeneration

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

Bilateral complete deafness is apparent from lack of response to loud noises; diagnostic evaluation should consider history, neurologic exam findings, and otoscopic exam findings. Unilateral or partial bilateral deafness may only be apparent on auditory testing and is generally of interest in preventive medicine (breeders).

DIFFERENTIAL DIAGNOSIS

- Primary behavioral/psychological disorder
- Canine cognitive dysfunction syndrome (geriatric dogs)

INITIAL DATABASE

- Distant and proximal physical examinations
- Neurologic examination (see p. 1311)
- Thorough aural examination (see p. 1316)

ADVANCED OR CONFIRMATORY TESTING

Brainstem auditory evoked response/potential (BAER or BAEP) testing using air or bone-conducting stimuli (see p. 1216)

TREATMENT

TREATMENT OVERVIEW

- Prevent hearing loss from developing or progressing.
- Improve hearing ability.

ACUTE GENERAL TREATMENT

- No treatment for congenital inherited sensorineural deafness; careful selection of breeding animals by only using non-deaf animals for breeding (perform BAER tests on untested adults and all puppies).
- No practical treatments for animals with sensorineural deafness. Custom-fit hearing aids are offered by some specialty practices (consult with neurologist or audiologist).
- For acquired conduction deafness, treat the underlying cause of the disease.
- Use ototoxic drugs with caution or not at all (topically) if the tympanum is not known to be intact.

RECOMMENDED MONITORING

Repeated BAER testing to monitor response to therapy in animals with incomplete deafness

PROGNOSIS AND OUTCOME

- Inherited sensorineural deafness and deafness resulting from degeneration of inner ear is permanent.
- Variable prognosis for animals with conduction deafness (depends on chronicity and/or severity of the disease)

PEARLS & CONSIDERATIONS

COMMENTS

- Unilaterally deaf animals are as likely as bilaterally deaf animals to produce deaf offspring.
- Animals with bilateral deafness require special care, including:
  - Keeping animals on leash, especially when near traffic
  - Obedience training using hand signals
  - To minimize the risk of bite injury, prevent children from startling the animal.
- Animals with presbycusis may have concurrent cognitive decline, accounting for behavioral changes.

PREVENTION

- Use non-deaf animals for breeding.
- For breeds predisposed to congenital deafness, use animals with non-blue irides for breeding.

CLIENT EDUCATION

- For dog breeders:
  - Inherited sensorineural deafness is a multifactorial genetic condition and is not easily eliminated from particular breeds.
  - Breeding unilaterally or bilaterally deaf animals together increases the incidence of deafness in the offspring; conversely, the incidence of deafness decreases when two hearing dogs are bred together.
  - Breeding two hearing dogs together can still result in producing unilaterally or bilaterally deaf puppies (for inherited deafness).
  - Avoid producing animals homozygous for the merle gene.
- For owners:
  - Inform owners that the dog has special training needs.
  - Recommend Susan Cope Becker's book, *Living with a Deaf Dog: A Book of Advice, Facts and Experiences about*

Canine Deafness (Cincinnati, 1997, Susan Cope Becker).

Dacryocystitis

BASIC INFORMATION

DEFINITION

Although *dacryocystitis* is technically inflammation of the lacrimal sac, the term is commonly used for describing inflammation anywhere along the tear drainage (i.e., nasolacrimal) system, including the lacrimal puncta, canaliculi, lacrimal sac, and nasolacrimal duct. Dacryocystitis is an acquired condition resulting in ocular discharge (see p. 777).

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats; no age or sex predisposition

GENETICS & BREED PREDISPOSITION

- Brachycephalic breeds (lacrimal stasis): most common conformation associated with dacryocystitis
- Some extremely dolichocephalic breeds (Doberman pinschers, collies, etc.) also have poor tear drainage and stasis due to a small, deeply set eye and loss of eye-to-lid contact in the medial canthal area.

RISK FACTORS

- The most common causes of dacryocystitis in dogs and cats are foreign bodies (e.g., plant awns that become lodged in the nasolacrimal system) and descending infections due to poor conformation and subsequent lacrimal stasis.
- Animals that spend time outdoors are at increased risk.

GEOGRAPHY AND SEASONALITY

- Areas with an abundance of plants
- Increased incidence in spring and summer

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Ocular discharge (serous, mucoid, purulent, or a combination)
- Owner may report swelling and/or draining tract in skin ventral to medial canthus.

PHYSICAL EXAM FINDINGS

Ocular discharge in the form of tears, mucus, or pus, with any or all of the following:

- Conjunctivitis
- Lacrimal punctal foreign body
- Swelling and signs of pain in the medial canthal area
- If sufficiently chronic, fistulous tracts may be present in the medial canthal area.

ETIOLOGY AND PATHOPHYSIOLOGY

- Most common cause of dacryocystitis is migration of foreign bodies, most frequently plant material, into the nasolacrimal system.
- Descending infections from ocular surface flora, often associated with poor tear drainage and lacrimal stasis, also incriminated with initiating inflammation.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Suspicion for the diagnosis arises based on chief complaint and physical exam findings indicative of ocular abnormalities including ocular discharge. Determination of whether dacryocystitis involves an obstruction or is secondary to inflammation is the key to diagnosis and prompt treatment. This is accomplished by checking for nasolacrimal passage of fluorescein dye and nasolacrimal flushing.

DIFFERENTIAL DIAGNOSIS

- Other causes of blockage of the nasolacrimal system:
  - Congenital disorders, including micropunctum or imperforate lacrimal punctum
  - Acquired disorders, including traumatic lacerations or neoplastic invasion or compression of the nasolacrimal drainage apparatus
- Other causes of ocular discharge (see p. 777)

INITIAL DATABASE

- Complete ophthalmic examination (see p. 1313) including:
  - Schirmer tear test (rule out keratoconjunctivitis sicca [KCS; see p. 1406] as cause for ocular discharge). Normal >15 mm after 1 minute in dogs, variable in cats.
  - Fluorescein dye application
    - Rule out corneal ulceration as cause for ocular discharge.
    - Fluorescein dye application also tests for nasolacrimal system patency.
      - Dye normally traverses the nasolacrimal apparatus to exit the nares within 5 minutes (dogs and cats).
      - Visualization of the dye in the nares can be assisted with a Wood's lamp (dye fluoresces).
      - False-negative results may occur if animal licks dye from nares before dye is visualized, or dye may drain caudally into nasopharynx (mainly brachycephalic breeds).
- Nasolacrimal flushing if suspect complete or partial nasolacrimal duct blockage:
  - May be done under firm restraint with topical ocular anesthesia (e.g., proparacaine 0.5% [dogs]).
  - Resistant animals or signs of discomfort warrant routine preanesthetic evaluation and subsequent sedation or general anesthesia (cats have small lacrimal puncta).
  - Lacrimal puncta can be cannulated but not distal nasal puncta (dogs and cats), which are difficult to identify in many or most individuals irrespective of dacryocystitis.
  - Identify dorsal and ventral lacrimal puncta (oval in dog and round in cat, with or without circumferential pigment), 1 to 2 mm from eyelid margin in palpebral conjunctiva near medial canthus.
  - Gently insert cannula or intravenous catheter (stylet removed; 22 to 24 gauge, dogs; 24 to 26 gauge, cats), with 3-mL syringe filled with sterile saline or eyewash attached, approximately 3 mm into the dorsal lacrimal punctum.
  - Slowly inject the saline/eyewash until it flows from the ventral lacrimal punctum (confirms puncta, canaliculi, and lacrimal sac are patent).
  - Next, occlude ventral lacrimal punctum with digital pressure and flush 3-12 mL saline/eyewash through the nasolacrimal duct.
  - Collect fluid/discharge at naris in sterile basin.
- Culture and sensitivity testing of purulent discharge if present
- Consider referral to a veterinary ophthalmologist if unable to establish patency of nasolacrimal system.

ADVANCED OR CONFIRMATORY TESTING

- Dacryocystorhinography (contrast study of nasolacrimal system) with standard radiography can identify an obstruction site.
- Recently, CT-dacryocystorhinography has been demonstrated to allow highly accurate characterization of lesions obstructing the nasolacrimal duct.

TREATMENT

TREATMENT OVERVIEW

Determine character (i.e., plant material, inflammatory debris, etc.) and location of obstruction and relieve it.

ACUTE GENERAL TREATMENT

- If foreign body is lodged in canaliculi or lacrimal sac, it may be manually removed by flushing lacrimal punctum.
- If a foreign body is present in nasolacrimal duct, removal may be accomplished by dacryocystotomy (surgical incision of nasolacrimal duct; referable procedure).

CHRONIC TREATMENT

- Care after any of the preceding surgeries would include topical antibiotic/steroid combination medication (neomycin/polymyxin /dexamethasone suspension or ointment q 4-6 h) for the first 2-4 postoperative weeks.
- Dacryocystotomy requires placement and maintenance of a Silastic cannula and oral antibiotics for 3-4 weeks after surgery.

POSSIBLE COMPLICATIONS

If foreign bodies are left in the nasolacrimal drainage system, scarring, permanent occlusion, and chronic epiphora may result.

PROGNOSIS AND OUTCOME

- Depends on underlying cause
- Good prognosis with successful removal of foreign body

PEARLS & CONSIDERATIONS

COMMENTS

- Prompt retrieval of foreign bodies from the proximal portions of the nasolacrimal system is essential; surgical removal from the nasolacrimal duct is technically difficult and has many potential complications.
- False-negative results can occur when attempting nasolacrimal fluorescein dye passage in brachycephalic breeds, because fluorescein may drain into the back of the oral cavity, owing to the characteristic shape of a brachycephalic dog or cat's maxilla.

PREVENTION

Keep pets away from areas with tall grass, especially in the late summer.

Eyelid Defects: Trauma, Masses

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Eyelid trauma is associated with any external injury to the eyelid predisposing to inflammation or laceration. Eyelid masses are very common and are associated with neoplastic or inflammatory conditions.

SYNONYMS

- Chalazion: hordeolum, meibomian gland cyst
- Meibomian glands: tarsal glands, palpebral glands

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats
- Eyelid trauma may occur at any age.
- Eyelid mass: average age 9-10 years (eyelid neoplasia, dogs) but depends on type of mass

GENETICS & BREED PREDISPOSITION

- Eyelid trauma: more common in young animals, outdoor animals, and sporting breeds of dogs
- Eyelid mass (dogs): more common in American cocker spaniel, boxer, poodle, golden retriever, Labrador retriever, English springer spaniel, beagle, collie, Siberian husky, and English setter

RISK FACTORS: Excessive sunlight and white hair in the periocular region both predispose to squamous cell carcinoma (SCC), the most common eyelid neoplasm in cats.

ASSOCIATED CONDITIONS & DISORDERS

EYELID TRAUMA

- Corneal/scleral trauma (see p. 249)
- Uveitis (see p. 1151)
- Eyelid mass:
  - Blepharitis (eyelid inflammation)
  - Conjunctivitis (see pp. 239 and 237)
  - Corneal ulceration (see p. 250)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Eyelid trauma:
  - Witnessed traumatic event
  - Swollen eyelid(s) (blepharoedema)
  - ± Eyelid laceration
- Eyelid mass:
  - Growth on eyelid and/or eyelid margin
  - Persistent or intermittent bleeding of eyelid
  - Signs of ocular pain if mass large and causing conjunctival and/or corneal irritation
  - Ocular discharge

EYELID DEFECTS Eyelid mass.

(Courtesy Dr. Phillip A. Moore.)

PHYSICAL EXAM FINDINGS

- Eyelid trauma (some or all of the following):
  - Blepharoedema
  - Eyelid laceration (partial- or full-thickness)
  - Blepharospasm
  - Ocular discharge
  - Conjunctival hyperemia/edema (chemosis)
  - Keratitis (ulcerative or nonulcerative)
- Eyelid mass (some or all of the following):
  - Mass located along eyelid margin or adjacent to margin of eyelid
  - Size, location, and appearance vary with type of mass:
    - Neoplasm associated with the meibomian gland appears as an irregular, raised, variably sized mass ± pigment.
    - SCC appears as an erosive, ulcerated mass along the eyelid, often near the medial canthus.
    - Chalazion (meibomian gland cyst) presents as smooth, raised, yellow to white mass associated with the meibomian gland.
  - Ocular discharge, blepharospasm, conjunctivitis, keratitis if mass irritating the eye
  - Eyelid hemorrhage
  - Lagophthalmos (incomplete closure of the eyelids)

ETIOLOGY AND PATHOPHYSIOLOGY

- Eyelid trauma is generally associated with blunt trauma, penetration by sharp objects, or self-mutilation (pawing at eye).
- Eyelid mass (neoplastic)
  - Common in dogs; most are benign.
  - Rare in cats; most are SCC (malignant).
  - Similar to those of the skin; arise from epithelial, mesenchymal, and melanogenic cells.
  - In dogs, 82% of eyelid neoplasms are sebaceous adenomas, papillomas, or melanomas.
  - Sebaceous gland tumors (sebaceous adenoma, sebaceous epithelioma, and sebaceous adenocarcinoma) arise from the meibomian glands.
- Focal eyelid inflammation: a chalazion is a pyogranuloma associated with retained meibomian gland secretions.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- The diagnosis of eyelid trauma is suspected based on the presence of blepharoedema and/or blepharitis with or without ocular discharge.
- The diagnosis of an eyelid mass is suspected based on the presentation of a "mass"-type lesion or swelling adjacent to or along the lid margin; confirmation of the nature of the mass requires cytologic and/or histopathologic assessment.

DIFFERENTIAL DIAGNOSIS

Eyelid swelling:

- Anaphylaxis
- Conjunctival/subpalpebral foreign body

INITIAL DATABASE

Complete ophthalmic examination (see p. 1313) including:

- Schirmer tear test
- Fluorescein dye application
- Intraocular pressures
- Examination of periocular (e.g., conjunctiva) and intraocular structures, especially if trauma suspected
- Examination of eyelid margin for extent of laceration or extent and point of origin of mass

ADVANCED OR CONFIRMATORY TESTING

- Fine-needle aspiration and cytologic evaluation of eyelid masses
- Histopathologic evaluation of all surgically removed eyelid masses

TREATMENT

TREATMENT OVERVIEW

Treatment goals are to restore normal eyelid conformation, eliminate ocular irritation, and prevent recurrence of eyelid mass. Treatment for an eyelid mass should be initiated early in the course of the disease to ensure normal eyelid conformation.

ACUTE GENERAL TREATMENT

- Eyelid trauma:
  - Laceration requires primary/surgical closure of wound.
  - If full-thickness laceration, close in two layers (conjunctiva followed by skin) starting at eyelid margin to ensure accurate apposition of eyelid margin.
- Eyelid mass:
  - Neoplasia:
    - Surgical removal:
      - If involves eyelid margin and ≤⅓ length of eyelid, remove by a full-thickness V-shaped or "house"-shaped excision.
      - Close in two layers (see Eyelid Trauma under Acute General Treatment above).
      - Eyelid margin mass > ⅓ eyelid length requires a plasty procedure to ensure proper eyelid length (e.g., H-plasty). Consider referral to ophthalmologist or surgeon.
    - Cryosurgery:
      - Useful in treating benign eyelid mass in older animals
      - May be performed under sedation
      - Recurrence rate higher with cryotherapy than with full-thickness excision.
- Chalazion:
  - Surgical treatment:
    - Scalpel incision of overlying palpebral conjunctiva with curettage; heals by second intention
  - Topical antibiotic/corticosteroid (e.g., neomycin-polymyxin-dexamethasone suspension) q 8 h for 7 days after surgery; corticosteroid contraindicated if cornea is not intact.

POSSIBLE COMPLICATIONS

- Poor apposition of eyelid margin results in cicatrix (scar) formation, predisposing to entropion or ectropion, or "step" to eyelid margin, resulting in corneal irritation and ulceration.

- Improperly placed sutures at the eyelid margin can predispose to corneal ulceration.
- Local regrowth of eyelid mass, if mass not completely removed

RECOMMENDED MONITORING

Reevaluate apposition of eyelid margin, and remove skin sutures 10 days after surgery.

PROGNOSIS AND OUTCOME

- Eyelid laceration: prognosis good if apposition of eyelid margin is achieved.
- Removal of eyelid neoplasm: dogs, prognosis good, majority are benign; cats, prognosis guarded, majority are malignant.
- Local recurrence is possible if an eyelid mass is not completely excised.

PEARLS & CONSIDERATIONS

COMMENTS

- Eyelid lacerations are treated surgically, not as open wounds, to prevent eyelid scarring, contraction, and distortion of the eyelid margin.
- Eyelid masses should be removed early to prevent the need for plasty procedures.

PREVENTION

Limit actinic radiation (sunlight) exposure in white cats to decrease the potential for SCC.

CLIENT EDUCATION

Recurrence is possible after the removal of any eyelid mass.

SUGGESTED READING

Stades FC, Gelatt KN: Diseases and surgery of the canine eyelid. In Gelatt KN, editor: Veterinary ophthalmology, ed 4, Ames, 2007, Blackwell Publishing, p 563.

AUTHOR: PHILLIP A. MOORE

EDITOR: CHERYL L. CULLEN

Exocrine Pancreatic Insufficiency

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A syndrome caused by insufficient secretion of pancreatic digestive enzymes by the exocrine pancreas

SYNONYM

EPI

EPIDEMIOLOGY

SPECIES, AGE, SEX: Occurs more commonly in dogs than in cats; any age. In dog breeds that are affected by pancreatic acinar atrophy (PAA), exocrine pancreatic insufficiency (EPI) is most commonly diagnosed in young adults. In other dog breeds and cats, EPI can occur at any age.

GENETICS & BREED PREDISPOSITION: In dogs, EPI most commonly occurs in the German shepherd, for which an autosomal recessive inheritance has been proposed. A breed predilection has also been reported for rough coated collies and Eurasians. There is no known breed predilection in cats. See Etiology, below, regarding PAA.

RISK FACTORS

- Chronic pancreatitis can lead to destruction of exocrine pancreatic tissue and EPI.
- Pancreatic adenocarcinoma or surgery could lead to obstruction of the pancreatic duct, leading to lack of pancreatic enzyme secretion into the small intestine.

ASSOCIATED CONDITIONS & DISORDERS: Many canine and feline patients with EPI have other gastrointestinal disorders. Dogs with EPI due to PAA commonly have secondary small-intestinal bacterial overgrowth (also termed antibiotic-responsive diarrhea [see p. 81]); other dogs and cats often have concurrent inflammatory bowel disease (see p. 605).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Weight loss is the most common clinical sign in both dogs and cats.
- Loose stools and less commonly diarrhea
- Ravenous appetite

PHYSICAL EXAM FINDINGS

- Poor body condition (Note: nowadays patients often are diagnosed much earlier in the disease process, and emaciated patients with EPI are rare.)
- Poor hair coat and sometimes in cats, greasy soiling of the hair coat

ETIOLOGY AND PATHOPHYSIOLOGY

- The most common cause of EPI in the dog is pancreatic acinar atrophy. This condition is mostly seen in German shepherds, rough coated collies, and Eurasians.
- The most common cause of EPI in the cat and the second most common cause of EPI in dogs is chronic pancreatitis.
- Other potential causes of EPI include obstruction of the pancreatic duct by a pancreatic adenocarcinoma and pancreatic aplasia or hypoplasia, but these have not yet been reported in dogs or cats. Surgical obstruction of the pancreatic duct, leading to EPI, has recently been described.
- Decreased secretion of exocrine pancreatic digestive enzymes leads to lack of digestive enzymes in the small intestine, which will lead to maldigestion and associated clinical signs.
- Secondary cobalamin deficiency is very common in dogs and occurs in almost all cats with EPI.
- In patients with EPI due to chronic pancreatitis, pancreatic inflammation may also lead to destruction of islets of Langerhans and cause concurrent diabetes mellitus.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The most reliable diagnostic test for EPI for both dogs and cats is serum trypsin-like immunoreactivity concentration (TLI), which is measured by a species-specific assay.

DIFFERENTIAL DIAGNOSIS

- Primary small intestinal disease (e.g., inflammatory or infiltrative bowel disease)
- Other secondary causes of chronic diarrhea and weight loss (i.e., hepatic failure, renal failure, hypoadrenocorticism, hyperthyroidism [cats])

INITIAL DATABASE

- CBC, serum chemistry profile, and urinalysis are usually within normal limits (including serum total protein concentration).
- Imaging studies are usually within normal limits.

ADVANCED OR CONFIRMATORY TESTING

- Serum TLI is the diagnostic test of choice for the diagnosis of EPI.
  - A severely decreased serum TLI concentration is diagnostic of EPI.
    - In dogs: ≤2.5 µg/L (canine TLI; reference range 5.7–45.2 µg/L)
    - In cats: ≤8.0 µg/L (feline TLI; reference range 12–82 µg/L)
  - Some patients with EPI may have a serum TLI concentration in the questionable range (>2.5 but <5.0 µg/L [dog]; >8.0 but <12.0 µg/L [cat]).
    - These patients most likely have chronic small-intestinal disease and should be evaluated accordingly and retested 4–6 weeks later.
- Other diagnostic tests are much less reliable and should *not* be used for the diagnosis of EPI:
  - Fecal proteolytic activity is only recommended in species for which a TLI assay is not available.
  - Fecal elastase concentration is only available in Europe. Positive test results must be confirmed with a cTLI test; the false-positive rate is high.

TREATMENT

TREATMENT OVERVIEW

- Pancreatic enzyme replacement is crucial.
- Cobalamin must be supplemented parenterally if cobalamin deficiency is present.

ACUTE GENERAL TREATMENT

- Oral enzyme replacement therapy
  - Starting dose: 1 tsp per 10 kg body weight with each meal
  - Tablets and capsules are not as effective as powder.
  - Premixing the pancreatic enzymes with the diet is not necessary.
- Parenteral cobalamin supplementation if the patient is cobalamin deficient (approximately 80% of dogs with EPI and virtually all cats with EPI are cobalamin deficient; see p. 220).

CHRONIC TREATMENT

- Oral enzyme replacement therapy:
  - Once patients have fully responded and gained back their original body weight, the amount of enzyme can be decreased to the lowest effective dose, titrated based on stool consistency and body weight.
- Oral antibiotic therapy (i.e., tylosin, 25 mg/kg PO q 12 h for 6 weeks) if canine patient does not respond to enzyme replacement therapy and is suspected of having antibiotic-responsive diarrhea
- Insulin therapy if patient has concurrent diabetes mellitus

NUTRITION/DIET

- Dietary fat restriction is not recommended.
- Several studies in dogs have failed to show any impact of diet on therapeutic response.
- Premium maintenance diet is sufficient.

POSSIBLE COMPLICATIONS

Enzyme supplementation can lead to oral bleeding in approximately 10% of patients:

- Most of these patients will normalize after reduction of the dose.
- Patients may rarely develop bleeding diathesis due to vitamin K deficiency, which must be treated with vitamin K supplementation.

RECOMMENDED MONITORING

Body weight, fecal quality, and serum cobalamin concentration after supplementation

PROGNOSIS AND OUTCOME

Most patients with EPI respond to therapy and have a normal life.

PEARLS & CONSIDERATIONS

COMMENTS

- Some patients may not respond to enzyme replacement therapy and cobalamin supplementation alone.
  - Many of these patients have concurrent small-intestinal disease (i.e., small-intestinal bacterial overgrowth/antibiotic-responsive enteritis, and/or inflammatory bowel disease).
  - If concurrent disease cannot be identified, gastric acid inhibition can be tried (i.e., omeprazole, 0.7 mg/kg PO q 12 h has been most useful).
- Fresh-frozen raw pancreas can also be used for enzyme replacement therapy (1–2 oz of ground raw pancreas equals about 1 tsp of powdered pancreatic extract).

AUTHOR: JÖRG M. STEINER

EDITOR: KEITH P. RICHTER

Ethylene Glycol Intoxication

BASIC INFORMATION

DEFINITION

Ethylene glycol (EG) intoxication manifests as the peracute onset of marked central nervous system (CNS) depression and progressive, dose-related metabolic acidosis and renal failure. Sources of EG are commonly found in automobile radiator fluid, aircraft and runway deicing products, home solar units, and portable basketball goal post bases, among others.

SYNONYMS

Ethylene alcohol poisoning, radiator antifreeze poisoning, 1,2-ethanediolmono-ethylene glycol poisoning, glycol alcohol poisoning, CAS 107-21-1 poisoning

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Animals of all ages, breeds, and both sexes are equally susceptible to EG poisoning.
- Cats are most sensitive to EG intoxication.
- Dogs are intermediate in sensitivity among the species.
- Dogs are more commonly exposed than cats. Intact young male dogs may be more likely to be involved.

RISK FACTORS

- Pets living outdoors or having free-range access to EG sources (e.g., garages)
- Northern climates or freezing temperatures provide increased opportunity, especially when water sources are limited (frozen), and antifreeze remains in the liquid state because of its low freezing point.
- Engine leak is the most common source of exposure in pets.
- In the home, the garage is one of the most common exposure locations.

GEOGRAPHY AND SEASONALITY

- EG poisoning cases can occur throughout the year; it is no longer considered a seasonal problem.
- Northern and colder climates are over-represented, but exposure can occur anywhere radiator fluid flushing is common. Summer automobile radiator flushing procedure is considered routine maintenance.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Indirect evidence of exposure:
  - Pet being near an automobile garage or work area
  - Roaming free in areas suspected or known to have EG sources
- Classic “drunken sailor” behavior (stupor, narcosis, stumbling, ataxia, falling, nausea) may be noted within 1-2 hours.
- Stupor phase gradually subsides over several hours.
  - Stupor phase may go unnoticed altogether, especially in outdoor pets.
  - Owner may note the pet “getting better.”
  - Patient is quiet, depressed, polydipsic, and polyuric.
- Patient gradually and steadily shows more weakness, depression, anorexia, and tachypnea/dyspnea as acute renal failure occurs (12–72 hours after ingestion).

PHYSICAL EXAM FINDINGS

- CNS depression, generalized weakness, hyporeflexia, knuckling, hypothermia, hypotension, tachycardia, vomiting, and polyuria
- Urinary bladder may be empty on palpation.
- Patient may have already progressed beyond the initial “drunk” phase and may not present as “classic,” thus potentially

confusing the picture.
    - Overt signs of acute renal failure (oliguria/anuria, anorexia, vomiting, renomegaly with signs of renal pain) begin 24–72 hours post ingestion.
- In severe intoxications, seizures, nystagmus, and tremors may occur in the first few hours post ingestion (grave prognosis).

ETIOLOGY AND PATHOPHYSIOLOGY

- Lethal dose of 95% ethylene glycol: 4.4 mL/kg (dog), 1.4 mL/kg (cat)
- Rapid oral absorption of EG
    - Blood levels detectable in <30 minutes
    - Initial CNS depression and narcosis, vasodilation, and hypotension with reflex tachycardia, diuretic effect
- Metabolism involves hepatic alcohol dehydrogenase oxidation of EG to the aldehyde (glycoaldehyde).
    - This oxidation is a saturable process; therefore it is the rate-limiting step.
    - Metabolic progression can be interrupted at this point with fomepizole or ethanol.
    - Glycoaldehyde is very toxic but quickly converts to glycolic acid.
    - Glycolic acid (30%–45% of metabolite load) is fairly stable, further oxidizes to glyoxylic acid, then further metabolism occurs along several paths to oxalic acid, glycine, formate, hippurate, CO2, and so on. Aldehyde and acid load create a high-anion-gap metabolic acidosis.
- Metabolites inhibit the citric acid cycle and substrate level phosphorylation, depress serotonin and pyruvate metabolism, and alter CNS amine levels.
- Secondary lactate accumulation, hypoperfusion, calcium oxalate formation, and precipitation in microvasculature and renal tubules occur.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A high index of suspicion should exist based on history alone (owner saw pet licking, or in the same room as, fluorescent green liquid). Treatment must be implemented early—prior to renal failure and possibly prior to definitive diagnostic confirmation in many cases—to avert toxic renal injury. The diagnosis is more straightforward, but the prognosis worse, >12–24 hours after ingestion when overt clinical signs emerge.

DIFFERENTIAL DIAGNOSIS

Rule out other causes of acute CNS depression, ataxia, acidosis, or acute renal failure: encephalitis, cranial trauma, intracranial neoplasia, diabetic ketoacidosis; or intoxication with barbiturates, aspirin, methanol, ethanol, isopropanol, propylene glycol, glycol ethers, vitamin D3, *Lilium* and *Hemerocallis* spp. (cats), nonsteroidal antiinflammatory drugs, grapes, or raisins.

INITIAL DATABASE

- Ethylene Glycol Test Kit screening tool (Allelic Biosystems: PRN Pharmacal Inc., Pensacola, Fla. [800-874-9764; www.prnpharmacal.com]). Recommended for use in dogs, not sensitive enough for cats (false negatives). Test can produce false-positive results with propylene glycol, glycerol, diethylene glycol (or other *cis*-1,2 diols), metaldehyde, and formaldehyde. Limited availability.
- React ethylene glycol test kit. PRN Pharmacal Inc., Pensacola, FL (800-874-9364; www.prnpharmacal.com). The React Test is fairly new in the market and its accuracy has not yet been determined.
- Serum chemistry panel including serum electrolytes (especially Ca^{++}, Mg^{++}, K^{+}, and P)
- Acid-base: blood pH, Pco2, Po2, serum bicarbonate
- Urinalysis: specific gravity, crystals, glucose, cellular debris
    - As in any cause of acute anuric renal failure, specific gravity will not necessarily be low.
    - Calcium oxalate monohydrate crystals (“picket fence boards,” flattened hexagon shapes: can be observed 18 hours after EG ingestion and are much more specific to ethylene glycol intoxication than calcium oxalate dihydrate crystals (“Maltese cross” or “square envelope” appearance:, which can occur from nutritional or laboratory artifactual causes as well as EG intoxication.
- Fluids: measure total input and output; body weight.
- Optional Wood's lamp examination (detects fluorescein dye in antifreeze); scan of muzzle, paws, vomitus, urine (excretes < 3–6 hours in humans) for fluorescence that subjectively supports exposure.

ADVANCED OR CONFIRMATORY TESTING

- EG and glycolic acid levels (serum, urine); requires STAT turnaround time to benefit early diagnosis in determining treatment approach

- Serum osmolality; requires colloid osmometer
  - Normal osmole gap: 5-10 mOsm/kg water (dogs and cats). Osmole gap = measured osmolality – calculated osmolality.
  - >20 mOsm/kg strongly suggestive of EG intoxication; parallels EG blood level. Significant increase within 1 hour of exposure.
- Anion gap
  - Normal anion gap: 10–25 mEq/L (dogs and cats)
  - >25 mEq/L is significant for diagnostic purposes
  - May note change by 3 hours, but may require 6 hours. Therefore, less preferred as an early diagnostic tool.
- Ultrasound: increased renal cortical echogenicity at 4-6 hours; late in the course, “halo sign” indicative of anuria, and grave prognosis.
  - *Note:* many normal, healthy cats have diffuse hyperechogenicity of renal cortices (avoid overinterpretation).
- Renal calcium level in postmortem tissue sample

TREATMENT

TREATMENT OVERVIEW

EG toxicosis is a medical emergency. Due to rapid progression and irreversibility of renal lesions, any patient suspected of consuming EG should be tested and decontaminated unless/until exposure has been ruled out; empirical treatment with fomepizole or ethanol is indicated if the index of suspicion is high and a confirmatory test is not available in time. The greatest window of opportunity for intervention is <8–12 hours post exposure in dogs, <2 hours post exposure in cats. Immediate decontamination of the patient (early induction of emesis and administration of activated charcoal) is indicated in all suspected or confirmed cases presented within 1 hour of exposure. Confirmed cases should also receive an antidote (fomepizole or ethanol) and be hospitalized for management of acid-base abnormalities, fluid diuresis for renal protection, and supportive care as dictated by progression of the case.

ACUTE GENERAL TREATMENT

- Induction of vomiting (see p. 1364) with hydrogen peroxide 3%: 0.25–0.5 mL/kg PO once; or apomorphine, 0.03 mg/kg IV or in conjunctival sac, then administration of activated charcoal (1–2 g/kg PO once). Can reduce absorption within 30–60 minutes; indicated if patient is a good risk. Some clinicians precede this by very rapidly feeding a tasty meal to provide a substrate for the vomiting if the pet has an otherwise empty stomach.
- Interrupt conversion to toxic metabolites with fomepizole (4-MP, 4-methylpyrazole, Antizol-Vet, Paladin Labs [www.antizol-vet.com]).
  - Loading dose: 20 mg/kg slow IV infusion
  - Then 15 mg/kg slow IV q 12 h × 3 treatments in the dog
  - Not effective in cats at labeled dose
- Off-label fomepizole: use in cats <3 hours after ingestion at 125 mg/kg slow IV infusion, then 31.25 mg/kg q 12 h × 3 treatments has shown significant success.
- Or interrupt conversion to toxic metabolites with 7% ethanol solution.
  - Loading dose: 8.6 mL/kg slow IV
  - Maintenance dose: 1.43-2.86 mL/kg/h constant rate infusion (CRI) to effect
    - Achieve serum ethanol concentrations of 100 mg/dL or lethargic/comatose state.
    - Duration: approximately 48 hours
  - Dogs treated with ethanol starting at 3 hours post ingestion of EG excrete 80% of EG intact.
- Hemodialysis (more effective) or peritoneal dialysis while on ethanol or fomepizole. Immediate dialysis on any patient showing clinical signs of toxicity will tend to increase the survival rate.
- Acid-base and perfusion management is critical to survival. Sodium bicarbonate CRI as needed for metabolic acidosis.
- Crystalloids: high infusion rate required to correct severe dehydration and hypoperfusion.
- Provide cofactors for metabolism of toxic compounds.
  - Pyridoxine, 1-2 mg/kg IV q 6 h
  - Thiamine, 50 mg slow IV q 6 h

CHRONIC TREATMENT

Dialysis to allow regeneration of damaged tubular basement membrane

POSSIBLE COMPLICATIONS

Renal compromise. May be salvageable, depending on degree of insult and response to intensive treatment.

RECOMMENDED MONITORING

Renal function (urinalysis, serum chemistry, biopsy, etc.) should be monitored as needed in surviving patients.

PROGNOSIS AND OUTCOME

- Dogs: fair to good if proper aggressive intervention within 8-12 hours; prognosis worsens by the hour if clinical signs are apparent and/or a large dose was ingested.
- Cats: guarded to poor at best in any case showing clinical signs. Aggressive intervention (interruption of metabolism with high doses of fomepizole, dialysis, acid-base management) within 3 hours of exposure may prove successful.

PEARLS & CONSIDERATIONS

COMMENTS

- Progression of irreversible, potentially life-threatening effects in patients that have ingested EG is rapid (hours); therefore, evaluation and treatment are urgent, even in animals without overt clinical signs.
- "Safe antifreeze" contains propylene glycol, which is less toxic compared to EG; much less risk of renal injury. Dogs would generally need to ingest 3–4 times more propylene glycol than EG to develop clinical signs.
- Use of injectable valium, phenobarbital, pentobarbital, or some commercial oral preparations of activated charcoal before using EG test kits can give a false-positive result due to presence of propylene glycol in them.

TECHNICIAN TIPS

- Calcium oxalate monohydrate urinary crystals (□) are strongly suggestive of ethylene glycol intoxication, whereas calcium oxalate dihydrate crystals (□) may also be caused by nutrition or refrigeration of the urine sample.
- Many human hospital laboratories have the capability of detecting and quantifying EG quickly in different body fluids and can be helpful if an EG test kit is not available on site.
- Antifreeze (ethylene glycol) is generally fluorescent green, viscous (like light syrup), and does not have a volatile odor; windshield washer fluid (not ethylene glycol) is generally translucent blue, pungent (volatile odor), and nonviscous (like water).

PREVENTION

Keep animals indoors and not in the garage, especially in freezing temperatures (frozen water sources, antifreeze remains in liquid state, thus is more attractive).

CLIENT EDUCATION

Lock antifreeze plastic containers away from chewing dogs. Use cat litter to clean up any spills, leaks. About 1 tsp (5 mL) of radiator antifreeze is lethal to an adult cat.

Esophagitis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Acute or chronic inflammation of the esophagus, often secondary to reflux of gastric acid, foreign bodies, or medications

SYNONYMS

Gastroesophageal reflux, reflux esophagitis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats of any age and either sex can be affected; females may be overrepresented.

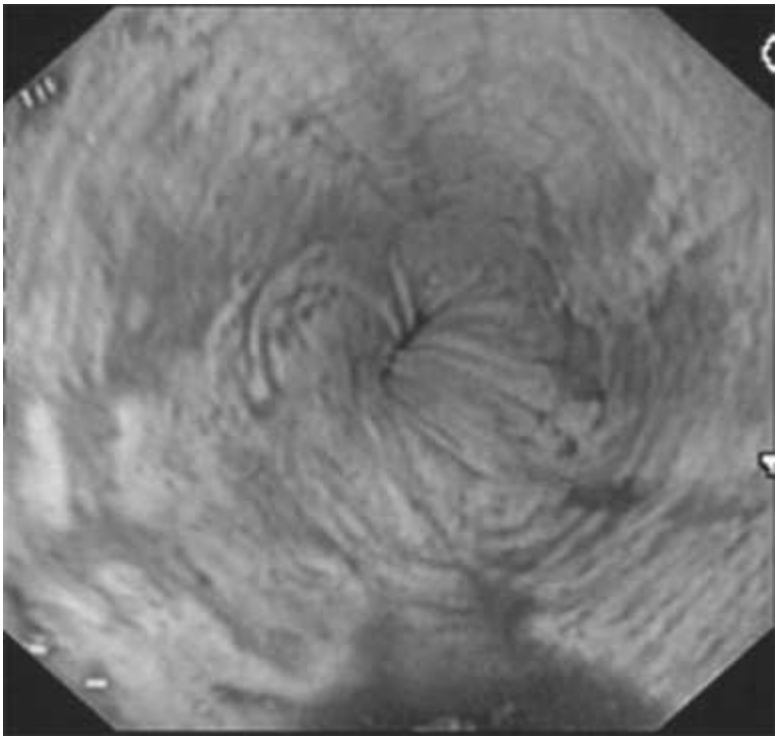
RISK FACTORS

- General anesthesia, even of short duration:
  - Most common cause of reflux esophagitis in the dog and cat
- Hiatal hernia or other causes of lower-esophageal sphincter dysfunction
- Esophageal foreign body
- Oral medications (e.g., tetracyclines, ciprofloxacin, NSAIDs) given without being followed by food or water administration
- Persistent vomiting
- Gastric hyperacidity (e.g., gastrinoma)

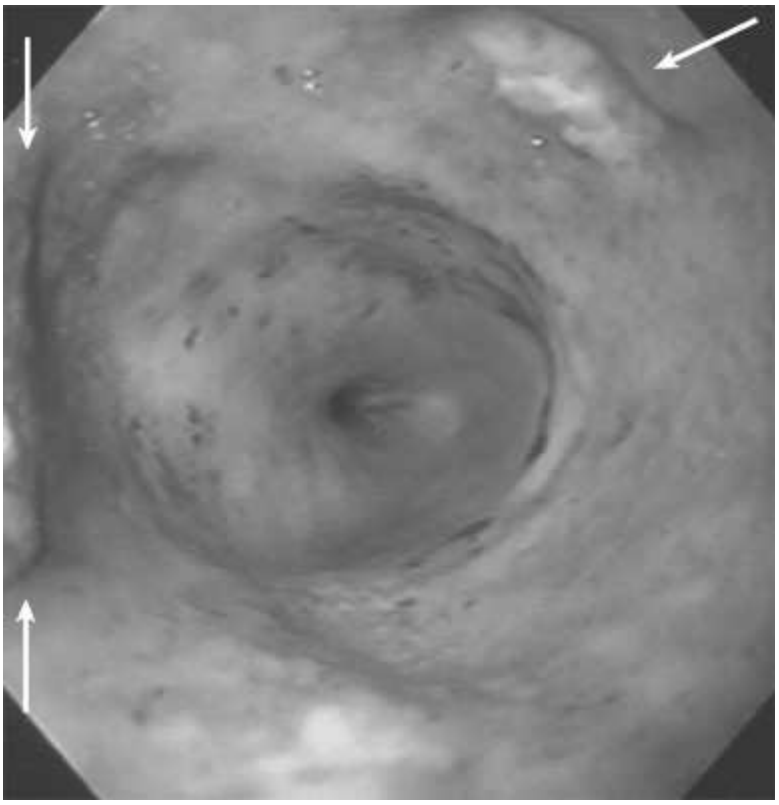
CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Mild esophagitis may be subclinical.
- Clinical signs may include:
  - Increased swallowing motions, ptyalism
  - Inappetence, anorexia, and/or odynophagia (discomfort when swallowing) due to pain
  - Regurgitation or vomiting
  - Reluctance to move or lie down
  - Cats may vocalize after eating as an indication of esophageal pain.
- Affected patients may have a history that reveals risk factors (above).



ESOPHAGITIS Endoscopic view of a patient with esophagitis. Note the longitudinal, darker patchy areas indicative of inflammation and mucosal erosion. Fluid pooling is apparent at the bottom of the image.



ESOPHAGITIS Endoscopic view of a patient with ulcerative esophagitis. Ulcers are apparent as deep depressions in the esophageal wall on the left edge of the image *(arrows)* and at the 1 o'clock position *(single arrow)*. Mucosal hemorrhages are also evident as darker, thin, circumferential streaks and pinpoint lesions on or near the gastroesophageal sphincter.

PHYSICAL EXAM FINDINGS: May be normal; abnormalities may include:

- Thin body condition
- Dehydration
- Ptyalism

- Pharyngitis
- Cranial abdominal/thoracic discomfort:
    - Hunched-up appearance
    - Guarding or pain on palpation

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology:
    - Premedicant drugs (atropine, benzodiazepines, phenothiazines, opioids) and anesthetic induction agents may decrease lower-esophageal sphincter tone, allowing gastroesophageal reflux.
    - Anatomic abnormalities (e.g., hiatal hernia) can increase risk of reflux esophagitis.
    - Ingested medications or chemicals can damage the esophagus because of their pH or osmolarity.
- Pathophysiology:
    - Esophageal mucosal contact with low-pH gastric fluid, pepsin, trypsin, bile salts, and/or alkaline fluid causes damage and inflammation, which may remain mucosal or involve all layers of the esophagus.
    - Caustic agent ingestion (e.g., detergents, alkalis, acids)
    - Volume, frequency, and duration of contact of material with esophagus affects the severity of esophageal damage.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

The diagnosis can be suspected in two contexts: a suggestive history and/or chief complaint or a vague presentation with nonspecific clinical signs. In either situation, esophagitis may be confirmed by direct endoscopic visualization (rules out impostors but requires expertise and equipment) or by response flexible endoscopic equipment or it may be suspected based on response to treatment (but other diseases may respond to therapy for esophagitis).

DIFFERENTIAL DIAGNOSIS

- Thermal damage (e.g., gavage/tube feeding with excessively hot liquids)
- Esophageal foreign body
- Megaesophagus
- Vomiting
- Neoplasia or mass lesions (intrinsic or extrinsic)
- Vascular ring anomaly
- Hiatal hernia
- Gastroesophageal intussusception

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis: often within normal limits
- Survey thoracic radiographs seldom diagnostic, but may show esophageal dilation
- Contrast esophagram sometimes demonstrates mucosal ulceration or hyperplasia, or decreased esophageal motility.

ADVANCED OR CONFIRMATORY TESTING

- Esophagoscopy typically allows definitive diagnosis, exclusion of other disorders, and evaluation of extent and severity based on gross appearance.
    - Biopsy of canine esophageal mucosa is difficult but occasionally reveals organisms (e.g., yeast *[Candida]* or hyphae *[Pythium]*).
    - Biopsy may be important in cats with chronic inflammation at lower-esophageal sphincter which may not be grossly obvious.
- Fluoroscopy often needed to detect lower esophageal sphincter dysfunction not due to hiatal hernia

TREATMENT 

TREATMENT OVERVIEW

Goals of therapy are to protect the esophageal mucosa from further damage, decrease the amount and frequency of reflux, and eliminate acid from reflux.

ACUTE GENERAL TREATMENT

- Lessen or eliminate gastric acid secretion.
  - H2 receptor antagonists (e.g., famotidine, 0.5–2 mg/kg PO or IV q 12–24 h): achieves maximal efficacy immediately but is not as effective as proton pump inhibitors
  - Proton pump inhibitors (e.g., omeprazole, 0.7–1 mg/kg PO q 12–24 h): most effective class of drugs but typically requires 2-5 days to reach maximal efficacy
- Minimize reflux by increasing lower-esophageal sphincter tone and keeping stomach empty
- Prokinetic drugs (e.g., metoclopramide, 0.2–0.5 mg/kg PO or SQ q 8 h; or cisapride, 0.1–0.25 mg/kg PO q 8–12 h).
- Sucralfate slurry (0.25–1 g/patient PO q 8 h):
  - Protects the esophageal mucosa from further damage

CHRONIC TREATMENT

- Treat until esophagitis resolves.
- Indefinite prokinetic and antacid therapy may be needed when lower-esophageal dysfunction is not amendable to surgical resolution.

NUTRITION/DIET

- Feed a moderate- to high-protein, low-fat diet; increases lower esophageal tone and encourages gastric emptying.
- If necessary, place gastrostomy tube to ensure nutrition and ability to medicate patient (see p. 1267).

POSSIBLE COMPLICATIONS

Esophageal stricture formation

RECOMMENDED MONITORING

- Normal eating without dysphagia, ptyalism, or regurgitation usually implies resolution.
- Hyporexia, dysphagia, ptyalism, or regurgitation necessitates reexamination for stricture or inflammation.
- Strictures may cause regurgitation beginning days to 4 weeks post injury.

PROGNOSIS AND OUTCOME

- If the cause can be eliminated, is not severe, and is recognized early and treated aggressively, prognosis is usually good.
- Prognosis is guarded if the cause cannot be resolved or if esophagitis is severe or patient develops long esophageal strictures.

PEARLS & CONSIDERATIONS

COMMENTS

- Decrease the risk of prolonged contact of medication with esophageal mucosa by administering water (e.g., 5-10 mL by syringe) following any dry oral medication (tablet or capsule) given without food.
- Consider reflux esophagitis in patients showing ptyalism, hyporexia, or regurgitation shortly after anesthesia.

PREVENTION

- Routine use of preanesthetic antacid drugs is of unknown efficacy and cost-effectiveness.
- Routine postanesthetic esophageal lavage and suction is of uncertain efficacy and cost-effectiveness.

CLIENT EDUCATION

Administer water (e.g., 5–10 mL by syringe trickled in the cheek pouch) following any dry oral medication (tablet or capsule) given without food.

Esophageal Stricture

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A circular band of scar tissue that forms after deep esophageal injury (foreign body or esophagitis resulting in inflammation that extends into the submucosal and muscular layers) and compromises food passage through the esophageal lumen (see pp. 406 and 367 for related information).

EPIDEMIOLOGY

SPECIES, AGE, SEX: Strictures due to foreign bodies (bones, fish hooks) are more common in dogs, and strictures due to chemical esophagitis (pills, caustic agents) are more common in cats.

RISK FACTORS

- Dogs: ingestion of bones, rocks, other foreign objects
- Cats: administration of medications not followed with water or food (capsules or uncoated tablets are the most common medications that lodge and cause esophagitis or stricture).
- Dogs or cats: gastroesophageal reflux due to anesthesia, persistent vomiting

ASSOCIATED CONDITIONS & DISORDERS

- Esophagitis (common)
- Esophageal foreign bodies (common)
- Esophageal neoplasia (rare)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Regurgitation is the classic presenting sign (distinguish from vomiting: regurgitation involves no prodromal signs or active retching).
- Difficulty swallowing or pain associated with swallowing (repeated swallowing efforts)
- Ptyalism/hypersalivation
- Inappetence
- Lethargy
- Weight loss (if the condition is long-standing)
- Cough, increased respiratory rate or effort may be seen if the patient has concurrent aspiration pneumonia.

PHYSICAL EXAM FINDINGS

- May be normal
- Weight loss
- Ptyalism or gagging
- Coughing, fever, or increased bronchovesicular sounds if aspiration pneumonia has occurred

ETIOLOGY AND PATHOPHYSIOLOGY

- Some of the more frequently reported causes of stricture formation are esophagitis secondary to chronic persistent vomiting, foreign bodies that lodge in the esophagus, and ingestion of caustic substances (including medications that lodge in the esophagus).
- A commonly reported cause of esophagitis in dogs and cats is reflux esophagitis due to general anesthesia; however, the incidence of stricture secondary to this cause of esophagitis is much less frequent.
- Infrequently reported causes of stricture formation in dogs and cats are hiatal hernias, esophageal *Pythium* spp. infection, esophageal neoplasia (the most common cause of stricture formation in humans), and esophageal surgery (to remove foreign bodies, masses).
- Esophageal stricture formation requires substantial esophageal injury (usually chemical or mechanical) resulting in

penetration or inflammation that extends to the submucosa or muscular layers. The normal repair process that follows this injury results in formation of fibrous connective tissue, and many times this occurs in a circular band of scar tissue that narrows or closes the esophageal lumen.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- Esophageal strictures are easy to diagnose (with endoscopy); the challenge is that there is a degree of clinical suspicion necessary to put the pieces together from the history and physical exam findings.
- History of regurgitation should prompt the consideration of esophageal disease and evaluation of thoracic radiographs. If no abnormality is seen and regurgitation is convincingly present, contrast radiography or esophageal endoscopy (confirmatory test of choice) is warranted.

DIFFERENTIAL DIAGNOSIS

Regurgitation:

- Esophagitis
- Esophageal foreign body
- Esophageal mass (granuloma, parasites, neoplasia)
- Esophageal motility disorders (megaesophagus, congenital or acquired)
- Esophageal diverticulum
- Persistent right aortic arch
- Gastroesophageal reflux during anesthesia (history of anesthesia is important)
- Gagging/dysphagia
- Oropharyngeal, nasopharyngeal disease

INITIAL DATABASE

- CBC, serum chemistry panel, urinalysis likely normal; changes are nonspecific.
  - Inflammatory leukogram present if aspiration pneumonia
  - Evidence of dehydration possible if stricture is severe
- Thoracic/abdominal radiographs are indicated in all regurgitating patients.
  - Plain thoracic films may be normal, may show evidence of megaesophagus (or air/food in esophagus cranial to the stricture), or may reveal signs of aspiration pneumonia.
  - Plain abdominal films are usually unremarkable unless there is an obvious gastric outflow obstruction that is causing persistent vomiting/gastroesophageal reflux.

ADVANCED OR CONFIRMATORY TESTING

- Endoscopy (see p. 1284) is the preferred diagnostic imaging tool of choice for definitive identification of esophagitis, other esophageal anomalies, and esophageal strictures. In addition, endoscopy can be used for facilitating balloon dilation of the stricture site—the best approach for long-term stricture management.
- Contrast films may reveal stricture site or esophageal motility defect if food or paste is used, but liquid barium or iodinated contrast agents may pass through the stricture undetected. Contrast studies are helpful if multiple strictures are suspected, because visualization with the endoscope will be limited to the first stricture site in many (see). Caution is advised when administration of contrast is contemplated; regurgitation of barium may result in aspiration.
- Fluoroscopy is often needed to identify a hiatal hernia or distal lower-esophageal sphincter defect leading to reflux.
- Abdominal ultrasound is indicated to rule out abdominal causes of persistent vomiting that may lead to reflux esophagitis.

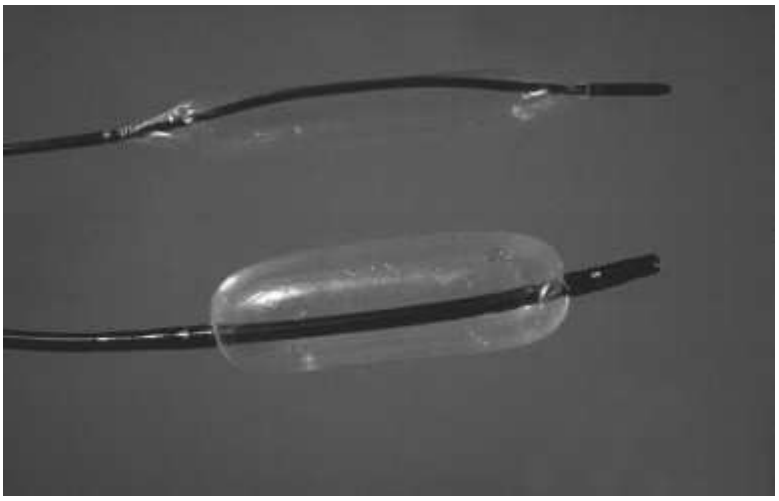
TREATMENT

TREATMENT OVERVIEW

Therapeutic goals are to protect the esophageal mucosa from additional injury, eliminate the underlying cause of the injury (if possible), adequately resolve regurgitation, and allow the patient to maintain nutrition and hydration by oral feeding.

ACUTE GENERAL TREATMENT

- Treatment of esophagitis if present (see p. 367) or other underlying causes of stricture (control vomiting, remove foreign body, etc.)
- If the stricture is mild (liquid or canned foods can pass through the stricture site with few or no clinical signs, and no weight loss is evident), management may be accomplished by dietary modifications (feeding liquid, gruel, or canned foods in frequent, small meals).
- In severe strictures refractory to such conservative management, the stricture must be dilated to allow liquids or gruels to pass. If this is not possible, a gastric feeding tube must be placed to allow maintenance of hydration and nutrition (see p. 1267).
- Dilation can be accomplished by balloon or by esophageal bougienage. Balloon dilation is the preferred means of dilation and entails passage of an inflatable balloon catheter into the stricture site, inflating the balloon to allow the pressure to tear/break down the scar tissue and thus increase the diameter of the esophageal lumen.
- Alternatively, bougienage involves the passage of rigid dilators of gradually increasing size through the stricture site. Both of these procedures are facilitated by concurrent use of endoscopic (or fluoroscopic) guidance to monitor the procedural success and identify complications (e.g., esophageal tear) early.
- Corticosteroids (e.g., prednisone, 0.5–1 mg/kg PO q 24 h × 5–10 days) may be considered in an attempt to delay fibrosis of recently dilated strictures. Delayed healing and the risk of immunosuppression are drawbacks that contraindicate higher dose or longer-term treatment.
- Lifelong dietary management is usually necessary. Complete resolution of the stricture and normalization of esophageal function are unlikely.



ESOPHAGEAL STRICTURE Photo illustration of a 180-cm, 15-mm outer diameter esophageal/pyloric balloon (CRE Wireguided balloon [Boston Scientific, Natick, Mass]). Upper balloon is undilated for comparison.

CHRONIC TREATMENT

- Many animals require several dilation procedures to achieve an esophageal opening sufficiently large to accommodate liquid or gruel diets.
- As for animals with esophagitis, long-term therapy may be needed. A cornerstone of treatment is the avoidance of hard foods.

POSSIBLE COMPLICATIONS

- The most important complication of esophageal stricture therapy is rupture or perforation of the esophagus during the ballooning or bougienage procedure.
- Complete recurrence of the stricture can occur if the dilation procedure is too aggressive, resulting in excessive inflammation.
- Aspiration pneumonia remains a possible complication if the stricture remains and the patient has episodes of regurgitation or does not have well-controlled dietary management (e.g., the dog gets into the garbage or is allowed to eat foods that will not pass).

ESOPHAGEAL STRICTURE Digital image obtained during esophagoscopy. A stricture site is apparent at center of image. Note that very little material (except small amounts of liquids) could pass through this opening.

ESOPHAGEAL STRICTURE Digital image obtained during esophagoscopy of same patient, illustrating placement of balloon in stricture site. Balloon is partially inflated and momentarily will be fully inflated for stretching the fibrous stricture, or cicatrix.

ESOPHAGEAL STRICTURE Digital image obtained during esophagoscopy after balloon dilation of esophageal stricture in same dog. Note degree of inflammation and bleeding at the site, but lumen diameter is markedly enlarged. Goal is to minimize degree of inflammation created to avoid stricture redevelopment post ballooning.

PROGNOSIS AND OUTCOME

- The prognosis for mild strictures is generally good.
- The prognosis for severe strictures requiring multiple balloon dilation procedures is guarded.
- If the patient can be managed on liquid or gruel diets, with minimal to no regurgitation, the treatment is considered successful. Most animals with severe strictures must consume a softened, semiliquid to liquid diet, as complete resolution of the stricture is not possible.

PEARLS & CONSIDERATIONS

COMMENTS

- Esophageal strictures should be viewed as a clinical problem with a favorable outcome, as long as appropriate dilation procedures are implemented and appropriate client expectations are achieved.

PREVENTION

- Prevent all dogs from eating bones, rocks, fish hooks, and other foreign objects.
- Oral medications should not be administered alone; they should be given with food or followed with food. If medication must be given on an empty stomach, it should be followed with water to prevent capsules or tablets from lodging in the esophagus.
- Do not tip surgical tables to a degree that will allow gastroesophageal reflux and esophagitis (a risk factor for iatrogenic strictures).

CLIENT EDUCATION

- The importance of giving water to a pet after administration of medications cannot be overstressed.
- The long-term successful management of dogs or cats with strictures requires strict, lifelong dietary management.

AUTHOR & EDITOR: DEBRA L. ZORAN

Esophageal Perforation

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

An uncommon condition consisting of a full-thickness defect in the esophagus with leakage of esophageal contents into the mediastinum and potentially the pleural space (For related information, see Foreign Body, Esophageal, p. 406; Esophagitis, p. 367.)

SYNONYMS

Esophageal laceration, esophageal rupture

EPIDEMIOLOGY

SPECIES, AGE, SEX

- No age or sex predilection
- Perforation has been reported in more dogs than cats:
  - Attributed to the less discriminate feeding behavior of dogs

GENETICS & BREED PREDISPOSITION: 86% of esophageal foreign bodies reported in dogs weighing <12 kg (26 lb)

RISK FACTORS

- Foreign body ingestion (see p. 406)
- Esophageal strictures can be related to balloon dilatation procedures (see p. 365)

ASSOCIATED CONDITIONS & DISORDERS

- Mediastinal abscess
- Pneumothorax
- Pyothorax
- Bronchoesophageal fistula

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: History associated with esophageal perforation includes:

- Retching, regurgitation, vomiting, ptyalism, anorexia
- Coughing, dyspnea
- Restlessness
- Cervical swelling, subcutaneous emphysema

PHYSICAL EXAMINATION FINDINGS

- Physical findings may include:
  - Fever
  - Subcutaneous emphysema
  - Rapid, shallow respiration consistent with pneumothorax or pyothorax
  - Moist rales on auscultation if aspiration pneumonia is present
  - Dehydration
- The duration of clinical signs associated with esophageal perforation is reported to be longer than with esophageal foreign body alone.

ETIOLOGY AND PATHOPHYSIOLOGY

- Sharp edges of a foreign body may lacerate the esophagus and more rarely the great vessels.
- Large foreign bodies can result in pressure necrosis of the esophageal wall; the greatest damage is usually associated with

pressure points of the foreign body against the esophageal wall.
- The most common site of foreign body lodgment (and therefore perforation) is the distal esophagus just cranial to the gastroesophageal junction; other sites include the thoracic inlet, heart base, and less often the cervical esophagus.
- Esophageal perforation can also be associated with esophageal trauma or balloon dilation of esophageal strictures.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is suspected based on presenting history and physical examination findings. Survey cervical and thoracic radiographs and contrast esophagram +/− esophagoscopy are required to confirm the diagnosis.

DIFFERENTIAL DIAGNOSIS

- Megaesophagus
- Hiatal hernia or gastroesophageal intussusception
- Intrinsic or extrinsic esophageal masses
- Neoplasia
- Parasite infestation
- Esophagitis
- Esophageal diverticulum
- Vascular ring anomaly
- Abnormal pharyngeal or esophageal motility

INITIAL DATABASE

- CBC:
  - Neutrophilic leukocytosis
  - More immature neutrophils are present with a perforated esophagus than with esophageal foreign body alone.
- Diagnostic imaging:
  - Survey cervical and thoracic radiographs
    - Esophageal foreign body
    - Air within the periesophageal tissues
    - Pneumomediastinum
    - Pneumothorax
    - Pleural effusion/pyothorax
    - Increased lung density with concurrent aspiration pneumonia
  - Contrast esophagram (see p. 1205)
    - Should be performed with water-soluble contrast if perforation is suspected
    - Has a false-negative rate of 14.5%
- Esophagoscopy:
  - Performed with care
    - Do not create or worsen pneumothorax.
  - Evaluate integrity and viability of esophagus.
    - Identify site of perforation.
  - Possible foreign body removal
- Analysis of pleural effusion if present:
  - Cytology
  - Bacterial culture and susceptibility testing (both aerobic and anaerobic area required)

TREATMENT

TREATMENT OVERVIEW

Treatment depends on location of the perforation and severity of associated problems. Surgical intervention beyond abscess drainage may or may not be indicated for cervical perforations but is required for thoracic perforations to avoid life-threatening consequences associated with leakage of contents. Nutritional support that bypasses the damaged esophagus (PEG tube) is essential.

ACUTE GENERAL TREATMENT

- Correction of fluid and electrolyte deficits
- Antimicrobial therapy:
  - Empirical therapy using an antibiotic with a broad spectrum of aerobic activity
    - Cefazolin, 22 mg/kg IV q 6 h
  - Definitive antimicrobial therapy should be based on results of microbiological culture and susceptibility testing.
    - Pleural fluid
    - Mediastinal abscess
- Surgical intervention:
  - Removal of foreign body if underlying cause ○ Repair of perforation
    - Primary closure
    - Resection and anastomosis
  - Débridement and lavage
    - Mediastinal abscess
    - Pyothorax
- Treatment of esophagitis:
  - H^2 antagonists (e.g., famotidine, 0.5 mg/kg IV q 12-24 h) or antisecretory agents (e.g., omeprazole, 0.7 mg/kg via feeding tube q 24 h) to decrease gastric acid production
  - Motility agents (metoclopramide, 0.2–0.5 mg/kg SQ or PO q 6–12 h; or cisapride, 0.1–1 mg/kg PO q 8–12 h) to promote normal gastroesophageal sphincter tone (reduce gastroesophageal reflux and esophagitis) and gastric emptying

CHRONIC TREATMENT

Treatment of pyothorax (see p. 956):

- Long-term antibiotic therapy:
  - Based on accurate identification of organism(s) involved
  - Up to 3 months of therapy may be required.

NUTRITION/DIET

- Nutritional support is necessary until the esophagus has healed and normal function has returned:
  - Feeding tube (PEG) to bypass esophagus (see p. 1270)
  - Usually 10-14 days required to allow esophageal wall to heal

POSSIBLE COMPLICATIONS

- Dehiscence of esophageal repair: recurrent leakage
- Esophageal diverticulum formation: secondary to the presence of a foreign body
- Esophageal stricture formation: secondary to damage caused by foreign body, surgical technique, or esophagitis

RECOMMENDED MONITORING

- If PEG tube has been placed:
  - Removal may be possible in 10–14 days; 7- to 10-day requirement prior to removal to allow proper adhesion of the stomach to the abdominal wall.
- Ensure that normal esophageal function returns:
  - Esophageal stricture, if it occurs, usually becomes clinically apparent 3-4 weeks post injury (manifestation and consequence: increasing problem of regurgitation)

PROGNOSIS AND OUTCOME

Prognosis associated with esophageal perforation is guarded owing to multiple possible complications and is specifically influenced by the presence or absence of:

- Mediastinitis/mediastinal abscess formation
- Development of pyothorax
- Development of esophageal stricture

PEARLS & CONSIDERATIONS

COMMENTS

Endoscopic evaluation and removal of esophageal foreign bodies must be done carefully, with special attention paid to the patient's ventilatory pattern, oxygen saturation, heart rate, and blood pressure. Insufflation with air in the presence of an esophageal perforation can lead to tension pneumothorax and acute cardiopulmonary compromise of anesthetized patients.

PREVENTION

Do not let dogs and cats eat foreign objects that have the potential to become lodged in the esophagus.

TECHNICIAN TIPS

- Postoperative nutritional support (PEG tube feeding) is necessary for these patients while the damaged esophagus heals:
  - Be familiar with PEG tube use.
  - Ensure that patient is receiving correct amount of food and water.
- Knowledge of and experience in working with thoracostomy tubes is important in the postoperative management of patients who have undergone a thoracotomy.
- In-hospital care may include:
  - Flushing wound/abscess pocket as directed
  - Keeping drain/drainage site clean and free of discharge
  - Administration of antibiotics as directed
  - Ensuring adequate analgesia is provided

Esophageal Neoplasia

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Benign or malignant tumor of the esophagus

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Rare in dogs and cats
- Older animals predisposed
- No sex predilection, although squamous cell carcinoma is more common in female cats

GENETICS & BREED PREDISPOSITION: No breed predilection

RISK FACTORS: *Spirocerca lupi* infection (see p. 1040), resulting in secondary sarcoma formation

GEOGRAPHY AND SEASONALITY: Areas where *S. lupi* is endemic, including the Middle East, Africa, and the southeastern United States

ASSOCIATED CONDITIONS & DISORDERS: Hypertrophic osteopathy has been reported, especially in *S. lupi*-induced sarcomas.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- The most common primary esophageal tumors are squamous cell carcinoma (cats), leiomyosarcoma (dogs), osteosarcoma, and fibrosarcoma; rarely, benign tumors such as leiomyoma or plasmacytomas may occur.
- Primary thyroid gland or mammary gland tumors may metastasize to the esophagus.
- Lymphoma may involve the esophagus, and generally when it does, multicentric lymphoma is present.
- Primary tumors arising from the thymus, heart base, or thyroid gland may extend directly into the esophagus.

HISTORY, CHIEF COMPLAINT

- Weight loss
- Discomfort with swallowing
- Dysphagia
- Regurgitation
- Lethargy, inappetence, dyspnea, cough (aspiration pneumonia)
- Less commonly, lameness or pain of the extremities associated with hypertrophic osteopathy

PHYSICAL EXAM FINDINGS

- Rarely, a palpable mass may be found in the ventral cervical region. Most often, however, no significant physical abnormalities are found.
- Thin body condition
- Melena
- Back pain from spondylitis of the caudal thoracic vertebrae caused by spirocercosis

ETIOLOGY AND PATHOPHYSIOLOGY

- Sarcoma formation has been correlated to infection with *S. lupi*.
- *S. lupi* causes persistent tissue irritation, resulting in aortic scarring and nodular esophageal granulomas, which can undergo neoplastic transformation.
- Metastasis to the esophagus from primary thyroid gland or mammary gland tumors is more common than primary esophageal neoplasia.

- Primary esophageal malignancies may metastasize to regional lymph nodes or lungs, less commonly to other organs.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Confirmation of diagnosis requires histopathology and often must be obtained surgically.

DIFFERENTIAL DIAGNOSIS

Any disease causing signs of partial esophageal obstruction (see p. 406) or megaesophagus (see p. 709)

INITIAL DATABASE

- Plain radiographs of the thorax (three views) and neck may show repeatable, excessive gas in the esophagus, presence of a mass, or megaesophagus, all proximal (orad) to the obstruction. Lung fields should be evaluated for metastases.
- Barium swallow (see p. 1205) to show an esophageal stricture or mass
- Esophagoscopy to visualize mass(es); often ulcerated, but leiomyomas are usually submucosal, well circumscribed, and not attached to overlying mucosa.
- Biopsy and histopathology, with samples usually obtained at the time of esophagoscopy
- CBC, serum biochemical profile, and urinalysis are usually normal, although some patients may be anemic due to chronic blood loss from friable esophageal tumors.
- Fecal flotation may show *S. lupi* ova, although a negative test does not rule out infection, as esophageal neoplasia may form long after initial exposure.
- Cytology of enlarged lymph nodes to differentiate reactive lymphadenopathy from metastasis

ADVANCED OR CONFIRMATORY TESTING

- CT or MRI to better delineate mass when radiographs are equivocal
- Exploratory surgery for histopathology when samples obtained during esophagoscopy are nondiagnostic

TREATMENT

TREATMENT OVERVIEW

Goals of treatment are relief of signs of partial esophageal obstruction and delay or prevention of disease progression.

ACUTE GENERAL TREATMENT

- Surgery when feasible; in general, difficult due to length of resection required in advanced cases and inability to obtain good exposure of the esophagus
- Placement of esophagostomy or gastrostomy tubes for feeding (see p. 1270)

CHRONIC TREATMENT

- Palliative radiation therapy for cervical esophageal masses
- Photodynamic therapy may be considered for superficial mucosal tumors, but efficacy is currently unknown.

NUTRITION/DIET

- Nutritional palliation with placement of feeding tubes
- Experimentation with a variety of food textures and elevated feedings may be necessary in dogs with megaesophagus.

BEHAVIOR/EXERCISE

No restrictions in activity are recommended.

POSSIBLE COMPLICATIONS

- Risk of short-term dehiscence or long-term stricture formation after esophageal surgery

- Risks associated with thoracotomy
- Risk of infection at site of feeding tube
- Palliative radiation usually not attempted for intrathoracic lesions, owing to relative intolerance of adjacent normal tissues such as the heart, lungs, and trachea

RECOMMENDED MONITORING

- Monitor body weight; ability to obtain adequate nutrition orally is often compromised.
- Thoracic radiographs and regional lymph nodes, looking for metastasis

PROGNOSIS AND OUTCOME

Long-term prognosis is usually very poor because of low likelihood of relieving clinical signs or preventing metastasis.

PEARLS & CONSIDERATIONS

COMMENTS

Little information is available about treating dogs with esophageal neoplasia, primarily because of the rarity of these tumors.

PREVENTION

Sarcoma formation may be prevented by avoiding *S. Iupi* infection.

TECHNICIAN TIPS

Clients may require in-depth counseling and training on how to optimally feed dogs with megaesophagus.

CLIENT EDUCATION

Quality of life is often very poor unless the tumor is benign and can be surgically excised.

Esophageal Diverticulum

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A rare disorder characterized by a pouchlike sacculation of the esophageal wall resulting in an area in which material can accumulate and remain

EPIDEMIOLOGY

SPECIES, AGE, SEX: Can happen in any age or sex, dog or cat

ASSOCIATED CONDITIONS & DISORDERS: Traction diverticula can be caused by tumors, infections, or scarring.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Congenital versus acquired
- Pulsion ("true diverticula") versus traction ("false diverticula")

HISTORY, CHIEF COMPLAINT

- Regurgitation may be seen, particularly with large diverticula.
- Prior thoracic inflammatory disease may be suggestive (opportunity for adhesion formation and therefore traction diverticulum), although diverticulum perforation or rupture with secondary pyothorax can occur with any type of diverticulum.

PHYSICAL EXAM FINDINGS

- Regurgitation may be noted in the exam room.
- No other findings are considered specific.

ETIOLOGY AND PATHOPHYSIOLOGY

- Pulsion diverticula are caused by herniation of the mucosa through the muscular wall of the esophagus, resulting in food retention within the diverticulum. This can be an acquired problem due to increased esophageal luminal pressure secondary to obstruction, esophagitis, stricture, foreign body, and similar problems; or it can be congenital, resulting from an inherent weakness in the esophageal wall or an abnormality of embryonic separation during development.
- Traction diverticula are caused by an extraesophageal lesion such as maturing fibrous connective tissue (typically an adhesion between the esophagus and another intrathoracic structure such as tracheal or hilar lymph nodes). This adhesion pulls a portion of the esophageal wall out of position as the connective tissue matures and contracts, creating a pouch. In dogs, it is suspected that the most likely cause of traction diverticula is a penetrating esophageal foreign body that results in adhesion formation outside the esophagus (see pp. 406 and).
- The main clinical utility of differentiating between these types is that surgery may correct a traction diverticulum (release adhesion), but pulsion diverticula are often due to an esophageal problem that may or may not be readily corrected surgically (e.g., vascular ring anomaly versus esophageal stricture, respectively).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Esophageal diverticulum may first be suspected based on clinical presentation (regurgitation) or based on incidentally found radiographic abnormalities. Confirmation generally occurs either during esophagoscopy with direct visualization of the lumen of the diverticulum, or with a barium contrast esophagram.

DIFFERENTIAL DIAGNOSIS

Regurgitation:

- Esophagitis
- Megaesophagus (idiopathic, secondary to systemic disease, or pediatric [transient or congenital]). In general, diverticula cause focal esophageal enlargement, whereas generalized esophageal enlargement should prompt the consideration of causes of megaesophagus (see 709). However, overlap exists between a true diverticulum and generalized or localized esophageal weakness (either congenital or acquired) when the latter is primarily represented by a large esophageal dilatation between the thoracic inlet and the base of the heart, somewhat similar to that seen with a vascular ring anomaly such as persistent right aortic arch. Such weakness is not a surgical lesion and is not a true diverticulum.
- Esophageal mass
- Esophageal stricture
- Vascular ring anomaly

INITIAL DATABASE

- CBC, serum chemistry profile, and urinalysis results are often normal unless there is systemic inflammatory disease (e.g., aspiration pneumonia).
- Plain thoracic radiographs:
  - Look for a localized density.
  - Distinguish focal from generalized esophageal disease (e.g., megaesophagus).
  - Assess for evidence of aspiration pneumonia.
  - Assess for evidence of mediastinitis or pleuritis (e.g., mediastinal widening, pleural effusion), as can occur with esophageal perforation.
- Contrast esophagram (see 1205):
  - Look for localized collection of contrast in a pouch outside the expected plane of the esophageal lumen.
  - Distinguish esophageal disease from pleural, mediastinal or pulmonary disease.
  - Distinguish from normal redundant esophagus seen in bulldogs and shar-peis.

ADVANCED OR CONFIRMATORY TESTING

- Esophagoscopy: find the outpouching, and distinguish traction from pulsion types.
- Histopathologic evaluation of resected pouch to look for cause of traction diverticulum

TREATMENT

TREATMENT OVERVIEW

- Try to resect pouch in animals that show clinical signs but do not have generalized esophageal weakness; however, there is substantial risk of dehiscence.
- Clinically silent diverticula should generally be left alone unless there appears to be substantial risk of perforation on endoscopy or contrast radiography.

ACUTE GENERAL TREATMENT

- Treat aspiration pneumonia if present (see p. 1419).
- Treat septic pleuritis/mediastinitis if present (see p. 956).
- Treat esophagitis or esophageal stricture as appropriate (see 367).
- Remove diverticulum surgically if appropriate.

CHRONIC TREATMENT

None unless esophageal stricture or esophageal hypomotility is present after diverticulectomy

NUTRITION/DIET

As for megaesophagus (see 709)

POSSIBLE COMPLICATIONS

- Perforation of diverticulum leading to pleural or mediastinal sepsis
- Aspiration pneumonia

PROGNOSIS AND OUTCOME

Guarded. Too few such cases have been identified and treated to produce objective prognostic information. No instances of self-resolution have been documented, however.

PEARLS & CONSIDERATIONS

COMMENTS

- A very rare condition in dogs and cats
- Must distinguish from the clinically insignificant redundant esophagus often seen in bulldogs and shar-peis.
- Can be difficult to recognize at esophagoscopy. If food is retained within them, diverticula can be seen easily during esophagoscopy. However, if the diverticulum is empty, it is just a fold of tissue that can be overlooked, especially if there is inadequate insufflation of the esophagus during the endoscopic examination. Adequate insufflation may require closing off the proximal esophagus manually to hold air in the esophageal lumen to facilitate evaluation.

Erythema Multiforme and Toxic Epidermal Necrolysis

BASIC INFORMATION

DEFINITION

Spectrum of acute, potentially severe and fatal mucocutaneous diseases defined by distinctive clinical and histopathologic findings. Uncommon this diagnosis is considered if dermatologic findings include annular ("target") lesions, erythematous eruptions, and epidermal/mucosal detachment, with secondary ulcerations.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats of any age and both sexes

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Based on clinical and histopathologic features, the erythema multiforme (EM)–toxic epidermal necrolysis (TEN) spectrum is divided into five different categories adapted from the Human International Consensus clinical classification: EM minor, EM major, Stevens Johnson syndrome (SJS), overlap syndrome (OS), and TEN. However, this classification should be considered a general guideline because it is not universally accepted. Furthermore, some cases can overlap these categories or present only a few clinical signs.

HISTORY, CHIEF COMPLAINT: A dermatosis with an acute onset and rapid deterioration. Systemic signs of illness and severe skin lesions are usually the main complaints. Therapeutic drug administration can be an important element of the history.

PHYSICAL EXAM FINDINGS

- The animal can be debilitated, especially with TEN. Fever precedes virtually all cases of TEN in humans.
- In more severe cases, internal organ function may be affected.

ETIOLOGY AND PATHOPHYSIOLOGY

- In dogs and cats, EM is usually associated with drug therapy or infections (herpesvirus, parvovirus) or is idiopathic.
- TEN is usually associated with drug therapy but can be idiopathic.
- The mechanism of the EM-TEN spectrum diseases seems to be immune mediated. A cell-mediated immune response directed toward various antigens is suspected in EM; a defective epidermal detoxification of drug byproducts, in addition to the cellular immune reaction, is proposed to explain TEN. Both processes lead to keratinocyte apoptosis via perforin/granzyme pathway and the ligation of Fas to its ligand FasL. Moreover, the overproduction of cytokines by cytotoxic T lymphocytes might play a major role by upregulating the adhesion molecules, recruiting lymphocytes, and contributing to keratinocyte apoptosis.

ERYTHEMA MULTIFORME AND TOXIC EPIDERMAL NECROLYSIS Idiopathic erythema multiforme in a Samoyed, showing lingual mucosa detachment.

(Courtesy Dr. Frédéric Sauvé.)

EM, Erythema multiforme; *SJS,* Stevens Johnson syndrome; *OS,* overlap syndrome; *TEN,* toxic epidermal necrolysis.

Dermatologic Examination	EM Minor	EM Major	SJS	OS	TEN
Flat or raised, focal or multifocal, target (concentric rings around a clear or crusty center) or polycyclic lesions	Yes	Yes	No	No	No
Number of mucosal surfaces involved	1 or fewer	>1	>1	>1	>1
Erythematous or purpuric, macular or patchy eruption (% of body surface affected)	<50	<50	>50	>50	>50
Epidermal detachment (vesicles, bullae, erosions, and ulcers) (% of body surface affected)	<10	<10	<10	10-30	>30

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The skin lesions are pleomorphic (varied in shape and appearance). Therefore, the differential diagnosis list is long. The presence of acute-onset skin lesions, particularly with epidermal detachment, signs of systemic illness, and a history of ongoing medication administration (or some combination of these features), should prompt the consideration of skin biopsies, which confirm the diagnosis.

DIFFERENTIAL DIAGNOSIS

Differentiation can be based on history (e.g., in contrast to burns), time course (EM-TEN typically worsens rapidly, unlike urticaria which tend to improve spontaneously and quickly), and ultimately histopathologic appearance.

- Superficial and deep infection (bacterial and fungal)

- Urticaria
- Systemic and cutaneous lupus erythematosus
- Cutaneous drug eruption
- Pemphigus vulgaris
- Vasculitis
- Bullous pemphigoid
- Epidermolysis bullosa
- Burns
- Ulcerative stomatitis
- Epitheliotropic lymphoma

INITIAL DATABASE

- No specific laboratory findings
- Routine dermatologic diagnostics tests should be performed as appropriate (skin scrapings, skin cytology, skin biopsy, fungal culture) based on differential diagnosis (see p. 1248).

ADVANCED OR CONFIRMATORY TESTING

- Hallmark histopathologic findings in skin biopsies include hydropic degeneration, single-cell apoptosis to full-thickness necrosis of the epidermis, dermal lymphohistiocytic cells infiltration, and subepidermal vesicles; hair follicles may be similarly affected. Skin biopsies also help by excluding other differential diagnoses.
- Since the histopathologic findings of EM and TEN might overlap, clinical classification (see table on preceding page) should be considered to differentiate these entities.

TREATMENT

TREATMENT OVERVIEW

- Goals are to stop the immunologic reactions causing the epidermal necrosis, prevent skin infection if the cutaneous barrier is ruptured, and provide supportive care if the animal is debilitated.

ACUTE GENERAL TREATMENT

- Try to find and correct the underlying cause. If any drug is being administered at the time of initial presentation, the first rule is to discontinue its use.
- May resolve spontaneously (EM)
- Severe cases of EM and TEN need supportive care:
  - Fluid therapy if fluid deficits/electrolyte imbalances/acid-base disturbances
  - Nutritional support
  - Maintain thermoregulation
  - Wound care (gentle washes with saline or chlorhexidine gluconate 0.05% solution, dermal protection to prevent infection or desiccation, and topical antibiotics)
- Necrotic epidermis, rich in cytokines, can help reepithelialization. Some authors recommend not to débride skin lesions unless infected.
- Systemic antibiotic therapy is warranted if there is evidence of bacteremia or sepsis; may be considered if cutaneous ulcerations are present.
- Use of glucocorticoids is controversial and usually not beneficial.
- Pentoxifylline (10 mg/kg PO q 8 h) has been useful in some cases.
- Intravenous immunoglobulin (Ig) therapy using human Ig (1 g/kg infused slowly IV over 4-6 hours) may be beneficial. A similar equine product is also available, but there are anecdotal reports of serious adverse effects.
- Severe oral ulcerations may require oral rinses with chlorhexidine 0.1%-0.2% solution or gel, or viscous lidocaine 2% application to the oral ulcers for comfort.

PROGNOSIS AND OUTCOME

- The prognosis is usually good in EM (except if the lesions are severe and extensive) and poor in TEN.
- The condition should improve within 3 weeks when the underlying cause is identified and eliminated.

PEARLS & CONSIDERATIONS

COMMENTS

- Ocular involvement has been reported.
- Some cases have been related to diet, so animals diagnosed with idiopathic disease should receive a hypoallergenic diet.

AUTHOR: FRÉDÉRIC SAUVÉ

EDITOR: MANON PARADIS

Epulides

BASIC INFORMATION

DEFINITION

- *Epulis* (plural *epulides)* is a nonspecific clinical descriptive term referring to a local, exophytic growth on the gingiva (e.g., focal fibrous hyperplasia, peripheral odontogenic fibroma, acanthomatous ameloblastoma, nonodontogenic tumors).
- This chapter focuses on peripheral odontogenic fibroma, giant cell epulis, and acanthomatous ameloblastoma, which are all benign tumors (that do not metastasize). Peripheral odontogenic fibromas and giant cell epulides do not invade bone, but acanthomatous ameloblastomas are locally invasive.

SYNONYMS

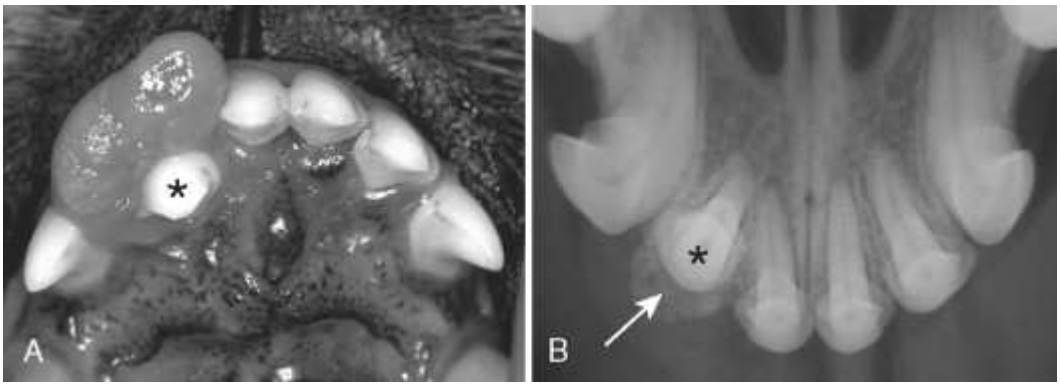
- *Peripheral odontogenic fibroma* replaces the terms *fibromatous* (or fibrous) *epulis* and *ossifying epulis.* Fibromatous epulis is distinguished from ossifying epulis by containing less bone or dental hard tissue within the tumor's soft tissue. Another synonym is *periodontal ligament tumor.*
- Giant cell epulis has also been called *giant cell tumor* or (peripheral) *giant cell granuloma.*
- *Acanthomatous ameloblastoma* replaces the terms *acanthomatous epulis* and *adamantinoma.*

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs:

- Prevalence: common (except giant cell epulis, which is rare)
- Distribution: peripheral odontogenic fibroma ~80%, acanthomatous ameloblastoma ~18%, and giant cell epulis ~2%
- Breed: acanthomatous ameloblastoma more commonly noted in Shetland sheepdogs
- Age: unknown for giant cell epulis; dogs with peripheral odontogenic fibroma usually >5 years old; dogs with acanthomatous ameloblastoma usually >7 years old (but can affect dogs as young as 1 year of age)
- Sex: conflicting results; female dogs more often affected than males with acanthomatous ameloblastoma, male dogs more often affected than females with peripheral odontogenic fibroma and giant cell epulis



EPULIDES A, Clinical photograph of rostral upper jaw in a dog with peripheral odontogenic fibroma. Note smooth-surfaced and minimally ulcerated/inflamed gingival mass associated with palatally displaced right maxillary second incisor *(asterisk)*. **B,** Dental radiograph of rostral upper jaw in same patient (radiograph arranged in labial mounting; rostral toward bottom of image, and patient's right side is on left of image). Note displaced right maxillary second incisor *(asterisk)* and presence of hard tissue *(arrow)* within tumor's soft-tissue shadow.

EPULIDES A, Clinical photograph of rostral lower jaw in a Shetland sheepdog with acanthomatous ameloblastoma. Note red, cauliflower-like and easily bleeding mass located between left mandibular third incisor and canine tooth. **B,** Dental radiograph of rostral lower jaw in same patient (radiograph arranged in labial mounting; rostral toward the top of image, and patient's left side is on right of image). Note displacement of involved teeth, lysis of alveolar bone *(asterisks)*, and sunburst pattern at left lateral mandibular border *(arrows)*.

Cats:

- Prevalence: uncommon
- Distribution: Peripheral odontogenic fibroma ~63%, giant cell epulis ~29%, and acanthomatous ameloblastoma ~8%
- Breed: no predilection reported
- Age: cats with single peripheral odontogenic fibroma and giant cell epulis usually >7 years old; acanthomatous ameloblastoma and multiple feline epulides particularly in young-adult cats
- Sex: no predilection reported

ASSOCIATED CONDITIONS & DISORDERS: oral tumors, benign (see p. 786). Hypercalcemia of malignancy has been reported in some dogs with acanthomatous ameloblastomas (increased serum concentrations of ionized calcium, total calcium, and parathyroid hormone-related peptide).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Peripheral odontogenic fibroma:
  - Slow growth; gingiva-like
  - Fibroblast is main component in mass.
  - Slow recurrence after incomplete excision
  - Multiple feline epulides may not originate from the periodontal ligament but may represent reactive lesions arising from the periosteum.
- Giant cell epulis:
  - Rapid growth; inflammatory and ulcerative changes ○ Multinucleated giant cell is main component in mass; osteoid and woven bone formation.
  - Rapid recurrence after incomplete excision
- Acanthomatous ameloblastoma:
  - Rapid growth; cauliflower-like
  - Basal cell is main component in mass.

HISTORY, CHIEF COMPLAINT

- Gingival mass noticed by owner or at routine oral examination
- Clinical complaints mostly absent with peripheral odontogenic fibromas; dysphagia, increased salivation, bloody oral

discharge, and halitosis occasionally reported with giant cell epulides and acanthomatous ameloblastomas.

PHYSICAL EXAM FINDINGS

- Peripheral odontogenic fibroma:
  - Firm, rarely ulcerated gingival mass that measures 0.5 to 3 cm in diameter
  - Located near canine, premolar, and molar teeth (less commonly in the incisor tooth area) and variably fixed to the gum line
  - Covered by oral epithelium; ulceration infrequent
- Giant cell epulis:
  - Soft, reddish purple
  - Ulcerated and inflamed
- Acanthomatous ameloblastoma:
  - Cauliflower-like, red, ulcerated, easily bleeding gingival mass that measures 0.5 to 10 cm in diameter
  - Most commonly located in the rostral lower jaw near incisor and canine teeth; less often in the rostral upper jaw (incisor and canine tooth area), caudal lower jaw (near first molar), and caudal upper jaw (near fourth premolar)

ETIOLOGY AND PATHOPHYSIOLOGY

- Peripheral odontogenic fibroma:
  - Mixed or mesenchymal (dependant on literature studied) odontogenic tumor
  - Arising from cells in the periodontal ligament
- Giant cell epulis: considered to be a variant of the peripheral odontogenic fibroma in which extensive ulceration and inflammation results in strongly increased osteoclastic activity, but the real origin remains unknown.
- Acanthomatous ameloblastoma:
  - Epithelial odontogenic tumor
  - Debatable whether arising from epithelial rests of Malassez in periodontal ligament (intraosseous/central ameloblastoma) or epithelial rests of Serres in gingival connective tissue (extraosseous/peripheral ameloblastoma)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis requires staging, including oral examination under anesthesia, thoracic radiographs, regional diagnostic imaging (dental radiographs, computed tomography), lymph node palpation and aspiration, and biopsy of the gingival mass.

DIFFERENTIAL DIAGNOSIS

Dogs:

- Gingival hyperplasia (often generalized)
- Pyogenic granuloma (uncommon)
- Dentigerous cyst (around crown of an unerupted tooth)
- Odontoma (not a real tumor, but a hamartoma, i.e., accumulation of normal cells in an abnormal manner)
- Viral papillomatosis (usually in puppies or immunocompromised adults)
- Plasmacytoma (usually solitary, pink-red, well circumscribed)
- Osteoma (slow-growing)
- Malignant melanoma (most common malignant oral tumor)
- Squamous cell carcinoma (second most common oral malignant tumor)
- Fibrosarcoma (third most common malignant tumor)
- Peripheral nerve sheath tumor (along major nerves)
- Osteosarcoma (usually osteolytic type; variant: multilobular tumor of bone)
- Lymphosarcoma (also look for lesions on skin around mouth and nasal plane, bilateral enlargement of tonsils and regional lymph nodes)
- Amyloid-producing odontogenic tumor (rare)
- Erythema multiforme (also look for lesions on skin)
- Autoimmune diseases (bullous pemphigoid, lupus erythematosus)
- Eosinophilic granuloma (usually on soft palate and lateral edges of the tongue)

Cats:

- Gingival hyperplasia, osteoma, plasmacytoma

- Squamous cell carcinoma (most common malignant oral tumor)
- Fibrosarcoma (second most common oral malignant tumor)
- Inductive fibroameloblastoma (rare)
- Amyloid-producing odontogenic tumor (rare)
- Eosinophilic granuloma (usually on upper lip, tongue, sublingual tissues, and palate)

INITIAL DATABASE

- Physical examination, chemistry screen, CBC
- Dental and skull radiographs:
  - Peripheral odontogenic fibromas are not invasive, and radiographic changes to alveolar bone are unlikely.
  - Acanthomatous ameloblastomas are invasive, and changes to alveolar bone are often visible on dental radiographs.
- CT: considered to be superior to radiography, particularly for maxillary and caudally located mandibular lesions
- Biopsy
  - Cytologic techniques are less diagnostic. Biopsy for histopathologic examination is the only definitive test to establish an accurate diagnosis.
  - For small lesions, excisional biopsy can be performed during the initial oral examination, which may be curative.
  - For larger lesions, an incisional biopsy should be performed. Confirmation of the tumor type will allow the clinician to properly plan for future definitive surgery.

ADVANCED OR CONFIRMATORY TESTING

CT is valuable to determine local disease extension and bony invasion in dogs with maxillary or caudal mandibular acanthomatous ameloblastoma. This facilitates achieving wide surgical margins and allows for radiation therapy planning.

TREATMENT

TREATMENT OVERVIEW

The primary goal of treatment is complete tumor removal with minimal functional and cosmetic compromise.

ACUTE GENERAL TREATMENT

- Surgery: conservative and radical
  - Peripheral odontogenic fibroma: gingival excision with conservative margins, extraction of the associated tooth (or teeth in case pinpointing the lesion to one tooth is difficult), and curettage of the alveolar socket(s) to remove the periodontal ligament; local excision without tooth extraction and socket curettage is rarely curative (recurrence is likely, as these tumors arise from cells in the periodontal ligament).
  - Acanthomatous ameloblastoma: mandibulectomy and maxillectomy with at least 1 cm margins (depending on location of the tumor)
- Radiation therapy: considered for nonresectable masses, incomplete resections, and recurrent tumors
  - Peripheral odontogenic fibroma: effective but rarely required, as surgical resection typically results in complete cure.
  - Acanthomatous ameloblastoma: effective, with tumor control achieved in about 90% of dogs, especially for smaller tumors; larger tumors (>4 cm) are more likely to recur (only about 30% tumor control); higher radiation doses may be required to improve control rates.
  - Acute and late side effects can occur, most notably radiation-induced tumors (many years after radiation therapy in about 3.5%–12.5% of dogs with acanthomatous ameloblastoma) and bone necrosis.
- Cryosurgery: causes cellular death after controlled freezing and thawing of the tumor.
  - Best for low-grade tumors <2 cm in diameter and adherent to or minimally invasive into one cortex; tumor should first be debulked and biopsied, followed by cryosurgery applied to underlying bone.
  - Inadequate for tumors with extensive fixation to or invasion into bone; full-thickness freezing of maxillofacial bones (such as the maxilla or mandible) can lead to bone necrosis, bone fracture, or oronasal fistula.
  - Despite maintenance of the bony framework and preservation of oral function, recurrence is more common than with surgical excision.

NUTRITION/DIET

Soft food and avoidance of chew treats/toys for 2 weeks after tooth extraction or radical resection (mandibulectomy, maxillectomy)

POSSIBLE COMPLICATIONS

- Wound dehiscence

- Incomplete resection and tumor recurrence
- Bone necrosis after cryosurgery or radiation therapy

RECOMMENDED MONITORING

- Clinical reexamination 2 weeks, 6 and 12 months, and then once yearly after definitive treatment
- Radiographic reexamination (for acanthomatous ameloblastoma) once yearly

PROGNOSIS AND OUTCOME

- Peripheral odontogenic fibroma and giant cell epulis: excellent prognosis (after complete gingival resection, tooth extraction and curettage of the alveolus); cats with multiple fibromas may have higher recurrence rates.
- Acanthomatous ameloblastoma: excellent prognosis (after mandibulectomy and maxillectomy procedures when clean histopathologic margins can be accomplished); smaller tumors and rostral location are positive prognostic factors because these masses are detected earlier and are easier to remove; postoperative radiation therapy may occasionally be required for tumor control.

PEARLS & CONSIDERATIONS

COMMENTS

- Because peripheral odontogenic fibromas and giant cell epulides arise from the periodontal ligament, excision limited to the gingiva will be inadequate, resulting in tumor recurrence. Gingival excision, extraction of the involved tooth and curettage of the alveolar sockets to remove any remaining periodontal ligament will usually be curative.
- Aggressive surgical excision (mandibulectomy, maxillectomy) is usually curative in dogs with acanthomatous ameloblastoma.
- Radiation therapy offers excellent long-term control for treatment of acanthomatous ameloblastoma, but malignant tumor development in the irradiated area several years later has been reported in some dogs.

PREVENTION

Early tumor detection (daily home oral hygiene and oral examination at every patient visit).

Epistaxis

BASIC INFORMATION

DEFINITION

Bleeding from the nasal cavity

SYNONYMS

Hemorrhagic nasal discharge, nosebleed

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dependent on underlying cause:

- Young purebred animals: coagulopathies
- Young to middle-aged animals: infectious diseases, trauma
- Middle-aged animals: acquired immune-mediated diseases
- Older animals: neoplasia

GENETICS, BREED PREDISPOSITION, AND RISK FACTORS

- Immune-mediated thrombocytopenia: young to middle-aged, small to medium female dogs
- Rickettsial disease: dogs living or traveling to endemic areas
- Thrombasthenia: otter hounds
- Thrombopathia (see p. 881): basset hounds
- von Willebrand disease: Doberman pinscher, Airedale, German shepherd, Scottish terrier, Chesapeake Bay retriever, and many other breeds; cats: Himalayan
- Hemophilia A: German shepherd and many other breeds; cats
- Hemophilia B: Cairn terrier, coon-hounds, Saint Bernard, and other breeds; cats
- Nasal lesions:
    - Aspergillosis: German shepherd, dolichocephalic breeds
    - Neoplasia: dolichocephalic breeds

CONTAGION & ZOONOSIS: Fungal infections (transmission potential appears low).

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: (Some or all may be present.)

- Nasal hemorrhage
- Sneezing
- Pawing at mouth and/or nose
- With coagulopathy: hematochezia, melena, hematuria, or hemorrhage
- Blindness, central nervous system (CNS) deficits possible with systemic hypertension

PHYSICAL EXAM FINDINGS

- Melena: from swallowing blood
- Nasal hemorrhage
- With coagulopathy: petechia, ecchymosis, hematomas, hematochezia, melena, and hematuria
- With coagulopathy or hypertension: retinal hemorrhages or detachment, CNS deficits

ETIOLOGY AND PATHOPHYSIOLOGY

Bleeding disorder:

- Thrombocytopenia:

    - Immune-mediated disease: idiopathic disease, systemic lupus erythematosus (SLE), drug reaction
    - Rickettsial disease: ehrlichiosis, Rocky Mountain spotted fever
    - Bone marrow disease: neoplasia, aplastic anemia, infectious (fungal, rickettsial, or viral)
    - Disseminated intravascular coagulopathy (DIC)
- Thrombopathia:
    - Congenital: von Willebrand disease, thrombasthenia, thrombopathia
    - Acquired: nonsteroidal antiinflammatory drugs (NSAIDs), hyperglobulinemia (ehrlichiosis, multiple myeloma), uremia, DIC
- Coagulation factor defect:
    - Congenital: hemophilia A (factor VIIIc deficiency) and hemophilia B (factor IX deficiency)
    - Acquired: anticoagulant rodenticide (warfarin) intoxication, liver disease, DIC

Nasal disease:

- Foreign body
- Trauma
- Infection: fungal *(Aspergillus, Cryptococcus, Rhinosporidium),* viral, or bacterial
- Inflammation: lymphoplasmacytic rhinitis
- Neoplasia
- Vascular malformations

Systemic disease:

- Hypertension: renal disease; hyperthyroidism; hyperadrenocorticism; idiopathic
- Hyperviscosity: multiple myeloma, ehrlichiosis, polycythemia
- Vasculitis: immune-mediated and rickettsial diseases

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is apparent on physical examination. Diagnostic testing first must evaluate the possibility of a systemic disorder (bleeding disorder, systemic hypertension). If none, evaluation of the nasal cavities consists of diagnostic imaging and biopsies.

DIFFERENTIAL DIAGNOSIS

See Etiology and Pathophysiology above.

INITIAL DATABASE

- CBC:
    - Anemia if sufficient hemorrhage has occurred
    - Thrombocytopenia or thrombocytosis
    - Neutrophilia: infection; neoplasia
    - Pancytopenia: bone marrow disease
- Urinalysis:
    - Usually normal
    - Hematuria (coagulopathy), isosthenuria with renal failure, proteinuria
- Serum biochemistry profile:
    - Hypoproteinemia if sufficient hemorrhage has occurred
    - Elevated urea with normal creatinine: gastrointestinal blood
    - Hyperglobulinemia: ehrlichiosis, multiple myeloma
    - Azotemia (with isosthenuria): renal failure–induced systemic hypertension
    - Elevated liver enzymes and total bilirubin: severe hepatic disease causing coagulopathy

ADVANCED OR CONFIRMATORY TESTING

- Other laboratory tests:
    - Coagulation profile: prolonged times with coagulation factor defects; normal with thrombocytopenia and thrombopathia
    - Antinuclear antibody test for SLE
    - Platelet function testing (bleeding time, von Willebrand factor analysis)
    - *Ehrlichia* and Rocky Mountain spotted fever titers/PCR

- Thyroid hormone assay in middle aged to old cats
- Diagnostic imaging:
  - Thoracic radiograph: metastatic neoplasia
  - Nasal series: open mouth and frontal sinus views
  - CT scan: more sensitive than radiographs for many nasal diseases
- Other diagnostic procedures:
  - Rhinoscopy, nasal flush, nasal biopsy indicated for suspected space-occupying disease, removing foreign bodies, and sampling nasal tissue
  - Cytologic and histopathologic examination
  - Bacterial and fungal culture and sensitivity testing
  - Bone marrow aspiration and cytology (± core biopsy) with pancytopenia
  - Blood pressure evaluation

TREATMENT

TREATMENT OVERVIEW

- Stop epistaxis
- Treat primary cause

ACUTE GENERAL TREATMENT

- Minimize activity or stimuli that precipitate hemorrhage episodes:
  - Environment
  - Consider tranquilization (e.g., opiates)
- Whole blood or packed red blood cell (RBC) transfusion; may be needed with severe anemia.
- In life-threatening cases of refractory, exuberant arterial epistaxis, both carotid arteries may be ligated without adversely affecting perfusion of the head (vertebral artery collaterals).

SPECIFIC TREATMENT

Coagulopathy:

- von Willebrand disease: plasma or cryoprecipitate for acute bleeding
- Hemophilia: plasma or cryoprecipitate for acute bleeding; no long-term treatment
- Anticoagulant rodenticide intoxication: plasma for acute bleeding and vitamin K supplementation
- Liver disease and DIC; treat underlying cause; plasma may be beneficial.
- Discontinue all NSAIDs.
- Hyperglobulinemia: plasmapheresis

Nasal disease:

- Radiotherapy: nasal tumors
- Topical clotrimazole therapy for fungal disease
- Surgery: if foreign body irremovable by rhinoscopy; fungal rhinitis *(Aspergillus* and *Rhinosporidium),* neoplasia

Systemic disease:

- Hyperviscosity: treat underlying disease (e.g., ehrlichiosis and multiple myeloma); plasmapheresis
- Vasculitis: doxycycline for rickettsial disease; prednisone for immune-mediated disease
- Hypertension: treat underlying disease (e.g., renal disease, hyperthyroidism, and hyperadrenocorticism); reduce weight if obesity is present; restrict sodium; antihypertensive medication.

POSSIBLE COMPLICATIONS

Anemia and collapsed state

RECOMMENDED MONITORING

- Platelet count with thrombocytopenia
- Coagulation profile with coagulation factor defects
- Blood pressure with hypertension

- Monitor clinical signs

PROGNOSIS AND OUTCOME

Dependent on cause

PEARLS & CONSIDERATIONS

COMMENTS

- Remember that epistaxis may indicate a systemic coagulopathy; use care when deciding which vein to use for blood sampling (prefer limb to jugular for compression), whether to perform centeses, and so forth.
- Epistaxis is not a diagnosis but a clinical sign.
- A systemic bleeding disorder may present as unilateral epistaxis.
- Rule out systemic diseases and coagulopathy before focusing on nasal disease.

CLIENT EDUCATION

Monitor for recurrence of presenting signs.

Episcleritis/Scleritis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Episcleritis: focal or diffuse inflammation of the episclera, a thin collagenous and vascular membrane that makes up the superficial layer of the sclera
- Scleritis: inflammation and thickening of the anterior and posterior sclera, involving cornea, uvea, and retina in advanced cases

SYNONYMS

Collie granuloma, fibrous histiocytoma, necrotizing scleritis, nodular fasciitis, proliferative keratoconjunctivitis, limbal granuloma, nodular granulomatous episcleritis/episclerokeratitis (NGE), nonnecrotizing deep scleritis, nonnecrotizing superficial scleritis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs; no age or sex predisposition

GENETICS & BREED PREDISPOSITION: Spaniel breeds, especially American cocker spaniel (episcleritis, scleritis), collie, Shetland sheepdog (NGE).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Episcleritis: primary (simple, nodular) or secondary
- Scleritis: necrotizing granulomatous or nonnecrotizing granulomatous

HISTORY, CHIEF COMPLAINT

- Episcleritis:
  - Pinkish-red growth on eye (nodular)
  - “Red eye” (diffuse)
  - Typically painless
- Scleritis:
  - Signs of ocular pain noted by owner: photophobia, blepharospasm, excessive tearing, inktan colored sector lesions near the limbus

PHYSICAL EXAM FINDINGS

- Episcleritis:
  - Conjunctival hyperemia
  - Engorgement of episcleral vessels
  - Thickening of episclera (partial or diffuse)
  - With nodular forms, multiple or single raised, pinkish-red mass(es) may be apparent at limbus; typically bilateral
  - ± Perilimbal keratitis with corneal vascularization and edema (e.g., nodular granulomatous episclerokeratitis)
- Scleritis:
  - Conjunctival hyperemia
  - Engorgement of episcleral vessels
  - Typically bilateral, mildly elevated, red lesions in the anterior sclera
  - Peripheral corneal vascularization and edema
  - Nongranulomatous anterior uveitis, (see p. 1151)
- Advanced scleritis: presence of signs of scleritis and any or all of the following:
  - Stromal keratitis (see Corneal Discoloration, p. 245)
  - Inflammation of the vitreous
  - Secondary glaucoma (see p. 448)
  - Retinochoroidal degeneration (see p. 983)
  - Cystic retinal detachment (see p. 985)

- Scleral thinning, which may cause subconjunctival iris prolapse

ETIOLOGY AND PATHOPHYSIOLOGY

- Episcleritis/scleritis:
  - Often idiopathic; immune-mediated disease
  - Association with positive *Toxoplasma* titers has been found.
- Episcleritis:
  - Primary:
    - Simple (uncommon): not associated with systemic disease; usually responsive to therapy; often self-limiting
    - Nodular (common): proposed pathogenesis of nodular granulomatous episcleritis involves production of inflammatory mediators by T lymphocytes and subsequent chemotaxis of histiocytes.
  - Secondary:
    - Develops as a result of inflammation extending to episclera from severe intraocular diseases including panophthalmitis/endophthalmitis (see Hypopyon, p. 583), chronic glaucoma, or ocular trauma
- Scleritis:
  - Nonnecrotizing granulomatous:
    - Characterized by infiltration of lymphocytes, plasma cells, and macrophages
    - Granulomatous response seen in cornea with corneal extension
    - ± Secondary uveitis
    - Damaged sclera replaced by fibrous tissue and/or cystic spaces, causing scleral thinning after several episodes
  - Necrotizing granulomatous (rare):
    - Aggressive disease causing necrosis of scleral collagen
    - Typically affects both anterior and posterior segments of the eye
    - Commonly associated with secondary uveitis, glaucoma, and retinal detachment
    - *Ehrlichia canis* infection reported in certain cases

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Episcleritis/scleritis should be strongly suspected on the clinical appearance of the affected globe(s), ruling out other causes of red eye, and response to treatment. If the ocular disease does not respond to medical therapy as expected, episcleral biopsy (usually referable procedure) for a histologic diagnosis is warranted.

DIFFERENTIAL DIAGNOSIS

- Nodular episcleritis; other pinkish, raised lesions:
  - Neoplasia:
    - Conjunctival neoplasia (e.g., mast cell tumor; hemangiosarcoma; histiocytoma)
    - Extension of intraocular tumor
- Granuloma (e.g., foreign body; parasitic—*Onchocerca* spp.)
- Granulation tissue
- Diffuse episcleritis/scleritis; other causes of red eye:
  - Conjunctivitis
  - Glaucoma
  - Uveitis

INITIAL DATABASE

- Complete ophthalmic examination (see p. 1313), including:
  - Schirmer tear test (normal >15 mm in 1 minute in dogs)
  - Fluorescein dye application
  - Intraocular pressures (normal >15 mm Hg and <25 mm Hg)
  - Examination of the anterior and posterior segments of the eye
- Cytologic examination of nodular lesion; may help differentiate neoplasia from inflammation (see Differential Diagnosis)

ADVANCED OR CONFIRMATORY TESTING

- Episcleral biopsy and histopathologic evaluation (nodular granulomatous episcleritis characterized by histiocytes, plasma cells, lymphocytes, and fibroblasts)

- Serologic titers for infectious diseases if supportive systemic signs (e.g., *T. gondii; E. canis)*
- Laboratory testing: canine rheumatoid factor, antinuclear antibody, lupus erythematosus cell identification negative in most cases
- Ocular ultrasound if ocular media opaque, compromising evaluation of deeper ocular structures; useful for ruling out concurrent ocular abnormalities (i.e., retinal detachment)

TREATMENT

TREATMENT OVERVIEW

Many forms of episcleritis respond well to topical corticosteroid application, tapered gradually to the lowest effective frequency. Therapeutic goals are to promote regression of disease, eliminate ocular pain, and keep disease in remission with maintenance therapy. Treatment of NGE and scleritis often requires topical and systemic therapies, including oral prednisone ± azathioprine.

ACUTE GENERAL TREATMENT

To be implemented only if fluorescein staining has ruled out corneal ulceration:

- Topical corticosteroids (e.g., 0.1% dexamethasone solution or ointment or 1% prednisolone acetate) q 6-8 h for 2-3 weeks then gradually tapered
- ± Topical cyclosporine (0.2%–2%) q 12 h; used in addition to corticosteroids in refractory cases.

CHRONIC TREATMENT

NGE and scleritis often require topical (see Acute General Treatment) and systemic therapy(ies) including:

- Prednisone 1-2 mg/kg PO q 24 h until clinical improvement then gradually tapered over 3-4 weeks until maintenance dose reached
- ± Azathioprine 1.5-2 mg/kg PO q 24 h until clinical improvement then gradually tapered to as low a dose as possible (e.g., 0.75-1 mg/kg PO q 24 h, then q 48 h, then once weekly for maintenance.
- Options if medical management ineffective:
    - Cryosurgery
    - Surgical excision

Alternative medical treatment includes tetracycline combined with niacinamide (PO q 8 h): 250 mg of each for dogs 10 kg; 500 mg of each for dogs >10 kg; clinical response may take 1-2 months; occasional gastrointestinal side effects from niacinamide.

POSSIBLE COMPLICATIONS

- Chronic ocular pain
- Uveitis
- Secondary glaucoma
- Blindness
- Azathioprine may cause severe life-threatening myelosuppression; potentially hepatotoxic.

RECOMMENDED MONITORING

- Monitor for regression of disease every 2–3 weeks until clinical signs resolve, then as needed depending on response to therapy.
- In animals receiving azathioprine therapy, CBC and liver enzymes should be assessed every 1–2 weeks for the first 2 months then regularly (e.g., monthly) once clinically stable.

PROGNOSIS AND OUTCOME

- Variable depending on underlying condition and cause
- Episcleritis: prognosis usually good
- Recurrence possible

PEARLS & CONSIDERATIONS

COMMENTS

Lifelong treatment is typically required.

TECHNICIAN TIP

Some ophthalmic drugs have virtually identical names for their formulations with and without corticosteroids. This similarity presents a risk of using the wrong drug. Prior to topical application, it is extremely useful for technicians to carefully read the label of the tube/vial and identify whether it contains corticosteroids and to check the medical record for consistency. Substitution error (especially administering corticosteroids when they are contraindicated) can be devastating and has been made by veterinarians, technicians, and clients.

AUTHOR: URSULA M. DIETRICH

EDITOR: CHERYL L. CULLEN

Epilepsy, Idiopathic

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A syndrome characterized by chronic recurrent seizures for which there is no identifiable cause. Other terms:

- Status epilepticus: a seizure lasting more than 5 minutes, or two or more seizures in which there is incomplete recovery of consciousness.
- Cluster seizures (also called *serial* or *acute repetitive seizures*): three or more isolated seizures occurring within a short period of time.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: commonly affected, 1-5 years old, slightly more common in males
- Cats: uncommonly affected compared with dogs, but not rare in this species

GENETICS & BREED PREDISPOSITION

- More common in large-breed dogs, but any breed can be affected.
- Inherited in beagle, Belgian Tervuren, keeshond, dachshund, British Alsatian, Labrador retriever, golden retriever, Shetland sheepdog, Irish wolfhound, Viszla, Bernese mountain dog, English springer spaniel, and probably others

ASSOCIATED CONDITIONS & DISORDERS: During status epilepticus, hyperthermia can occur secondary to muscle activity.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- One or more seizures
- Most common are generalized tonic-clonic seizures characterized by loss of consciousness and sustained contraction of all muscles, followed by paddling motions of the limbs or rhythmic muscle contractions, especially of the limbs and masticatory muscles.
- Also possible are milder generalized tonic-clonic seizures in which consciousness is maintained, and focal seizures in which only part of the body is involved (e.g., fly-biting movements).
- With idiopathic epilepsy, the interictal period (period between seizures, after recovery) is normal, and owners do not report evidence of ongoing neurologic deficits.
- An effort should be made to clarify any possible sources of intoxication (e.g., lead, ethylene glycol, organophosphate, carbamate, metaldehyde).

PHYSICAL EXAM FINDINGS

- Normal unless examined immediately after a seizure when temporary postictal deficits are possible, including generalized ataxia, abnormal behavior, and blindness that proceed to resolve over minutes to hours.
- Persistent neurologic deficits such as hemiparesis, abnormal behavior, or visual deficits are inconsistent with idiopathic epilepsy and suggest an underlying structural neurologic lesion.
- Persistent fontanelle may or may not be associated with hydrocephalus; however, it offers an acoustic window for ultrasonography to pursue this diagnosis.
- A fundic examination is essential. Uveal, retinal, or optic disk diseases that may correlate with causes of seizures and are inconsistent with idiopathic epilepsy include optic neuritis, feline infectious peritonitis, toxoplasmosis/neosporosis, systemic mycoses, rickettsial diseases, systemic hypertension, lymphoma, and metastatic neoplasia.

ETIOLOGY AND PATHOPHYSIOLOGY

Theories include inborn abnormalities in neuronal excitability, neurotransmitter, or receptor function.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Idiopathic epilepsy is a clinical diagnosis based on the typical age of onset, lack of persistent neurologic deficits, and exclusion of other potential causes based on laboratory testing. A presumptive diagnosis of idiopathic epilepsy may be made without comprehensive diagnostic testing when the patient's signalment and history are consistent with epilepsy, and physical and neurologic examination findings and initial database results are normal. In such cases, further testing may be pursued if deterioration or failure to respond to medication is noted. By declining a comprehensive evaluation, the patient's owner must assume the responsibility that an underlying progressive lesion, rather than epilepsy, may be present.

DIFFERENTIAL DIAGNOSIS

- Metabolic disorders: hepatic encephalopathy including portosystemic shunt, hypoglycemia, polycythemia, hypocalcemia
- Toxins: lead, ethylene glycol, organophosphate, carbamate, metaldehyde
- Brain malformations: hydrocephalus, lissencephaly
- Inherited degenerative diseases such as lysosomal storage diseases
- Encephalitis: granulomatous meningoencephalitis, necrotizing encephalitis, distemper, tickborne infections, fungal encephalitis, *Neospora caninum, Toxoplasma gondii*, feline infectious peritonitis
- Neoplasia: primary and metastatic brain tumor
- Vascular lesions: infarct, hemorrhage
- Head injury
- Also consider nonepileptic episodes such as syncope, narcolepsy, exercise-induced weakness, vestibular dysfunction, and episodes of pain.

INITIAL DATABASE

- CBC: generally unremarkable. Nucleated red blood cells and/or basophilic stippling suggest lead toxicosis rather than epilepsy; acanthocytes nonspecifically suggest hepatic disease.
- Serum chemistry profile, urinalysis: help identify hypoglycemia, hepatic encephalopathy, and renal failure (uremic encephalopathy) as possible causes of seizures instead of idiopathic epilepsy. Fasting hypercholesterolemia may suggest hypothyroidism and attendant central nervous system effects if hyperlipidemia is severe. Hypocalcemia can produce intense muscle tremors that may be misinterpreted as seizures. Hyperglobulinemia in cats raises the possibility of feline infectious peritonitis–based encephalitis as the cause of seizures rather than epilepsy.
- Serum bile acids (preprandial and postprandial):
    - Elevation of either or both suggests hepatic encephalopathy (portosystemic shunt, cirrhotic/fibrosing liver disease, other) rather than idiopathic epilepsy.
    - However, moderate elevations in bile acids routinely may occur soon after a seizure of any cause. In these cases, it is warranted to recheck bile acids 2-4 weeks later to see if the abnormality persists.
- Blood lead concentration if potential exposure

ADVANCED OR CONFIRMATORY TESTING

- Brain CT/MRI and cerebrospinal fluid (CSF) analysis are indicated in the following patients presenting with seizures and no identifiable systemic cause: dogs <1 year or <5 years, dogs with persistent neurologic deficits, and cats. Results of these imaging procedures and CSF analysis are normal with idiopathic epilepsy (diagnosis of exclusion).
- Electroencephalography (EEG) may show abnormalities that confirm seizure activity but are not pathognomonic for idiopathic epilepsy.

TREATMENT

TREATMENT OVERVIEW

Status epilepticus and cluster seizures require emergency treatment because they can lead to life-threatening complications such as hyperthermia and brain damage; prolonged seizures become progressively refractory to treatment. Long-term treatment with anticonvulsant drugs is instituted if seizures are severe and/or frequent. Daily medication is not indicated in patients with a single seizure, seizures caused by a transient condition (e.g., acute intoxication), or isolated seizures separated by a long period of time. Daily medication is indicated in patients with more than one isolated seizure per month, clusters of multiple seizures per day, or a clear pattern of increasing frequency or severity of seizures.

ACUTE GENERAL TREATMENT

- To stop an active seizure: diazepam 0.5–1 mg/kg IV to effect
- If the seizure does not stop with three doses of diazepam, administer:
  - Pentobarbital 3–15 mg/kg, slow IV; *or*
  - Propofol 1–8 mg/kg IV to effect followed by continuous infusion at 0.1 mg/kg/min titrated to effect.
- If the seizure stops with the above therapy but recurs soon after, there are several options:
  - Load with phenobarbital: 12-24 mg/kg slow IV or IM, single dose, followed by maintenance doses of 2-3 mg/kg slow IV, IM, or PO q 12 h; *or*
  - Diazepam continuous rate infusion: 0.5–1 mg/kg/h in 2.5% dextrose + 0.45% saline. Titrate based on seizure control and sedation.

CHRONIC TREATMENT

- Initial therapy with either phenobarbital (dog, cat) or bromide (dog)
  - Phenobarbital:
    - Initial dose: 2-3 mg/kg PO q 12 h (dog, cat) subsequently adjusted based on clinical effects and therapeutic monitoring
    - Steady-state serum concentrations are reached about 10 days after starting therapy or changing the dose.
    - Common side effects: polyuria/polyphagia, sedation, ataxia
  - Potassium bromide:
    - Initial dose: 20-30 mg/kg PO q 24 h (dog), subsequently changed based on clinical effects and therapeutic monitoring
    - Cats: substantial risk of pneumonitis
    - Steady-state serum concentrations are reached 2-3 months after starting therapy or changing the dose.
    - For more rapid control of seizures in dogs with frequent, severe seizures, administer a loading dose: 50–66 mg/kg PO q 6-8 h × 48 hours.
    - Common side effects: polyuria/polyphagia, sedation, ataxia
- If seizures are not adequately controlled despite target serum concentrations of the first drug, adding a second drug while continuing the first drug may be effective. If the seizures become well controlled, it may be possible to gradually wean the first drug.
- Other drugs:
  - Zonisamide (5 mg/kg if used alone, or 10 mg/kg in combination with phenobarbital PO q 12 h [dog]; or 5–10 mg/kg PO q 24 h [cat]; higher dose as combination due to hepatic enzyme induction by phenobarbital). Add-on therapy when seizures are not controlled with initial drug. Initial therapy to avoid side effects of phenobarbital or bromide.
  - Levetiracetam (20 mg/kg PO q 8 h; dog, cat). Add-on therapy with bromide. Initial therapy to avoid side effects of phenobarbital or bromide.
  - Gabapentin (100–300 mg PO total q 8 h; dog, cat). Add-on therapy when seizures are not controlled with initial drug.
  - Clorazepate (0.5–1 mg/kg PO q 8 h; dog, cat). Add-on therapy when seizures are not controlled with initial drug.
  - Felbamate (15–45 mg/kg PO q 8 h, dog). Add-on therapy when seizures are not controlled with initial drug.
  - Pregabalin (2–4 mg/kg PO, q 12 h, dog). Add-on therapy when seizures are not controlled with initial drug. Start at low end of dose to minimize sedation.
- For dogs that suffer clusters of multiple seizures despite daily medication, at-home administration of diazepam per rectum can decrease the need for emergency veterinary care. The client administers 2 mg/kg of parenteral diazepam solution per rectum using a syringe and urinary catheter or teat cannula, repeated for a maximum total of 3 doses within 24 hours.

DRUG INTERACTIONS

- Phenobarbital may decrease the effect of chloramphenicol, corticosteroids, doxycycline, propranolol, and metronidazole. Other depressants and chloramphenicol may increase the effect of phenobarbital.
- Bromide: higher chloride intake increases bromide elimination, which increases the dose requirement; lower chloride decreases bromide elimination.

POSSIBLE COMPLICATIONS

- Phenobarbital-induced hepatotoxicity (see p. 871):
  - Minimized by avoiding serum concentrations <35 mcg/mL
  - Evidence of hepatotoxicity: increases in bile acid concentrations; proportionally larger increases of ALT compared to alkaline phosphatase; icterus, weight loss, ascites if very severe and advanced
  - Potentially reversible if phenobarbital is stopped early enough
- Phenobarbital rarely causes hematologic abnormalities, including neutropenia, anemia, and thrombocytopenia; the drug must be stopped if these abnormalities occur.
- Bromide increases the risk of pancreatitis and may be associated with megaesophagus.

RECOMMENDED MONITORING

- Phenobarbital:
  - Measure serum concentrations 14 days after starting therapy or changing dose, when seizures are not adequately controlled, when signs of dose-related toxicosis occur, and every 6–12 months.
  - Blood sample is obtained immediately before the next dose is due (trough serum level), namely 8–12 hours after preceding dose was given.
  - Blood should *not* be drawn into serum separator tubes, as the separator material may artifactually reduce phenobarbital concentrations in vitro.
  - Target range: 20–35 mcg/mL (85-150 mmol/L).
  - Measure bile acids every 6–12 months to screen for hepatotoxicity.
- Bromide:
  - Measure serum concentrations 1 month and 3–4 months after starting therapy or changing dose, when seizures are not adequately controlled, when signs of dose-related toxicity occur, and every 6-12 months.
  - Because of the drug's extremely long elimination half-life, blood samples need not be drawn a certain number of hours after dosing.
  - Target range: 1–2 mg/mL (100–200 mg/dL; 1000–2000 µg/mL) when used concurrently with phenobarbital and 2–3 mg/mL (200–300 mg/dL; 2000-3000 µg/mL) when used as monotherapy

PROGNOSIS AND OUTCOME

- About 70% of dogs with idiopathic epilepsy can be adequately treated with phenobarbital and/or bromide and enjoy a good quality of life.
- In general, dogs with idiopathic epilepsy have a normal lifespan. However, some dogs with recurrent episodes of status epilepticus requiring emergency treatment have a decreased expected lifespan (≈8 years, versus ≈11 years).

PEARLS & CONSIDERATIONS

COMMENTS

- A common cause of poor seizure control is failure to reach target serum concentrations before switching to a second drug.
- Referral to a neurologist is considered if the diagnosis is uncertain or if the seizures are not adequately controlled within 3 months.

PREVENTION

- Animals with idiopathic epilepsy should not be bred because of potential genetic factors.
- Females should be spayed because estrus tends to increase seizures.

CLIENT EDUCATION

Client education is vital; the client must understand the goal of treatment, potential side effects, and need for periodic monitoring and dose adjustment. The client must agree that the benefits of treatment outweigh the side effects and must not alter treatment without consulting the attending veterinarian.

Eosinophilic Granuloma Complex

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Cats: several conditions affecting the oral cavity, lips, and skin, grouped together based on typical clinical presentation and an eosinophilic infiltrate histopathologically.
- Dogs: rare disease process characterized by single or multiple ulcerated lesions in oral cavity.

SYNONYMS

- Eosinophilic granuloma (cutaneous or oral): collagenolytic granuloma, linear granuloma
- Eosinophilic ulcer (oral): indolent ulcer, rodent ulcer
- Feline eosinophilic skin diseases (dermatoses)

EPIDEMIOLOGY

SPECIES, AGE, SEX: Lesions are more common in young animals, female cats, and male dogs.

GENETICS & BREED PREDISPOSITION

- Cats: no breed predisposition; genetic predisposition hypothesized (from a colony of related pathogen-free cats)
- Dogs: Siberian huskies, Alaskan malamutes, Cavalier King Charles spaniels (CKCS); unknown hereditary basis

RISK FACTORS: In one publication, 90% of cats with eosinophilic ulcers were feline leukemia virus (FeLV) positive.

CONTAGION & ZOONOSIS: Multiple cases in multicat households and experimental transmission from one area of a cat to another suggest an infectious or allergic etiology.

GEOGRAPHY AND SEASONALITY: Worldwide; warm weather seasonality may be observed.

ASSOCIATED CONDITIONS & DISORDERS: Miliary dermatitis or symmetric alopecia may be noted concurrently in cats.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Lesions may be insidious in onset.

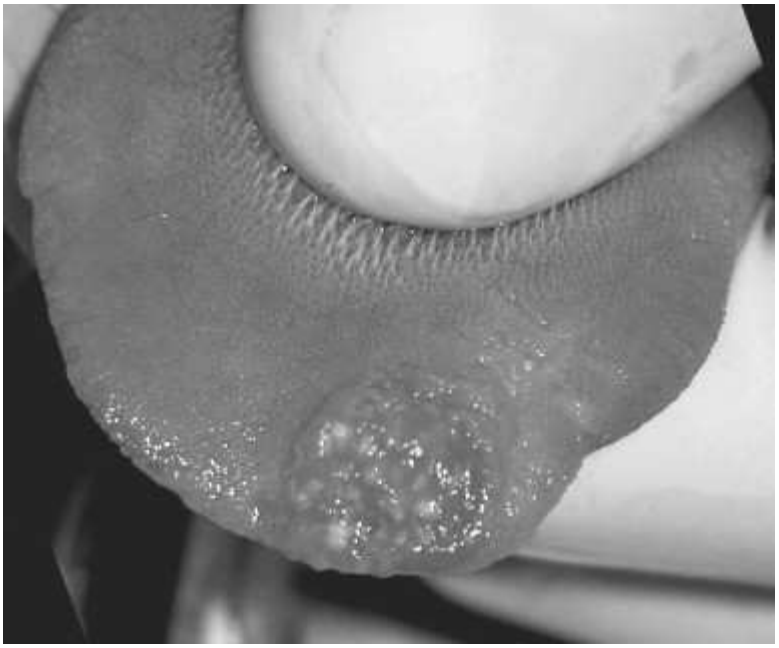
- Skin lesions associated with pruritus, pain
- Oral lesions associated with dysphagia, ptyalism, halitosis, inappetence

PHYSICAL EXAM FINDINGS: Three major forms in cats (all three forms may be observed in the same patient):

- Eosinophilic granuloma
  - Erythematous, alopecic, raised, linear skin lesions on lateral thorax, lateral shoulder, or caudal aspect of thighs; variable pruritus and pain
  - Nodules in oral cavity (dorsal and lateral tongue surfaces, hard and soft palate, glossopharyngeal folds) or at chin; surface often is speckled with small, dense white areas.
- Eosinophilic ulcer
  - Well-demarcated ulcer (raised edges surround a pink-yellow ulcerated surface) on the upper lip (midline or adjacent to the maxillary canine tooth); may also affect the philtrum; nonpruritic, apparently painless
- Eosinophilic plaque
  - Erythematous, raised plaquelike skin lesions, commonly on the ventral abdomen, perianal region and medial thighs; variable pruritus and pain

Two major forms in dogs:

- Single or multiple (often confluent) ulcerated lesions on soft palate and lateral pharyngeal mucosa; especially noted in CKCS
- Firm, raised, yellowish to brownish-pink, irregular, ulcerated lesions with well-demarcated edges on lateral or ventral tongue surfaces or lingual frenulum; especially noted in Siberian huskies and Alaskan malamutes



EOSINOPHILIC GRANULOMA COMPLEX Eosinophilic granuloma near the tip of the tongue in a cat.

(Courtesy Dr. Alexander M. Reiter, University of Pennsylvania.)

EOSINOPHILIC GRANULOMA COMPLEX Eosinophilic ulcer of the upper lip and philtrum in a cat.

(Courtesy Dr. Edmund J. Rosser, Michigan State University.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Different forms may be regarded as different reaction patterns to underlying antigenic stimulation (hypersensitivity reaction), most commonly arthropods (fleas, mosquitoes), food, and contact or environmental (house dust mites, pollens) allergies.
- Other reported causes include viral and bacterial infections, chronic trauma, poor oral hygiene, genetic heritable eosinophilic dysregulation and autoimmune reaction.

DIAGNOSIS

OVERVIEW STATEMENT

The diagnosis is primarily visual and is confirmed by biopsy.

DIFFERENTIAL DIAGNOSIS

- Eosinophilic granuloma and plaque: cutaneous lymphoma, mast cell tumor, squamous cell carcinoma, demodicosis, dermatophytosis, bacterial pyoderma, mycobacterial infection
- Eosinophilic ulcer: squamous cell carcinoma, dermatophytosis, herpesvirus, calicivirus, FeLV, and *Cryptococcus*
- Lip/oral cavity lesions: squamous cell carcinoma, fibrosarcoma, focal inflammation due to a foreign body, trauma, or an infectious agent
- All forms: some cases are idiopathic.

INITIAL DATABASE

- Microscopic examination of plucked hair (trichogram), acetate tape preparation, skin scraping and flea-combing samples to rule out ectoparasites; alternatively, an improvement following appropriate empirical ectoparasiticidal therapy also supports parasitosis.
- Woods lamp examination/bacterial, fungal, mycobacterial cultures: negative
- Cytologic examination of the surface of lesions may reveal large numbers of eosinophils and bacterial or *Malassezia* overgrowth.
- Mild to moderate eosinophilia may occasionally be noted on CBC (rare in cats and inconsistent in dogs with oral lesions).
- Feline immunodeficiency virus/FeLV testing

ADVANCED OR CONFIRMATORY TESTING

- Skin biopsies reveal a superficial to deep to interstitial to diffuse predominantly eosinophilic dermal infiltrate +/− flame figures (collagen fibers surrounded by eosinophilic material).
- Oral biopsy is indicated to rule out neoplasia such as squamous cell carcinoma and fibrosarcoma and establish a diagnosis.
- Adverse food reaction: improvement with 8–10 weeks of elimination diet trial; relapse upon oral challenge

TREATMENT

TREATMENT OVERVIEW

- Treatment of choice consists of early and aggressive glucocorticosteroid therapy.
- Treat secondary infection and underlying cause where appropriate.
- Surgical excision and laser therapy can be attempted for single oral lesions.

ACUTE GENERAL TREATMENT

- Oral glucocorticosteroids: 1–2 mg/kg prednisone or prednisolone PO q 12 h initially, then taper to lowest effective dose. Prednisolone is a superior choice in cats (unpredictable absorption or metabolism of prednisone).
- Injectable glucocorticosteroids: 4 mg/kg methylprednisolone (maximum 20 mg, Depo-Medrol) can be given 2-3 times, 2 weeks apart. This should not be a standard therapy. Side effects include induction of congestive heart failure, diabetes mellitus, and hyperadrenocorticism (alopecia, thin or inelastic skin, skin fragility syndrome, hyperpigmentation, medially curled pinnae, bruising, poor hair coat, demodicosis, dermatophytosis, weight gain, steroid hepatopathy).
- Oral clavulanic acid–potentiated amoxicillin (Clavamox) at an average dose of 13.6 mg/kg q 12 h for 3 weeks has been shown to significantly decrease the size of eosinophilic cutaneous plaques in cats.
- Oral cyclosporine (5 mg/kg PO q 24 h initially, then taper to q 48 h) is an effective alternative to corticosteroids in cats with presumed or confirmed atopic dermatitis. This medication is available in a capsule and a liquid form. The liquid allows more flexible dosing but is bitter tasting. Main side effects include vomiting, diarrhea, soft stools, and very rarely, fatal acute toxoplasmosis.

CHRONIC TREATMENT

- If fleas are present, a rigorous flea control program should be started.
- Allergen-specific immunotherapy (desensitization) for the treatment of atopic dermatitis based on the results of intradermal test and/or aeroallergen-specific immunoglobulin E serum test.

NUTRITION/DIET

Strict elimination diet in proven cases of adverse food reaction

POSSIBLE COMPLICATIONS

- Inadequate initial therapy may result in refractory lesions.
- Oronasal communication may result after surgical excision of palatal lesions.

PROGNOSIS AND OUTCOME

Good

PEARLS & CONSIDERATIONS

COMMENTS

- Feline eosinophilic granuloma complex is not a specific diagnosis. A primary underlying cause is likely to be present and should be investigated.
- Squamous cell carcinoma and eosinophilic granuloma of the tongue and sublingual tissues can clinically appear very similar. Biopsy and histopathologic examination are essential to obtain an accurate diagnosis.

PREVENTION

If an underlying allergic cause can be determined and controlled, the problem can be prevented from reoccurring.

CLIENT EDUCATION

- Skin lesions tend to wax and wane, so reoccurrence is unpredictable except in seasonal cases.
- Since glucocorticosteroids mask the problem rather than eliminating it, an effort should be made to identify the cause and possibly use other types of treatment if effective.
- Cats can (rarely) outgrow the disease over time.

EDITORS: ALEXANDER M. REITER, MANON PARADIS

Eosinophilic Bronchopneumopathy

BASIC INFORMATION

DEFINITION

Idiopathic infiltration of airways, interstitium, and sometimes alveoli and/or nasal cavities with inflammatory infiltrates characterized by a high proportion of eosinophils. The disease is well recognized but not common.

SYNONYMS

Pulmonary infiltrates with eosinophils (PIE), canine idiopathic eosinophilic bronchopneumopathy (EBP; the most current term), eosinophilic pneumonia, eosinophilic bronchitis

EPIDEMIOLOGY

SPECIES, AGE, SEX: Primarily a disease of dogs of any age with no sex predilection. Cats are not affected.

GENETICS & BREED PREDISPOSITION

Any breed can be affected, although Siberian huskies have been suggested as a breed predisposed to the disease.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Animals that have EBP most often present with a chronic cough that is unresponsive or poorly responsive to antimicrobial therapy. Cough may be intermittent, frequent, or persistent and is usually accompanied by a terminal gag/retch. Affected animals may have very productive coughing to the point of expectoration of respiratory secretions onto the floor or may experience gagging and retching.
- Nasal discharge, which can be serous or mucopurulent, may also be a presenting complaint.
- Exercise intolerance
- Depression (uncommon)
- Weight loss in affected dogs is rare.

PHYSICAL EXAM FINDINGS

- Cough
- Crackles, wheezes, and increased bronchovesicular sounds heard during thoracic auscultation
- Tachypnea
- Hyperpnea/dyspnea
- Fever
- Bronchospastic reactions, such as expiratory dyspnea and wheezes, are rarely observed.

ETIOLOGY AND PATHOPHYSIOLOGY

- A hypersensitivity reaction is suspected as the main pathophysiologic process underlying the disease.
- The precipitating cause is rarely identified.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Clinical presentation is no different from many other causes of chronic cough. Peripheral eosinophilia may be seen on a CBC, and nonspecific changes are typical on thoracic radiographs. A functional clinical diagnosis rests on identifying sterile eosinophilic inflammation in the airways on bronchoscopy.

DIFFERENTIAL DIAGNOSIS

Other diseases associated with eosinophilic respiratory inflammation:

- Respiratory parasites (*Oslerus* and *Capillaria* spp., others)
- Respiratory infection (bacterial, fungal)
- Pulmonary neoplasia (primary or metastatic)
- Heartworm infection
- Eosinophilic granulomatosis, which on radiographs appears more as a nodular pulmonary disease

INITIAL DATABASE

- CBC:
  - Inflammatory leukogram
  - Peripheral eosinophilia is not always present.
- Serum biochemical profile and urinalysis results are usually normal.
- Thoracic radiographs commonly show bronchial and peribronchiolar patterns; increases in interstitial markings, alveolar patterns, and lobar consolidation or bronchiectasis may also be observed.
- Heartworm test results are negative.
- Fecal examinations (flotation, sedimentation techniques) will be negative for parasites and ova.

ADVANCED OR CONFIRMATORY TESTING

- Bronchoscopic abnormalities:
  - A common finding is green to yellow-green mucus, often abundant, in airways.
  - Airway mucosa may appear reddened, thickened, nodular, or polypoid; airway collapse may be evident during expiration.
- Examination of respiratory washes or brush cytologic examination shows a mix primarily of neutrophils and eosinophils. Infectious agents, neoplastic cells, or evidence of respiratory parasites are not expected with this disease.
- Culture of respiratory washes will be negative for pathogens in some cases; in those that have positive culture results, clinical signs persist in the face of antimicrobial therapy.

TREATMENT

TREATMENT OVERVIEW

Most dogs with EBP will require glucocorticoids to resolve clinical signs and eosinophilic inflammation.

ACUTE GENERAL TREATMENT

Immunosuppressive dosage of glucocorticoids (e.g., prednisone, 1-2 mg/kg PO q 24 h) initially.

CHRONIC TREATMENT

Glucocorticoids on a slowly tapering (weeks to months) dosage schedule are often needed for control of clinical signs:

- Clinical signs are likely to recur if glucocorticoids are administered inconsistently or if tapering occurs too quickly.
- Low-dose glucocorticoid therapy may be needed in some animals. Administer the lowest dose q 24-48 h to control clinical signs.
- Inhaled corticosteroids can manage the disease and may have the advantage of reducing side effects associated with oral corticosteroids.

POSSIBLE COMPLICATIONS

- Side effects of glucocorticoid therapy such as polyuria, polydipsia, and polyphagia are expected in treated animals.
- Untreated or inadequately treated patients may develop bronchiectasis (an irreversible airway change).

RECOMMENDED MONITORING

- Clinical signs
- Thoracic radiographs

PROGNOSIS AND OUTCOME

- Prognosis is generally good with appropriate doses of glucocorticoids for appropriate periods of time. Some animals may be able to be completely weaned from glucocorticoids.
- Excessively rapid cessation of glucocorticoids may provoke a relapse of clinical signs.

PEARLS & CONSIDERATIONS

COMMENTS

Hyposensitization against antigens identified by allergy testing has been associated with alleviation of clinical signs or control of clinical signs with smaller doses of glucocorticoids in a small number of reported animals. The amount of clinical benefit derived from hyposensitization and the role of hyposensitization in long-term management need additional investigation; hyposensitization may be a consideration for animals in which side effects of glucocorticoids are unacceptable or intolerable to owners.

PREVENTION

There is no reliable means of preventing this disease.

TECHNICIAN TIPS

Stained slides of sputum from dogs with EBP have high numbers of eosinophils that are easily recognized with rapid staining methods, so making slides of fresh sputum, even that obtained from the floor or ground, can be quite informative in these patients.

CLIENT EDUCATION

Clients should understand the importance of consistent treatment with glucocorticoids, particularly during the initial stages of treatment.

Entropion/Ectropion

BASIC INFORMATION

DEFINITION

- *Entropion* is a common condition that consists of the inversion of part or the entire eyelid margin toward the eye; may be developmental or acquired.
- *Ectropion* is a well-recognized condition that consists of the eversion of part or the entire eyelid margin away from the eye; may be developmental or acquired.

SYNONYMS

Inrolled eyelid (entropion); everted eyelid (ectropion)

EPIDEMIOLOGY

SPECIES, AGE, SEX

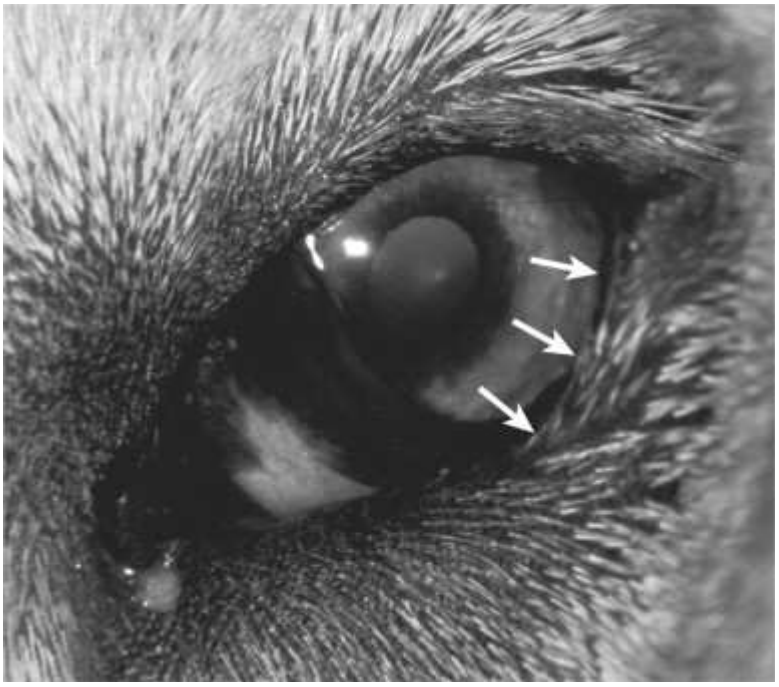
- Entropion:
  - Dogs common; cats less common
  - Can occur at any age; developmental entropion usually develops in dogs <1 year of age
- Ectropion:
  - Dogs
  - Age variable, depends on cause

GENETICS & BREED PREDISPOSITION

- Developmental entropion:
  - Lateral entropion: English bulldog, chow chow, shar-pei, Saint Bernard, boxer, rottweiler, pointers, spaniels, and all retrievers
  - Medial canthal entropion: miniature and toy poodles, English bulldog, Cavalier King Charles spaniel, Maltese, and brachycephalic breeds including Pekingese, pug, and shih tzu; brachycephalic cats
  - Genetic basis not fully understood; considered inherited as a simple dominant trait, with complete penetrance in some breeds of dogs
- Developmental ectropion: bloodhound, Saint Bernard, Great Dane, bullmastiff, Newfoundland, and some spaniel breeds
- Combination entropion-ectropion affecting the same lid: bloodhound, Saint Bernard, and English bulldog

RISK FACTORS

- Developmental entropion and ectropion: breed predisposition
- Acquired entropion: ocular conditions that stimulate blepharospasm (e.g., see Conjunctivitis: Dogs, p. 239, Cats, p. 237; Corneal Ulceration, p. 250)
  - Eyelid trauma (see p. 373)
  - Blepharitis
  - Old age and associated loss of orbicularis oculi muscle tone
  - Phthisis bulbi (see Ocular Size Abnormalities, p. 778)
  - Enophthalmos (see Orbital Disease, p. 790)
- Acquired ectropion:
  - Eyelid trauma
  - Blepharitis
  - Old age and associated loss of orbicularis oculi muscle tone
  - Facial nerve paralysis



ENTROPION/ECTROPION Entropion of ventrolateral eyelid in a dog (*arrows*). Note prolapse of third eyelid and mild mucoid ocular discharge at the medial canthus, which are common concurrent findings.

ASSOCIATED CONDITIONS & DISORDERS

- Conjunctivitis
- Keratitis (ulcerative and nonulcerative)
- See Risk Factors above.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Developmental and acquired forms.

HISTORY, CHIEF COMPLAINT

- Entropion:
  - Ocular discharge
  - Blepharospasm
  - "Red eye"
  - Visible inrolling of eyelid
  - ± Vision impairment in severe cases
- Ectropion:
  - Ocular discharge
  - "Red eye"
  - Droopy/long lower eyelid

PHYSICAL EXAM FINDINGS

- Entropion:
  - Inversion of the eyelid (see figure) and some or all of the following:
    - Conjunctivitis (cats, see p. 237; dogs, see p. 239)
    - Epiphora or mucoid to mucopurulent ocular discharge
    - Blepharospasm
    - Protrusion of the third eyelid (see figure)
    - Nonulcerative keratitis (see Corneal Pigmentation, p. 246; Corneal Vascularization, p. 254)
    - Ulcerative keratitis (see Corneal Ulceration, p. 250)
- Ectropion:
  - Eversion of the lower eyelid and some or all of the following:
    - Conjunctivitis
    - Lagophthalmos (incomplete closure of the eyelids)

ETIOLOGY AND PATHOPHYSIOLOGY

Dogs:

- Developmental entropion:
  - Related to abnormal skull and palpebral fissure (eyelid opening) conformation
  - Associated with misdirection of the lateral canthal ligament in mesaticephalic (intermediate facial somato-type; neither brachycephalic nor dolichocephalic) breeds
  - Upper eyelid entropion can be associated with ptosis and weight from excessive dorsal skinfolds
  - Associated with microblepharon (small eyelids)
- Acquired entropion:
  - Decreased orbital support (decreased orbital mass, phthisis bulbi, or retractor bulbi muscle contraction) predisposes to loss of lid support (see Orbital Disease, p. 790).
  - Secondary to blepharospasm
  - Secondary to scarring and contraction of the eyelid from a previous eyelid injury and/or inflammation
- Developmental ectropion:
  - Mild ectropion is a desired feature in some breeds (i.e., hounds).
  - Related to abnormal skull and palpebral fissure conformation
  - Associated with laxity of the palpebral fissure related to macroblepharon
- Acquired ectropion:
  - Transient ectropion results from laxity of the eyelid from relaxation or following excessive exercise in breeds with long lower eyelids.
  - Scarring and contraction of the eyelid from a previous eyelid injury and/or inflammation
  - Facial nerve paralysis

Cats:

- Developmental entropion:
  - Medial canthal entropion in brachycephalic breeds
- Acquired entropion:
  - Decreased orbital support associated with loss of orbital and periorbital fat predisposes to loss of eyelid support.
  - Secondary to blepharospasm
  - Associated with scarring and contraction from chronic conjunctival and/or eyelid inflammation

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of entropion is suspected based on the presence of ocular irritation (epiphora, conjunctivitis, or keratitis) and is confirmed based on identification of abnormal lid conformation (inversion of part or all of the eyelid). Ectropion is diagnosed on physical examination: eversion of the lower eyelid. For both disorders, an ophthalmic examination is indicated to identify lesions caused by the eyelid malformation.

DIFFERENTIAL DIAGNOSIS

- Entropion:
  - Usually readily diagnosed on clinical examination; must be differentiated from:
    - Distichiasis (see Distichiasis/Ectopic Cilia/Trichiasis, p. 319): one or more cilia emerge from the meibomian glands instead of the normal peripheral lid margin.
    - Trichiasis (see Distichiasis/Ectopic Cilia/Trichiasis, p. 319): normal eyelid or facial hair directed toward, and contacting, the conjunctiva or cornea
- Ectropion:
  - Usually readily diagnosed on clinical examination: apparent even before handling the patient

INITIAL DATABASE

Complete ophthalmic examination (see p. 1313) including:

- Schirmer tear test (normal >15 mm after 1 minute in dogs, variable in cats)
- Fluorescein dye application
- Intraocular pressures
- Careful examination of conformation of eyelid margins, conjunctiva, and cornea

ADVANCED OR CONFIRMATORY TESTING

- Variable depending on underlying cause of acquired entropion and/or ectropion
- With entropion, apply topical anesthetic (e.g., proparacaine 0.5%) to eye to evaluate degree of spastic entropion (i.e., entropion secondary to ocular pain versus developmental entropion or entropion from primary ocular disease such as ulcerative or nonulcerative keratitis). Spastic entropion temporarily resolves or decreases in severity within a few minutes of proparacaine application.
- Examine animal in a relaxed state to determine extent of entropion and/or ectropion and to select most appropriate corrective surgical technique; restraining the animal or manipulation of the head at examination can increase the severity of blepharospasm and exaggerate the degree of entropion.

TREATMENT

TREATMENT OVERVIEW

- The treatment goals for entropion are to resolve any underlying painful ocular disease (e.g., conjunctivitis, keratitis) and restore normal lid conformation (temporary versus permanent repair).
- The treatment goals for ectropion are to restore normal lid conformation only if severe and predisposing to chronic ocular irritation. Mild ectropion is normal for some larger-breed dogs.

ACUTE GENERAL TREATMENT

Entropion:

- Treat underlying condition(s)
- Temporary correction until adult conformation reached (i.e., in puppies), or until underlying condition resolved:
    - Roll eyelids away from eye by placing temporary tacking or temporary tarsorrhaphy sutures to prevent chronic ocular pain and blepharospasm and to prevent corneal pigmentation, vascularization, ulceration, and scarring.
    - If successful, may not require permanent repair
- Permanent correction once adult conformation reached (increases success) and no other underlying condition (see Chronic Treatment)

CHRONIC TREATMENT

- Chronic *entropion* in mature animal requires some form of surgery to evert the eyelid margin.
    - Cases of mild entropion:
        - Consider Hotz-Celsus procedure (surgical procedure involving excision of an elliptical section of skin adjacent to the lid margin).
    - Lateral canthal entropion:
        - Creation or cutting of the lateral canthal ligament (modified Wyman's lateral canthoplasty or lateral canthal tenotomy, respectively)
        - Hotz-Celsus procedure and eyelid shortening procedure may be needed.
    - Medial canthal entropion:
        - Medial canthoplasty procedure (e.g., pocket flap or Wyman technique)
        - Localized Hotz-Celsus procedure
    - Ptosis and upper eyelid entropion:
        - Stades procedure to evert upper eyelid margin
- Ectropion:
    - Surgery rarely needed unless severe or if concurrent with entropion elsewhere on the lid
    - Cases of severe ectropion:
        - Consider modified Kuhnt-Szymanowski technique (lid-shortening procedure)
    - Cicatricial (scar-induced) ectropion
        - V-Y blepharoplasty may be used

POSSIBLE COMPLICATIONS

- Temporary tacking sutures may pull through skin, necessitating repeat procedure(s) until animal is mature or until underlying condition is resolved.
- Undercorrection or overcorrection of entropion
- Correction of subclinical ectropion predisposing to entropion

RECOMMENDED MONITORING

- Leave the temporary tacking sutures or temporary tarsorrhaphy in place until adult conformation reached or for 2–3 weeks until concurrent ocular disease resolves.
- Permanent entropion and/or ectropion repairs require suture removal approximately 10-14 days after surgery.

PROGNOSIS AND OUTCOME

- Prognosis for restoring normal eyelid conformation is good.
- Recurrence of entropion is possible, depending on underlying cause and surgical treatment.

PEARLS & CONSIDERATIONS

COMMENTS

- Treat any concurrent ocular disease before surgically correcting entropion.
- No single surgical procedure is effective for correction of all forms of entropion and/or ectropion (see Chronic Treatment above for some options).
- Err on the side of undercorrection when performing entropion surgery; further future correction is much easier to manage than the other extreme (overcorrection causing ectropion).
- Correction of naturally occurring ectropion is rarely needed unless severe or occurs in conjunction with entropion on the same eyelid.

PREVENTION

Avoid breeding affected or closely related dogs with developmental entropion or clinically significant developmental ectropion.

CLIENT EDUCATION

If the initial repair is ineffective, additional surgical procedures may be needed.

AUTHOR: PHILLIP A. MOORE

EDITOR: CHERYL L. CULLEN

Endocarditis, Infective

BASIC INFORMATION

DEFINITION

Endocarditis is inflammation of the endocardial surface of the heart (endocardium). *Infective endocarditis* is microbial infection of the endocardium. *Vegetative endocarditis* is a specific form of endocarditis where structures (vegetations) composed of platelets, fibrin, microorganisms, and inflammatory cells adhere to heart valves or cling to septal defects, chordae tendineae, or the mural endocardium. Endocarditis (both the term and the disease) is unrelated to the most common form of chronic valvular heart disease in dogs, myxomatous valve disease or *endocardiosis*.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Endocarditis is uncommon in dogs and rare in cats.
- Dogs: male > female, large breeds > small breeds.
- In the dog, the left-sided heart valves (aortic and mitral) are by far the most frequently affected.

RISK FACTORS

- Congenital aortic valve disease (e.g., subaortic stenosis) and other congenital heart diseases that cause disturbances of blood flow and subsequent changes in the endocardium
- Glucocorticoid use predisposes to endocarditis, and many cases appear to have a nosocomial origin. Infected intravenous catheters, prosthetic heart valves, heart surgery, and interventional cardiac catheterization all enhance the risk.
- Infection with potentially immunosuppressive organisms (e.g., *Bartonella* spp., *Ehrlichia* spp.) enhances the risk of endocarditis.
- Predisposing factors for endocarditis in dogs include sources of chronic bacteremia (e.g., urinary tract infection, discospondylitis) and systemic illnesses that facilitate bacterial infection (e.g., diabetes mellitus, hyperadrenocorticism/Cushing's disease).

GEOGRAPHY AND SEASONALITY:

Infective endocarditis is recognized more in warmer climates (e.g., southern and western United States).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Endocarditis is classified as acute or subacute-chronic based on the duration, rate of progression, and severity of clinical signs.

HISTORY, CHIEF COMPLAINT

- Extracardiac manifestations of systemic infection and inflammation are the source of most of the historic complaints.
- Manifestations of fever (e.g., lethargy, anorexia) are the most common sign, although they may be intermittent, minimal, or even absent in patients with less virulent organisms (e.g., *Bartonella* spp., some gram-positive organisms) or severe debilitation.
- Weight loss
- Reluctance to move (back pain, polyarthritis)
- Intermittent lameness (muscle embolization, polyarthritis)

PHYSICAL EXAM FINDINGS: Most patients diagnosed with endocarditis have a heart murmur:

- The murmur may be newly recognized or may have changed in intensity, quality, timing, or duration. Many animals with endocarditis have a preexisting heart murmur (e.g., from subaortic stenosis).
- The presence of a diastolic murmur in a systemically ill animal dramatically raises the index of suspicion for infective endocarditis.
- Aortic insufficiency often causes a soft, blowing murmur with a distant quality that is difficult to hear.

ETIOLOGY AND PATHOPHYSIOLOGY

- *Staphylococcus* spp., *Streptococcus* spp., *Erysipelothrix* spp., *Corynebacterium* spp., and *Escherichia coli* have been the most common bacterial isolates in canine infective endocarditis.
- *Bartonella* spp. is being isolated with increasing frequency and appears to have a tropism for the aortic valve.
- A wide variety of other organisms has been cultured from individual cases, with many nosocomial cases involving *Pseudomonas* spp., *Proteus* spp., or other antibiotic-resistant isolates. Anaerobic bacteria (e.g., *Bacteroides* spp.) are occasionally found.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Endocarditis is suspected based on clinical signs and the presence of a heart murmur on physical exam. The index of suspicion may increase substantially based on echocardiographic findings, but a positive bacterial blood culture is required to establish the clinical diagnosis.

DIFFERENTIAL DIAGNOSIS

- Presenting complaints of animals with infective endocarditis tend to be vague and associated with some aspect of systemic illness (e.g., fever, lameness).
- Endocarditis should be included in the differential diagnosis of any persistent fever of unknown origin, especially in the presence of a heart murmur.

INITIAL DATABASE

- Definitive diagnosis requires the synthesis of clinical, laboratory (microbiologic), and echocardiographic data.
- CBC or serum biochemical changes are not specific.
- Echocardiography reveals an oscillating mass at a site of endocardial injury (i.e., a mass near but separate from the valve, whose movements are distinct from those of the valve; it is important to note that this excludes valves that are merely thickened, as in myxomatous valve disease/endocardiosis).
- Two separate blood cultures must be positive for a typical organism and obtained by separate venipunctures an hour apart (three cultures are recommended if time, money, and patient size permit; at least two must be positive).
- In acutely ill patients with apparent sepsis syndrome, three blood cultures 5-10 minutes apart should be obtained if the patient's size permits, followed by empirical antibiotic therapy.

ADVANCED OR CONFIRMATORY TESTING

- Patients with suspected or definite endocarditis should have electrocardiograms recorded (and repeated regularly during their clinical course), because the onset of AV or bundle-branch block suggests perivalvular extension of the infection.
- When blood cultures from suspected infective endocarditis patients remain sterile after 72 hours of incubation, the laboratory should intensify efforts to grow fastidious organisms such as *Bartonella* spp., and the clinician should initiate alternative (e.g., serologic, PCR) assessment.
- Panbacterial PCR amplification of the 16s ribosomal bacterial DNA from patients with suspected or definite endocarditis is available. Currently, the sensitivity of this technique is equivalent to standard blood culture techniques.

TREATMENT

TREATMENT OVERVIEW

- Provide effective antiinfective therapy to minimize valve damage.
- Manage complications (e.g., heart failure).

ACUTE GENERAL TREATMENT

- Treatment is usually begun with parenteral antibiotic combinations in hospitalized dogs, but once the fever has resolved and clinical improvement (e.g., return of appetite) is evident (generally not more than 3-5 days), treatment is completed on an outpatient basis with oral antibiotics.
- Treatment is based on blood culture and sensitivity results; these results are not available for the first critical hours or days of therapy.

- Empirical antibiotic therapy for dogs with a clinical history and echocardiographic findings compatible with endocarditis is started with a combination of fluoroquinolone and penicillin-based antibiotics. Parenteral enrofloxacin (5 mg/kg IV q 12 h) and amoxicillin (20 mg/kg IV q 8 h) are most often chosen.
- Although discussed by some veterinary authors, anticoagulation does not appear to diminish the risk of bacterial embolization in humans and is not generally recommended.

CHRONIC TREATMENT

- Therapy is generally continued for 12 weeks, and blood cultures are ideally obtained after 10-14 days (on antibiotics) and then again 1 week after stopping antibiotics.
- If *Bartonella* spp. is identified by culture or serology, azithromycin, 5–10 mg/kg PO q 24 h is recommended for the first 7 days, then every other day for 6–12 weeks.

POSSIBLE COMPLICATIONS

Congestive heart failure, renal failure, or neurologic events are the complications that appear to have the greatest influence on prognosis.

PROGNOSIS AND OUTCOME

- Prognosis at the time of diagnosis is guarded, owing to the future possibilities of embolic complications and/or congestive heart failure.
- Factors negatively associated with short-term survival include thrombocytopenia, renal complications, and thromboembolism.
- Long-term prognosis depends primarily on the valve damage that has been done at the time of diagnosis, as well as the response to antibiotic therapy.
- Recurrence or treatment failure is likely with inadequate duration of therapy, inappropriate antibiotic selection, or owner noncompliance.
- Despite optimal therapy and therapeutic monitoring, cure rates for endocarditis do not appear to be especially promising in dogs, and heart failure or deteriorations due to recurrent embolic events is often the long-term result.

PEARLS & CONSIDERATIONS

COMMENTS

- Although both can cause valve thickening and heart murmurs, taking a broader perspective of the case can more clearly demonstrate the differences between acute bacterial endocarditis (typically medium- to large-breed dogs of any age, overt clinical signs of recurrent infection/sepsis, new-onset heart murmur; overall, occurs uncommonly) and endocardiosis (medium- to small-breed dog, generally older adult, no link to overt signs of infection, murmur may be new in onset or long standing; common).
- The murmur of aortic insufficiency is often heard best by placing the diaphragm of the stethoscope in the animal's left armpit, with the animal lying on its left side (on top of the stethoscope).
- A high index of suspicion for endocarditis is warranted in cases of disco-spondylitis and in any animal with fever and a diastolic murmur.
- With appropriate therapy, prognosis appears to be better for animals with less aggressive organisms such as *Bartonella* spp. if valve damage is not too severe at time of diagnosis.

PREVENTION

Animals with subaortic stenosis, animals with cardiac implants (e.g., transvenous pacemakers), and animals that have undergone balloon valvuloplasty should receive routine antibiotic prophylaxis for all procedures that are likely to induce transient bacteremia.

CLIENT EDUCATION

Owner compliance is perhaps an even bigger issue in the treatment of endocarditis than it is with other heart diseases, and effective explanation of the rationale for extended (often expensive) antibiotic treatment and a guarded prognosis is therefore critical.

EDITOR: ETIENNE CÔTÉ

Encephalopathy, Vascular

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Brain dysfunction caused by ischemia, or lack of oxygen delivery. These are most commonly focal events (i.e., infarcts or strokes) but occasionally manifest as widespread brain ischemia (i.e., global ischemia).

SYNONYMS

Infarct, ischemic encephalopathy, stroke, cerebrovascular accident

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats of any age and either sex

GENETICS & BREED PREDISPOSITION:

Cavalier King Charles spaniels may be predisposed to cerebellar infarcts; this may be related to local pressure abnormalities due to caudal occipital malformation syndrome in this breed. Greyhounds may also be predisposed to brain infarction, possibly related to their relatively high resting blood pressure. Brachycephalic breeds may be predisposed to developing global brain ischemia.

RISK FACTORS: Focal ischemic events (strokes): hypertension, hypercoagulability, and hyperviscosity. The most prevalent diseases that cause these disturbances in patients with vascular encephalopathy are chronic kidney disease and hyperadrenocorticism. Other conditions include diabetes mellitus, hypothyroidism, hyperthyroidism, hepatic failure, pheochromocytoma, and infectious diseases. Feline ischemic encephalopathy has been linked to intracranial migration of *Cuterebra* larvae. Risk factors for global brain ischemia include inadequate anesthetic monitoring, cardiac arrest, severe hypoxemia, and the use of ketamine in anesthetic protocols (especially in brachycephalic breeds).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Focal brain ischemic events (strokes, infarcts) can be small (lacunar) or large (territorial) and either hemorrhagic or nonhemorrhagic (the latter are more common). Global brain ischemia usually involves some degree of diffuse oxygen deprivation in the brain and is much less common than focal brain ischemia.

HISTORY, CHIEF COMPLAINT

- The characteristic historic feature of both focal and global ischemic encephalopathy is acute to peracute onset of brain dysfunction, which is nonprogressive after the first 24 hours.
- Typical chief complaints include sudden-onset, mentation change, vocalizing/crying, or seizures.

PHYSICAL EXAM FINDINGS

- Physical and neurologic examination findings depend primarily on the underlying disorder leading to the ischemic event (physical examination findings) and the region of the brain affected by the ischemic event.
- Strokes affecting the cerebrum (e.g., propulsive pacing, disorientation, seizures), diencephalon/midbrain (e.g., depression, obtundation/coma), or cerebellum (hypermetria, intention tremor) are seen with some frequency in affected dogs.

ETIOLOGY AND PATHOPHYSIOLOGY

- Interruption of oxygen delivery to brain tissue
- Disruption of cellular energy metabolism (i.e., ATP production)
- Brain necrosis and edema
- Generation of cytotoxic mediators of secondary brain injury

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on a history of sudden-onset neurologic deficits that are typically nonprogressive and asymmetric. Suspicion is heightened when a procoagulable state or other possible inciting factor is identified. Confirmation requires intracranial imaging (e.g., MRI).

DIFFERENTIAL DIAGNOSIS

- Brain neoplasm
- Inflammatory brain disease: sterile or infectious encephalitides
- Trauma (suggested at outset if history unknown, or supportive of trauma)

INITIAL DATABASE

- CBC, serum biochemistry profile: abnormalities depend on underlying cause (e.g., polycythemia or hyperglobulinemia with hyperviscosity syndrome); changes consistent with kidney disease if hypertension; hypoalbuminemia with hypercoagulability due to loss of antithrombin III (protein-losing nephropathy or enteropathy).
- Neurologic examination (see p. 1311): deficits according to site of ischemia; symmetric deficits with global ischemia, asymmetric with focal ischemia
- Serial blood pressure measurement (see p. 1209): rule out systemic hypertension.
- Urinalysis: pathologic proteinuria in cases of hypercoagulability due to protein-losing nephropathy

ADVANCED OR CONFIRMATORY TESTING

- MRI of brain (see p. 1302): diagnostic test of choice
  - Helps differentiate focal from global ischemia, but this distinction should be apparent from the history and neurologic exam alone.
- Cerebrospinal fluid examination (see p. 1228): may be unremarkable or show nonspecific changes.

TREATMENT

TREATMENT OVERVIEW

Therapeutic goals include:

- Minimize secondary brain swelling and tissue damage
- Treat underlying cause of brain ischemia
- Physical rehabilitation (see p. 1329)

ACUTE GENERAL TREATMENT

- Mannitol, 0.5–1 g/kg body weight slowly IV over 10-15 minutes
- Oxygen supplementation

CHRONIC TREATMENT

- Treat underlying condition (e.g., antihypertensive drugs if hypertension is documented).
- Physical rehabilitation

POSSIBLE COMPLICATIONS

- Recumbency-associated pneumonia
- Pressure sores (see p. 174)
- Recurrent stroke
- Exacerbation of underlying condition leading to ischemic event

RECOMMENDED MONITORING

- Serial neurologic examinations
- Blood pressure (if hypertension documented)
- Progression or regression of underlying condition (e.g., diabetes control, control of hyperadrenocorticism)

PROGNOSIS AND OUTCOME

- Most patients recover fully from focal ischemic events.
- Prognosis for stroke is more closely associated with the underlying cause than the stroke event itself
- Global brain ischemia is associated with a more guarded prognosis than focal brain ischemia.

PEARLS & CONSIDERATIONS

COMMENTS

- Recovery from vascular encephalopathy may take several weeks to several months.
- Aggressive physical therapy and nursing care are essential to a positive outcome.
- History and symmetry versus asymmetry of neurologic deficits are the main elements that allow the differentiation of global versus focal ischemia, respectively.
- Although dogs and cats can develop vascular encephalopathy (a true stroke) as described previously, overall this disorder occurs much less commonly than acute vestibular syndrome, which is an acute disorder that does not involve the brain (peripheral vestibular disease), does not involve infarction, and yet is often referred to inaccurately as a “stroke.”

AUTHOR & EDITOR: CURTIS W. DEWEY

Emphysema and Pulmonary Bullae

BASIC INFORMATION

DEFINITION

- *Emphysema:* pathologic accumulation of air within an organ or tissue
- *Bulla:* an air-filled space within the pulmonary parenchyma that arises from alveolar distention or destruction of alveolar walls
- *Bleb:* an accumulation of air within the mesothelial covering and layers of elastic fibers and connective tissue cells that comprise the visceral pleura

SYNONYM

Bullous emphysema

EPIDEMIOLOGY

SPECIES, AGE, SEX

Reported most commonly in dogs of middle age, although dogs of any age can be affected. Cats are rarely affected.

GENETICS & BREED PREDISPOSITION

- A familial or genetic predisposition has not been demonstrated.
- Large, deep-chested dog breeds are considered at greater risk of pulmonary blebs and bullae.

RISK FACTORS

- Congenital bronchial hypoplasia (uncommon) reported in both dogs and cats.
- Chronic obstructive pulmonary diseases are a recognized risk factor in people and could be so in dogs (e.g., chronic sterile bronchitis).

ASSOCIATED CONDITIONS & DISORDERS

- Congenital bronchial hypoplasia
- Congenital bronchial cartilage hypoplasia/dysplasia
- Spontaneous pneumothorax
- Pneumomediastinum (uncommon)
- Subcutaneous emphysema (uncommon)
- Pneumopericardium (uncommon)

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Congenital forms of bullous lung disease have been described, usually secondary to bronchial hypoplasia or bronchial cartilage defects.

HISTORY, CHIEF COMPLAINT

- Animals may be clinically normal:
  - A pulmonary bleb or bulla may be found incidentally during thoracotomy or thoracoscopy.
- Clinical signs, when present, can be acute, intermittent, or slowly progressive:
  - Anorexia
  - Lethargy
  - Respiratory distress
    - The rupture of a bleb or bulla, causing spontaneous pneumothorax, is typically associated with acute dyspnea.
  - Cough

- Exercise intolerance

PHYSICAL EXAM FINDINGS

- Respiratory distress
- Increased inspiratory effort (pneumothorax from ruptured bleb or bulla)
- Increased expiratory effort (pulmonary emphysema without pneumothorax)
- Tachypnea
- Tachycardia
- Diminished heart and lung sounds on one or both sides if pneumothorax
- Subcutaneous emphysema in occasional patients

ETIOLOGY AND PATHOPHYSIOLOGY

- Histopathologic assessment of resected tissues classifies lesions as blebs or bullae.
- Exact mechanisms leading to bulla or bleb formation are not defined:
  - Suspected to reflect the effects of distensile or traction forces on the lung surface, or the effects of inflammation or degradative enzymes in the alveoli to break down alveolar walls.
  - Increased alveolar pressure relative to transpleural pressure may also contribute.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Definitive diagnosis usually depends on exclusion of other causes of pneumothorax after evaluation of patient history, physical examination, and radiographic imaging, and then surgical observation of typical lesions.

DIFFERENTIAL DIAGNOSIS

- Other causes of pneumothorax:
  - Trauma, either blunt or penetrating, to the thoracic wall, trachea, esophagus, or pulmonary parenchyma
- Inflammatory lung disease
- Neoplastic lung disease
- Parasitic lung disease, especially *Paragonimus kellicotti* and *Dirofilaria immitis*
- Obstructive airway disease
- Migrating foreign bodies

INITIAL DATABASE

- Thoracic radiographs:
  - May demonstrate the features of pneumothorax (see p. 889)
  - Often unremarkable; observation of a bleb or bulla is uncommon.
  - Animals with paragonimiasis may have thick-walled bullae evident, even with pneumothorax.
  - Thoracic radiographs may in some cases show air-filled dilations within the parenchyma.
  - Occasional animals may have pneumomediastinum, pneumopericardium, or subcutaneous emphysema evident.
- Results of a CBC, biochemical profile, and urinalysis are typically unaffected by the disease.
- Hypoxemia will be the most consistently present abnormality on arterial blood gas analysis.
- Fecal examinations (flotation and sedimentation techniques) to rule out respiratory parasites

ADVANCED OR CONFIRMATORY TESTING

- Definitive diagnosis is usually made by detection of bullae, blebs, or air leaking from the lung surface during thoracotomy or thoracoscopy and confirmed with histopathologic examination of resected tissue.
  - Median sternotomy is the preferred approach in patients with spontaneous pneumothorax.
  - Cranial lung lobes are most commonly affected, although other lung lobes can also have lesions.
- Tracheoscopy, bronchoscopy, and esophagoscopy are usually normal in patients with bullous lung disease unless airway hypoplasia is present.
- In a small number of reported cases, CT scans of the thorax have proved more sensitive than plain thoracic radiographs for the detection of bullous lung lesions in dogs with spontaneous pneumothorax.

TREATMENT

TREATMENT OVERVIEW

- Improve respiratory function and oxygenation in patients with respiratory distress, typically by thoracocentesis, as most such patients will have pneumothorax.
- Remove bullae or blebs.
- Treat underlying obstructive disease, if present

ACUTE GENERAL TREATMENT

- Thoracocentesis if pneumothorax is present (see p. 1338):
  - Thoracostomy tubes with continuous suction may be needed in some patients for management of persistent air accumulation.
- Oxygen provided by mask, nasal catheter, oxygen cage
- Cage rest

CHRONIC TREATMENT

- Long-term resolution of spontaneous pneumothorax from rupture of blebs or bullous lung lesions, if not from parasitic diseases, is most reliably achieved with surgical resection of the affected lung tissue by either partial or complete lung lobectomy.
  - Persistence or recurrence of clinical signs is more likely if the patient is managed nonsurgically.
  - Partial or complete lung lobectomy may be accomplished via thoracotomy or thoracoscopy.
- Treat underlying obstructive disease, if present

POSSIBLE COMPLICATIONS

- Pneumothorax from leakage at suture or staple site of a lobectomy
- Postoperative complications of infection, wound dehiscence

RECOMMENDED MONITORING

- Clinical signs
- Thoracic radiographs

PROGNOSIS AND OUTCOME

Prognosis is good with surgical resection of bullous lung lesions.

PEARLS & CONSIDERATIONS

COMMENTS

- Often in patients with spontaneous pneumothorax of uncertain origin and no history of trauma, bleb or bulla rupture ultimately is found to be the underlying cause.
- Some animals can be successfully managed with nonsurgical methods (thoracocentesis, thoracostomy tubes), but the literature supports early lung lobectomy for the best long-term outcomes.
- Affected animals can have multiple lesions scattered over different lung lobes, and lung lobes on both sides of the thoracic cavity can be affected. It is thus imperative to examine the entirety of both lungs during thoracotomy or thoracoscopy.

PREVENTION

There is no means of preventing the disease. Animals with congenital bronchial hypoplasia should probably not be bred.

TECHNICIAN TIPS

- Thoracocentesis is most often done at around the 7th or 8th intercostal space, so these areas should be clipped in

preparation for the procedure.
- When the goal of thoracocentesis is to remove air, preferred recumbency is that in which the patient is most comfortable.

CLIENT EDUCATION

Nonsurgical treatment approaches are more likely to be associated with persistence or recurrence of clinical signs. Postsurgical outcomes are usually excellent.

AUTHOR & EDITOR: RANCE K. SELLON

Electrocution

BASIC INFORMATION

DEFINITION

The passage of electricity through tissue, resulting in electrophysiologic disruption of the tissue

EPIDEMIOLOGY

SPECIES, AGE, SEX

Most common in young cats and dogs (5 weeks to 1.5 years of age), with no sex predilection

RISK FACTORS

Young age and environmental access

GEOGRAPHY AND SEASONALITY

Seasonal associations: Christmas holidays (decorative holiday lights) or perhaps most often from late spring to early autumn, when owners are likely to operate electrical devices (e.g., fans), and there may be an increase in acquisition of puppies and kittens.

ASSOCIATED CONDITIONS & DISORDERS

Noncardiogenic pulmonary edema, cardiac arrhythmias, oral burns, and seizures

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

High-voltage injury versus low-voltage injury, based on the nature and intensity of the current. The most severe injuries result from a high-current and high-voltage situation and thus produce a worse clinical outcome. Electrical sources can produce energy levels that range from relatively low (e.g., 9-volt battery) to intermediate (e.g., household outlets) to very high (e.g., electrical metal utility cover). Household current is the most common.

HISTORY, CHIEF COMPLAINT

Sometimes witnessed; other times the owner reports sudden onset of dyspnea, collapse, or dysphagia.

PHYSICAL EXAM FINDINGS

- Oral burns: to the tongue, palate, and commissures of the lips
- Respiratory problems: dyspnea (harsh lung sounds, upper airway edema), cyanosis, coughing
- Cardiac problems: arrhythmias (ventricular fibrillation), asystole
- Neurologic abnormalities: loss of consciousness, focal muscle tremors, seizures

ETIOLOGY AND PATHOPHYSIOLOGY

- Electricity (usually 60 Hz of alternating current and 120 volts is found in most households in North and much of South America; in most of the rest of the world, it is usually 50-60 Hz of alternating current and 220 volts) disrupts the electrophysiologic activity of tissue, causing muscle spasms, ventricular arrhythmias, and vasomotor changes in the central nervous system, resulting in acute pulmonary edema. The electric energy is also transformed into heat, which can cause coagulation of tissue proteins. Sudden death may result from these processes.
- Electrocution is almost always accidental, typically with a young pet chewing on an electric cord.

ELECTROCUTION A, Dorsoventral thoracic radiograph of a 4-month-old male English bulldog that chewed on an electrical cord and was presented for evaluation of severe dyspnea. Heavy interstitial infiltrate is distributed caudally and symmetrically *(left-right)*. **B,** Same dog 2 weeks later after making a complete recovery. Infiltrate has resolved.

(Courtesy Dr. Julio Lopez, California Animal Hospital.)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

If unwitnessed, the diagnosis is suspected if it is a young pet with the presence of oral burns and dyspnea. Thoracic radiographs classically show noncardiogenic edema (interstitial/alveolar pattern with a caudodorsal distribution).

DIFFERENTIAL DIAGNOSIS

Chemical or thermal burns, exposure to fire, and smoke inhalation

INITIAL DATABASE

Initial database is dependent on the severity of injury. In some cases, if the animal has no physical exam abnormalities, no testing is required. In other cases, if the pet is dyspneic or pulmonary crackles are auscultated, chest radiographs are warranted. In severely affected animals, CBC, serum biochemistry profile, coagulation profile, and urinalysis are warranted.

ADVANCED OR CONFIRMATORY TESTING

Pulse oximetry or arterial blood gas analysis may be useful to document hypoxemia. However, in young or small animals, the stress of arterial sample collection should be weighed against the potential benefits.

TREATMENT

TREATMENT OVERVIEW

Treatment mainly consists of supportive care, but the degree of intervention depends on the severity of the case. Burns should be cleaned; if severe, surgical débridement is indicated when the patient is stable. Noncardiogenic pulmonary edema is treated with supplemental oxygen administration. If severe or if pharyngeal edema is present, intubation and ventilation may be necessary.

ACUTE GENERAL TREATMENT

Noncardiogenic pulmonary edema is treated with rest and supplemental oxygen (see pp. 1318 and p. 1362).

CHRONIC TREATMENT

Treat burns with antibiotics, wound cleaning, soft food/feeding tube if burns are in the mouth, surgical débridement, and closure. Puppies in particular will commonly eat despite severe oral injury.

NUTRITION/DIET

If oral burns are severe and the patient will not eat, enteral nutrition may be instituted via placement of a nasoesophageal (see p. 1267) or esophagostomy (see p. 1269) tube.

POSSIBLE COMPLICATIONS

Infection of nonhealing burns, acute lung injury, acute respiratory distress syndrome. A rare but possible long-term complication is cataract formation.

RECOMMENDED MONITORING

Respiratory rate and effort, as well as the healing of any burns, should be monitored.

PROGNOSIS AND OUTCOME 

Depends on the degree of noncardiogenic pulmonary edema. Cats appear to do better than dogs in overall survival. Critical period is the first 24-48 hours after electrical shock; if the animal survives this period, he/she will likely survive to discharge with minimal/no permanent aftereffects.

PEARLS & CONSIDERATIONS 

COMMENTS

Noncardiogenic pulmonary edema can be difficult to treat. There are no known specific treatment recommendations.

PREVENTION

- When left unobserved, puppies and kittens should be crated or otherwise confined so access to electrical cords in use can be avoided.
- Remove access to wires that are plugged into outlets.

TECHNICIAN TIPS

When administering treatments to these pets, stress should be minimized, and treatments should be conducted in a stepwise manner.

CLIENT EDUCATION

Education about reexposure, removal of damaged or faulty electrical cords

SUGGESTED READING

Drobatz KJ, et al: Noncardiogenic pulmonary edema in dogs and cats: 26 cases (1987-1993). J Am Vet Med Assoc 206:1732–1736, 1995.

EDITOR: ELIZABETH ROZANSKI

Elbow Luxation

BASIC INFORMATION

DEFINITION

Dislocation between brachium (humerus) and antebrachium (radius and ulna)

SYNONYM

Elbow dislocation

EPIDEMIOLOGY

SPECIES/AGE/SEX

- Uncommon in dogs; rare in cats
- Any breed, age, or sex for traumatic luxations
- Juvenile dogs for congenital luxations

GENETIC & BREED PREDISPOSITION

- Congenital luxations generally more common in small breeds of dogs, but radial head luxation specifically occurs more frequently in larger breeds.
- Suspected hereditary predisposition
- Chondrodystrophic breeds are prone to asynchronous growth between radius and ulna, thereby resulting in subluxation.

RISK FACTORS

Forelimb trauma

ASSOCIATED CONDITIONS & DISORDERS

Some forms of congenital luxation may be associated with more generalized joint laxity syndromes.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Traumatic
- Congenital, complete
- Congenital, partial (radial head luxation only)

HISTORY, CHIEF COMPLAINT

- Forelimb trauma secondary to motor vehicle accident, fall, or rough play/fighting
- Spontaneous lameness/deformity in young dog

PHYSICAL EXAM FINDINGS

- Traumatic: non-weight-bearing lameness with antebrachium and paw abducted, elbow flexed, and severe elbow swelling and pain
- Congenital: partial weight-bearing lameness and joint thickening; discomfort during range-of-motion maneuvers

ETIOLOGY AND PATHOPHYSIOLOGY

- Majority of traumatic luxations are lateral (proximal radius/ulna are lateral to distal humerus).
- Medial luxations are associated with severe soft-tissue derangements.
- Traumatic injuries may cause avulsion fracture(s) of collateral ligament(s).

- Congenital/developmental luxations and subluxations may be associated with asynchronous growth of the radius and ulna.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on history, physical exam, and radiographs (sedated patient) of the affected limb, to include carpus, elbow, and shoulder joints.

DIFFERENTIAL DIAGNOSIS

- Distal humeral fracture
- Monteggia fracture (cranial displacement of radial head and proximal ulna fracture)
- Elbow neoplasia

INITIAL DATABASE

- Craniocaudal and mediolateral radiographs of the elbow
- Survey radiographs for other traumatic injuries, especially thoracic cavity
- Radiographs of the contralateral elbow in patients with congenital or developmental luxations
- Assess for neurologic injury: check for limb withdrawal and pain sensation.

TREATMENT

TREATMENT OVERVIEW

Goal of therapy is to achieve anatomic reduction of joint surfaces so normal joint mobility is restored, with eventual return to full weight bearing and elimination of discomfort.

ACUTE GENERAL TREATMENT

- Traumatic elbow luxations are best managed via early closed reduction before muscle contraction makes manipulations difficult (see Pearls, below, and for closed reduction procedure).
- Patient must be anesthetized for reduction.
- Concurrent injuries may result in postponement of anesthesia and early reduction.
- If closed reduction is not achieved, open reduction and reconstruction of the collateral ligaments are indicated.
- If open reduction is needed, the limb should be bandaged to reduce patient discomfort and tissue swelling before surgery.
- Appropriate analgesics should be administered.
- Congenital/developmental luxations do not require “acute” treatment, but intervention is preferred to help slow progression of secondary osteoarthritis.
- Congenital luxations are less amenable to closed reduction.
- Congenital luxations may require osteotomies or ostectomies for treatment.

CHRONIC TREATMENT

- Immobilization with elbow bandaged in extension for 1–2 weeks
- Initially, a heavy padded bandage (or more rigid splint for open reductions and those with severe collateral ligament damage), with gradual reduction in bandage thickness/stiffness as swelling subsides and stability increases
- Gentle, passive range-of-motion (flexion/extension) physiotherapy instituted after bandage removal
- Continued use of analgesic/antiinflammatory agents as needed for patient comfort

POSSIBLE COMPLICATIONS

- Recurrent luxation/instability
- Articular cartilage damage and secondary osteoarthritis
- Ligament damage
- Reduced range of motion from pericapsular fibrosis
- Chronic lameness

RECOMMENDED MONITORING

- Postreduction radiographs to confirm restoration of joint congruency
- Weekly bandage check/change until removal
- Lameness evaluations 2, 4, and 8 weeks after surgery; radiographs at 2 weeks, also at 6-8 weeks if open reduction/implants

PROGNOSIS AND OUTCOME

- Good if mild articular cartilage or ligamentous lesions
- Chronic fibrosis will result in a permanently thickened elbow.
- Most dogs with properly treated traumatic luxations will return to normal or near-normal function.
- More guarded prognosis for congenital/developmental luxations
- Severe complications/failures might necessitate salvage surgery (arthrodesis, total joint arthroplasty, or amputation).

PEARLS & CONSIDERATIONS

COMMENTS

- Early diagnosis is critical for promoting successful closed reduction.
- Closed reduction achieved by flexing elbow (moves anconeal process caudally), followed by abduction of the antebrachium, with the paw flexed (moves anconeal process medially, attempting to “hook” anconeal process medial to lateral epicondylar crest of the humerus), followed by adduction and pronation of the antebrachium (attempting to “snap” the radial head medially to its proper location under the capitulum of the humerus as the anconeal process acts as a fulcrum).
- Can consider paralyzing the patient pharmacologically (requires ventilation of patient for gas exchange) to achieve greater muscle relaxation to facilitate reduction maneuvers.

CLIENT EDUCATION

- Bandage/splint care
- Controlled activity (kennel/leash)
- Passive range-of-motion physiotherapy after removal
- Neuter dogs with congenital luxations, owing to potential heritability.

EDITOR: JOSEPH HARARI

Elbow Hygroma

BASIC INFORMATION

DEFINITION

Fluid-filled (serum) cavity between skin and bony prominence (olecranon)

SYNONYMS

Elbow seroma, olecranon bursitis (incorrect term, as tendon bursa is not involved)

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs: any age, either sex

GENETICS & BREED PREDISPOSITION

Large-breed, heavy dogs

RISK FACTORS

- Insufficient callus over elbow
- Thin skin
- Small amount of subcutaneous fat
- Chronic pressure trauma to elbow
- Lying on hard surfaces

ASSOCIATED CONDITIONS & DISORDERS

Orthopedic problems (hip dysplasia) that increase trauma to skin and other soft tissues overlying the elbows as dog rises or lies down

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Gradually enlarging, fluid-filled swelling over point of elbow
  - Initially soft, then more turgid as fluid accumulates
- Ulceration of overlying skin may develop if continued trauma

PHYSICAL EXAM FINDINGS

Fluid-filled, fluctuant to turgid swelling over the point of the elbow. Unilateral or bilateral.

ETIOLOGY AND PATHOPHYSIOLOGY

- Caused by chronic repetitive pressure and trauma to the elbow
- Serum accumulates in subcutaneous space superficial to triceps fascia over the olecranon.
- Over time, fibrous proliferation occurs, causing nonpitting, nonpainful thickening of skin and subcutis.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on patient signalment, presenting history, and physical examination findings. Confirmation requires fine-needle aspiration cytology of the fluid-filled swelling.

DIFFERENTIAL DIAGNOSIS

- Abscess
- Neoplasia

INITIAL DATABASE

- If indicated, presurgical CBC, serum chemistry profile, urinalysis
- Fine-needle aspiration cytologic evaluation with or without bacterial culture and sensitivity: rule out abscess, neoplasia.
- Radiographs of elbow: rule out underlying orthopedic problems (degenerative joint disease, olecranon fracture).

TREATMENT 

TREATMENT OVERVIEW

Successful treatment of this problem requires:

- Complete drainage of fluid from the cavity and prevention of its reaccumulation
- Apposition and subsequent healing of fibrous tissue surfaces of the cavity together to obliterate the cavity and prevent reformation Prevention of continued trauma to the elbows and therefore recurrence of the problem

ACUTE GENERAL TREATMENT

Three suggested methods of treatment:

- Aseptic aspiration of fluid and pressure coaptation bandage
  - Rarely successful for larger or chronic hygromas
- Penrose drainage and padded bandage
- Suture obliteration and padded bandage

CHRONIC TREATMENT

- Padded bandage must remain in place for at least 4 weeks to allow the fibrous tissue surfaces to heal together and thereby obliterate the subcutaneous space in which fluid could accumulate.
- Dog should be restricted from lying on hard surfaces.
  - Suitable padded bedding should be provided.
- Elbow(s) should be padded until healing and adequate protective callus have developed.

POSSIBLE COMPLICATIONS

- Recurrence
  - Penrose drain removed too soon
  - Inadequate period of bandaging to allow fibrous healing to occur
  - Suitable padded bedding not provided after bandages have been removed
- Infection
  - Repeated needle drainage
  - Inadequate sterile surgical technique
  - Inadequate protective bandage over Penrose drains
- Development of a chronic nonhealing ulcer over olecranon
  - Infected hygroma
  - Dehiscence of suture line after surgery
  - Continued trauma to hygroma

RECOMMENDED MONITORING

- See Chronic Treatment above
- Observe elbow area for evidence of:
  - Recurrence of the hygroma

  - Infection of the overlying skin
  - Development of necrosis/ulceration of the overlying skin
- Be aware that problem may develop on other elbow if preventive measures are not taken.

PROGNOSIS AND OUTCOME

- Good with appropriate treatment
- Poor if:
  - Hygroma becomes infected
  - Dehiscence of suture line occurs
  - Nonhealing ulcer develops
- May require extensive reconstructive surgery to correct these problems

PEARLS & CONSIDERATIONS

COMMENTS

- *Do not* attempt surgical excision of the hygroma.
- Successful primary closure is difficult to achieve with excision, owing to tension and motion at surgical site; high risk of complications.

PREVENTION

- Dog should be restricted from lying on hard surfaces:
  - Especially if other orthopedic problems are present that restrict the dog's ability to rise and lie down
  - Suitable padded bedding should be provided.
- Elbow(s) should be padded until adequate protective callus has developed.

TECHNICIAN TIPS

In-hospital care:

- Ensure adequate bedding is provided to reduce pressure trauma to elbow(s).
- Ensure that bandage(s) remain securely in place and are clean and dry.
- Assist patient in getting up and down and ambulating as needed, to prevent additional elbow trauma.
- Client education before and at time of patient discharge: correct bandage care including being aware of potential problems/complications. Advise clients on home management/prevention:
  - Assisting dog getting up and down and ambulating while leg(s) bandaged
  - Appropriate bedding, avoiding hard surfaces
  - Purchase of custom-made elbow pads

CLIENT EDUCATION

Seek veterinary care and advise as soon as hygroma develops: easier to treat and less risk of complications if treated early (e.g., before infection).

Elbow Dysplasia

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- A common group of developmental disorders including fragmented medial coronoid process (FCP), ununited anconeal process (UAP), osteochondritis dissecans (OCD), and elbow incongruity (uneven radial head and medial coronoid surfaces) that cause degenerative joint disease in the elbow
- FCP is a separation of the medial aspect of the coronoid process from the ulna.
- UAP is a failure of the anconeal process to fuse to the ulna.
- Osteochondrosis is an abnormality of endochondral ossification, whereas OCD implies separation of the diseased cartilage from the subchondral bone.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Primarily in dogs between 6 and 9 months old
- FCP may be present in older dogs with degenerative joint disease.

GENETICS & BREED PREDISPOSITION

Elbow dysplasia is hereditary but also is associated with rapid growth and high-energy diet.

- UAP is found primarily in German shepherds, basset hounds, and Saint Bernards.
- FCP and OCD affect primarily retriever breeds, Bernese mountain dogs, and rottweilers.

Other large breed dogs may be affected by elbow dysplasia, including the Newfoundland, mastiff, and Australian shepherd; however, elbow displasia is also becoming more prevalent in smaller breeds.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of lameness on one or both forelimbs, often worse after exercise
- Reluctance to play or take long walks

PHYSICAL EXAM FINDINGS

- Lameness on one or both forelimbs
- Pain on manipulation of the elbow, especially on extension
- If osteoarthrosis is advanced, crepitation or effusion may be palpable along with a decreased amount of flexion to the joint (reduced range of motion).

ETIOLOGY AND PATHOPHYSIOLOGY

- OCD occurs when there is osteochondrosis (a failure of endochondral ossification), which leads to cartilage thickening and fissure formation.
    - Factors such as diet, rapid growth, hormonal imbalance, trauma, and genetics may lead to the development of OCD as well as FCP and UAP.
- Joint incongruity, leading to increased pressure on the anconeus, has been implicated as a cause for UAP.
    - UAP may also be a form of osteochondrosis with abnormal thickened cartilage, leading to failure of unification.
- The underlying pathophysiology of FCP is unknown but is believed to be secondary to elbow incongruity or a form of osteochondrosis.
    - Incongruity of the joint, especially an increase in length of the ulna in relation to the radius, can lead to increased weight-bearing load on the medial aspect of the coronoid process, leading to fissuring and fragmentation.
    - Osteochondrosis may lead to a delay in ossification of the coronoid region and subject the joint to fragmentation when weight bearing.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Radiography is the standard means of diagnosing elbow dysplasia. However, canine elbow dysplasia can be present without radiographic signs, and advanced imaging (nuclear scintigraphy, ultrasonography, CT, and MRI) or arthroscopy may help diagnose subtle lesions.

DIFFERENTIAL DIAGNOSIS

- Panosteitis
- OCD of the shoulder
- Elbow luxation

INITIAL DATABASE

- CBC and serum chemistry panel based on signalment:
  - Consider before treatment or sedation/anesthesia
  - Generally unremarkable for elbow dysplasia alone
- Mediolateral, craniocaudal, and flexed lateral radiographs of both elbows:
  - An oblique craniocaudal view with the elbow flexed 30° and rotated medially 15° may help to assess the medial coronoid process.
  - The flexed lateral is the best radiographic view to identify a UAP.
  - OCD is seen on the medial condyle of the humerus, primarily on the craniocaudal view.
  - Elbow congruity is best assessed on the mediolateral view, and the beam should be centered on the elbow joint.

ELBOW DYSPLASIA Mediolateral *(left panel)* and craniocaudal *(right panel)* projections of a canine elbow with fragmented medial coronoid process *(arrows)*.

(Courtesy Dr. J. Harari; reproduced with permission.)

ELBOW DYSPLASIA Mediolateral projection of a flexed canine elbow joint with an ununited anconeal process *(arrowheads).*

(Courtesy Dr. J. Harari; reproduced with permission.)

ADVANCED OR CONFIRMATORY TESTING

- A bone scan can be used for localizing the lameness if a complete orthopedic examination and radiographs are inconclusive.
- CT or MRI can be used for characterizing and delineating the elbow lesion.
- Arthroscopy can be used to confirm abnormalities in the elbow joint found with imaging modalities.
- Arthrocentesis may be performed to rule out other causes of joint effusion.

TREATMENT

TREATMENT OVERVIEW

In persistently lame dogs with elbow dysplasia, treatment involves removal of the FCP, OCD, or UAP fragment, which will result in an improvement in limb function. In dogs with elbow incongruity, surgery to improve congruity will minimize ongoing degenerative changes to the joint. However, degenerative joint disease is still expected to progress in most cases of elbow dysplasia.

ACUTE GENERAL TREATMENT

- Elbow arthroscopy via a medial portal is used for treatment of FCP and OCD and to assess elbow incongruity.
  - The FCP is identified and removed with grasping forceps or a motorized shaver.
  - Curettage or removal of the medial coronoid process via a subtotal coronoid ostectomy can be used when fissuring or chondromalacia of the coronoid is present without gross fragmentation.
  - OCD lesion is identified and the cartilage flap removed. A motorized shaver is used for removing fragments and to treat the underlying subchondral bone. Osteochondral autograft transfer is being researched as a treatment option for OCD lesions.
- A sliding humeral osteotomy has been proposed to redistribute forces within the medial compartment of the elbow, thereby decreasing pain associated with medial coronoid disease.
- In skeletally mature dogs, a UAP is often surgically removed via a lateral approach.
  - Various other surgical procedures have been described, such as lag screw fixation. However, these approaches result in no better success and have a higher complication rate related to the implants.
- In skeletally immature dogs, a dynamic ulnar osteotomy may be used for removing the pressure on the anconeal process and allowing bone or fibrous union of the fragment.
  - This may be used simultaneously with lag screw fixation of the anconeal process. Lag screw fixation causes compression of the anconeal process to the ulna and leads to bone fusion.
- If elbow incongruity exists, a dynamic ulnar osteotomy is performed to allow proximal movement (triceps muscles pull) of the

ulna to improve joint congruency.
    - An intramedullary pin is placed in the ulna by some surgeons to provide stabilization and reduce callus formation.
- Total elbow replacement or elbow arthrodesis may be performed in dogs with moderate to severe elbow osteoarthritis secondary to elbow dysplasia.

CHRONIC TREATMENT

- If an ulnar osteotomy is performed, postoperative placement of a soft padded bandage for 2-4 weeks is used for support.
- Exercise should be restricted to short leash walks for 4-6 weeks after surgery.
- Physical therapy may be useful to maintain range of motion within the elbow joint after surgery.
- Medical therapy may be necessary after surgery if a significant amount of degenerative joint disease is present.
    - Nonsteroidal antiinflammatory drugs (NSAIDs):
        - Aspirin, 10–25 mg/kg PO q 8-24 h; *or*
        - Carprofen, 2 mg/kg PO q 12 h; *or*
        - Etodolac, 10–15 mg/kg PO q 24 h *or*
        - Deracoxib, 1–2 mg/kg PO q 24 h (may use 3-4 mg/kg PO q 24 h for first 7 days only); *or*
        - Meloxicam, 0.1 mg/kg PO q 24 h; *or*
        - Meclofenamic acid, 1.1 mg/kg PO q 24 h after eating, 5 days maximum; *or*
        - Tepoxalin, 10 mg/kg PO q 24 h (new product, objective data pending); *or*
        - Others
    - Chondroprotective agents:
        - Polysulfated glycosaminoglycan, 5 mg/kg IM once weekly × 4–6 weeks; *or*
        - Pentosan polysulfate (from beech-wood hemicellulose) 3 mg/kg SQ once weekly; *or*
        - Oral formulations (glucosamine, chondroitin sulfate, hyaluronan): according to formulation/labeled instructions

POSSIBLE COMPLICATIONS

- Infection
- Implant failure if performing lag screw fixation

RECOMMENDED MONITORING

- Suture removal and recheck 2 postoperative weeks
- Repeat radiographs 6 postoperative weeks if an ulnar osteotomy, lag screw fixation of the anconeal process, sliding humeral osteotomy, or total elbow replacement was performed.

PROGNOSIS AND OUTCOME

- Surgery will help alleviate lameness for OCD, FCP, and UAP, but most affected dogs will continue to have progressive DJD and need medical therapy.
- Prognosis for return to full function depends on the degree of preexisting DJD.
- Medical treatment consisting of weight control, exercise restriction, NSAIDs, and polysulfated glycosaminoglycan therapy is reported to have a similar outcome to surgical treatment of OCD and FCP.

PEARLS & CONSIDERATIONS

COMMENTS

- Clinical signs of FCP may not correlate with radiographic evidence of disease.
    - Initial radiographic change will be mild osteophytosis on the anconeal process.
    - Some dogs may show mild or no radiographic changes, yet be profoundly lame; such a patient needs MRI, CT, or arthroscopy.
    - Conversely, some dogs are not lame, yet have radiographic evidence of DJD.
    - Hence, treatment is directed toward the patient and not the radiograph.
- Unilateral forelimb lameness may not be detectable if bilateral forelimb disease is present.
- Because of the prevalence of bilateral disease, both elbows may undergo arthroscopy with one anesthetic episode if clinically indicated.
- The anconeal process does not fuse until 4-5 months of age and cannot be diagnosed radiographically as ununited before that time.
- When manipulating the elbow to check for pain, avoid movement of the shoulder, which may obscure localization of the

discomfort.

CLIENT EDUCATION

Because of the hereditary component of elbow dysplasia, affected dogs should not be used for breeding.

Eisenmenger's Syndrome

BASIC INFORMATION

DEFINITION

Uncommon syndrome involving any large communication between the left and right sides of the heart, in association with severe pulmonary hypertension, which results in right-to-left shunting of blood.

SYNONYMS

- Eisenmenger's physiology or reaction
- Eisenmenger's complex (large, nonrestrictive ventricular septal defect [VSD] plus pulmonary hypertension causing right-to-left shunting with or without dextroposition of the aorta)
- The term *cyanotic congenital heart disease* includes Eisenmenger's syndrome as well as right-to-left cardiac shunts without pulmonary hypertension (i.e., VSD with concurrent pulmonic stenosis).

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats
- Young animals
- Female dogs more predisposed to patent ductus arteriosus (PDA); 15% of dogs with PDA may develop severe pulmonary hypertension.

GENETICS & BREED PREDISPOSITION

Dependent on the underlying cause:

- PDA: quasi-continuous or threshold trait with high degree of heritability. Miniature and toy poodles, collie, Pomeranian, Shetland sheepdog, American cocker spaniel, German shepherd, Maltese, keeshond, Yorkshire terrier.
- VSD: autosomal-dominant trait with incomplete penetrance or a polygenic trait. English springer spaniel, English bulldog.

RISK FACTORS

Living at high altitude

ASSOCIATED CONDITIONS & DISORDERS

Eisenmenger's syndrome can originate from an isolated cardiac defect (i.e., PDA) or from a combination of VSD or ASD and PDA.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Dyspnea (most common sign in cats)
- Exercise intolerance
- Syncope
- Lethargy
- Cough
- Cyanosis
- Hind limb collapse

PHYSICAL EXAM FINDINGS

- Heart murmur (timing and location determined by defect[s] present)
- Right or left apical systolic murmurs (inconsistent)
- Tachycardia

- Tachypnea
- Generalized or regional cyanosis, depending on underlying cause
- Loud second heart sound
- Split second heart sound

ETIOLOGY AND PATHOPHYSIOLOGY

- Size of the defect and severity of pulmonary hypertension determine the degree of shunting and thus the occurrence and extent of clinical signs.
    - Hypoxemia from shunting of venous blood into the arterial circulation leads to erythropoietin production and polycythemia.
    - Polycythemia, if severe, can produce hyperviscosity and pulmonary embolism, central neurologic signs, and/or coagulopathies.
- Congenital:
    - High pulmonary vascular resistance is maintained after birth.
    - Abnormal maturation of the pulmonary vasculature
- Acquired:
    - Large systemic-pulmonary communication (left-to-right shunt) offers minimal resistance to systolic flow.
    - Relative flows are determined by systemic and pulmonary vascular resistance.
    - Prolonged pulmonary hypertension leads to pulmonary vascular disease, an abnormal maturation of the pulmonary vasculature, and right ventricular hypertrophy.
    - Pulmonary arterial histologic features: medial muscular hypertrophy, laminar intimal fibrosis, necrotizing arteritis, plexiform lesions.
    - With progression, pulmonary vascular resistance may increase to a value greater than the systemic vascular resistance, causing right-to-left or bidirectional shunting (mixing of venous and arterial blood).

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected in a young patient presenting with dyspnea, cyanosis, and collapsing episodes. Polycythemia and right heart enlargement are usually present. An echocardiogram with contrast is required for confirmation.

DIFFERENTIAL DIAGNOSIS

- Radiographic/electrocardiographic:
    - Right heart enlargement: other types of cardiac disease (pulmonic stenosis, tetralogy of Fallot, heartworm disease, tricuspid valve dysplasia, atrial septal defect), cor pulmonale
- Echocardiographic:
    - Pulmonic stenosis
    - Tetralogy of Fallot
    - Heartworm disease

INITIAL DATABASE

- CBC: polycythemia (usually progressive with age)
- Heartworm test: antigen, antibody (cats), and microfilaria tests
- Thoracic radiographs: right heart enlargement, enlarged main pulmonary artery, normal to mildly enlarged pulmonary vasculature
- Systemic arterial blood pressure measurement: hypotension contraindicates performing phlebotomy without fluid replacement
- Electrocardiogram: tall P waves in lead II, deep S waves in lead II, right axis deviation; arrhythmias are uncommon
- Echocardiogram:
    - 2D: right ventricular hypertrophy, enlarged main pulmonary artery, identification of structural defects
    - M mode: right ventricular free wall and septal hypertrophy, septal flattening, paradoxical septal motion
    - Color flow Doppler: aliased or laminar flow across the congeni-tal defect, tricuspid regurgitation (uncommon)
    - Spectral Doppler: tricuspid regurgitant velocity > 3.5 m/s, pulmonic insufficiency velocity > 3 m/s, reversed E/A ratio of mitral valve inflow profile, midsystolic notching of the pulmonary flow profile (severe cases)
    - Contrast echo: contrast appears in the left heart (intracardiac shunt) or in the abdominal aorta (extracardiac shunt).

ADVANCED OR CONFIRMATORY TESTING

- Cardiac catheterization: used for confirming diagnosis and to assess degree of shunting

- Angiogram: outlines the congenital defect(s) (PDA, VSD, ASD or aorticopulmonary communication)
- Pressure measurements: increased pulmonary artery pressures. With large defects, right and left ventricular pressures have a tendency to equalize.
- Oximetry: decreased aortic Po2
- Transesophageal echocardiography: better identification of the congenital defect

TREATMENT

TREATMENT OVERVIEW

Initial control of polycythemia and signs of hyperviscosity can be achieved with periodic phlebotomies. Hydroxyurea and a phosphodiesterase-V inhibitor (to reduce severity of pulmonary hypertension) may be started if clinical signs persist. Consider referral to cardiologist for diagnosis and advice on treatment plan.

ACUTE GENERAL TREATMENT

- Phlebotomy: if PCV > 60%. Withdrawal of 10%-20% of circulating blood volume (= 1-2 mL/kg) with or without intravenous fluid replacement. Repeated as needed (typically every several weeks) based on recurrence of clinical signs.
- Calcium channel blocker (e.g., amlodipine), phosphodiesterase V inhibitors (e.g., sildenafil): reduce pulmonary hypertension (see 935)

CHRONIC TREATMENT

Medical therapy:

- Hydroxyurea, 20-25 mg/kg PO q 12-24 h until hematocrit is lower; then 25-50 mg/kg PO q 48 h as needed to maintain stable hematocrit. Recommended when patient requires frequent phlebotomies.
- Diuretics, ACE inhibitors, and antiarrhythmics following the treatment guidelines. See Heart Failure, Acute/ Decompensated, 468; Heart Failure, Chronic, 470; Ventricular Arrhythmias (Premature Ventricular Complexes, Ventricular Tachycardia), .

BEHAVIOR/EXERCISE

Restrict exercise and excitement in patients with collapsing or syncopal episodes.

DRUG INTERACTIONS

Hydroxyurea: reversible bone marrow suppression (pancytopenia), anorexia, vomiting and diarrhea, sloughing of nails are possible.

RECOMMENDED MONITORING

Recheck examinations should include: CBC, serum renal profile, and systolic blood pressure measurement.

PROGNOSIS AND OUTCOME

Long-term prognosis is guarded to poor, depending on severity of pulmonary hypertension.

PEARLS & CONSIDERATIONS

COMMENTS

- Large systemic-pulmonary communications are uncommon in dogs and cats.
- Surgery is contraindicated, owing to severe pulmonary hypertension.

PREVENTION

Do not breed affected animals.

TECHNICIAN TIPS

- Check mucous membranes for cyanosis. The jugular vein is usually the best phlebotomy site; when administering fluids, use a different vein (e.g., cephalic vein)

CLIENT EDUCATION

- Monitor respiratory rate at rest, exercise tolerance, and appetite.
- Advise client not to breed affected animals.

Moore KW, Stepien RL: Hydroxyurea for treatment of polycythemia secondary to right-to-left shunting patent ductus arteriosus in 4 dogs. J Vet Intern Med 15(4):418–421, 2001.

AUTHOR: JOAO S. ORVALHO

EDITOR: ETIENNE CÔTÉ

Ehrlichiosis, Canine Monocytic

BASIC INFORMATION

DEFINITION

Tick-transmitted disease caused by *Ehrlichia canis* or *Ehrlichia chaffeensis* infection. These organisms predominantly infect circulating monocytes, macrophages, and lymphocytes, causing nonspecific signs (fever, anorexia, lethargy, inappetence), bleeding, anemia, and cytopenias. Chronically, *E. canis* infection can cause bone marrow suppression, pancytopenia, glomerulonephritis, and death.

SYNONYMS

Canine monocytotropic ehrlichiosis *(E. canis),* human monocytic ehrlichiosis *(E. chaffeensis),* tropical pancytopenia

EPIDEMIOLOGY

SPECIES, AGE, SEX

Ehrlichiosis is most commonly seen in dogs; rarely in cats.

GENETICS & BREED PREDISPOSITION

German shepherd dogs have a more fulminant illness, owing to reduced cellular immune response.

RISK FACTORS

E. canis is transmitted by *Rhipicephalus sanguineus* (brown dog tick), whereas *E. chaffeensis* is transmitted by *Amblyomma americanum* (lone star tick) or *Dermacentor variabilis* (American dog tick). *R. sanguineus* is an urban tick capable of completing its entire life cycle indoors (exposure risk when boarding, pet stores, etc.) Therefore, access to wooded areas, outdoor activities, and tick season are risk factors for *E. chaffeensis* infection but not for *E. canis* infection.

CONTAGION & ZOONOSIS

Most *Ehrlichia* spp. may be infectious to humans, but there is no direct dog-to-dog or dog-to-human transmission. Personal protective equipment (gloves and safety glasses) should be used when handling biological samples (inoculation risk).

GEOGRAPHY AND SEASONALITY

E. canis infection has been found in most tropical and subtropical regions in the world, based on distribution of the vector. Because of different disease forms (acute, subacute, and chronic), there is no true seasonality. *E. chaffeensis* has been described predominantly in the United States, with emergence in South Korea, southern China, and Cameroon.

ASSOCIATED CONDITIONS & DISORDERS

Other tickborne diseases (Rocky Mountain spotted fever, cyclic thrombocytopenia, babesiosis, bartonellosis, hepatozoonosis) may occur concurrently.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Acute phase: onset 8-20 days post infection; signs last 2-4 weeks and may resolve spontaneously.
- Subclinical phase: onset 6-9 weeks post infection; clinically inapparent cytopenias
    - The infection may be cleared spontaneously at this time (uncommon) but if not, the chronic phase ensues.
- Chronic phase: onset is weeks to months after infection; signs are variable in severity, ranging from mild illness to a life-threatening syndrome.

HISTORY, CHIEF COMPLAINT

- History may include tick exposure weeks/months earlier; not always recalled by pet owners.
- Overt signs: depression, anorexia, weight loss, ocular or nasal discharge, bleeding tendencies, lameness.
- Clinical signs of the chronic phase may include overt bleeding, cachexia, lameness, ocular, and neurologic abnormalities.

PHYSICAL EXAM FINDINGS

- Fever may be present but is not always detected.
- Joint pain and shifting leg lameness
- Hepatomegaly, splenomegaly, peripheral lymphadenopathy, increased vesicular breath sounds
- Bleeding disorders: cutaneous and/or mucosal petechiae, ecchymoses, unilateral or bilateral epistaxis, melena, retinal hemorrhage, hyphema
- Signs of uveitis: blepharospasm, photophobia, excessive lacrimation, hyperemia of scleral vessels, and decreased intraocular pressure. Blindness due to retinal detachment can occur.
- Neurologic signs: ataxia, seizures, vestibular signs, anisocoria, and hyperesthesia (severe cases)
- Subcutaneous edema due to chronic protein-losing nephropathy (chronic cases) or vasculitis
- Arrhythmias due to vasculitis and myocardial injury may occur in severe cases.
- Mild cases may have unremarkable clinical findings.

ETIOLOGY AND PATHOPHYSIOLOGY

- Ticks acquire the organism by feeding as either larvae or nymphs on infected animals. No transovarial transmission occurs in the tick (i.e., life cycle requires the mammal).
- When an infected tick ingests a blood meal, the organism is transmitted via saliva to the vertebrate host.
- Infection leads to multiplication in mononuclear cells and tissues (spleen, liver, and lymph nodes).
- Infected cells attach to vascular endothelium in lungs, kidneys, joints, myocardium, and meninges, leading to vasculitis and subendothelial tissue infection and the acute phase of disease initially.
- Thrombocytopenia occurs secondary to increased platelet consumption and decreased platelet half-life, as a result of antiplatelet antibodies production, platelet migration-inhibition factor production, and splenic sequestration.
- Dysfunction of remaining platelets (thrombocytopathy) may occur secondary to antiplatelet antibodies binding to platelet receptors.
- Systemic inflammation may occur, with varying degrees of thrombosis, hyperviscosity, and red cell destruction.
- Subclinical phase is a result of ongoing bone marrow effects.
- Those unable to clear the infection in the subclinical phase develop chronic disease with hyperglobulinemia and immune complex formation, as well as bone marrow suppression, possibly leading to pancytopenia.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on the presence of anorexia, fever, lethargy, and/or bleeding tendencies in a dog with tick exposure, hematologic and clinical chemistry abnormalities, and response to therapy. Presumptive diagnosis is often based on specific antibody detection. Definitive diagnosis depends upon visualization of the organisms, microbial DNA amplification and genetic sequencing, or a fourfold change in antibody titers between acute and convalescent samples, but treatment often is indicated in patients showing overt clinical signs of ehrlichiosis before such results are available.

DIFFERENTIAL DIAGNOSIS

- Acute phase is similar to Rocky Mountain spotted fever (see p. 994).
- Chronic disease differentials include immune-mediated diseases, myeloma, lymphoma, hepatozoonosis, malignant histiocytosis, leukemia, myelodysplasia, leptospirosis, bartonellosis, and babesiosis.

INITIAL DATABASE

- CBC, serum biochemistry profile, urinalysis
  - Thrombocytopenia (mild to severe) is the typical finding in all stages of illness, but absence does not rule out ehrlichiosis.
  - Neutropenia, nonregenerative anemia, lymphocytosis (sometimes marked), monocytosis, and eosinophilia may be observed.
  - Hyperglobulinemia is common; polyclonal gammopathy is typical, but in rare cases a monoclonal gammopathy is present.
  - Increase in alanine aminotransferase (ALT) and alkaline phosphatase (ALP) activities.
  - Pathologic proteinuria (e.g., elevated urine protein/creatinine ratio in the absence of urinary tract infection) occurs

secondary to glomerulonephritis.
- Fundic examination: retinal hemorrhages/detachment may be seen.
- Abdominal imaging if splenomegaly/signs of abdominal pain
- Lymph node aspirates if lymphadenopathy
- Arthrocentesis and limb radiography if signs of polyarthritis. Sterile, nonerosive polyarthritis with predominance of nondegenerate neutrophils may occur.
- Bone marrow aspirate if pancytopenia is present
- Cerebrospinal fluid tap if neurologic signs are present
- Antinuclear antibody and Coombs' tests: to help identify primary or secondary immune-mediated disease. Coombs' test may be positive in *Ehrlichia* infection.

ADVANCED OR CONFIRMATORY TESTING

- Buffy coat, blood smear evaluation: rarely identify morulae in mononuclear cells (many false-negative results)
- Serologic titers: IFA or ELISA (antibody tests):
  - Negative results may occur in acute cases. Confirmation with a convalescent titer (2–4 weeks later; ≥fourfold increase) is necessary for definitive diagnosis.
  - Positive results suggest exposure, not infection. Antibody titers can persist from months to more than a year.
  - Antibodies from dogs infected with *E. canis* cross-react with *E. chaffeensis* antigens and occasionally with *E. ewingii* (IFA only) but do not cross-react with *Anaplasma phagocytophilum* antigens.
- PCR amplification: may be applied to tissue or whole blood. It provides definitive diagnosis, since it can differentiate between *A. phagocytophilum*, *A. platys*, *E. canis*, *E. chaffeensis*, *E. ewingii*, and other bacteria from the Anaplasmataceae family. False-negative PCR tests can occur if low numbers of circulating organisms.

TREATMENT

TREATMENT OVERVIEW

- The treatment of choice for both *E.canis* and *E. chaffeensis* infection is doxycycline or tetracycline, with rapid clinical improvement (beginning within 24-48 hours) in the majority of cases. Dogs with slow or partial recovery might be coinfected with other tickborne organisms. There is no consensus whether or not the antibiotic therapy clears these organisms from infected dogs, and chronic subclinical infections may be possible. Some manifestations such as glomerulonephritis may persist after treatment, but progression should be halted.

ACUTE GENERAL TREATMENT

- Clear organism:
  - Doxycycline, 5–10 mg/kg PO or IV q 12 h for 28 days (treatment of choice); *or*
  - Tetracycline, 22 mg/kg PO q 8 h for 21 days (alternative treatment)
  - For puppies under 1 year of age: chloramphenicol, 15-25 mg/kg PO (or IV, SQ) q 8 h for 14-21 days (to avoid discoloration of the teeth)
- Supportive care depends on clinical manifestation (i.e., transfusions for anemia, analgesics for polyarthritis pain).
- The authors do not routinely use corticosteroids for the treatment of ehrlichiosis. Reduction of ehrlichial antigens through appropriate antibiotic therapy should reduce secondary immune-mediated pathology. Despite being controversial, some clinicians have used corticosteroids at immunosuppressive doses (e.g., prednisone, 2–4 mg/kg PO q 24 h during first 2–7 days of acute stage).

CHRONIC TREATMENT

Chronic infections can occur with *E. canis;* however, response to doxycycline after 28 days of treatment is expected.

DRUG INTERACTIONS

- Imidocarb dipropionate or enrofloxacin are not effective against *Ehrlichia canis*.
- Tetracycline derivatives should not be used in the last half of pregnancy. Oral doxycycline should be given with food to avoid GI effects (nausea and vomiting). Tetracycline derivatives should not be given concomitant with oral antacids, cathartics, or other GI products containing cations (aluminum, calcium, magnesium, zinc, or bismuth).

POSSIBLE COMPLICATIONS

- Hemorrhage from severe thrombocytopenia or disseminated intravascular coagulation (DIC)

- Protein-losing glomerular disease
- Blindness associated with retinal hemorrhages and detachment
- Immune-mediated diseases
- Medullary aplasia and persistent pancytopenia
- Sudden death due to organ failure may occur in chronic cases.
- Dogs receiving incomplete or inadequate treatment may enter the subclinical phase.

RECOMMENDED MONITORING

- Resolution of clinical, hematologic, and biochemical abnormalities should be used to assess the response to therapy.
- Antibody titers may persist for months to years despite the absence of infection, so serologic testing is unreliable as a monitoring tool.
- PCR may aid in monitoring the response to treatment: a positive PCR test post treatment would be consistent with a treatment failure or reinfection.

PROGNOSIS AND OUTCOME

- Good prognosis with quick improvement in acute and mild chronic cases. Expect dramatic positive response to doxycycline or tetracycline beginning within 24-48 hours.
- Severely pancytopenic patients with hemorrhagic complications or concurrent infections have a guarded to poor prognosis.

PEARLS & CONSIDERATIONS

COMMENTS

- *E. canis* infection occurs in some cats, with clinical signs resembling acute canine monocytic ehrlichiosis.
- *E. canis* has been detected in at least six sick humans in Venezuela. Human *E. canis* cases have not been described from other countries.
- *E. chaffeensis* is the most frequent *Anaplasma*/*Ehrlichia* infection in humans in the United States, with 1137 cases reported in 2008.
- *E. chaffeensis* may produce similar but less severe signs in dogs than *E. canis*, although as a result of cross-reactivity, the true incidence of *E. chaffeensis* in dogs is poorly defined.

PREVENTION

Adequate tick control is the best prevention.

TECHNICIAN TIPS

- Low platelet numbers might increase bleeding time after blood sample collection.
- Despite a relatively low risk of infection, handling biological samples from animals suspected of *Ehrlichia* spp. or *Anaplasma* spp. infection should always be performed with precautions and with adequate personal protective equipment.

CLIENT EDUCATION

- Infected dogs pose little to no hazard to humans, so long as ticks are well controlled.
- Dogs are sentinels of human exposure to the pathogen in the shared environment; therefore owners should take proper actions to prevent tick bites.

EDITOR: DOUGLASS K. MACINTIRE

Edema, Subcutaneous

BASIC INFORMATION

DEFINITION

Subcutaneous edema is the local or generalized observable swelling from excessive fluid accumulation within the interstitial tissue spaces under the skin. Under normal circumstances, only a small amount of fluid leaks from vessels to form interstitial fluid, which is then removed by lymphatic vessels.

SYNONYMS

Peripheral edema (edema of the paws and legs), anasarca (generalized, massive subcutaneous edema)

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats: any age, either sex

RISK FACTORS

Severe hypoproteinemia (from kidney, liver, or gastrointestinal disease), right-sided heart failure, systemic inflammation/vasculitis, extensive trauma or heat, hereditary or congenital malformation of the lymphatic system

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

Pitting edema versus nonpitting edema

HISTORY, CHIEF COMPLAINT

Limb swelling or a swollen appearance may be historical findings suggestive of subcutaneous edema.

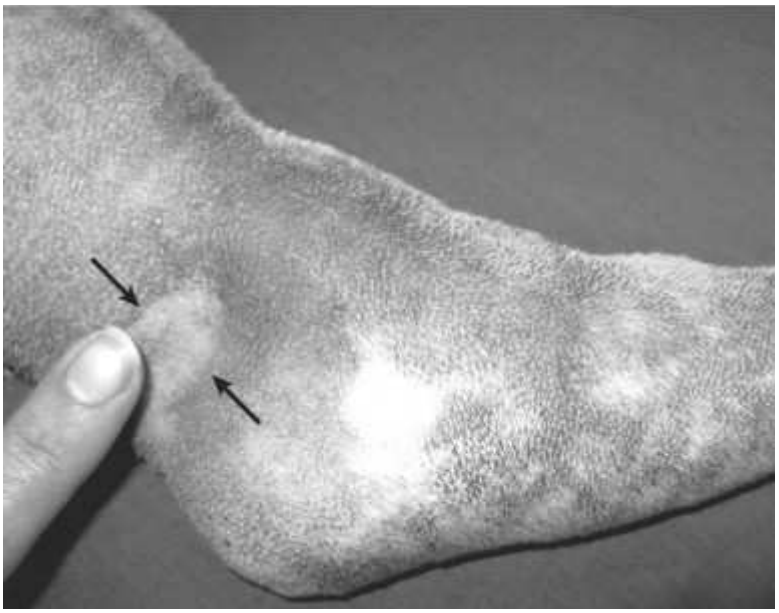
PHYSICAL EXAM FINDINGS

- The subcutaneous tissues appear locally or diffusely swollen.
- The hock with its lateral saphenous vein, the Achilles tendons, and the bony prominence of the mandible are useful to evaluate for subcutaneous edema; these areas are well defined even in obese animals.
    - With edema, these areas are less defined and have a “jelly-like” appearance of the skin.
- Edema is by definition nonpainful and neither very warm nor very cool to the touch unless secondary infection is present.
- Edema tends to accumulate where gravity draws it, where lymphatic obstruction or insufficiency is greatest, or a combination of both. Therefore, the pattern of edema distribution can be variable.
- It may be possible to “pit” edema: digital pressure exerted on edematous skin may leave a depression, or pit, for several seconds after the pressure is released. Pitting edema represents interstitial fluid accumulation, whereas nonpitting edema is formed by intra-cellular swelling (e.g., a wheal). In dogs and cats, pitting edema is more common than nonpitting edema.
- Hyperemia, or the reddening of the subcutaneous tissue due to engorgement of oxygenated blood, indicates an active process causing arteriolar dilation. Congestion, or the cyanotic (“blue-red”) appearance of the subcutaneous tissue, is a passive process that occurs as worsening congestion leads to accumulation of deoxygenated hemoglobin. Capillary bleeding can occur uncommonly as a result of chronic congestion and may appear as petechiae, purpura, ecchymosis, or hematoma.

ETIOLOGY AND PATHOPHYSIOLOGY

- More fluid leaves the capillaries than enters:
    - Increased hydrostatic pressure in vessels
        - Right-sided congestive heart failure
        - Impaired venous flow
        - Iatrogenic fluid overload

    - Decreased plasma oncotic pressure
        - Hypoalbuminemia due to increased loss (protein-losing nephropathy/enteropathy, nephrotic syndrome) or decreased production (cirrhosis, malnutrition)
    - Increased vascular permeability
        - Allergic response causing increased histamine
        - Acute inflammation
        - Burn injury
- Normal volume of interstitial fluid not reabsorbed by the lymphatic system:
    - Lymphatic obstruction (usually localized)
        - Neoplasia
        - Inflammation
        - Trauma



EDEMA, SUBCUTANEOUS Subcutaneous edema in the hindlimb of a dog. In this image, the clinician just removed her index finger after applying digital pressure for several seconds, revealing the depression or pit *(arrows)* that characterizes pitting edema.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Subcutaneous edema can be identified on physical exam (readily if it is very pronounced but less easily if it is mild in degree). The presence of subcutaneous edema warrants assessing the serum albumin concentration and also ruling out heart disease (thoracic radiographs, echocardiogram).

DIFFERENTIAL DIAGNOSIS

When edema affects only one leg, local factors such as neoplasia, trauma, or phlebitis should be considered. Swollen extremities and ventral edema are uncommonly seen with congestive heart failure. In the rare instance (in small animals) where subcutaneous edema is present secondary to congestive heart failure, the edema is usually symmetric in distribution.

INITIAL DATABASE

- CBC: evaluate for hypoalbuminemia, anemia, or inflammation.
- Serum biochemistry profile: evaluate for electrolyte abnormalities.

ADVANCED OR CONFIRMATORY TESTING

Thoracic radiographs, echocardiography, and electrocardiography: evaluate for right-sided congestive heart failure.

TREATMENT

TREATMENT OVERVIEW

The therapeutic goal is to identify the cause and reverse it if possible.

ACUTE AND CHRONIC TREATMENT

- Management of subcutaneous edema is typically nonemergent and is primarily achieved by treatment of the underlying condition while considering specific therapies to restore water balance within the body.
- Patients with decreased oncotic pressure (hypoproteinemia), decreased osmotic balance (anemia), or increased endothelial permeability (inflammation) may benefit from plasma products, hetastarch, or dextran 70 to increase intravascular volume and favor water retention within the vasculature.
- Patients with increased hydrostatic pressure secondary to severe right-sided heart failure can benefit from potent loop diuretics such as furosemide. Furosemide causes increased sodium excretion by the kidneys, with resultant water loss and edema mobilization from the interstitial tissues.
- Trauma, inflammation, or neoplasia causing subcutaneous edema should be addressed primarily.

PROGNOSIS AND OUTCOME 

The prognosis for patients with subcutaneous edema depends on the underlying condition and the ability to treat and resolve this primary disease. Edema due to inflammation or infection, congestive heart failure, or hypoproteinemia can often be successfully managed or resolved. Treatment response for lymphatic obstruction is variable; lymph-edema (see p. 667) can be challenging to manage long term, and there is no curative therapy.

AUTHOR: MANDI SCHMIDT

EDITOR: ETIENNE CÔTÉ

Eclampsia

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Moderate to severe hypocalcemia of the lactating female, most often occurring in the first four weeks postpartum.

SYNONYMS

Lactation tetany, periparturient hypocalcemia, puerperal tetany

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: younger, postparturient bitches
- Cats: rare in queens

GENETICS & BREED PREDISPOSITION

More likely to occur in small-breed dogs, although any lactating bitch may be affected

RISK FACTORS

- Primiparous bitches may be at greater risk.
- Decreased nutrition in the periparturient period as a result of stress or underlying illness.
- Excess dietary calcium during gestation
- Large litter size is thought to be a risk factor.

ASSOCIATED CONDITIONS & DISORDERS

Hypoglycemia can arise secondarily due to energy demands of tetany.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- *Prepartum* eclampsia
- *Intrapartum* eclampsia
- *Postpartum* eclampsia (most common)

HISTORY, CHIEF COMPLAINT

Lactating bitch with signs of aberrant behavior, ataxia, muscle tremors, seizures, and/or tetany

PHYSICAL EXAM FINDINGS

In approximate order of disease progression/severity:

- Anxiety, restlessness, pacing, whining, disinterest in pups
- Pruritus and biting at feet
- Ataxia, staggering, and muscle stiffness
- Panting; respiration eventually becomes labored as the condition progresses.
- Mydriasis and diminished pupillary light reflexes
- Tachycardia or bradycardia
- Muscle tremors, collapse, clonic spasms (tetany), and seizures (musculoskeletal signs are often exaggerated with tactile stimulus).
- Hyperthermia secondary to tetanic muscle contractions

- Arrhythmias: premature ventricular complexes

ETIOLOGY AND PATHOPHYSIOLOGY

- Circulating ionized calcium is depleted due to lactation and fetal development, possibly in conjunction with underlying nutritional imbalance.
- Decreased circulating ionized calcium alters cellular membrane potentials and allows for spontaneous discharge of nerve fibers to induce contraction of skeletal muscles and alteration of central nervous system function.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A presumptive diagnosis (based on history, clinical signs, and physical exam) warrants immediate treatment. Response to therapy is the most reliable diagnostic aid.

DIFFERENTIAL DIAGNOSIS

- Hypocalcemia of alternate origin
- Hypoglycemia (may be concurrent)
- Cerebral edema (possibly secondary in eclampsia ± hypoglycemia)
- Toxin ingestion

INITIAL DATABASE

- Total serum calcium < 6–7 mg/dL (<1.5–1.74 mmol/L) is the characteristic biochemical finding of eclampsia.
    - Calculated ionized calcium < 3.5-4 mg/dL (<0.87-1 mmol/L)

ADVANCED OR CONFIRMATORY TESTING

Blood glucose should be evaluated to rule out hypoglycemia as a primary or secondary contributor to clinical signs.

TREATMENT

TREATMENT OVERVIEW

Treatment is primarily aimed at alleviating clinical signs of hypocalcemia via parenteral calcium therapy while monitoring for bradycardia and/or arrhythmias. Secondary hypoglycemia and hyperthermia must also be addressed in the seizuring animal.

ACUTE GENERAL TREATMENT

- Intravenous (IV) administration of a 10% calcium gluconate or calcium borogluconate solution *slowly*, at a rate of 1-1.5 mL/kg over 10-30 minutes or until resolution of clinical signs.
    - Calcium chloride solutions are not recommended; risk of perivascular corrosive effects if the solution extravasates.
    - Electrocardiographic (ECG) monitoring is warranted during administration (see Recommended Monitoring below).
- IV calcium gluconate administration may be repeated in the event of a relapse; refractory cases should be reevaluated for hypoglycemia.
- The IV dose of calcium gluconate required to resolve clinical signs can be diluted 1:1 in saline for subcutaneous administration in 3 equal doses over 24-48 hours to prevent immediate relapse.
- Severe hyperthermia > 104°F should be controlled with ice packs or alcohol baths (see p. 480).

CHRONIC TREATMENT

- Remove puppies for 24-36 hours to reduce maternal calcium loss through lactation; in the event of recurrence, remove puppies permanently.
- Puppies can be fed milk replacer every other day to decrease lactation demand on the bitch until weaning at age 3 weeks.
- In high-risk cases, lactation can be ceased using a prolactin inhibitor.
    - Cabergoline, 5 mcg/kg PO q 24 h for 7 days

NUTRITION/DIET

- Oral calcium replacement therapy for the bitch is recommended until weaning.
  - 20 mg/kg calcium carbonate PO q 8 h
  - Calcium carbonate antacid tablets available over the counter (e.g., Titralac, Tums) typically contain 500-750 mg calcium carbonate per tablet. See label for exact content.
  - Vitamin D^3 supplementation aids in calcium absorption and homeostasis.
    - Over-the-counter products: 50 IU/kg PO q 24 h

BEHAVIOR/EXERCISE

If puppies are weaned to stop lactation, monitor dam for self-milking (licking own mammary glands, which can induce milk letdown).

DRUG INTERACTIONS

- Avoid tetracyclines or other potential calcium chelators.
- Use of calcium carbonate antacids will affect absorption of oral medications.
  - Administer calcium carbonate at least 1 hour before or after other medications.
  - Consult product labels for potential interactions.

POSSIBLE COMPLICATIONS

Overly rapid or unmonitored IV calcium administration can lead to severe bradycardia, ventricular arrhythmias, hypotension, and death.

RECOMMENDED MONITORING

- Cardiac monitoring by auscultation and/or ECG is required during IV calcium therapy. If severe bradycardia and/or arrhythmias develop, discontinue IV calcium until heart rate and rhythm normalize, then readminister at a decreased rate.
- Rectal temperature should be monitored until hyperthermia has resolved.

PROGNOSIS AND OUTCOME

Prognosis is good to excellent with immediate treatment and subsequent management.

PEARLS & CONSIDERATIONS

COMMENTS

- Treatment should be initiated immediately based on signalment, history, and physical examination.
- Recurrence is possible up to the end of lactation.
- Preventive *prepartum* calcium supplementation is *not* recommended, as it may promote the development of eclampsia.
- Preventative *postpartum* calcium supplementation is recommended, as it may prevent recurrence during a subsequent lactation.
- Hypoglycemia is a common concurrent disorder.

PREVENTION

Bitches should be maintained on a high-quality food during pregnancy.

TECHNICIAN TIPS

Knowing the signs of hypocalcemia (Physical Exam, above) helps technicians quickly identify a patient in need of calcium.

CLIENT EDUCATION

Owners are to be cautioned that affected bitches may develop eclampsia in subsequent litters, and nutritional management and careful attention to early clinical signs are required.

AUTHOR: JONATHAN SPEARS

EDITOR: MICHELLE KUTZLER

Echinococcosis

BASIC INFORMATION

DEFINITION

- Cestode (tapeworm) infection with larval stages (hydatid cysts) that causes hydatid disease, primarily in humans:
  - Cystic echinococcosis is caused by *Echinococcus granulosus*.
  - Alveolar echinococcosis is caused by *E. multilocularis*.
  - Polycystic echinococcosis is caused by *E. vogelii* or *E. oligarthrus*.
- *Hydatid cyst disease* refers to the clinical condition in which intermediate hosts have multiple, often large intraparenchymal cysts containing brood capsules that in turn contain protoscolices in serous fluid.
- When ingested by the canine or feline definitive host, *protoscolices* will develop to adult tapeworms within the host's small intestine.

SYNONYMS

Hydatid disease; hydatidosis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- *E. granulosus* definitive hosts are dogs and other canids; intermediate hosts are sheep, goats, swine, cattle, horses, camels, and humans.
- *E. multilocularis* definitive hosts are foxes and less frequently dogs, cats, coyotes, and wolves. Intermediate hosts are small rodents.
- *E. vogelii* definitive hosts are bush dogs and dogs; intermediate hosts are rodents.
- *E. oligarthrus* definitive hosts are wild felids; rodents are intermediate hosts.

RISK FACTORS

Exposure and ingestion of intermediate hosts (rodents, cattle, sheep) harboring the hydatid cysts

CONTAGION & ZOONOSIS

- Highly zoonotic
- Humans (and other suitable intermediate hosts) become infected by ingestion of eggs from the feces of definitive hosts.
- Once ingested, the organism spreads, and cysts may develop in various organs.

GEOGRAPHY AND SEASONALITY

- *E. granulosus* occurs worldwide; more frequent in rural, grazing areas.
- *E. multilocularis*: northern hemisphere
- *E. vogelii* and *E. oligarthrus*: Central and South America

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Absence of clinical signs (definitive hosts, e.g., dogs and cats)
- Diarrhea (occasionally dogs and cats)
- Hydatid cyst disease (intermediate hosts, e.g., humans, sheep, cattle)

HISTORY, CHIEF COMPLAINT

- Clinical signs of hydatid disease in domesticated animals are uncommon; humans are most commonly affected by disease.
- Intermediate host's signs relate to location and size of cyst and the species of *Echinococcus* infecting the host.

- Definitive hosts with adult tapeworms may have enteritis.

PHYSICAL EXAM FINDINGS

- Generally unremarkable (dogs, cats)
- Adult tapeworms are small, ranging from 1.2-10 mm in length. These tapeworms have a limited number of proglottids (only 3 or 4), and even the gravid (most distal) proglottids would be very difficult to observe grossly.
- Respiratory signs, abdominal distension, and other signs of hydatid cyst disease are not expected in dogs or cats, because they are definitive hosts, not intermediate hosts.

ETIOLOGY AND PATHOPHYSIOLOGY

- *E. granulosus* adults reside in the small intestine of the definitive host (dogs, coyotes, wolves).
- Eggs are passed into the feces where they are ingested by an intermediate host (e.g., cattle, sheep, horses).
- In the intermediate host, the organism invades the small intestine and spreads through the circulatory system, entering organs of predilection. The organism develops into a thick-walled unilocular (single compartment) cyst that gradually enlarges.
    - Typically, liver, lungs, and other organs (central nervous system, bone, heart) are affected.
- Definitive host becomes infected by ingestion of raw hydatid cyst within the visceral organs of intermediate hosts.
- *E. multilocularis* larval growth remains in the proliferative stage, resulting in invasion of surrounding tissues. The liver is primarily affected, with occasional metastasis to the brain and lungs. The organism develops into a thin-walled multilocular (demonstrating many compartments) cyst that easily spreads, thus overtaking the affected organs.
- *E. vogelii* larvae have a predilection for the liver.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The main concern is zoonosis: this is an extremely pathogenic zoonotic parasite, so great care should be taken when handling any feces from a dog suspected of harboring adult *E. granulosus.* The diagnosis is confirmed in tissue (histopathologic analysis of a biopsy or necropsy specimen) or PCR.

DIFFERENTIAL DIAGNOSIS

Other taeniids, to include many tapeworms within the genera *Taenia* and *Multiceps*.

INITIAL DATABASE

Fecal examination may reveal eggs which are identical to other taeniids. Among the three genera (*Echinococcus*, *Taenia*, and *Multiceps*), the eggs of the taeniids are very similar in their structure. Each egg has a centralized portion that demonstrates 6 tiny hooklets. This central portion is surrounded by a striated egg shell that surrounds the egg. Latex gloves should be worn when handling suspect feces, and strict observance of lab biosafety is essential. All materials related to the fecal flotation procedure should be autoclaved prior to disposal. Feces should be disposed of with similar caution.

ADVANCED OR CONFIRMATORY TESTING

- Diagnosis in definitive hosts is by coproantigen or DNA detection.
- Hydatid cysts at necropsy, with accompanying histopathologic examination

TREATMENT

TREATMENT OVERVIEW

Due to the zoonotic nature of this parasite, appropriate anthelminthic therapy treatment is critical for eliminating the adult cestode.

TREATMENT

- Adult stages of the parasite may be treated with praziquantel, 2.5-7.5 mg/kg PO or SQ once.
- Hydatids require surgical removal from humans who serve as intermediate hosts. The thick-walled unilocular cysts of *E. granulosus* are less difficult to remove, but the thin-walled multilocular cysts of *E. multilocularis* are quite invasive and almost

impossible to remove. The organs infected by the hydatid cyst will also affect the prognosis.
- Epsiprantel (Cestex): dogs, 5.5 mg/kg PO once; cats, 2.75 mg/kg PO once. Single doses eliminate *E. multilocularis* in over 99% of animals, but there may be residual worm burdens in some animals.

POSSIBLE COMPLICATIONS

Gastrointestinal adverse effects may be seen with antiparasitics.

RECOMMENDED MONITORING

Regular fecal flotation. Again, use caution when handling suspect feces.

PROGNOSIS AND OUTCOME

- Definitive hosts may have enteritis.
- Prognosis for intermediate hosts, including humans, depends on location of cysts.

PEARLS & CONSIDERATIONS

COMMENTS

Echinococcosis does not cause hydatid cyst disease in definitive hosts such as dogs and cats. Therefore, its interest in small-animal medicine mainly revolves around the risk of zoonosis.

PREVENTION

- Vaccine available for intermediate hosts (sheep and cattle)
- Hygiene, to avoid human acquisition of the infection through fecal-oral contamination from dogs and cats
- Avoid consumption of raw or undercooked meat or viscera by humans, dogs, or cats.

TECHNICIAN TIPS

Think safety—use extreme caution! Due to the extreme pathogenicity of this parasite, all suspect feces should be collected and properly disposed. One cannot simply throw this feces away refuse or wash it down the drain; it should be incinerated.

CLIENT EDUCATION

Eggs can infect humans by contamination via the fecal/oral route: poor hygiene, dog licking anus or perineum and in turn licking the human's face, thus transferring infective eggs to the human's mouth.

AUTHOR: CHARLES M. HENDRIX

EDITOR: DOUGLASS K. MACINTIRE

1ST EDITION AUTHOR: LISA M. TIEBER NIELSON

Frostbite

BASIC INFORMATION

DEFINITION

Tissue damage caused by exposure to cold agents or temperatures; effects may be reversible with rewarming, or may be irreversible due to necrosis

SYNONYM

Hypothermic injury

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Any animal exposed to cold environmental temperatures, especially if the body temperature falls <34°C (<93°F). Young animals outdoors, or those in poor body condition, are at greater risk.
- Affected tissues often include the tail, testicles, and pinnae.

GENETICS AND BREED PREDISPOSITION: Hairless or shorthaired breeds of dogs and cats are predisposed.

RISK FACTORS: Low ambient temperatures

GEOGRAPHY AND SEASONALITY: Winter months in temperate to cold climates

ASSOCIATED CONDITIONS & DISORDERS: Hypothermia

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- History of exposure to cold temperatures or agents.
- Lesions visible to the owner will depend on the time course since the cold injury occurred.
- Animals may be presented for evaluation of acute injury (e.g., hit by car) and white, waxy, frostbitten skin, or injury may not be noticed until later stages when tissue sloughing is occurring.

PHYSICAL EXAM FINDINGS

- Dependent on extent of exposed parts of the body:
  - Mild cold injury to the extremities may go undetected (toe tips, ear tips, tail tip).
  - Very extensive regional cold injury may be evident as a frozen limb or other severe cold injury.
- Acutely affected animals have pale areas of skin that are cool to the touch, with or without freezing of deeper tissues.
- Affected body parts may appear either numb or hyperesthetic, and cyanosis may be evident.
- As the affected area thaws, the tissue may become reddened and swollen:
  - Depending on the extent of affected tissue, the thawing process may be associated with signs of intense pain.
- Affected skin may blister.
- Days after the frostbite has occurred, the tissues may appear shrunken and discolored and may begin to slough if necrotic. Days to weeks after injury, alopecia and sloughing may occur.

ETIOLOGY AND PATHOPHYSIOLOGY

- Cold induces vasoconstriction to affected tissue, as well as endothelial damage and thrombosis.
- Freezing results in crystallization of extracellular fluid that results in a fluid shift from the cell to the extracellular space. The change in electrolyte concentration within the cell then leads to change in cellular proteins.
- Lack of nutrients as well as direct cellular damage results in local tissue damage.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is entirely based on history of exposure to cold and physical examination findings. Patients may be prone to frostbite if debilitated by preexisting disorders (various metabolic or other diseases), and diagnostic testing for these as indicated by history and physical exam is appropriate.

DIFFERENTIAL DIAGNOSIS

Burn injuries may appear similar

INITIAL DATABASE

- None required
- Routine laboratory evaluation if systemic illness
- Imaging and further evaluation as dictated by other disorders or injuries (e.g., if frostbite is caused by cold exposure after the patient was hit by a car)

TREATMENT

TREATMENT OVERVIEW

Prevent further damage to tissues from continued cold exposure or self-trauma and secondary infection by using aseptic technique in handling wounds. Allow damaged tissue to declare itself prior to extensive débridement or amputation.

ACUTE GENERAL TREATMENT

- Prevent further contact with source of cold.
- Ensure further contact with source of cold is prevented.
- Gently apply warm compresses to the area.
    - Do not rub or massage, which could cause further tissue damage.
- Immerse affected areas if possible in warm (102°F-104°F or 39°C-40°C) water.
    - Avoid warmer temperatures that may potentiate tissue injury.
- Dry affected areas: apply light non-compressive bandages if integrity of skin is not intact.
- Administer prophylactic antibiotics if appropriate (e.g., cefazolin, 22 mg/kg IV q 8 h).
- Débride infected wound or sloughing tissue

CHRONIC TREATMENT

- Prevent further exposure of the tissue to freezing, particularly during the healing process.
- Assess necrotic tissue conservatively.
    - Do not amputate or débride large areas early on in the healing process unless signs of infection or sepsis are present.
    - Necrotic tissue can act as a protective covering; often, when necrotic tissue is removed, deeper tissue is healing.
- Tissue damaged by frostbite will likely be more susceptible to cold injury in the future.

POSSIBLE COMPLICATIONS

- Tissue necrosis
- Infection

PROGNOSIS AND OUTCOME

- Variable depending on amount of tissue affected:
    - Extremities (ear tips, toes, tail tip) may slough or require amputation without affecting quality of life or longevity.
    - More substantial frostbite (e.g., limbs) carries a greater risk of systemic complications such as infection and therefore a more guarded prognosis.
- Hypothermia may complicate frostbite and alter the prognosis, depending on severity.

PEARLS & CONSIDERATIONS

PREVENTION

- Avoid exposure to very low ambient temperature.
- Bring animals indoors during periods of low ambient temperature.

TECHNICIAN TIPS

Wear gloves when handling frostbitten regions to reduce the risk of infecting the patient.

AUTHOR: GEOFF HEFFNER

EDITOR: ELIZABETH ROZANSKI

Fractures, Abnormal Healing

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Delayed union: bone healing that is slower than expected
- Nonunion: failure of a fracture to heal or a fracture in which the fractured ends have stopped healing
- Malunion: fracture healing causing abnormal bone/limb alignment or function

EPIDEMIOLOGY

SPECIES, AGE, SEX: Older patients may take longer to heal.

GENETICS & BREED PREDISPOSITION

- Increased incidence of avascular nonunion with radius and ulna fractures in toy breed dogs
- Feline tibial fractures may be at greater risk of nonunions than those in dogs.

CLINICAL PRESENTATION

HISTORY/CHIEF COMPLAINT

- Continued lameness after fracture stabilization
- Abnormal limb angulation
- Decreased muscle mass of the affected limb

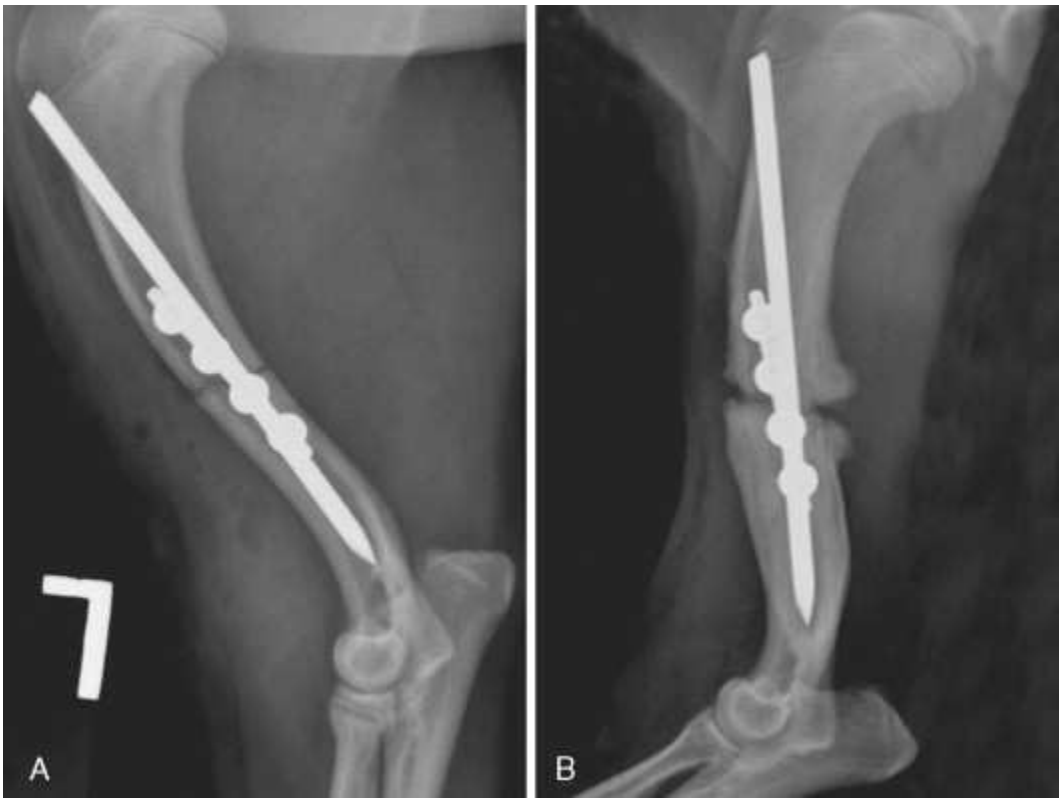
PHYSICAL EXAM FINDINGS

- Lameness
- Muscle atrophy
- Crepitus or obvious instability of the affected bone
- Palpably excessive callus formation in the face of physical instability
- Limited range of motion of the affected limb
- Discomfort on limb manipulation
    - Most animals with delayed union or nonunion experience only a moderate level of discomfort (worse with infection or sudden change in implant stability).
    - Draining tracts or warmth/evidence of inflammation over the fracture site possible with implant-associated osteomyelitis

ETIOLOGY AND PATHOPHYSIOLOGY

- Many factors affect fracture healing:
    - Fracture environment, patient's ability to heal, and veterinary decisions about case management
    - Other factors that can cause abnormal fracture healing:
        - Fracture site infection
        - Excessive fragmentation or bone loss results from open fractures where bone fragments are lost or from inappropriate surgical intervention when bone fragments are discarded or lost.
        - Inadequate fracture stabilization or immobilization
        - Poor vascular supply to the fracture site caused by the initial trauma, excessive or inappropriate surgical manipulation, or inappropriate selection of surgical implants
        - Inadequate fracture reduction and interposition of soft tissue in the fracture gap
        - Inappropriate or inadequate implant selection or application
- Fracture site stability is vital to decrease the risk of delayed union or fracture nonunion.
    - Motion at the fracture site increases interfragmentary strain, resulting in decreased healing.
- Other factors that may influence normal bone healing include:
    - Polytrauma
    - Metabolic diseases
- Lack of radiographic evidence supportive of bone healing (blurring of fracture lines, increased fracture gap opacity, callus

formation)
- Nuclear scintigraphy can be used to evaluate the fracture site for activity.



FRACTURES, ABNORMAL HEALING A,Midshaft humeral fracture following surgical stabilization. **B,** Same fracture at 8 weeks reexamination. The radiographic interpretation is a delayed union. There is a moderate amount of callus formation, a widening of the fracture gap, and increased intramedullary opacity. If the radiographic appearance is the same at 12-16 weeks, the diagnosis is changed to a nonunion.

(Courtesy Dr. John Hathcock, Auburn University.)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- Diagnosis of a delayed union or nonunion requires a complete history and is based on a quantitative judgment of radiographic evidence of healing.
- Clinical findings include decreased limb usage, sudden changes in limb usage, and increased bone pain.
  - Fracture stability is unaffected unless there is a failure of implants.
- Delayed unions and nonunions are normally identified during the routine follow-up examinations for fracture repair.
- Malunions may be present anytime.
  - Fracture malunion may involve animals that have changed owners, recently been adopted, or found as strays.
  - In some case, malunions may cause an idiopathic lameness.

FRACTURES, ABNORMAL HEALING A, Lateral radiograph of a comminuted femur fracture. **B,** Fracture healed as a malunion. Note lack of long-bone alignment and excessive callus formation. Opacity and smooth surface of fracture callus indicate a chronic malunion.

(Courtesy Dr. John Hathcock, Auburn University.)

DIFFERENTIAL DIAGNOSES

- Nonunions can be categorized as either viable or nonviable based on clinical signs and radiography of the fracture.
- Viable (active) nonunions are associated with nonbridging callus but still have potential to achieve bone union.
- With viable nonunions, the biological environment is generally adequate for fracture healing, and union is achieved by neutralization of uncontrolled fracture forces.
- Nonviable nonunions have minimal or no callus formation. There may be an increased fracture gap width or increased radiolucency at the fracture site.
- Nonviable nonunions are less common. It is more difficult to achieve clinical union in these patients.
- Some nonunions may form a pseudoarthrosis as the fracture ends stop trying to achieve osseous union and instead form a false joint between the fragments.
    - A pseudoarthrosis is caused by instability at the fracture site.
    - A true pseudoarthrosis may develop a true joint space and synovial cartilage within the space.
- Differential diagnoses for malunions include:
    - Congenital or breed-associated bone malformations
    - Abnormal growth patterns of bones due to soft-tissue abnormalities
    - Other osteoproliferative diseases or neoplasia should be considered when bone malformations are seen without history of previous fracture.

INITIAL DATABASE

Radiographs:

- Routine reexamination and radiographic evaluation is important to monitor all fracture healing.
- Radiographic interpretation indicates lack of progression or no bony healing over a period of months. This interpretation must be done with the understanding that animals of various ages will differ in healing time for clinical union.
    - Most young, skeletally immature animals demonstrate clinical union in less than 12 weeks. Older animals should have radiographic union by 4-6 months.
    - The time to union will also be influenced by the type of fracture fixation used to stabilize the fracture. Less rigid implants (e.g., intermedullary pins) normally have greater callus formation and are radiographically healed sooner than more rigid types of fixation (e.g., dynamic compression plate DCP).
- An appropriate radiographic schedule would be postoperative films 7-10 days to access fracture and implant stability, 30 days for progression, and 60 days to begin to evaluate for fracture union.
    - Good-quality, orthogonal views are essential to accurately evaluate the fracture.
    - Radiographic union may lag behind clinical union.
- Radiographs will contain evidence of malalignment of fracture fragments which may lead to malunion.

ADVANCED OR CONFIRMATORY TESTING

- Scintigraphy can be used to evaluate the fracture site for activity.
- Other advanced imaging techniques, such as CT or MRI, may aid in making the diagnosis and in monitoring healing.

TREATMENT

TREATMENT OVERVIEW

The goal of treatment for delayed union or nonunion is to achieve fracture union. This requires diagnosis and understanding of the reasons causing impaired fracture healing.

ACUTE AND CHRONIC TREATMENT

- Treatment for a *delayed union*is aimed at augmenting or continuing the original therapeutic plan rather than striking off in an entirely new direction.
    - The exception to this would be if the original plan was completely inadequate (e.g., external coaptation) for the fracture type.
    - If implant stability and blood supply to the fracture site are adequate (i.e., a delayed union), then patience and regular radiographic monitoring are warranted.
    - If the implants are stable but a poor biological environment exists, healing is promoted by bone grafting.
- Treatment for a *nonunion*requires the elimination of those factors that negatively affect healing and replacing Fractures, Abnormal Healing them with factors that would promote healing.
    - Goal is to alter the local fracture environment to promote healing of the fracture.
    - Identify the reason(s) for the nonunion:
        - Patient problems are uncommon as a cause for nonunion
            - Revision surgery
        - Correct implant problems:
            - Remove loose or broken plates, additional implants are needed for fracture stabilization
        - Improve fracture environment
            - Débridement of the fracture ends, removal of sequestra, addition of cancellous bone graft or other substances to promote bone healing (e.g., bone morphogenic protein, demineralized bone matrix)
            - Removal of excessive callus is not required but may allow for better plate contouring. Done with caution, since excessive débridement may further delay bone healing.
        - Atrophic nonunion will require resection of the fracture ends. This will shorten the limb length but should provide better fracture apposition and allow for compression across the fracture site. It will also expose adjacent medullary cavity to promote the in growth of vascular supply and mesenchymal cells.
- Important considerations for nonunions:
    - Bone grafting is critical for successful treatment of nonunions to fill in defects, promote osteogenesis, and hasten healing time.
    - Rigid fixation is essential
        - Stabilization with DCP plate is considered to be the fixation method of choice; plate/rod combination or interlocking nail may be alternative techniques.
        - Circular and linear fixators should be used by experienced surgeons for treatment of nonunions.
            - These can be used to promote distraction osteogenesis.
            - Open wound management may be required in patients that have traumatic injury or infected fracture sites.
    - Wound infections are treated based on culture and susceptibility testing.
    - Aggressive physical therapy is appropriate for the recovery period.

- Prognosis for eventually achieving fracture union is generally good, with exception of toy breeds.
- Many *malunions*don't require treatment. In cases where treatment is appropriate, practitioners should consider referral to an orthopedic specialist. Surgical restoration of malunions are complicated and difficult procedures.
- Use of corticosteroids may have a negative effect on bone healing.
- Cisplatin has been shown to effect bone healing, but these effects were not considered to be clinically relevant.

POSSIBLE COMPLICATIONS

- Intervention does have the potential to create further complication by continued selection of inappropriate implants, surgical destruction of a positive biological environment, surgical planning, or bacterial contamination of the fracture site.
- Complications (pain, donor-site infection, decreased limb use, donor-site fracture, inadvertent soft-tissue or neurologic damage, etc.) can rarely occur during bone graft harvesting.

RECOMMENDED MONITORING

- Postoperative care instructions require communication between the surgeon(s) and owner. There needs to be a clear understanding of expectations and follow-up requirements.
- All recommendations should be clearly written for owners.
- Additional fracture stabilization or increased restrictions on the animal's activity level may be required.

PROGNOSIS AND OUTCOME

- For delayed unions, the prognosis is generally good if the underlying conditions causing the delay in healing can be resolved.
- Nonunions have a more guarded prognosis for healing, especially in toy breeds.
- Malunions have a varied prognosis.
    - If the limb is functional but shortened, the animal will likely adapt to this by decreasing joint angles to compensate.
    - If the limb function is impaired, reconstructive procedures may be required to permit normal ambulation.
    - If joint angles are compromised by the malunion, the joint is prone to develop degenerative joint disease and osteoarthritis.

PEARLS & CONSIDERATIONS

COMMENTS

Delayed unions and nonunions are normally associated with poor decision making or technical failures on the part of the surgeon. Patient factors and owner compliance are less common as a reason for nonunions.

CLIENT EDUCATION

- Clients need to understand they are an important part of this process from the beginning.
- Owner compliance with postoperative instructions for exercise restriction, follow-up examinations, appropriate physical therapy, and consistent administration of all medications is critical to achieving a successful outcome.
- Owners of animals with a fracture malunion must understand restorative orthopedic procedures are not always effective, and complications can arise that affect bone healing or limb function.

Fractures of the Tibia and Fibula

BASIC INFORMATION

DEFINITION

Fractures of the tibia and fibula account for 20% of long-bone fractures and include avulsion of the tibial tuberosity, separation of the proximal or distal tibial physis, tibial shaft fractures, and fractures of the medial or lateral malleolus of the tibia.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Tuberosity avulsions and physeal fractures occur in immature animals.

RISK FACTORS

- Direct trauma
- Indirect trauma from muscle contraction (avulsion fractures)
- Torsional athletic injuries
- Bone tumors or metabolic bone disease

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Acute lameness, usually secondary to trauma

PHYSICAL EXAM FINDINGS

- Pain, swelling, and crepitus at the fracture site
- Stifle joint effusion with proximal physeal and tuberosity avulsion fractures
- Tarsocrural (hock) instability due to medial or lateral malleolar fractures

ETIOLOGY AND PATHOPHYSIOLOGY

- Because of sparse soft-tissue coverage, tibial fractures are often open.
- Most fibular fractures occur with tibial fractures and are not repaired unless stability of the stifle or hock is compromised.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

History and physical examination will identify most tibial and fibular fractures. Radiographs are used to confirm the diagnosis and determine the best method for repair.

DIFFERENTIAL DIAGNOSIS

- Osteochondrosis of the tibial tuberosity
- Primary or metastatic bone neoplasia
- Stifle or hock luxation

INITIAL DATABASE

- Craniocaudal and lateral radiographs, including both the stifle and hock
- Radiographs of the contralateral leg to help differentiate traumatic physeal separation from the normal appearance of an open physis (growth plate) in immature animals
- Stress radiography (general anesthesia) if a nondisplaced malleolar fracture or collateral ligament injury is suspected
- CBC, serum chemistry panel, and urinalysis based on patient stability and American Society of Anesthesiologists patient classification (see p. 1372).

TREATMENT

TREATMENT OVERVIEW

Fracture stabilization for rapid bone healing and early return to normal ambulation, without compromising bone growth

ACUTE GENERAL TREATMENT

- Nonsurgical treatment (if patient will tolerate splinting and exercise restriction; see p. 1336):
  - External coaptation (limb splinting) is used for minimally displaced, stable tibial physeal fractures. For adequate immobilization, the splint/cast must extend above the distal femur.
  - Minimally displaced tibial shaft fractures may be treated with external casting or splinting, especially if the fibula is intact and can act as an internal splint.
  - Incomplete or nondisplaced malleolar fractures usually heal with external splinting.
- Surgical treatment:
  - Tibial tuberosity avulsions are treated with a tension-band wire technique.
  - Displaced or unstable proximal tibial shaft or physeal fractures are treated with small cross pins, cancellous bone screws, or a small buttress plate.
  - Proximal fibular fractures are stabilized with a bone screw or tension-band band wire technique to preserve the insertion of the lateral collateral ligament.
  - For multiple or complex tibial shaft fractures, or for large and active dogs requiring more rigid support, treatments include intramedullary pinning, interlocking nails, bone plates, and external fixators.
  - In highly comminuted shaft fractures, rigid fixation (e.g., bone plating) is used for spanning the fracture site and providing spatial alignment of the fracture ends without disturbing their soft-tissue attachments (biological osteosynthesis). This preserves the vascular supply to the fracture bed and fosters new bone growth.
  - Displaced or unstable malleolar fractures require accurate fixation with a cancellous screw, two small cross pins, or a tension-band wire technique.

CHRONIC TREATMENT

- Casts and splints used in immature animals will require frequent monitoring and adjustment as the patient grows. They are removed once radiographic signs of healing are evident.
  - Usually 6-12 weeks depending on patient age
  - Younger patients heal more quickly.
  - Exercise restriction should be continued another 3-4 weeks.
- Bone plates are removed after bone union (5-12 months) in patients with discomfort or cold intolerance.
- Intramedullary pins are removed after healing to prevent later damage to the stifle articular cartilage.
- Implants used for stabilizing physeal fractures are removed after healing to avoid premature physeal closure.

POSSIBLE COMPLICATIONS

- Delayed union or nonunion
- Patellar luxation following poorly reduced tibial tuberosity avulsion fractures
- Degenerative joint disease (intraarticular fractures or implants)
- Osteomyelitis (open or highly comminuted fractures, or poor surgical asepsis)
- Growth disturbances causing limb shortening or angular limb deformity

RECOMMENDED MONITORING

Regular physical and radiographic examinations until clinical recovery (see p. 417)

PROGNOSIS AND OUTCOME

Physeal, simple shaft, and malleolar fractures in young, healthy patients heal by 1-3 months. Complex injuries in older patients heal more slowly, with increased risk of complications.

PEARLS & CONSIDERATIONS

COMMENTS

To avoid iatrogenic femoral condyle, cruciate ligament, or meniscal damage, nor-mograde intramedullary pinning of the tibia is preferred over retrograde pinning.

Fractures of the Spine/Luxations of the Spine

BASIC INFORMATION

DEFINITION

Well-recognized disorders primarily due to trauma and causing spinal instability, spinal cord damage, or spinal nerve damage

EPIDEMIOLOGY

SPECIES, AGE, SEX: Any dog or cat but most commonly younger animals

RISK FACTORS: Trauma; focal or diffuse bone demineralization due to vertebral column neoplasia (primary or secondary) infection, chronic phosphorus and calcium imbalances, osteoporosis, nutritional secondary hyperparathyroidism

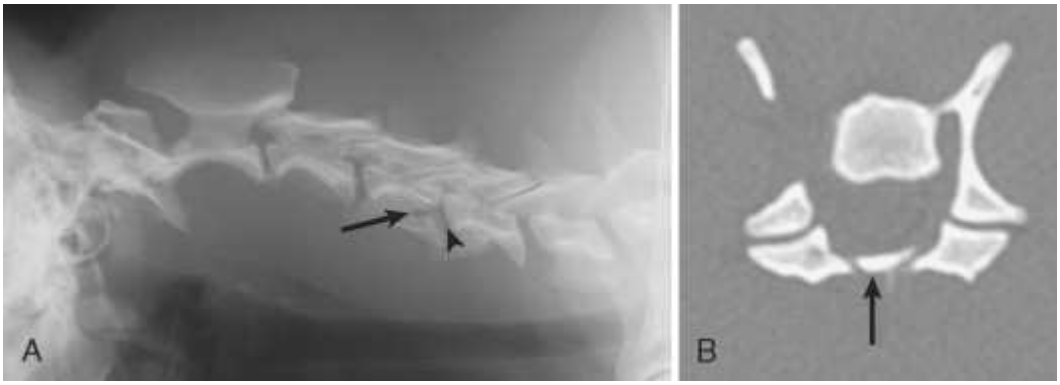
CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Trauma (most commonly vehicular trauma, less frequently falls, bite, and gunshot wounds)
- Spinal pain, swelling, or deformity
- Weakness or inability to stand/walk

PHYSICAL EXAM FINDINGS

- Signs of hypovolemic/hypotensive shock in acute trauma patients
- Guarding of neck, arched back, spinal hyperpathia and/or deformation
- Crepitus, excessive spinal movement in unstable fractures
- Neurologic deficits depend on localization and severity of lesion (proprioceptive, motor, or sensory deficits); monoparesis, paraparesis, or tetraparesis; upper motor neuron (UMN) or lower motor neuron (LMN) signs; loss of central recognition of pain; are-flexia; ipsilateral Horner's syndrome; enlarged UMN or LMN bladder.
- Spinal reflexes for fractures involving spinal cord segments:
  - C1-C5: UMN to the front and UMN to the hind limbs
  - C6-T2: LMN to the front and UMN to the hind limbs
  - T3-L3: Normoreflexia to the front and UMN to the hind limbs
  - L4-S3: Normoreflexia to the front and LMN to the hind limbs



FRACTURES OF THE SPINE/LUXATIONS OF THE SPINE Radiograph of canine cervical spine, lateral view **(A)** showing an oblique C4 vertebral body fracture through caudal endplate *(arrow),*with ventral displacement. Intervertebral disk space at C4-C5 is collapsed *(arrowhead).*CT of C4 vertebra, transverse view (**B**; dorsal is at the bottom of the image) showing a laminar fragment compressing the spinal cord *(arrow).* This lesion could not be detected with cervical radiographs.

ETIOLOGY AND PATHOPHYSIOLOGY

- Traumatic vertebral fractures result from forces causing spinal hyperextension, hyperflexion, compression, and/or rotation.
- Fractures occur most commonly at the craniocervical, cervicothoracic, thoracolumbar, and lumbosacral junctions.

- A decrease in spinal canal diameter may cause mechanical injury to nervous tissue.
- Secondary pathophysiologic events include ischemia, hemorrhage, alteration in blood flow to the spinal cord, and edema. These secondary effects are often more harmful than the initial mechanical injury.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is most commonly suspected based on the history of trauma associated with spinal hyperpathia and/or deformation and/or neurologic deficits associated with myelopathy; confirmation requires diagnostic imaging (spinal radiography, CT, and/or MRI).

DIFFERENTIAL DIAGNOSIS

Intervertebral disk disease, meningomyelitis, diskospondylitis, vertebral osteomyelitis, congenital malformations, spinal neoplasia

INITIAL DATABASE

- CBC, serum chemistry, urinalysis, thoracic and abdominal radiographs: generally unremarkable
- Spinal survey radiographs to detect discontinuity and fracture lines of vertebral column, malalignment of intervertebral space, and/or articular facets
- In cooperative patients, initial radiographs could be taken without sedation or anesthesia.

ADVANCED OR CONFIRMATORY TESTING

- Spinal radiographs of anesthetized, stable patients permit more accurate positioning and characterization of lesions (e.g., for surgical planning). Care must be taken to avoid iatrogenic exacerbation of injury when handling the anesthetized patient.
- CT or myelogram to exclude compression of spinal cord by herniated disk material or bone fragments
- MRI: superior for soft tissue (e.g., spinal cord)

TREATMENT

TREATMENT OVERVIEW

Initial treatment frequently requires stabilization of patients in shock. External coaptation may be needed for temporary and definitive fracture stabilization; pain management and physical rehabilitation are critical for recovery. Evaluation by a neurologic or orthopedic specialist is recommended.

ACUTE GENERAL TREATMENT

- Initial medical management:
  - Shock treatment in trauma patients
  - Tape thoracolumbar fracture patients to rigid board, and apply neck brace to patients with cervical fractures, to minimize further spinal cord damage. Sedate fractious or agitated patients.
  - Methylprednisolone sodium succinate: 30 mg/kg bodyweight once IV
  - Pain management with opiates or nonsteroidal antiinflammatory drugs
- Definitive treatment:
  - Decision of nonsurgical (strict confinement, neck or back brace, and pain management) versus surgical management (surgical spinal cord and nerve-root decompression, fracture reduction, and subsequent stabilization with implants) is based on initial neurologic status, serial reevaluations, spinal stability, and presence of concurrent injuries.
  - Unstable injuries result from lamina, pedicle, dorsal spinous process, and articular facet fractures and supra-spinous/interspinous ligament tears.
  - Stable injuries result from disk protrusion, ventral longitudinal ligament rupture, avulsion of ventral vertebral body.
- Nonsurgical management for patients with mild neurologic signs (pain, proprioceptive and motor deficits) and/or stable fractures that respond to medical management
- Surgery for patients with more severe neurologic signs (uncontrollable pain, minimal motor function, paresis or plegia), with unstable fractures or lesions not improving with medical management
  - Stabilization with internal implants: pins, wires, plates, or screws
  - Methylmethacrylate can be used for solidifying implants.
  - External fixators have been used less frequently.

CHRONIC TREATMENT

- Supportive care: appropriate bedding with traction for patients, bladder expressions in patients without bladder control
- Wheelchairs for patients with loss of hind limb function

NUTRITION/DIET

- Food and water needs to be placed near immobilized patients.
- Hand feeding in upright position for tetraplegic patients.

BEHAVIOR/EXERCISE

- Strict cage rest and short leash walks until radiographic evidence of healing
- Physical rehabilitation: assisted standing and walking, aquatherapy, gait and proprioceptive training

DRUG INTERACTIONS

Do not give steroidal and nonsteroidal antiinflammatory medications simultaneously.

POSSIBLE COMPLICATIONS

- Respiratory arrest due to cervical fractures
- Hemorrhage
- Neurologic deterioration
- Myelomalacia
- Infection
- Implant failure

RECOMMENDED MONITORING

- Serial neurologic evaluations
- Respiratory monitoring with cervical fractures and trauma patients

PROGNOSIS AND OUTCOME 

- Patients with pain sensation: good prognosis for functional recovery
- Patients with loss of pain sensation: fair to guarded prognosis
- Severed spinal cord or areflexia: grave prognosis
- Perioperative mortality for surgical stabilization of cervical vertebral fractures is up to 36%. Nonsurgical treatment often provides reasonable outcome.

PEARLS & CONSIDERATIONS 

COMMENTS

- Up to 20% of patients with traumatic spinal fractures have a second fracture.
- Radiographs may not reflect maximal spinal displacement. Therefore, neurologic evaluation is often more helpful than radiographic evaluation for prognosis.
- Radiographs have moderate sensitivity for spinal fractures and subluxations and low negative predictive values for canal narrowing or fragments within canal.

CLIENT EDUCATION

Care for paralyzed patients is laborious. It can take months until improvement is observed, and return to function cannot be guaranteed.

Fractures of the Scapula

BASIC INFORMATION

DEFINITION

Scapular fractures involve the spine, body, neck, or glenoid regions of the bone.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats of either sex and any age

RISK FACTORS: Trauma to the proximal aspect of the forelimb

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Forelimb trauma secondary to motor vehicle/firearm accidents, falls, or fighting

PHYSICAL EXAM FINDINGS: Variable degree of lameness. Swelling, bruising, open wounds around scapula. Pain during palpation of shoulder joint.

ETIOLOGY AND PATHOPHYSIOLOGY

- Uncommon fractures representing 0.5%-2.5% of all fractures treated at referral hospitals
- Can be associated with regional injury to cervicothoracic spine, thoracic structures (pulmonary contusions, pneumothorax), and brachial plexus
- Extensive medial and lateral musculature provide soft-tissue support and extraosseous vascularity to fractured bone segments.
- Fractures are classified based on location: body, spine, neck, and glenoid *or*stable/unstable extraarticular versus intraarticular lesions.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Radiography is critical in establishing a diagnosis.

DIFFERENTIAL DIAGNOSIS

- Shoulder luxation
- Dorsal displacement of the scapula

INITIAL DATABASE

- Mediolateral and caudocranial radiographic projections of proximal aspect of limb
- CBC and serum chemistry panel based on American Society of Anesthesiologists patient classification (see p. 1372)
- Electrocardiogram and thoracic radiography

ADVANCED OR CONFIRMATORY TESTING

Distoproximal, axial radiographic projection with limb pulled caudally delineates occult lesions.

TREATMENT

TREATMENT OVERVIEW

Treatment goals are fracture stabilization for bone healing and maintenance of glenoid (joint) congruency.

ACUTE GENERAL TREATMENT

- Minimally displaced, nonarticular fractures can be stabilized for 1 month with external bandage support such as a Velpeau sling or spica splint (see p. 1336).
- Severely displaced, malaligned, nonarticular, or glenoid (joint) lesions require internal support with implants.
- Spine or body fractures are stabilized with orthopedic wire or bone plate/screws.
- Neck fractures are stabilized with small pins or bone plate/screws.
- Glenoid fractures require alignment of joint surface and are stabilized with screws or pins.
- Avulsions of the acromion process or supraglenoid tubercle require tension-band wiring to counteract distraction by the deltoideus and biceps muscles, respectively.

CHRONIC TREATMENT

- Bandage support for 4-6 weeks for comminuted lesions and tenuous fixations
- Controlled ambulation and passive flexion/extension exercises to maintain muscle tone and joint motion for 6 weeks until radiography confirms bone healing

POSSIBLE COMPLICATIONS

- Suprascapular nerve damage with neck fracture or surgical repair
- Malalignment of fractured bone segments
- Degenerative joint disease with glenoid fractures
- Infection
- Implant failure

RECOMMENDED MONITORING

- Lameness evaluation 1-3 months after injury and treatment
- Radiography at 6-10 weeks to evaluate fracture healing

PROGNOSIS AND OUTCOME

- Based on severity of injury
- Good to excellent for nonarticular lesions

PEARLS & CONSIDERATIONS

COMMENTS

- Scapular fractures can be missed if lameness is mild or ambulation is not evaluated at hospital admission (e.g., patient is carried in).
- Fractures are often identified during thoracic radiography of trauma patients.
- Suprascapular nerve damage is characterized by atrophy of supraspinatus and infraspinatus muscles.
- Scapular fractures tend to heal well because of abundant periosseous vascularity and cancellous bone supply distally.

AUTHOR & EDITOR: JOSEPH HARARI

Fractures of the Radius and Ulna

BASIC INFORMATION

DEFINITION

Fractures of the radius involve the head, shaft, or medial styloid process; fractures of the ulna involve the olecranon, shaft, or lateral styloid process.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs and cats of either sex or any age

RISK FACTORS: Forelimb trauma

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Trauma from motor vehicle/firearm accidents, falls, and fights causing forelimb lameness

PHYSICAL EXAM FINDINGS: Variable degrees of lameness, soft-tissue swelling, bruising, and open wounds associated with an antebrachial injury

ETIOLOGY AND PATHOPHYSIOLOGY

- Nearly 20% of all fractures in dogs and cats involve the radius and ulna.
- The radius is the primary weight-bearing bone and is the most often stabilized; conversely, ulnar fractures can realign during repair of the radius and will heal in situ.
- The radius and ulna are a paired bone system connected by annular, collateral, and interosseous ligaments. Therefore growth-plate trauma and disturbed growth in either bone will cause a forelimb deformation (see Angular Limb Deformities, p. 78).
- Diminished vascularity in the distal aspect of the bones in small and toy breeds will cause impaired bone healing.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

In most cases, the diagnosis is grossly obvious on physical exam. Radiographs are confirmatory and help triage the fracture for optimal treatment.

DIFFERENTIAL DIAGNOSIS

- Elbow joint luxations
- Humeral condyle fractures
- Carpal luxations and fractures
- Radial nerve or brachial plexus injury

INITIAL DATABASE

- CBC, chemistry panel, electrocardiogram, thoracic radiography based on patient's American Society of Anesthesiologists patient classification (see p. 1372)
- Standard craniocaudal and mediolateral radiographic projections of forelimb

TREATMENT

TREATMENT OVERVIEW

- Initial external bandage and caudal splintage support are useful in reducing patient morbidity.
- Goals of treatment are:
    - Anatomic or functional realignment of fractures to maintain proximal and distal joint (elbow and carpus) congruency and parallelism
    - Tension-band stabilization (pins, wires, or bone plate/screws) of olecranon fractures to neutralize distraction by the triceps muscles
    - Tension-band pinning/wiring or screw fixation of styloid process fractures to provide collateral ligament support

ACUTE GENERAL TREATMENT

- First aid: external heavy bandage support to limit soft-tissue swelling, reduce bone fragment motion, provide limb support, and cover open wounds
- Lavage, débridement, and deep microbial culture and sensitivity assay of open, contaminated lesions
- Antibiotic (therapeutic or prophylactic), analgesic, and nonsteroidal antiinflammatory therapies as indicated
- Radial shaft fractures are stabilized with bone plate/screws applied cranially, or external skeletal fixation (ESF) with percutaneous pins applied mediolaterally (type 2) or angled craniocaudally (type 1b).
- Fresh autogenous cancellous graft tissue or commercially available allo-graft should be used for enhancing fracture healing (see p. 1212).
- Severely displaced ulnar fractures in large dogs can be stabilized with an intramedullary pin or bone plate/screws.
- Proximal ulnar fracture(s) with cranial displacement of the radial head (Monteggia fracture) requires reduction and stabilization of the bones with screws or small pins and suturing of the annular ligament.
- Casting of radius/ulnar fractures can only be recommended for minimally displaced, stable lesions in young, non–small-breed dogs.

CHRONIC TREATMENT

After surgical intervention: bandage support, sometimes with caudal splintage, and controlled exercise until radiographic and clinical evidence of bone union

POSSIBLE COMPLICATIONS

- Implant failure, stress protection (osteopenia), and cold conduction with the use of bone plate and screws for stabilization of radial fractures
- Pin tract sepsis and instability with ESF pins and frames
- Poor healing of distal radial and ulnar fractures in small, toy breeds
- Nonunion, delayed union, or malunion secondary to intramedullary (radial) pinning

RECOMMENDED MONITORING

Clinical and radiographic evaluations 4-6 and 10-12 weeks after surgery (see p. 417)

PROGNOSIS AND OUTCOME

- Bone plates/screws and ESF yield the most consistent clinical recoveries and return of limb functions.
- Casts are effective for minimally displaced fractures in young, healthy patients.
- Intramedullary pinning of the radius causes malunions and carpal joint damage and is rarely indicated.

PEARLS & CONSIDERATIONS

COMMENTS

- Irreparable proximal or distal lesions of the radius and ulna may require arthrodesis of the adjacent joint (elbow or carpus) to salvage the limb.
- ESF can be used in a minimally invasive or closed approach to preserve the soft tissues during a “biological” surgical approach.
- Patients with ESF require more intensive postoperative care than those treated with a bone plate/screws.
- Plate removal is infrequently required after bone union in dogs that are lame due to cold conduction or have radiographic evidence of osteopenia under the implant.
- Toy breed dogs with distal radial/ulnar fractures often have unsatisfactory healing without surgical intervention (i.e., plating).

AUTHOR & EDITOR: JOSEPH HARARI

Fractures of the Pelvis

BASIC INFORMATION

DEFINITION

Pelvic fractures include ilial, ischial, pubic, and acetabular fractures; sacroiliac luxation and sacral fractures are also often included.

EPIDEMIOLOGY

SPECIES/AGE/SEX

Active, outdoor, sexually intact, roaming animals are most likely to be injured by motor vehicles. Dogs lying in driveways may be inadvertently run over.

RISK FACTORS

- Motor vehicle trauma and falling in juries (e.g., high-rise apartment buildings)
- Also can occur in racing dogs (greyhounds) as a spontaneous acetabular fracture

ASSOCIATED CONDITIONS & DISORDERS: Multisystemic polytrauma, especially urologic and neurologic

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Blunt force trauma in pets
- Racing injury (acetabular fracture) in greyhounds
- Occasional penetrating injuries (e.g., gunshot wounds)

HISTORY, CHIEF COMPLAINT: Severe hind limb trauma from motor vehicle accident or fall, inability to walk with one or both hind limbs pain

PHYSICAL EXAM FINDINGS

- Lameness in one or both pelvic limbs; possibly nonambulatory patient
- Palpable crepitus and/or pain on manipulation of leg(s)
- Palpable deformity of the pelvic canal during rectal examination
- Contusion (bruising) of skin overlying site(s) of injury

ETIOLOGY AND PATHOPHYSIOLOGY

- Very common sequela to blunt force trauma
- Normal boxlike pelvic structure accounts for frequency of injuries affecting two or more sites in the pelvis.
- Direct blows to the greater trochanter of the femur may cause an isolated impaction fracture of the adjacent acetabulum, with displacement of the femoral head through the medial acetabular wall into the pelvic canal.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on history and results of physical and radiographic examinations.

DIFFERENTIAL DIAGNOSIS

- Spinal fracture/luxation and spinal cord injury
- Long-bone fracture in pelvic limb

- Coxofemoral luxation(s)
- Concurrent orthopedic and soft-tissue injuries possible

INITIAL DATABASE

- Thoracic and abdominal radiographs; abdominal ultrasonography for visceral and abdominal wall injuries
- Neurologic examination
- CBC, serum biochemistry panel, and urinalysis (especially before sedation or anesthesia)
- Electrocardiogram to identify dysrhythmia due to traumatic myocarditis

ADVANCED OR CONFIRMATORY TESTING

- Multiple-view radiographs (lateral, oblique lateral(s), ventrodorsal) for assessment of the two hemipelves, sacroiliac joint, sacrum, tail, and distal lumbar spine. Narcotic sedation/general anesthesia usually required.
- CT to assess extent of injuries, identify sacral fractures, and for surgical planning (especially complex sacral fractures)
- Urinary tract imaging (e.g., contrast radiography) as needed to evaluate disrupted ureter(s), urinary bladder, or urethra

TREATMENT

TREATMENT OVERVIEW

- Elimination of pain
- Restoration of normal ambulation
- Restoration of pelvic canal diameter
- Prevention of secondary injuries to nerves from unstable or malunion of bone fragments

ACUTE GENERAL TREATMENT

- Analgesia compatible with other systemic injuries
- Ensure patent/functional urinary conduit.
- Surgery delayed until patient is adequately stabilized
- Injuries affecting the transmission of weight-bearing forces from the limb to the spine usually require surgery. These injuries involve acetabular, iliac, sacroiliac, and sacral disruptions.
    - Acetabular fractures are usually stabilized with plate/screws or pins/wires/screws, and methylmethacrylate bone cement.
    - Iliac fractures are usually stabilized with plate(s)/screws.
    - Sacroiliac and sacral body injuries are usually stabilized with screws/pins.
- External skeletal fixators sometimes employed for stabilization
- Patient size, degree of displacement, inherent stability, risk of secondary nerve injuries, and presence of other injuries help determine which injuries should be managed operatively versus conservatively (cage rest).

CHRONIC TREATMENT

- Confinement and sling support for 1-2 months, analgesics as needed
- Monitor for delayed signs of abdominal trauma (e.g., biliary disruption/leakage, delayed manifestations of lower urinary tract rupture) and cardiac complications (myocarditis/ventricular dysrhythmia).
- Protection of paw(s) if knuckling from sciatic neurapraxia

POSSIBLE COMPLICATIONS

- Malunions resulting in pelvic canal compromise, with secondary constipation/megacolon or dystocia
- Malunions or callus formation resulting in sciatic nerve impingement or entrapment, with neurapraxia
- Urethral damage or rupture
- Coxofemoral osteoarthritis (acetabular fractures)
- Persistent neuralogic deficits
- Persistent lameness or gait alteration
- Iatrogenic sciatic nerve injury during surgical manipulations
- Ventral abdominal hernia secondary to prepubic tendon avulsion or displaced pubic fracture

RECOMMENDED MONITORING

- Periodic radiographs to assess fracture healing
- Periodic clinical examinations including rectal palpation to assess improvement/resolution, function, and comfort
- Electromyography as needed in patients with peripheral nerve injuries/dysfunction

PROGNOSIS AND OUTCOME

- Increased risk for prolonged or persistent disability with fractures of the acetabulum or fractures associated with nerve injuries
- Improved prognosis for return to function when injuries that involve the sacrum, sacroiliac joint, ilium, or acetabulum are treated with anatomic reduction and rigid fixation of bone fragments.
- Intensive nursing care is involved for most patients and includes padded rest area, cleanliness following eliminations, pain management, nutrition, and physical therapy.

PEARLS & CONSIDERATIONS

COMMENTS

- Look for secondary injuries to the pelvic girdle (sacroiliac joints, sacral wings, and sacral body) with any diagnosis of pelvic fracture. Use oblique radiographic views to isolate the hemipelves. Always get at least two orthogonal radiographic views to avoid missing fractures where the bone ends overlap on one view.
- Acetabular fractures require accurate reconstruction of the articular surface to reduce the risk of osteoarthritis. Controversy exists as to whether fractures that involve only the caudal third of the acetabular articular surface require surgical treatment, but in general, all acetabular fractures would have a better prognosis with accurate anatomic reduction and stabilization.
- If acetabular repair cannot be achieved or if disabling osteoarthritis develops, a salvage surgery (hip replacement or femoral head/neck excision) usually is needed for a functional result.

PREVENTION

- Reduce free roaming by use of leashes, fences, neutering, and window screens to prevent falls from open windows.
- Counsel clients to always use precautions when backing up on driveways and in garages.

CLIENT EDUCATION

- Proper confinement/activity restriction during healing and recovery.
- Pets with acetabular fractures may require an acute or delayed salvage-type surgery (femoral head/neck resection).
- Acetabular fractures in particular might require revision surgery (hip replacement or excision arthroplasty) if the initial repair fails or disabling arthritis ensues.

Piermattei DL, Flo GL: Brinker, Piermattei and Flo's handbook of small animal orthopedics and fracture repair, ed 4, Philadelphia, 2007, WB Saunders, pp 395–421.

AUTHOR: JAMES M. FINGEROTH

EDITOR: JOSEPH HARARI

Fractures of the Metacarpus and Metatarsus

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Metacarpal and metatarsal fractures account for 5% of long-bone fractures and may involve the proximal base, body, or distal head of the metacarpal or metatarsal bone.

SYNONYM

Fracture of the paw

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Young, athletic dogs are at increased risk.
- Male racing dogs have a greater incidence of injury (increased muscle mass and late growth plate closure).

RISK FACTORS

- Direct trauma
- Repetitive stress from racing (greyhounds) in a counterclockwise direction, causing fatigue fractures of the right medial and left lateral metacarpal bones. Poor training and nutritional deficiencies increase the risk and severity of these fractures.

ASSOCIATED CONDITIONS & DISORDERS: Carpal hyperextension (concurrent damage to the carpometacarpal ligaments). See also Shearing/Degloving Injuries, p. 1016.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Acute lameness
- Poor racing performance and subsequent lameness

PHYSICAL EXAM FINDINGS

- Pain, swelling, and crepitus of the affected foot
- Joint effusion, palpable dorsally, with intraarticular fractures
- Valgus (lateral) or varus (medial) displacement if the fracture involves the collateral ligament insertion on metacarpus (MC)/metatarsus (MT) II or V
- Luxation of the phalanx with distal condylar fractures

ETIOLOGY AND PATHOPHYSIOLOGY

- Proximal fractures usually involve MC II and IV in the front leg and MT III in the rear leg.
- The central metacarpals/metatarsals (MC/MT III and IV) are the major weight bearers, and these fractures cause significant lameness and loss of structural integrity.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Physical examination will usually identify most MC/MT fractures. Radiographs are used for better defining the extent of injury, to determine the best method of repair, and to monitor alignment post reduction.

DIFFERENTIAL DIAGNOSIS

- Joint luxation
- Sesamoid bone fracture
- Cellulitis, stress periostitis, or foreign body

INITIAL DATABASE

- Lateral and craniocaudal radiographs
- Stress radiographs of the carpus and digits, if an intraarticular fracture or collateral ligament damage is suspected
- CBC, serum biochemistry panel, and urinalysis based on the American Society of Anesthesiologists (see p. 1372) patient classification

ADVANCED OR CONFIRMATORY TESTING

Thermography, bone scintigraphy, or CT imaging for stress fractures or suspected lesions not identified with radiography

TREATMENT 

TREATMENT OVERVIEW

Fracture stabilization for bone healing and early return to normal ambulation and to minimize degenerative joint disease

ACUTE GENERAL TREATMENT

- A fitted cast or molded splint is recommended for:
  - Nondisplaced proximal fractures
  - Incomplete and acute stress fractures in greyhounds
  - Simple shaft fractures involving one or two bones, provided one of the central weight-bearing bones (III or IV) is intact
  - Minimally displaced multiple MC/MT fractures in cats and small dogs
- Surgical repair (internal fixation) is recommended for:
  - Displaced proximal fractures; lag screw or tension band wire fixation
  - Simple shaft fractures involving the weight bearing bones, especially in large breed or working dogs. Repair options include lag screw or cerclage wire, small intramedullary pins or K wires, or external fixators.
  - Comminuted, severely displaced, or nonunion shaft fractures are treated with a 1.5-to 2.5-mm bone plate.
  - Distal intraarticular fractures with instability of the metacarpophalangeal or metatarsophalangeal joint are treated with a lag screw or interfragmentary wire.

CHRONIC TREATMENT

Metacarpal and metatarsal fracture repairs are supported postoperatively with a molded splint or cast until radiographic signs of bone union.

- If a cast or splint is the primary method of fixation, it is removed after clinical union (6 weeks in young animals, longer in older patients).
- When used to supplement internal fixation, the splint may be removed in 3-4 weeks. Exercise is restricted for another 3-4 weeks.
- Bone plates and intramedullary pins penetrating the proximal or distal cortex should be removed after healing.
- Bone screws, wires, and toggled intramedullary pins may usually be left in place.

POSSIBLE COMPLICATIONS

- Healing may be delayed in unstable or highly comminuted fractures.
- Poor fracture alignment, inadequate fixation, and premature implant failure may result in a malunion or nonunion.
- Intraarticular fractures or incorrect pin placement can damage the articular cartilage and interfere with joint motion, resulting in degenerative joint disease and chronic lameness.

RECOMMENDED MONITORING

Regular (2-4 week intervals) physical and radiographic examinations until healing achieved

PROGNOSIS AND OUTCOME

- Good for simple fractures with adequate reduction and fixation
- Guarded for articular, highly displaced, or comminuted fractures

PEARLS & CONSIDERATIONS

COMMENTS

- External splints require diligent monitoring to prevent iatrogenic skin injury.
- Even with multiple MC/MT fractures, a good outcome is possible with external coaptation, provided adequate reduction and support is achieved.

SUGGESTED READING

Piermattei DL, Flo GL, DeCamp CE: Fractures of the carpus, metacarpus, and phalanges. In Brinker, Piermattei, and Flo's handbook of small animal orthopedics and fracture treatment, ed 4, Philadelphia, 2006, WB Saunders, pp 412–420.

AUTHOR: ELIZABETH J. LAING

EDITOR: JOSEPH HARARI

Fractures of the Mandible and Maxilla

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Mandibular fractures can involve either the horizontal body or vertical ramus of the mandible; separation of the mandibular symphysis also can occur. The *condyle*is the articular surface at the caudalmost aspect of the mandible has a condylar process that articulates with the mandibular fossa of the temporal bone in the temporomandibular joint.
- Maxillary fractures can involve the incisive, nasal, frontal, maxillary, palatine, zygomatic, or temporal bones.

SYNONYM(S)

Jaw fractures, maxillofacial fractures

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Traumatic jaw fractures are more likely to occur in younger animals; pathologic jaw fractures are more likely in older animals.
- Mandibular fractures are more common than maxillary fractures.
- In dogs, areas near the mandibular canine and caudal cheek teeth are often involved.
- In cats, the region of the mandibular symphysis and the condylar process are often involved.

GENETICS & BREED PREDISPOSITION: Mandibular fractures in dogs occur more often in smaller breeds.

RISK FACTORS

- Traumatic fracture: vehicular trauma, bites, kicks, hits, high-rise falls, gunshots, and secondary to tooth extraction
- Pathologic fracture: advanced periodontitis, neoplasia, metabolic disease

ASSOCIATED CONDITIONS & DISORDERS: Tooth fractures (see p. 1102), tooth displacement injuries (see p. 1000), temporomandibular joint luxation (see p. 1078), high-rise syndrome, craniofacial (see p. 529) and soft-tissue injuries to structures of the head

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Head trauma (e.g., hit by car)
- Malocclusion
- Recent dental procedure
- Oral/nasal bleeding
- Dropped lower jaw

PHYSICAL EXAM FINDINGS: Malocclusion, inability to close or open the mouth, swelling, bruising of face/oral cavity, tongue extrusion, nasal bleeding, stertor, dysphagia, oral bleeding, blood-tinged saliva, drooling, crepitus, palpable or visible fracture lines

ETIOLOGY AND PATHOPHYSIOLOGY

- Symphyseal separation/perisymphyseal fracture: most common mandibular injury in cats
- The most common sites for mandibular fracture in dogs are the areas near the last premolar (fourth premolar) and first and second molars, followed by the area just caudal to the canine tooth.
- Concurrent injuries to the head, thorax, or both are common and may require urgent treatment and delay surgical repair of maxillary/mandibular fractures.
- Surgical repair should avoid damage to mandibular canal, which contains the inferior alveolar nerve, artery and vein.
- In small dogs, tooth roots often reach into the ventral mandibular cortex and leave little bone farther ventrally.
- Favorable versus unfavorable mandibular fractures:
    - Favorable mandibular fracture: oblique fracture line running in a rostroventral direction; relatively stable (muscle

forces hold fracture segments in apposition)
- Unfavorable mandibular fracture: oblique fracture line running in a caudoventral direction; unstable (muscle forces lead to displacement of fracture segments)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on history and physical examination; the fracture may be grossly apparent or may be subtle. Radiography under general anesthesia is often confirmatory and is indicated in all cases to determine optimal treatment. Note that nutritional support will be important if the patient cannot prehend and swallow food, and esophagostomy tube placement may be performed under general anesthesia prior to or immediately after jaw fracture management.

DIFFERENTIAL DIAGNOSIS

- Trigeminal neuritis/neuropathy (cranial nerve V)
- Temporomandibular joint luxation
- Open-mouth jaw locking
- Primary dental/periodontal disease
- Neoplasia

INITIAL DATABASE

- CBC/serum chemistry panel: generally unremarkable
- Head radiographs of stable, sedated patient can provide limited information.
- Open-mouth, oblique, lateral and ventrodorsal views, and intraoral dental radiographs are preferred, and general anesthesia is usually necessary (see p. 1246).
- Thoracic/abdominal radiographs to delineate other traumatic lesions
- Cranial nerve exam

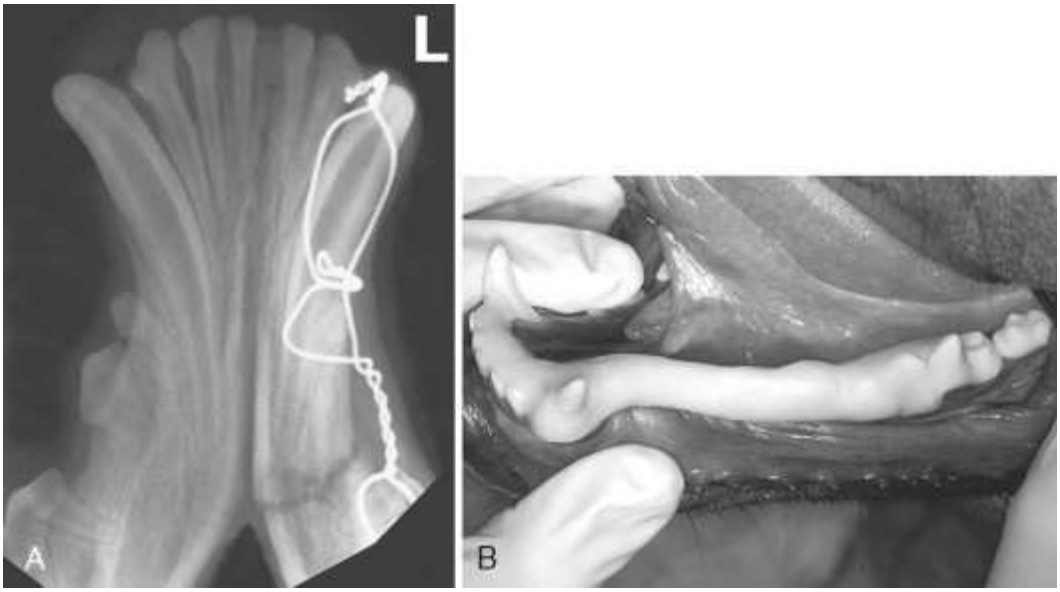
ADVANCED OR CONFIRMATORY TESTING

CT provides high resolution for maxillary and caudal mandibular fractures (however, a proper diagnosis can be obtained without CT in most cases).

TREATMENT

TREATMENT OVERVIEW

Acutely, all patients should receive adequate analgesia (systemic and/or local). Immediate fracture stabilization may be achieved with application of a custom-made muzzle. Long-term goals are to restore dental occlusion and restore oral functions.



FRACTURES, MANDIBLE AND MAXILLA An 8-month-old dog presented for evaluation and treatment of a left mandibular fracture between first premolar and third premolar *(arrow).*Second premolar is missing. Radiograph is arranged in labial mounting; rostral is toward top of image, and patient's left is on right of image.

(Copyright Dr. Alexander M. Reiter.)

FRACTURES, MANDIBLE AND MAXILLA A, Intraoperative radiograph of same patient. Fracture was first reduced with interdental wiring. **B,** Open-mouth view of same patient; rostral is to left. An intraoral splint was then fabricated covering the wire and tooth crowns.

(Copyright Dr. Alexander M. Reiter.)

ACUTE GENERAL TREATMENT

- Teeth may need to be removed to allow occlusion or closure of soft-tissue defects.
- Mandible:
  - Body:
    - Muzzling in stable or minimally displaced fracture. Muzzle should be flexible (nylon or white cotton hospital-type tape) and be sufficiently snug to immobilize fracture while still allowing the patient to drink water and lick liquid food. Favorable mandibular fractures in animals <6-8 months old often do not require treatment other than suturing of torn soft tissues and placing a tape muzzle for 2-3 weeks.
    - Interdental wiring and intraoral composite splint (preferred noninvasive technique of jaw fracture repair)

        - Intraosseous/interfragmentary wiring
        - Circumferential wire for symphyseal separation/perisymphyseal fracture
        - Percutaneous external fixation
        - Bone plating
    - Ramus:
        - Fractures rarely require any particular treatment beyond muzzling (snug tape muzzle through which the patient can still eat/drink). The muscle forces (temporal, masseter, and medial/lateral pterygoid muscles) hold the fracture segments in apposition.
        - If the mandible is displaced, resulting in malocclusion, treatment is required; noninvasive techniques first (maxillomandibular fixation, e.g., composite bridge between maxillary and mandibular canine teeth) before placing intraosseous wiring or bone plates.
        - Condylar process fractures may require condylectomy if there is progressive difficulty in opening the mouth (temporomandibular joint ankylosis).
- Maxilla:
    - Interdental wiring and intraoral composite splint, intraosseous wiring, bone plating
    - Midline palatal separation: primary (surgical) soft tissue closure if no tension; interquadrant wiring with or without composite splint if severe distraction
- Adjunctive treatment: broad-spectrum antibiotic therapy (e.g., amoxicillinclavulanate, 13.75 mg/kg PO q 12 h) for 1-2 weeks with open/contaminated fractures

CHRONIC TREATMENT

- Teeth causing mild malocclusion can be surgically reduced (without pulp exposure) or extracted.
- Tape muzzles are removed in 2-6 weeks, composite bridges in 5-8 weeks.
- Partial mandibulectomy possible for chronic nonunions
- Oronasal fistulas (see p. 795) may need secondary or delayed closure.
- Adjunctive treatment: oral instillation of dilute (0.12%) chlorhexidine solution or gel for 2-4 weeks; brushing of teeth and intraoral splints

NUTRITION/DIET

Nutritional support during healing. Blenderize food into liquid slurry, or place esophagostomy tube (see p. 1267) while patient is under general anesthesia.

POSSIBLE COMPLICATIONS

- Malocclusion
- Damage to dental structures
- Soft-tissue infection
- Osteomyelitis/sequestrum
- Implant failure
- Tongue and other soft-tissue trauma from exposed wires or plates
- Delayed union, nonunion
- Oronasal fistula
- Temporomandibular joint ankylosis
- Local pyoderma due to muzzle (transient)
- Malnutrition (very uncommon)

RECOMMENDED MONITORING

- Body weight (monitor adequate nutrition)
- Recheck at postoperative 2 weeks; remove skin sutures.
- Radiographs at 5-8 weeks and 6 months to evaluate bone healing
- Interdental wires, intraoral splints, and external fixators are removed after fracture healing (5-8 weeks). Bone implants may be left in place if soft-tissue damage and osseous abnormalities are absent.
- Teeth in fracture lines require radiographic monitoring in 6-12 months to determine pulp vitality.

PROGNOSIS AND OUTCOME

- Good to excellent if proper occlusion is established
- Fractures with tooth loss and severe periodontitis may heal slowly and by fibrous union only.

PEARLS & CONSIDERATIONS

COMMENTS

- Teeth in the fracture line should be preserved whenever possible, as they contribute to stability and alignment; should be removed if severely loose, fractured, or diseased.
- Administration of inhaled anesthetics via a pharyngostomy or temporary tracheostomy will aid with proper bone/teeth alignment during surgery.
- An esophagostomy feeding tube will reduce stress on repair(s), aid healing, and provide nutrition.
- Plates must have exact bone contour, or malocclusion will result.
- Minimally displaced maxillary fractures and fractures of the mandibular ramus may not require surgery beyond soft tissue closure.
- The mandible is a curved and small bone, containing neurovascular structures in its mandibular canal. Thus, intramedullary pinning is inappropriate, as it does not provide rotational stability and causes damage to nerves and vessels that supply teeth and lips.

TECHNICIAN TIPS

- Technicians should learn how to fabricate tape muzzles in cats and dogs and be able to give instructions to pet owners on the appropriate management of the patient at home.
- Patients with tape muzzles or composite bridges between maxillary and mandibular canine teeth may have compromised thermoregulation and should not be outdoors on warm or hot days. Restriction in mouth opening also bears the risk of aspiration in the regurgitating or vomiting patient.
- Tape muzzles may be removed during drinking and eating and put back in place once feeding is completed to reduce the possibility of local pyoderma from a soiled muzzle.

AUTHOR & EDITOR: ALEXANDER M. REITER

Fractures of the Humerus

BASIC INFORMATION

DEFINITION

Humeral fractures commonly involve the proximal physis, greater tubercle, metaphysis, diaphysis, supracondylar region, or condyle.

EPIDEMIOLOGY

GENETICS & BREED PREDISPOSITION: Spaniel breeds have a higher incidence of condylar fractures, possibly related to a reduced intraosseous blood supply.

RISK FACTORS

- Forelimb trauma from gunshot injuries, falls, or motor vehicle accidents
- Focal bone lesions (e.g., osteosarcoma or other bone neoplasm) or diffuse bone disease (e.g., nutritional, metabolic, or inherited) in cases of pathologic fractures

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Severe trauma to the forelimb

PHYSICAL EXAM FINDINGS: Non–weight-bearing lameness with swelling, pain, instability of the humerus

ETIOLOGY AND PATHOPHYSIOLOGY

- Thoracic wall, cardiopulmonary, and brachial plexus injuries may be present.
- Most fractures involve the middle-or distal-third segments.
- Condylar fractures involve the lateral portion more frequently than the medial; can be due to incomplete ossification in young dogs.
- Humeral fractures not caused by severe trauma may be pathologic fractures; these fractures are difficult to treat and may heal very slowly or not at all.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of humeral fracture is suspected with acute non–weight-bearing lameness in a forelimb and confirmed with radiographs.

DIFFERENTIAL DIAGNOSIS

- Brachial plexus injury
- Pathologic fractures secondary to neoplasia
- Elbow or shoulder luxation
- Cervical spinal cord disease (disk herniation, tumor, etc.)

INITIAL DATABASE

- CBC and chemistry panel based on American Society of Anesthesiologists patient classification (see p. 1372)
- Mediolateral and craniocaudal radiographs of the bone
- Electrocardiogram and thoracic radiography to evaluate for myocarditis or pneumothorax secondary to trauma
- Establish presence of deep pain perception and voluntary motor function in the limb to determine normal nerve function.

ADVANCED OR CONFIRMATORY TESTING

CT scan or MRI can be used to evaluate bone if pathologic fracture secondary to neoplasia is suspected.

TREATMENT

TREATMENT OVERVIEW

Treatment of humeral fractures commonly requires fracture stabilization to restore limb function and joint congruency (when involving the joint). If the fracture is displaced or comminuted, external coaptation is often unsuccessful, and referral to a surgeon would be warranted.

ACUTE GENERAL TREATMENT

- In young animals, minimally displaced fractures that do not involve a joint space may be treated with external coaptation such as a spica splint. The splint should remain on the leg until there is radiographic evidence of fracture healing.
- Most humeral fractures require surgical treatment with open reduction and internal/external fixations:
  - Physeal and metaphyseal fractures require stabilization with divergent pins.
  - Fractures of the greater tubercle require tension-band wiring.
  - Diaphyseal fractures require stabilization with a plate/screws, plate/rod, interlocking nail, or external fixation.
  - Supracondylar fractures require stabilization with cross-pinning, plate/screws, or plate/rod fixation.
  - Condylar fractures require stabilization with a lag screw and an antirotational Kirschner wire or small pin.

CHRONIC TREATMENT

- A carpal flexion bandage may be placed to prevent weight bearing for the first 2-3 weeks (see p. 1336).
- A spica bandage can also be used for limiting postoperative forelimb motion.
- Exercise restriction until radiographs confirm good fracture healing
- Elbow range-of-motion exercises multiple times daily maintain joint mobility.

POSSIBLE COMPLICATIONS

- Iatrogenic damage to the radial nerve with mid-diaphyseal fracture repair
- Degenerative joint disease with condylar fractures
- Infection
- Implant failure

RECOMMENDED MONITORING

- Suture removal and examination at 2 postoperative weeks
- Physical and radiographic examinations at 4-6 and 8-10 postoperative weeks to evaluate limb functions and bone healing (see p. 417)

PROGNOSIS AND OUTCOME

- Good to excellent with proper bone realignment, joint congruency, healing, and rehabilitation, along with minimal trauma occurring to soft-tissue structures (nerves, vessels, muscles)
- Guarded to poor with pathologic humeral fractures; healing is delayed or clinically nonexistent, pain often persists, and surgical repair is difficult or contraindicated (leading to amputation or euthanasia).

PEARLS & CONSIDERATIONS

COMMENTS

- Because cardiopulmonary injury may be present, patients should be stabilized before surgery/anesthesia.
- An osteotomy of the olecranon will improve visualization/reduction of a supracondylar or bicondylar fracture.
- Condylar fractures are difficult to identify on a single (lateral) radiographic projection.
- A disproportionately mild degree of trauma as a cause for humeral fracture should prompt the suspicion of a pathologic fracture and underlying bone disease.

SUGGESTED READING

Piermattei DL, Flo GL, DeCamp CL: Fractures of the humerus. In Brinker, Piermattei, and Flo&#65533;s handbook of small animal orthopedics and fracture repair, ed 4, Philadelphia, 2006, WB Saunders, pp 297–324.

AUTHOR: RAVIV J. BALFOUR

EDITOR: JOSEPH HARARI

Fractures of the Femur

BASIC INFORMATION

DEFINITION

Fractures of the femur may be classified as proximal (physis, femoral head or neck, trochanter), midshaft (diaphyseal), or distal (supracondylar, condylar).

SYNONYM

Capital (head) physeal fracture: “slipped” capital epiphysis or physis

EPIDEMIOLOGY

RISK FACTORS: Trauma to the caudal trunk or hind limbs

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Trauma to the caudal trunk/limb:
  - Motor vehicle accident
  - High-velocity impact
  - Falls
- Femoral capital physeal fractures in cats may occur without a history of trauma.

PHYSICAL EXAM FINDINGS

- Lameness
- Swelling, bruising, or shortening of limb
- Crepitation/pain at hip/stifle joint
- Loss of sensation to medial (femoral nerve) or lateral (sciatic nerve) digits due to regional soft-tissue swelling, bruising, and transient peripheral nerve dysfunction

ETIOLOGY AND PATHOPHYSIOLOGY

- Most common (45%) long-bone fracture
- Concurrent injuries to abdominal wall or organs, pelvis, and lumbar spine are common.
- Capital physeal fracture (immature animals) disrupts ascending vessels and compromises healing.
- Extensive hemorrhage with midshaft fractures contributes to shock.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on a history of trauma (most dogs, many cats) and typically severe to non–weight-bearing hindlimb lameness, proximal limb pain, soft-tissue swelling, and discoloration. Plain radiography is confirmatory.

DIFFERENTIAL DIAGNOSIS

- Coxofemoral luxation*
- Acetabular/pelvic fracture*
- Bone neoplasia and pathologic fracture*
- Spinal trauma: bilateral hindlimb paresis/paralysis, abnormal reflexes

INITIAL DATABASE

- Craniocaudal and lateral radiographs of affected hind limb and pelvis ± lumbar spine
- Abdominal and thoracic radiographs if whole-body trauma
- CBC/serum biochemistry panel dictated by systemic signs and patient stability
- Evaluation of medial/lateral sensations of digits
- Comprehensive neurologic exam to evaluate for spinal trauma

ADVANCED OR CONFIRMATORY TESTING

Biopsy if pathologic fracture suspected radiographically

TREATMENT

TREATMENT OVERVIEW

The goals of therapy are restoration of limb function and alignment, as well as reconstruction of damaged articular surface.

ACUTE GENERAL TREATMENT

- External coaptation (casts, splints, etc.) is usually ineffective and carries a high likelihood of inducing complications.
- Fractures involving the joint space require accurate joint reconstruction.
- Midshaft fractures are stabilized with bone plate/screws, external fixator, interlocking nail, intramedullary pins/cerclage, or plate/rod.
- Condylar fractures are repaired with lag screws, pins.
- Trochanteric fractures are repaired with pin and tension-band wiring or lag screws to counteract pull of gluteal muscles.
- Femoral neck fractures are repaired with multiple small pins, lag screw(s).
- Femoral head/neck ostectomy can be performed for neck and capital physeal fractures in cats and small dogs.

CHRONIC TREATMENT

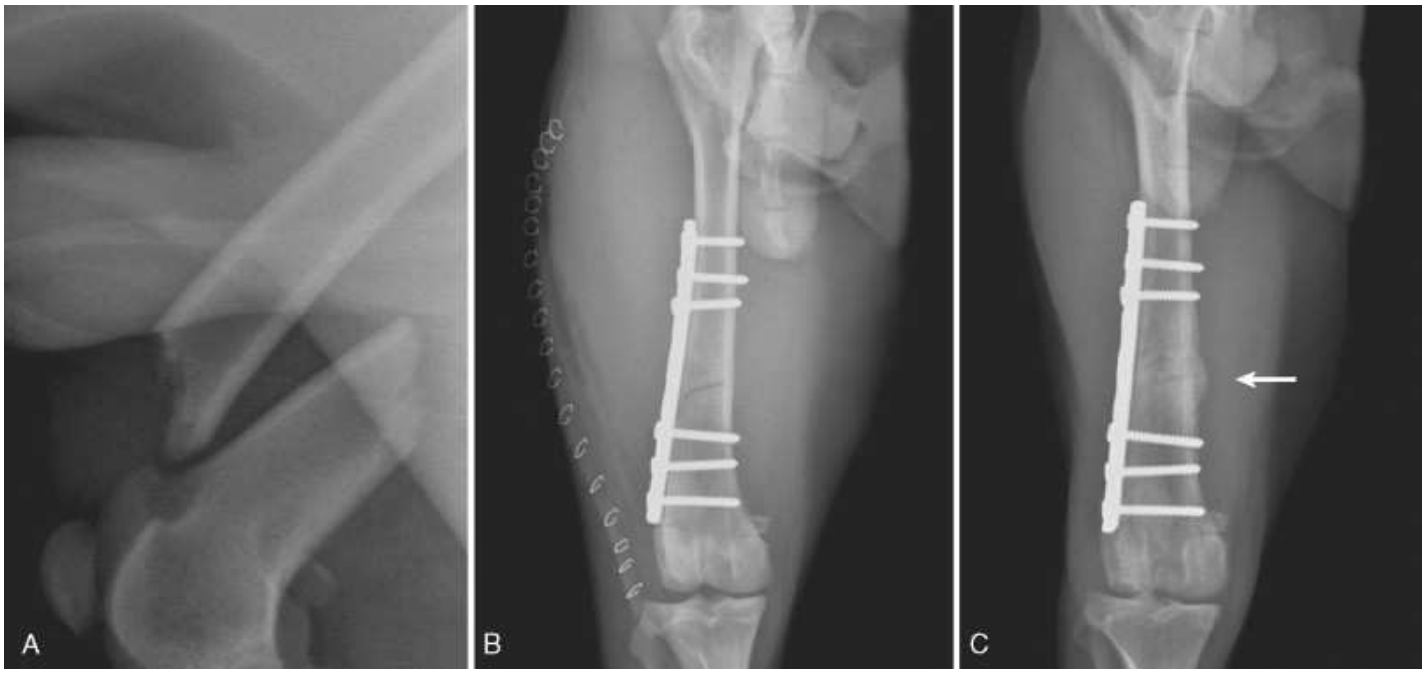
- Restricted activity until radiographs at 4-6 weeks to assess healing
- Radiograph early for suspected complications based on clinical signs of recurrent lameness, fever, limb swelling, peri-incisional draining tracts
- Femoral head/neck resection for failed proximal repairs

POSSIBLE COMPLICATIONS

- Malunion, nonunion (inadequate fixation)
- Degenerative joint disease (articular fractures)
- Sciatic nerve damage (retrograde intramedullary pin placement)
- Decreased hip motion with femoral head ostectomy
- Implant failure
- Infection
- Quadriceps contracture and inability to flex the stifle (young dogs with midshaft and distal femoral fractures)
- Limb shortening

RECOMMENDED MONITORING

- Lameness evaluation every 4 weeks for 2-3 months; expect gradual gait improvement.
- Evaluate patients with distal fractures 2 weeks after surgery to assess stifle mobility and avoidance of restrictive fibrosis.
- Radiographs every 4-6 weeks to evaluate fracture healing (1-3 months based on patient age) and implant stability; initiate physical rehabilitation and controlled activity based on normal imaging findings.



FRACTURES, FEMUR A, Lateral view of transverse, distal-third femoral fracture in an 18-month-old male Boxer weighing 45 lbs. **B,** Postoperative ventrodorsal radiograph of femoral fracture stabilized by a bone plate and screws applied to lateral aspect of bone. **C,** One-month follow-up radiograph

illustrating endosteal healing of fracture, along with a periosteal callus *(arrow)* on medial aspect of bone.

PROGNOSIS AND OUTCOME

- Based on severity of injury and presence or absence of complications (nerve damage, infection, etc.)
- Associated neuropraxia (temporary nerve damage): may need 2-12 weeks to assess for functional recovery
- Good to excellent for nonarticular lesions treated with appropriate surgical intervention
- Quadriceps contracture/tiedown requires physical therapy or surgical intervention.

PEARLS & CONSIDERATIONS

COMMENTS

- Additional orthopedic injuries of the same or other limbs are common.
- Initial proprioceptive deficits of the affected limb can be due to pain, shock, and fracture edema, and not a spinal injury.

SUGGESTED READING

EDITOR: JOSEPH HARARI

Legend:- *Radiography will elucidate the lesion.

Fracture Disease

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Fracture disease includes muscle contracture, implant failure, inadequate bone union, and joint disease. These result in abnormal limb function.

SYNONYM

Fracture complications

EPIDEMIOLOGY

SPECIES, AGE, SEX: Muscle contracture is most common in young dogs with distal femoral or humeral fractures.

RISK FACTORS

- Limb trauma
- Poor surgical technique

ASSOCIATED CONDITIONS & DISORDERS: Trauma to other body systems

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Quadriceps contracture, joint ankylosis

FRACTURE DISEASE A 1-year-old, mixed-breed dog with quadriceps contracture after distal femoral fracture repair and no physical therapy to retain stifle joint range of motion. Note hyperextension of limb.

HISTORY, CHIEF COMPLAINT: Lack of normal limb function after fracture repair

PHYSICAL EXAM FINDINGS: Lameness, disuse atrophy of skeletal muscle, decreased range of motion of affected joint(s), draining tracts, nonhealing surgery site, fibrosis of major muscle groups.

ETIOLOGY AND PATHOPHYSIOLOGY

- Severe soft-tissue damage from injury/surgery and subsequent fibrosis
- Incongruent articular cartilage after joint fracture repair

- Inadequate postoperative rehabilitation to enhance limb function
- Nerve injury preventing use of limb
- Inappropriate use of implants during repair
- Excessive or unrestricted patient activity after surgery

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is made when a patient has poor return to function after sustaining a fracture. Radiographs and ancillary tests are useful for defining the extent of the disorder.

DIFFERENTIAL DIAGNOSIS

- Bone neoplasia
- Joint luxation
- Osteomyelitis
- Joint infection

INITIAL DATABASE

- Orthopedic and neurologic exams to evaluate limb function
- Orthogonal view radiography of affected bone(s)
- CBC, chemistry panel, urinanalysis, electrocardiogram based on patient American Society of Anesthesiologists classification (see p. 1372)

ADVANCED OR CONFIRMATORY TESTING

- Muscle biopsy (see p. 1305)
- Electromyography (see online chapter: Electromyography and Nerve Conduction Velocity)
- Nerve conduction studies (see online chapter: Electromyography and Nerve Conduction Velocity)

TREATMENT

TREATMENT OVERVIEW

Restoration of limb function(s)

ACUTE GENERAL TREATMENT

- Accurate joint reconstruction
- Adequate alignment and stable fixation of long-bone fracture(s)
- Gentle, aseptic surgical technique; avoidance of excessive soft-tissue dissection
- Initiation of physical therapy immediately after fracture repair
- Use of analgesics to alleviate patient discomfort and enhance movement

CHRONIC TREATMENT

- Replacement of failed implants and restabilization of fracture(s)
- Resection of scar tissue to regain joint range of motion
- Intensive postoperative rehabilitation (see p. 1329)

POSSIBLE COMPLICATIONS

Limb dysfunction: muscle atrophy, tissue fibrosis, degenerative joint disease

RECOMMENDED MONITORING

- Physical rehabilitation immediately after fracture repair to maintain joint(s) range of motion
- Serial radiography to evaluate bone healing

- Serial physical examinations to evaluate limb function

PROGNOSIS AND OUTCOME

- Poor if joint ankylosis or muscle contracture occurs
- Poor if irreversible nerve damage
- Joint fusion or limb amputation may be required in failed cases.

PEARLS & CONSIDERATIONS

COMMENTS

- Prevention is essential and easier than therapy.
- Avoid external splintage for humeral and femoral fractures.
- Consider case referral to an orthopedic specialist.
- In juvenile dogs, the coxofemoral joint will tend to luxate in a dorsal direction as the quadriceps contract.

PREVENTION

- Proper implant usage and fracture fixation allowing postoperative ambulation
- Anatomic joint surface reconstruction is a key goal.
- Avoid reliance on external coaptation to stabilize fractures.
- Use postoperative physical therapy to maintain limb function.

CLIENT EDUCATION

- Patients must be controlled after fracture fixation to prevent loss of implant stability.
- Physical therapy is necessary after surgery.
- Frequent recheck examinations are required to assess limb function and bone healing.

Foreign Body, Respiratory Tract

BASIC INFORMATION

DEFINITION

Inhaled, penetrating, or migrating objects that cause obstruction or inflammation of the respiratory tract

SYNONYMS

Migrating foreign body, nasal foreign body, tracheal/bronchial foreign body

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats can be affected. May be more prevalent in young or active animals.

GENETICS & BREED PREDISPOSITION

- Pyothorax secondary to aspiration of grass awn is most common in young or middle-aged medium to large hunting/sporting dogs.
- Small dogs are more prone to bone foreign body in the nasopharynx.

GEOGRAPHY AND SEASONALITY

May be more common during hunting season or in areas with oat/cereal fields or grass awns (“foxtails”)

ASSOCIATED CONDITIONS & DISORDERS

- Aspergillosis or bacterial rhinitis with chronic intranasal foreign body
- Focal tracheal stenosis with chronic intratracheal foreign body (granuloma)
- Lobar pneumonia with a foreign body in a bronchus
- Bronchoesophageal fistula with penetration of esophageal foreign body through bronchus
- Pyothorax with thoracic migration of foreign body into or through pleural space

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Rhinitis
- Tracheitis or tracheobronchial obstruction
- Pyothorax (empyema)

HISTORY, CHIEF COMPLAINT

- Nasal foreign body:
  - Nasal discharge
  - Acute onset of sneezing
  - Pawing at face or other signs of discomfort
- Nasopharyngeal foreign body:
  - Stridor
  - Sneezing
  - Halitosis possible with chronicity
- Tracheal/bronchial foreign body:
  - Acute onset of coughing, dyspnea
  - Chronic cough
  - Halitosis
  - Hemoptysis

- Retching/vomiting may occur
- Exercise intolerance or cyanosis if severe obstruction
- Temporary or recurring response to antibiotics in some chronic cases

- Intrathoracic foreign body:
  - Anorexia
  - Lethargy
  - Weight loss
  - Fever
  - Increased respiratory effort
  - Poor performance

PHYSICAL EXAM FINDINGS

- Nasal foreign body:
  - Decreased air movement through one nostril. Assessment:
    - By differentially occluding each nostril one at a time and either listening closely for air flow or watching for movement of an object held in the expected path of air flow (wisp of cotton ball, or of the pet's hair)
    - By holding a glass microscope slide in front of the nostrils and observing for fogging of the glass
  - Nasal discharge: unilateral bloody or blood-tinged, progressing to mucopurulent; may become bilateral after several months
  - Possibly ocular discharge
- Nasopharyngeal foreign body:
  - Stertor
  - Halitosis
  - Reverse sneezing
  - Acute onset of vomiting, retching, or gagging
- Tracheal/bronchial foreign body:
  - Dyspnea, which can be inspiratory and expiratory and worsens with degree of obstruction
  - Tachypnea
  - Cough
  - Increased respiratory noise: stridor; high frequency wheeze with partial obstruction
  - Cyanosis, collapse, or acute death with severe obstruction
- Intrathoracic foreign body (signs reflect pyothorax most often; see p. 956):
  - Cough
  - Fever
  - Increased inspiratory effort
  - Muffled heart sounds
  - Respiratory sounds muffled ventrally on thoracic auscultation
  - Pleural fluid line on percussion of the thoracic wall
  - Thorax may be noncompressible in cats with pyothorax.

ETIOLOGY AND PATHOPHYSIOLOGY

- Nasopharyngeal foreign body is usually bone in dogs.
- Inhalation most common path of entry for nasal, tracheal, bronchial, thoracic foreign bodies
  - Grass awns (seeds) and other plant material most common foreign objects
  - Plant material aspirated into lungs may migrate into pleural space (see Pyothorax, p. 956; Pneumothorax, p. 889)
- Sharp esophageal or gastric foreign bodies may migrate into lungs or pleural space.
- Local inflammatory reaction and contamination may result in secondary bacterial or fungal infection.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis of nasal, tracheal, and bronchial foreign bodies is suspected based on acute onset of clinical signs or chronic focal lung disease that can be responsive to antibiotics on a recurring basis. Confirmation can be made on radiographs (most often tracheal foreign bodies); however, endoscopy is often required. Migrating intrathoracic grass awns should be suspected in sporting/hunting breeds with a history of cough and fever that have focal pulmonary opacities, pleural effusion, and pleural thickening on radiographs or CT.

DIFFERENTIAL DIAGNOSIS

- Nasal foreign body:
  - Neoplasia
  - Fungal infection such as aspergillosis, cryptococcosis
  - Nasopharyngeal polyp
  - Lymphocytic-plasmacytic rhinitis
  - Nasal mites
  - Bacterial rhinitis
  - Oronasal fistula or tooth root abscess
  - Nasal trauma
  - Nasopharyngeal stenosis
- Nasopharyngeal foreign body:
  - Polyp
  - Granuloma
  - Neoplasia
  - Rhinitis
- Tracheal/bronchial foreign body:
  - Laryngeal paralysis
  - Tracheal collapse
  - Elongated soft palate
  - Trauma
  - Neoplasia
  - Infection
- Lung or intrapleural foreign body:
  - Bronchopneumonia
  - Pyothorax from trauma or systemic disease
  - Neoplasia

INITIAL DATABASE

- CBC
  - Neutrophilic leukocytosis, possibly with left shift and toxic neutrophils, with pyothorax, secondary bronchopneumonia, or severe secondary rhinitis
  - Eosinophilia possible with tracheobronchial grass awns
- Serum biochemistry profile and urinalysis often unremarkable with nasal, nasopharyngeal, or airway foreign bodies
  - With pyothorax from pleural foreign bodies, hypoalbuminemia, hypoglycemia, or proteinuria may be seen.
- Radiographs: findings other than radiopaque foreign body may include:
  - Nasal foreign body:
    - Increased intranasal soft-tissue opacity
    - Local bone destruction with chronic disease
  - Tracheal foreign body:
    - Increased airway soft-tissue/fluid opacity on cervical or thoracic films
    - Noncardiogenic pulmonary edema with severe obstruction
  - Bronchial foreign body:
    - Ill-defined peribronchial radiopacity
  - Lung or bronchial foreign body:
    - Lung consolidation with secondary bronchopneumonia
  - Intrapleural foreign body:
    - Focal pulmonary interstitial to alveolar opacities, most common in caudal or accessory lobes
    - Pleural effusion, pleural thickening
    - Collapsed lung lobes
    - Spontaneous pneumothorax may occur with penetrating or migrating thoracic foreign bodies.
- Cytologic evaluation/culture of nasal cavity to identify organisms associated with secondary rhinitis
- Neutrophilia on transtracheal wash cytologic study with tracheobronchial foreign body
- Pyothorax: inflammatory exudates (degenerate neutrophils ± bacteria) on cytologic study of pleural fluid obtained by thoracocentesis. Macrophages and plasma cells increase with chronicity.
  - Common organisms cultured from pyothorax: obligate anaerobes *(Fusobacterium), Nocardia asteroides*, *Actinomyces*in dogs; anaerobes, *Pasteurella multocida*in cats

ADVANCED OR CONFIRMATORY TESTING

- Nasopharyngeal foreign bodies may be visible in anesthetized patients by soft-palate retraction during oropharyngeal exam or retroflexed nasopharyngoscopy.
- Endoscopy is generally diagnostic for tracheal foreign bodies and some bronchial foreign bodies (may be obscured by mucopurulent exudates).

- Intranasal foreign bodies may be visible with anterior rigid scope or posterior flexible scope, although nasal discharge may obscure view.
    - Nasal flushing (see online chapter: Nasal Flush) removes discharge to improve visualization. Retrograde flushing may force nasal foreign bodies out through the nares.
- CT of nasal cavity: mucosal thickening, focal bone thickening and destruction; may not differentiate foreign body rhinitis from nasal aspergillosis.
- CT of animals with migrating grass awns: focal interstitial to alveolar pulmonary opacities, primarily in the right caudal lung lobe, and enlarged lymph nodes. Foreign body seen on CT in 33% of animals.
- Contrast rhinography or bronchography are rarely used but may outline radiolucent foreign body.

TREATMENT

TREATMENT OVERVIEW

Goals include oxygenation of the patient if needed, removal of the foreign body, and treatment of secondary infections. Animals in respiratory distress from obstruction may require immediate anesthesia and foreign-body retrieval.

ACUTE GENERAL TREATMENT

- Oxygen supplementation (see p. 1318).
- Sedation if extremely stressed (i.e., such that the anxiety is contributing to dyspnea):
    - Acepromazine, 0.1-0.5 mg total dose IM or IV if young and not systemically ill
    - Butorphanol, 0.2-0.4 mg/kg IV may be given additionally q 2-4 h as needed
- Rehydrate as needed.
- Thoracocentesis if respiratory compromise from pleural effusion or pneumothorax (see p. 1338)
- Immediate anesthesia and foreign body removal if trachea completely obstructed
    - Tracheostomy (see p. 1344) may be needed for short-term airway management.
- If possible, nonsurgical removal of nasal, laryngeal, tracheal, and some bronchial foreign bodies
    - Foreign bodies often removed endoscopically with forceps, basket retrievers
    - Nasal foreign bodies sometimes removed during retrograde or antegrade lavage/flush
    - Some tracheal foreign bodies removed with vacuum suction or passage of balloon (Fogarty) catheter beyond foreign body and then inflation and retraction of balloon. Tracheal foreign bodies in cats removed with forceps retrieval (24-in. custom-made grasping forceps) under fluoroscopic guidance.
- Rhinotomy (dorsal or ventral), tracheotomy, bronchotomy, or lung lobectomy for nonretrievable intraluminal foreign bodies
    - Lobectomy if lung lobe consolidation. Histopathologic evaluation and culture (aerobic and anaerobic) of excised tissue.
    - Anesthetic/oxygen delivery via contralateral bronchus intubation recommended for unilateral bronchotomy. Total IV anesthesia with endotracheal or endobronchial oxygen delivery if gas leakage expected.
- Lung lobectomy if bronchopneumonia secondary to foreign body or bronchoesophageal fistula
- Bilateral thoracostomy tubes or thoracotomy (median sternotomy for generalized disease) and thoracic lavage/drainage for pyothorax
    - Lavage through large-diameter chest tubes with sterile, lukewarm isotonic fluids (20 mL/kg) q 12 h for 5-7 days.
- Surgical exploration if intrathoracic mass, radiographic evidence of pulmonary or mediastinal lesions, pneumothorax, *Actinomyces*, or no improvement with medical therapy
- For pyothorax or bronchopneumonia, broad-spectrum antibiotics

CHRONIC TREATMENT

- Antibiotic therapy for secondary infections, based on culture/sensitivity
    - Ampicillin or amoxicillin plus clavulanic acid, 12.5-20 mg/kg PO q 12 h for obligate anaerobes, *Pasteurella*spp., *Actinomyces*spp.
    - Trimethoprim sulfa, 10-15 mg/kg PO q 12 h (possibly higher, but may increase risk of adverse effects); or amikacin for *Nocardia*spp.
    - For pyothorax, antibiotics are administered for 1-2 months.
- Bronchodilators (e.g., aminophylline, 10 mg/kg PO q 8 h) for 3-5 days after endoscopic removal of bronchial foreign bodies

POSSIBLE COMPLICATIONS

- Inability to oxygenate during endoscopy or surgery
- Increased severity of obstruction with flushing, foreign body manipulation, or endoscopic trauma (mucosal swelling)
- Pulmonary abscess or recurrent pyothorax if migrating foreign body remains or inappropriate antibiotic therapy used
- Chronic rhinitis possible if turbinates are removed during rhinotomy

RECOMMENDED MONITORING

- Tracheal/bronchial/lung/thoracic foreign bodies: repeat radiographs or endoscopy if clinical signs recur.
- Pyothorax or pneumonia: repeat radiographs 1 week after discontinuing antibiotics or if clinical signs recur.

PROGNOSIS AND OUTCOME

- Outcome excellent if patient survives foreign-body extraction and secondary infections are treated appropriately.
    - Bronchopulmonary abscess develops with foreign body migration if tracheobronchial grass awn present for more than 2 weeks.
- Complication and mortality rates higher with chronicity
- Tracheobronchial plant material can fragment, requiring multiple endoscopic episodes for complete removal.

PEARLS & CONSIDERATIONS

COMMENTS

- Some nasal foreign bodies can be removed with vigorous flushing (see online chapter: Nasal Flush).
- Right bronchial system more likely to be affected by inhaled bronchial foreign body because of direct tracheobronchial path
- Grass awns usually migrate to multiple sites, including pericardial sac, in dogs with pyothorax.
- If sulfur granules or branching filamentous gram-positive rods (suspicion of *Actinomyces*infection) are seen during cytologic examination of the pleural fluid, consider long-term treatment (4-6 weeks) with antibiotics.

TECHNICIAN TIPS

- During rhinoscopy for foreign body, fluids from lavaging or hemorrhage will pour out of the nares and nasopharynx; therefore, the endotracheal tube should be in place and inflated during the procedure.
- Teeth and pieces of dental calculus may become tracheal or bronchial foreign bodies if not removed from the mouth after dental cleaning.
- Intubation and endoscopy may inadvertently force tracheal foreign bodies toward the tracheal bifurcation or into the bronchi. Affected animals may require an emergency thoracotomy and intubation of the distal trachea or bronchus through the thoracotomy site; therefore, materials should be available for clipping, prepping, and thoracotomy.

CLIENT EDUCATION

- Acute onset of coughing in high-performance sporting dogs during hunting or harvest season may indicate tracheobronchial foreign body.
- Provide indestructible bones and toys that are appropriately sized for the dog.

Foreign Body, Oral

BASIC INFORMATION

DEFINITION

Foreign object lodged or embedded in the oral cavity

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dog and cat, either sex. Potentially more of a problem in younger animals.

RISK FACTORS

- Habit of chewing on foreign objects:
  - Bones, sticks, string
- Longer-haired dogs playing or running in grassy/wooded areas
- Interacting with a porcupine

ASSOCIATED CONDITIONS & DISORDERS

- Retrobulbar abscess
- Submandibular/intermandibular abscess
- Necrosis of intraoral structures
- Linear foreign body gastrointestinal obstruction

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Dog playing or running in grassy or wooded area
- Dog seen interacting with porcupine
- Animal seen chewing on foreign object
- Signs of oral discomfort (pawing at mouth, face rubbing, reluctance to eat hard food)
- Facial swelling: exophthalmos, strabismus possible
- Nonspecific signs: depression, anorexia, vomiting

PHYSICAL EXAM FINDINGS

- Nonspecific findings:
  - Depression, pyrexia, dehydration
- Reluctance to open/discomfort on opening mouth
- Facial swelling:
  - Exophthalmos
  - Strabismus
  - Submandibular/intermandibular swelling
- Halitosis
- Oral discharge (hemorrhagic, purulent)
- Findings related to the foreign body:
  - Bone or stick lodged across hard palate, between premolars/molars, or encircling mandible (short segment of large diameter bone)
  - Burrs stuck in lingual, palatine, gingival mucosa
  - String foreign body around base of tongue
  - Porcupine quills in and around muzzle and oral cavity
- Penetrating oral injury, possibly associated with external facial swelling
- Findings associated with gastrointestinal linear foreign body:
  - Abdominal palpation: pain, plicated intestines

ETIOLOGY AND PATHOPHYSIOLOGY

- Foreign body penetration of the oral cavity may result in abscess formation in the surrounding tissues (most commonly retrobulbar or submandibular/intermandibular)
- Foreign body lodged between the maxillary premolars/molars can cause necrosis of the underlying palatine mucosa and palatine bone and development of oronasal fistula
- Burrs embedded in the oral mucosa—may incite granulomatous reaction
    - Focal: mass
    - Diffuse: across the whole surface of the tongue
- Linear foreign bodies (see p. 407) caught around the base of the tongue can become embedded into the tongue.
    - Can be difficult to identify
    - Can cause a significant inflammatory/granulomatous reaction

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis is suspected based on patient signalment, presenting history, and physical, including oral examination findings. Thorough oral examination may have to be performed under general anesthesia, owing to pain. Confirmation requires identification of an intraoral foreign body and/or fine-needle aspiration cytology of facial swelling/mass.

DIFFERENTIAL DIAGNOSIS

- Oral mass: neoplasia
- Facial swelling: neoplasia or salivary mucocele

INITIAL DATABASE

- CBC:
    - Neutrophilia associated with inflammation or infection
- Oral examination: general anesthesia usually necessary (see Acute General Treatment)
- Fine-needle aspiration of facial swelling:
    - Cytologic examination to confirm inflammation +/− infection
    - Microbiologic culture and sensitivity testing (aerobic and anaerobic)
- Ultrasound examination:
    - Exophthalmos
    - Facial swelling (abscess versus neoplasia)

ADVANCED OR CONFIRMATORY TESTING

- Histopathologic examination of biopsied oral mass
    - Foreign body granuloma versus neoplasia
- CT or MRI: extent of abscess/granulomas

TREATMENT

TREATMENT OVERVIEW

Removal of the foreign body may involve either direct extraction from the oral cavity or surgical exploration of an identified abscess. Associated inflammation, abscess formation and/or cellulitis are treated by surgical exploration, débridement and medical management. If a linear foreign body is found, appropriate surgical intervention of the gastrointestinal tract is indicated (see p. 407).

ACUTE GENERAL TREATMENT

Following induction of general anesthesia:

- Oral examination:
    - Routine (foreign material may be found incidentally)
    - Because could not be performed in awake patient (e.g., fractious behavior, physical obstruction)
- Radiographs:

    - Radiopaque foreign body
    - Soft-tissue swelling (abscess)
    - Destruction of underlying bone
- Removal of foreign body from oral cavity:
    - Porcupine quills: grasp at base (nearest to skin) with forceps and extract gently (see p. 1331).
    - Bone or stick: if tightly wedged, may be easier to remove by cutting (e.g., with Stryker saw) first
    - Release linear foreign body caught around base of tongue.
- Burrs embedded in oral mucosa:
    - Surgical débridement to remove plant material and chronic granulomatous lesions. Open wounds will rapidly be covered by proliferating mucosa.
- Surgical exploration, débridement, and lavage of abscess pocket(s):
    - Retrobulbar area explored through incision in oral mucosa just caudal to last upper molar tooth or through existing penetrating wound
- Provide postoperative drainage until abscess has resolved (submandibular/intermandibular).Antibiotic therapy for bacterial infection:
- Long-term therapy based on results of microbiologic culture and sensitivity tests
- Empirical therapy until results available:
    - Cefazolin, 22 mg/kg IV q 6 h, if animal receiving IV fluids and unable to take oral medications; *or*
    - Amoxicillin, 10-20 mg/kg PO q 12 h

CHRONIC TREATMENT

- Antibiotic therapy (see Acute General Treatment above) until resolution of infection
- Reconstructive surgery of damage caused to oral cavity by foreign body:
    - Oronasal fistula

NUTRITION/DIET

- If lesions or wounds that might hinder oral feeding are present in the oral cavity, it will be necessary to provide alternative route for nutrition and antibiotic administration.
    - Esophagostomy tube or PEG tube (see p. 1267 and p. 1270)
    - Reexamine oral cavity in 10-14 days. If healed, patient can return to oral feeding, and tube can be removed.

POSSIBLE COMPLICATIONS

- Failure to remove foreign body:
    - Persistent/recurrent abscess
    - Development of draining tract
- Development of late-onset tissue necrosis:
    - Osteomyelitis
    - Oronasal fistula

RECOMMENDED MONITORING

- Repeat visits to veterinarian as necessary
    - To ensure oral lesions or wounds heal
    - To ensure abscess has resolved (allowing drain removal)
    - To remove feeding tube once oral problems have healed
- Observe for recurrence of abscess and development of draining tract.

PROGNOSIS AND OUTCOME

- Usually good, provided all foreign material has been removed and abscess pockets are adequately drained
- Recurrent problems likely to occur or chronic draining tract may develop if:
    - Failure to remove all foreign material, especially porcupine quills
    - Late-onset tissue necrosis develops (oronasal fistula, osteomyelitis)

PEARLS & CONSIDERATIONS

COMMENTS

In situations where multiple foreign bodies are present in the oral cavity (porcupine quills, burrs), it is essential to ensure that a thorough examination is performed, extending throughout the entire pharynx, to ensure all foreign material is removed.

PREVENTION

Avoid situations that could lead to foreign bodies injuring or becoming lodged in the oral cavity.

TECHNICIAN TIPS

- In-hospital care may include:
  - Keeping drain/drainage site clean and free of discharge
  - Changing bandages as directed
  - Administration of antibiotics as directed
  - Ensuring adequate analgesia is provided
  - Ensuring that patient is receiving adequate nutritional support if NPO

CLIENT EDUCATION

- Do not let animals play with or chew on objects such as sticks that could cause penetrating oral injuries, or linear objects (fishing line, yarn, etc.) that could act as linear foreign bodies.
- Do not let dogs interact with porcupines.

AUTHOR & EDITOR: RICHARD WALSHAW

Foreign Body, Linear Gastrointestinal

BASIC INFORMATION

DEFINITION

A common disorder involving ingestion of a linear object that lodges in the proximal alimentary system (commonly under the tongue or at the pylorus) and causes plication of intestines along the length of the object

SYNONYM

String foreign body

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Young animals are at risk for foreign object ingestion.
- Linear foreign body is a more common diagnosis in cats than dogs.
- Dogs with linear foreign bodies are generally older than cats.
- Cats frequently present with string or thread ingestion, while dogs ingest fabric such as clothing or carpet.

RISK FACTORS

Some animals are more prone to ingesting foreign objects than others (individual behavior) irrespective of age.

GEOGRAPHY AND SEASONALITY

December to January: ingestion of Christmas tree “icicles” (long, thin strips of foil-like plastic) or ribbons

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Owners may witness object ingestion.
- String may be visualized protruding from the anus.
- Clinical signs vary with duration of foreign body ingestion, as well as presence of a partial or complete obstruction.
- Vomiting, anorexia, ptyalism, depression, and weight loss (if chronic) are typical.

PHYSICAL EXAM FINDINGS

- Thorough examination at the base of the tongue should be performed to inspect for anchored foreign material.
    - In cats, elevation of the base of the tongue is best accomplished by opening the mouth via depressing the lower jaw using an index fingernail for pressure on the lower incisors. The thumb of the same hand is then used for externally pressing upward (dorsally) in the intermandibular space.
    - In dogs or cats, a complete examination may require sedation or general anesthesia.
- Painful and bunched intestines maybe detected with careful abdominal palpation.
- Dehydration, depression, or shock; severe with complete obstruction or peritonitis

ETIOLOGY AND PATHOPHYSIOLOGY

- Anchoring of ingested linear material around base of tongue, at the pylorus, or in the proximal intestinal tract
    - Without an anchor point, ingested linear foreign bodies may simply pass through the gastrointestinal (GI) tract without complication.
- Peristalsis results in plication of intestines along the length of the fixed material.
- Obstruction of intestinal tract results.
- Due to peristalsis, continued sawing action of the foreign material along mesenteric border may result in intestinal erosion and perforation and the development of peritonitis (see p. 865).
- Presence of an associated intussusception (see p. 622) is possible.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Any history of vomiting or anorexia in a dog or cat should prompt an inspection of the base of the tongue during physical examination; a circumferential erosive lesion containing the foreign body is pathognomonic. If no such finding is apparent, diagnostic imaging is indicated in all young animals presenting with vomiting, anorexia, abdominal pain, or a history of foreign-body ingestion. Plain abdominal radiography is often sufficient for a diagnosis, but occasionally the disorder is only confirmed during abdominal exploratory surgery.

DIFFERENTIAL DIAGNOSIS

- All other causes of intestinal obstruction such as neoplasia, intussusception, granuloma, stricture, adhesions, or volvulus
- Ileus

INITIAL DATABASE

- CBC: normal or shows evidence of inflammation/sepsis due to peritonitis
- Serum chemistry profile:
  - Hypokalemia associated with vomiting, anorexia
  - Hypoglycemia associated with peritonitis
  - Azotemia associated with dehydration
  - Hyponatremia may be more commonly seen in dogs with linear foreign bodies than in those with discrete foreign bodies.
- Urinalysis: unremarkable
- Abdominal radiographs:
  - Characteristic findings include plication of intestines with or without eccentric “comma-shaped” intraluminal gas bubbles.
  - Dogs may be more likely than cats to have characteristic radiographic findings, allowing the diagnosis of linear foreign body to be made radiographically.
- Abdominocentesis with fluid evaluation is indicated if peritonitis is suspected.

ADVANCED OR CONFIRMATORY TESTING

- Contrast radiography or abdominal ultrasound may be used if survey radiographic findings are inconclusive.
- Abdominal ultrasound:
  - May document a tortuous path of the proximal intestine as well as presence of an intraluminal linear object
  - May document associated disorders such as an intussusception or peritonitis
  - However, limited efficacy when gas or barium is present in the intestine
- Noniodinated contrast material is often recommended for upper GI radiographic contrast series, as up to 16% of cats and 41% of dogs may have perforation of the intestinal tract.
  - However, the advantage of iodine (will be resorbed from the peritoneal cavity if perforation exists, unlike barium) must be weighed against its reduced degree of contrast, foul taste (compliance), and the access to any spilled barium at the time of laparotomy, because surgical intervention is indicated if perforation is confirmed.

TREATMENT

TREATMENT OVERVIEW

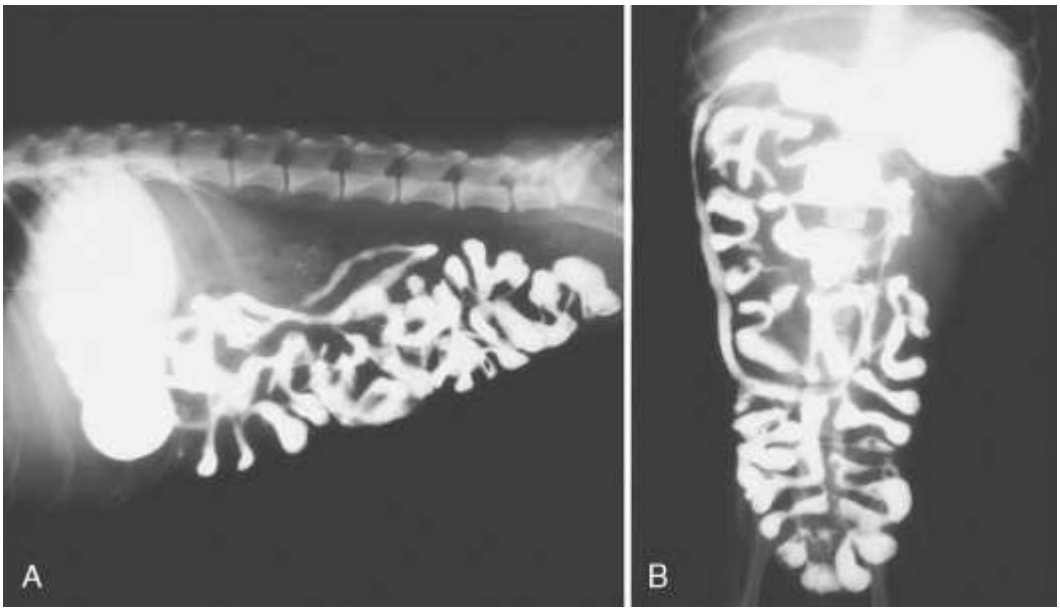
Rehydration and rapid surgical intervention are recommended. Specific goals are to:

- Correct dehydration and electrolyte imbalances.
- Remove obstructing foreign body:
  - Although conservative treatment in the cat has been reported, the high likelihood of perforation and the associated morbidity of peritonitis dictate that these cases be treated as surgical emergencies.
  - Conservative treatment is not de scribed in the dog, owing to the high risk of development of peritonitis.

ACUTE GENERAL TREATMENT

- Intravenous fluid therapy with electrolyte (potassium) supplementation according to need

- Prophylactic antibiotics:
  - Cefazolin, 22 mg/kg IV q 2 h during the perioperative period
- Surgical intervention includes thorough inspection of the entire intestinal tract for evidence of perforation.
- If the linear foreign body is fixed around the base of the tongue, it should be cut at this point.
- Foreign material is removed through a single or multiple enterotomies.
- Gastrostomy is performed to remove any foreign material trapped in the stomach, particularly at the pylorus.
- Single enterotomy removal using a red rubber catheter has been reported for use when no intestinal perforations are present.
  - This technique involves a single duodenal enterotomy with attachment of a red rubber catheter to the linear object. The enterotomy is closed, and the catheter with attached object is advanced distally until removed from rectum.
- If any necrosis, perforation, or intussusception of the intestines is present, a resection and anastomosis should be performed.
- Omentum or serosal patch may be placed to reinforce suture line.
- Change gloves and surgical instruments prior to abdominal lavage and closure.



FOREIGN BODY, LINEAR GASTROINTESTINAL Lateral **(A)** and ventrodorsal **(B)** radiographic projections of upper gastrointestinal (UGI) barium study. Patient had a gastrointestinal linear foreign body. Characteristic teardrop-shaped appearance of small-intestinal segments is apparent.

(Courtesy Dr. Richard Walshaw.)

CHRONIC TREATMENT

Postoperative considerations:

- Continue rehydration and daily electrolyte monitoring.
- NPO 6-12 hours after enterotomy, 12 hours after resection and anastomosis
- Administer GI protectants or antiemetics as needed.

NUTRITION/DIET

Feeding tube placement (typically esophageal) at the time of surgery should be considered in animals with marked weight loss, hypoalbuminemia, or in those patients with evidence of peritonitis.

POSSIBLE COMPLICATIONS

- Dehiscence; animals should be monitored in hospital for 48-72 hours postoperatively for signs of peritonitis. Risk factors include presence of preoperative peritonitis, serum albumin concentration <2.5 g/dL, and presence of a foreign body (versus neoplastic disease).
- Ileus
- Short bowel syndrome; unlikely if less than 70% of small intestine resected
- Stricture
- Recurrence

RECOMMENDED MONITORING

The following parameters should be monitored q 6-12 h until discharge from hospital:

- Body temperature
- Blood glucose
- Electrolytes
- Hematocrit and total solids
- Presence of abdominal pain

PROGNOSIS AND OUTCOME

- Delay in surgical intervention may increase risk of perforation and peritonitis.
- Presence of peritonitis or free abdominal gas on radiographs is associated with increased rate of mortality in the dog.
- Morbidity and mortality are 50% higher for dogs than cats.

PEARLS & CONSIDERATIONS

COMMENTS

- Do not put forceful traction on the linear object before or during surgery; this may cause iatrogenic laceration of the mesenteric border of the small intestine.
- Consider placing an intraoperative feeding tube (see p. 1267 , p. 1270 , and p. 1273) in these patients based on preoperative nutritional status, degree of patient debilitation, or anticipated postoperative anorexia.

EDITOR: RICHARD WALSHAW

Foreign Body, Esophageal

Additional Images Available on Website

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Any solid object that lodges in the esophagus

EPIDEMIOLOGY

SPECIES, AGE, SEX

Dogs and cats of any age, either sex

GENETICS & BREED PREDISPOSITION

Smaller dogs and cats seem to be affected more commonly.

RISK FACTORS

Feeding bones

ASSOCIATED CONDITIONS & DISORDERS

- Esophagitis is common.
- Esophageal perforation can cause septic mediastinitis, pyothorax, and/or pneumothorax.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Nonpenetrating foreign objects (main concerns: esophagitis, aspiration pneumonia)
- Penetrating foreign objects (main concerns: mediastinitis, pyothorax, esophagitis, aspiration pneumonia)

HISTORY, CHIEF COMPLAINT

- Acute onset of regurgitation is very suggestive.
  - Distinguish acute vomiting (active abdominal contractions leading to expulsion of food) from acute regurgitation (passive evacuation of food from the esophagus out of the mouth).
- Anorexia and ptyalism often occur (especially in cats).
- Some patients drink water but will not attempt to eat solid food.
- Dyspnea, nonspecific signs including lethargy and anorexia, and/or signs suggesting general discomfort may be seen if perforation occurs.
- Rarely, pressure of foreign object on trachea causes coughing or choking.

PHYSICAL EXAM FINDINGS

- Ptyalism occasionally noticed during exam
- Dysphagia or gagging may be seen during exam.
- Dyspnea/fever sometimes seen secondary to perforation and mediastinitis/pleuritis

ETIOLOGY AND PATHOPHYSIOLOGY

- Bones are the most common cause in dogs.
- Other causes include food boluses, fishhooks, rawhide treats, and dental chew toys.
- Hairballs are important in cats.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

An essential component of the history is asking whether the patient's behavior is one of frequent chewing or mouthing of objects (propensity to foreign-body ingestion). Thoracic radiographs are the screening test of choice; endoscopy is both confirmatory and therapeutic.

DIFFERENTIAL DIAGNOSIS

Regurgitation:

- Esophagitis
- Megaesophagus (acquired [idiopathic or secondary to systemic disease], or congenital)
- Esophageal mass
- Esophageal stricture
- Vascular ring anomaly

INITIAL DATABASE

- CBC and serum biochemistry panel: to look for evidence of inflammation and to prepare for anesthesia
- Plain thoracic radiographs:
  - Differentiate esophageal foreign body from megaesophagus (often generalized, as opposed to esophageal dilation associated with foreign body, which when present is seen cranial to the foreign body) and other thoracic masses (consider location relative to esophagus using at least two radiographic views).
  - Most foreign objects will be seen with good-quality films, but poultry bones and rawhide may be relatively radiolucent, requiring excellent technique for detection.
  - Evidence of pneumothorax, pneumomediastinum, and pleural effusion: any are suggestive of esophageal perforation.
  - Esophageal foreign objects can look like lung lesions radiographically.
  - Assess for complications: aspiration pneumonia and/or evidence of perforation (mediastinal widening, pleural effusion suggesting mediastinitis or pleuritis/pyothorax, respectively).
- Contrast esophageal radiographs:
  - Seldom needed and may obscure visualization during endoscopy
  - Risk of aspiration of contrast material

ADVANCED OR CONFIRMATORY TESTING

Esophagoscopy:

- Definitive differentiation of esophageal foreign body from esophagitis
- With good technique, the foreign object can virtually always be seen.

TREATMENT

TREATMENT OVERVIEW

Goals are to remove the foreign object and resolve any complications (e.g., esophagitis or perforation with resulting pleural/mediastinal sepsis).

ACUTE GENERAL TREATMENT

- Esophagoscopy to remove foreign object and determine degree of esophagitis (see p. 1279).
  - If foreign object cannot be removed, it can sometimes be pushed into the stomach where it is removed surgically or allowed to dissolve.
- Can use Foley catheter in some cases (i.e., place balloon behind foreign object, inflate balloon, then pull the catheter out so that the balloon draws the foreign object orad and out). Only for use with foreign objects that have no sharp edges.
- Surgery if endoscopy is unsuccessful at removing the foreign object
- Prokinetics (e.g., metoclopramide, 0.2-0.4 mg/kg IM or SQ PO q 8 h) and/or antacid (famotidine, 0.5-2 mg/kg IV, IM, SQ, or PO q 12-24 h; or omeprazole, 0.7-1 mg/kg PO q 12-24 h) to treat esophagitis (see p. 367). Do not give antacids if bone has been pushed into the stomach (gastric acid needed to dissolve the bone).
- Appropriate treatment of pulmonary disease/pleuritis if a perforation occurs

CHRONIC TREATMENT

Mechanical dilation of consequent stricture formation, if necessary (see p. 365)

NUTRITION/DIET

Place gastrostomy feeding tube (see p. 1270) if severe esophagitis is present.

POSSIBLE COMPLICATIONS

- Cicatrix leading to partial or complete esophageal obstruction
- Esophageal perforation leading to septic pleuritis/mediastinitis
- Excessive insufflation of air during endoscopy can cause tension pneumothorax.
- Severe bleeding is rare but possible when manipulating/removing foreign object.

PROGNOSIS AND OUTCOME

- Good if there is no perforation and esophagitis is not severe
- Good to guarded if severe, near-circumferential esophagitis is likely to cause stricture
- Guarded to poor if perforation has caused severe septic mediastinitis or pleuritis

PEARLS & CONSIDERATIONS

COMMENTS

- Rigid endoscopes are usually more effective than flexible ones in removing foreign objects.
- If a contrast esophagram is required, use a water-soluble iodide contrast agent; do not use barium.

TECHNICIAN TIP

Technicians involved in postoperative care of these patients should be familiar with use and maintenance of feeding tubes.

PREVENTION

- Avoid feeding bones.
- Be careful about allowing dogs to have/swallow rawhide chews.
- Use caution when dogs are in the area around baited fish hooks.
- Do not medicate cats with dry tablets or capsules; follow the medication with water or food.

Footpad Disorders

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Pathologic condition involving the footpad skin. The most common causes are trauma, contact dermatitis, cornification defects, pigmentation disorders, autoimmune disease, secondary bacterial infection, and self-trauma.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats. Although uncommon, footpad diseases are more frequently seen in cats in comparison to dogs, which develop more often interdigital lesions (see p. 891)
- Dogs less than 1 year of age: hereditary footpad hyperkeratosis, collagen disorder of the footpads of German shepherds, familial vasculopathies, acrodermatitis, junctional and dystrophic epidermolysis bullosa, and acral mutilation syndrome.
- Older dogs: superficial necrolytic dermatitis (SND; previously called *hepatocutaneous syndrome*) and epitheliotropic lymphoma

GENETICS & BREED PREDISPOSITION

- Vitiligo: Siamese cats and Belgian Groenendael dogs
- Footpad hyperkeratosis: Irish terriers and Dogues de Bordeaux
- Collagen disorders of the footpads: German shepherds
- Familial vasculopathy: German shepherds and Jack Russell terriers
- Acral mutilation syndrome: German shorthaired and English pointers, English springer spaniels, and French spaniels
- Dermatomyositis: Beauceron dogs (footpad lesions)
- Uveodermatologic syndrome: Akitas, Alaskan malamutes, and Siberian huskies
- Zinc-responsive dermatosis: Alaskan malamutes (genetic defect involving enteric zinc absorption) and Siberian huskies
- Systemic lupus erythematosus (SLE): collies, Shetland sheepdogs, and German shepherds

GEOGRAPHY AND SEASONALITY

Leishmaniasis in endemic areas

RISK FACTORS

- Lacerations/trauma: outdoor activities, roaming
- Footpad calcinosis cutis: renal failure and hyperparathyroidism
- SND: hepatopathy or glucagonproducing pancreatic tumor

ASSOCIATED CONDITIONS & DISORDERS

- SLE: systemic signs, depending on the organs involved
- Feline paraneoplastic alopecia: pancreatic carcinoma or bile duct carcinoma
- Xanthomatosis: can be associated with diabetes mellitus in cats
- Feline plasma cell pododermatitis: possible concurrent feline immunodeficiency virus (FIV) infection or renal glomerulonephritis and amyloidosis
- Uveodermatologic syndrome: granulomatous uveitis
- Cutaneous horns: possible concurrent feline leukemia virus (FeLV) infection in cats

FOOTPAD DISORDERS Swollen, ulcerated footpad in a cat with plasma cell pododermatitis.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Skin lesions located on one or multiple footpads. Self-trauma and lameness may be observed. Foot involvement may also be part of a more generalized condition. With footpad lacerations, owner-observed bleeding often is the first sign.

PHYSICAL EXAM FINDINGS

- Number of feet affected: lesions on multiple feet (see Associated Conditions and Disorders above) versus on one foot only (neoplasia, trauma, infection)
- Depending on the disease, several changes can be present on the footpads:
  - Swelling and inflammation
  - Hyperkeratosis
  - Cracking and fissuring
  - Ulcers
  - Depigmentation or hyperpigmentation
  - Draining tracts
  - Change in footpad texture
  - Signs of pain on walking, or during handling of the paw(s)

ETIOLOGY AND PATHOPHYSIOLOGY

Footpad lesions can arise following various pathomechanisms, including:

- Direct trauma
- Contact with an irritant or corrosive substance, which can result in skin injury and inflammation
- Development of antibodies or activated lymphocytes against normal body constituents (autoimmune diseases), or against inciting antigens (drugs, bacteria, viruses), causing tissue damage
- Altered process of cornification (proliferation/differentiation/desquamation) resulting in hyperkeratosis
- Defective melanin production or a destruction of melanocytes, leading to pigment disorders. Moreover, a disorder at the basal epidermal cell level can result in hypopigmentation.
- Hereditary sensitive neuropathy in acral mutilation syndrome
- In addition to primary etiologies, self-trauma and secondary bacterial infection can result in footpad lesions.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Extent of testing varies widely and is adapted to each case. The diagnosis will be based on dermatologic examination as well as on complementary testing, which will vary depending on the list of possible differential diagnoses.

DIFFERENTIAL DIAGNOSIS

- Environmental: trauma, irritant contact dermatitis, calcinosis cutis caused by percutaneous penetration of calcium salts, and thallium toxicosis
- Hereditary: see Genetics & Breed Predisposition above.
- Allergic/immune-mediated:
    - Dogs: pemphigus foliaceus, SLE, vasculitis, toxic epidermal necrolysis, erythema multiforme, cryoglobulinemia and cryofibrinogenemia (cold agglutinin disease), bullous pemphigoid, epidermolysis bullosa aquisita, uveodermatologic syndrome, and drug reactions
    - Cats: eosinophilic granuloma complex, pemphigus foliaceus, SLE, erythema multiforme, toxic epidermal necrolysis, vasculitis, cryoglobulinemia and cryofibrinogenemia (cold agglutinin disease), drug reactions, and plasma cell pododermatitis
- Nutritional: zinc-responsive dermatosis
- Endocrine/metabolic:
    - Dogs: SND and footpad calcinosis cutis (often associated with chronic kidney disease and parathyroid hyperplasia)
    - Cats: paraneoplastic alopecia and xanthomatosis (idiopathic or associated with diabetes mellitus)
- Neoplastic: epitheliotropic cutaneous lymphoma, squamous cell carcinoma, fibrosarcoma, mast cell tumor, etc.
- Infectious: canine distemper, cowpox-virus infection in cats, subcutaneous or systemic mycotic infections, canine papillomatosis, and hookworm and *Pelodera*dermatitis
- Miscellaneous: noninflammatory hypomelanosis (vitiligo) or hypermelanosis (lentigo in orange cats), cutaneous horns, idiopathic footpad hyperkeratosis seen in older dogs, and idiopathic sterile granulomas and pyogranulomas

INITIAL DATABASE

- History and general examination are very important in the diagnostic process.
- Cytology of any exudates: bacteria, inflammatory cells, acantholytic keratinocytes (pemphigus), and fungal organisms
- CBC/biochemistry panel/urinalysis: results variable, depending on suspected cause
- Thoracic/abdominal imaging, if relevant, to confirm systemic disease (e.g., SND) or to stage tumors

ADVANCED OR CONFIRMATORY TESTING

- Skin biopsies for histopathology and possibly immunofluorescence or immunohistochemical stainings
- Endocrine tests and serology depending on suspected disease
- Coombs' test: cold agglutinin disease
- Antinuclear antibody test (ANA): positive in virtually all patients with SLE

TREATMENT

TREATMENT OVERVIEW

The goal of treatment is to reach permanent cure or control of the disease; however, sometimes palliative treatment is the only option (e.g., malignancy).

ACUTE TREATMENT

Depends on etiology of the lesion and possible secondary infection

- Foot soaks or bandages sometimes useful
    - Hyperkeratotic lesions: warm water foot soaks for 5-10 minutes, followed by application of a softening agent (e.g., petroleum jelly). The owners should be warned that this can be messy.
    - For more severe hyperkeratosis, daily foot soaks in 50% propylene glycol. Improvement is expected within a few days. Lifelong maintenance therapy (1-2 times weekly as needed) is often required.
    - Draining lesions can benefit from foot soaks in warm water with added Epsom salts (magnesium sulfate, 30 mL/L) for 10 minutes q 12-24 h, until draining stops.
- Surgery can be considered for some diseases: closure of uncontaminated sharp lacerations, excision of cutaneous horns and other tumors, surgical débridement of devitalized tissues.
- Medication varies depending on underlying cause.

PROGNOSIS AND OUTCOME

Will vary according to the disease; generally good with localized lesions, reversible causes, and dedicated owners, and guarded to poor with systemic illness that is progressive

PEARLS & CONSIDERATIONS

COMMENTS

- Successful therapy is based on identifying the underlying cause.
- Skin biopsies are often needed for the diagnosis of footpad disorders.

PREVENTION

Advise against breeding of animals with hereditary diseases.

Food Allergy, Gastrointestinal

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Food allergy and food intolerance are repeatable adverse reactions to specific dietary components that respond to exclusion of the causative agent. Food allergy is immune-mediated, whereas food intolerance is not.

SYNONYMS

Dietary/food hypersensitivity, adverse reaction to food

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs and cats
- Reported age 4 months to 14 years; up to 33% of cases in dogs <1 year old

GENETICS & BREED PREDISPOSITION

- Dogs: cocker spaniel, springer spaniel, Labrador retriever, collie, miniature schnauzer, shar-pei, West Highland white terrier, Wheaten terrier, boxer, dachshund, dalmatian, Lhasa apso, German shepherd, and golden retriever at increased risk
- Irish setter, soft-coated Wheaten terrier: familial gluten-sensitive enteropathy
- Cats: Siamese and Siamese-cross

RISK FACTORS

- Increased intestinal permeability (e.g., viral enteritis, inflammatory bowel disease [IBD])
- Immunoglobulin (Ig) A deficiency
- Allergic disease (atopy)

GEOGRAPHY AND SEASONALITY

Usually nonseasonal, as the provocative agent is typically part of the normal diet

ASSOCIATED CONDITIONS & DISORDERS

- Gastrointestinal (GI): antibiotic-responsive enteritis (small-intestinal bacterial overgrowth), IBD, exocrine pancreatic insufficiency, pancreatitis, chronic gastritis, gastroesophageal reflux, lymphangiectasia
- Skin disease: dermatologic food allergy, (see p. 400), atopic dermatitis (see p. 106)

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Vomiting, weight loss, intermittent signs of abdominal pain, soft feces, diarrhea, excessive flatulence, increased frequency of defecation, irritable demeanor, and/or concurrent cutaneous signs
- The allergen(s) typically have been ingested for months to years before signs develop. If an allergen is ingested intermittently, the owner may note an association between ingestion and occurrence of signs.

PHYSICAL EXAM FINDINGS

- Systemic: thin body condition, decreased appetite, weight loss, lethargy, urticaria/angioedema/anaphylaxis
- GI-specific: as above (History), diarrhea
- Skin: pruritus (face, neck, ears, ventral trunk, and feet), otitis externa, urticaria, or angioedema. In cats, self-inflicted alopecia or miliary dermatitis may be observed.
- Allergic conjunctivitis possible

ETIOLOGY AND PATHOPHYSIOLOGY

- Food allergens + altered GI mucosal barrier or poor oral tolerance
- Gliadin in gluten portion of wheat, barley, or rye serves as potent antigen (see online chapter: Gluten-Sensitive Enteropathy)
- Abnormal immunologic response (often IgE mediated)
- Immediate and/or delayed hypersensitivity reaction
- Altered GI structure and function (any level of GI tract from stomach to large intestine)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Dietary hypersensitivity is diagnosed based on negative results of routine diagnostic tests, GI biopsy results indicating inflammation (if biopsy performed), and positive response to an elimination food trial. An accurate diagnosis depends on ensuring that: (1) an elimination diet is truly novel (complete dietary history elicited by veterinarian and provided by owner, and all ingredients ever ingested are eliminated during the trial), (2) client compliance is optimal, and (3) confounding factors (e.g., treatment with antibiotics or corticosteroids) do not occur concurrently.

DIFFERENTIAL DIAGNOSIS

- Any chronic GI disorder (e.g., lymphangiectasia, IBD, lymphoma, enteritis [bacterial, viral, fungal])
- Dietary indiscretion
- Pancreatic disease (pancreatitis, exocrine pancreatic insufficiency [EPI])
- Liver disease
- Hyperthyroidism (cats)
- Metabolic/endocrine (diabetes mellitus, hypoadrenocorticism, acid/base or electrolyte disturbances)

INITIAL DATABASE

- Dietary history:
    - Thoroughly evaluate the current diet, including regular food, treats, snacks, human food, scraps, flavored medications, and anything else ingested; read all ingredient labels
    - CBC: often unremarkable; mild anemia of chronic disease, increased eosinophils or basophils possible
    - Serum biochemistry profile: nonspecific changes
    - Urinalysis: nonspecific; dogs with chronic inflammatory diseases may have concurrent proteinuria (protein-losing nephropathy)
    - Fecal flotation and smear: rule out parasitism
    - Feline immunodeficiency virus/feline leukemia virus testing in cats
    - Serum T4 thyroid profile: for hyperthyroidism in cats

ADVANCED OR CONFIRMATORY TESTING

- Elimination food trial: diagnostic test of choice; both diagnostic and therapeutic
- Intradermal skin or serum allergen testing (patients with concurrent cutaneous signs); however, both skin and serum tests for specific food allergens are unreliable and do not correlate with results of elimination food trials.
- Abdominal radiography and ultrasonography to rule out other causes of GI disease (e.g., evidence of ob-struction, masses, infiltration, non-GI abdominal lesions); findings usually unremarkable.
- GI endoscopy with biopsies to rule out other structural GI diseases. With food allergy, as with IBD, nonspecific increases in lymphocytes, plasma cells, or eosinophils in the lamina propria are found; confirmation requires favorable response to dietary modification.
- Serum trypsin-like immunoreactivity (to rule out EPI)
- Serum bile acids: hepatopathies; severe GI disease may falsely lower serum bile acid concentrations.

TREATMENT

TREATMENT OVERVIEW

- Control clinical signs; usually achievable solely by eliminating the provocative dietary component(s).
    - Feed a limited number of protein sources (with high digestibility), such as novel protein sources or protein hydrolysate–containing diet.

- Avoidance of wheat, barley, or rye ingredients (gluten-induced enteropathy)
- Long-term control: feed a satisfactory diet not containing the provocative component(s); most owners prefer a commercial diet. Must be sustainable for months to years. Identify treats without the allergen.

NUTRITION/DIET

- Elimination food trial lasting 4 to 8 weeks:
  - Provide a single specific food, ideally with a novel protein (e.g., venison, duck, or other meat not found in foods previously eaten by the pet) and carbohydrate source. Commercial or homemade limited-antigen or hydrolyzed protein diets may be used. Many commercial limited-antigen diets are available; selection is based on patient's current diet and avoidance of known provocative ingredients.
  - *No* other food (or supplements, treats, chewable medications, or other consumables) may be consumed during the trial. Because the problem is immune mediated, even a single violation can reactivate hypersensitivity.
  - Client compliance is essential. Both deliberate (e.g., treats, human foods and snacks, etc.) and inadvertent (e.g., chewable heartworm tablets) violations of the trial must be avoided.
- GI signs typically start to abate within days, and substantial improvement usually occurs within 4 weeks:
  - Although partial improvement is expected within 4 weeks, up to 8 weeks may be needed before significant abatement of clinical signs occurs.
  - Absence of clinical improvement after 8 weeks of strict diet adherence makes food allergy extremely unlikely.
- Skin lesions may take 8 weeks or longer to resolve, although significant improvement is seen within 8 weeks in the vast majority of cases.
- Concurrent treatment with corticosteroids (prednisone, 1-2 mg/kg PO q 24 h, tapering to lowest effective dose and stopping if signs resolve; prednisolone is preferred for cats) is often necessary but will invalidate conclusions if implemented during the trial.
  - If a positive response to the diet is seen, a food challenge is performed to confirm the diagnosis and unambiguously identify the provocative antigen. Additional ingredients are added individually until the signs recur. Clients often are reluctant to do this, but if the patient becomes allergic to the current hypoallergenic diet, there is no way to identify which specific ingredient was allergenic to permit rational choice of an alternative diet.
  - Challenge with the regular food(s) usually results in recrudescence of clinical signs within hours to a few days.
  - Any diet without allergens identified via provocative challenge may be fed, even regular commercial diets.
  - Absence of signs within 14 days of continuous provocative challenge makes any improvement during the trial unlikely to have resulted from diet therapy.

POSSIBLE COMPLICATIONS

- Inappetence, weight loss
- Nutritional-related problems if imbalanced homemade food used
- Intestinal neoplasia (lymphoma) as consequence of chronic GI inflammation

RECOMMENDED MONITORING

If clinical improvement and resolution of clinical signs occur with the trial diet, diagnosis of food sensitivity is confirmed by recurrence of the same clinical signs (provocative challenge) after reintroduction of the original diet (including all treats, snacks, flavored medications, etc.).

PROGNOSIS AND OUTCOME

Good prognosis if offending foods or ingredients are identified and eliminated from the diet

PEARLS & CONSIDERATIONS

COMMENTS

- Food hypersensitivity should be a differential diagnosis in almost all animals presenting with chronic GI signs.
- Although it can be difficult to convince owners to complete a strict food trial for 4-8 weeks, they should be encouraged to do so, as food sensitivity is a “good” disease (i.e., entirely curable by simply changing the diet).
- Using a food diary during the elimination trial helps the owner monitor clinical response and compliance.

TECHNICIAN TIPS

Gradual transition to a new food is critical for a pet with health problems and may be the single most important thing animal caretakers can do to help a pet accept a new food. Mixing more of the new food with less of the old food over a period of at least seven days can make acceptance optimal as a transition into the elimination trial. An alternative method for transitioning, especially for cats, is to offer the new food side by side with the old food in identical dishes, instead of mixing them both in the same dish.

CLIENT EDUCATION

- Human food sources, snacks, treats, and food for other animals (e.g., dog having access to cat food) can be an allergen.
- Provide a handout listing all items the animal may not ingest during the food trial to be read by all household members.
- Contact the owner during the first week of the food trial to check that the elimination diet has been started, provide support, and address any problems that may have arisen (e.g., patient will not eat the food).

AUTHOR: PHILIP ROUDEBUSH

EDITORS: DEBRA L. ZORAN, KATHRYN E. MICHEL

Food Allergy, Dermatologic

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A well-recognized, abnormal response to an ingested food or food additive that produces clinical signs affecting the skin, most commonly pruritus

SYNONYMS

The preferred term is *dermatologic adverse food reaction* (DAFR). The terms *food allergy* or *food hypersensitivity* are often incorrectly used synonymously with adverse food reaction. These terms more accurately refer specifically to the subcategory of adverse food reactions that have an immunologic basis. The term *food intolerance*, also encompassed within DAFR, is reserved for the subcategory of adverse food reactions without an immunologic basis and includes metabolic food reactions, food poisoning, food idiosyncrasies, and pharmacologic reactions to food.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: from 4 months to 14 years:
  - Up to one-third of cases occur in dogs <1 year old.
- Cats: from 6 months to 12 years:
  - 50% develop signs by 2 years

GENETICS & BREED PREDISPOSITION

- Dogs: no strong breed predilection
- Cats: the Siamese cat may be at increased risk.

RISK FACTORS

Risk factors include certain foods or food ingredients, poorly digestible proteins, any disease that increases intestinal mucosal permeability, selective IgA deficiency, age (<1 year), and concurrent allergic disease.

GEOGRAPHY AND SEASONALITY

Nonseasonal

ASSOCIATED CONDITIONS & DISORDERS

- 20%-30% of cases may have concurrent atopic dermatitis or flea allergy dermatitis
- 10%-15% of cases may have concurrent gastrointestinal (GI) signs such as vomiting and/or diarrhea
- Secondary skin infections with bacteria and yeast are common.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- The chief complaint is of nonseasonal pruritus, recurrent pyoderma, or otitis externa.
- There may be a history of a poor response to glucocorticoid therapy.
- Adverse food reactions with an immunologic component (food allergy, food hypersensitivity) usually develop after prolonged exposure to a food allergen, whereas food intolerance may occur after a single exposure, as immune mechanisms are not involved.

PHYSICAL EXAM FINDINGS

- No specific pattern of skin lesions exists

- Dogs:
  - Lesion distribution: feet, face, axillae, perineal region, inguinal region, rump, and ears.
  - 25% may show only otitis externa
  - Lesions may consist of papules, pustules, wheals, angioedema, erythema, ulcers, excoriations, lichenification, alopecia, scales, crust, acute moist pyotraumatic dermatitis.
- Cats:
  - Lesion distribution: usually centered around the head and neck but may be generalized
  - Manifestations may consist of generalized pruritus without lesions; miliary dermatitis; pruritus with self-trauma centered around the head, neck, and ears; self-induced alopecia; scaling dermatoses; lesions of the eosinophilic granuloma complex; angioedema; urticaria; conjunctivitis.

ETIOLOGY AND PATHOPHYSIOLOGY

- A variety of etiologies are proposed to cause DAFR.
- The majority are attributed to food allergies; however, immunologic tests are rarely performed to confirm this suspicion.
- Common food allergens in dogs include beef, dairy products, wheat, eggs, chicken, lamb, and soy. Common food allergens in cats include beef, dairy products, and fish.
- Food allergies are thought to be the result of primarily a type I hypersensitivity reaction, although type III and IV reactions have also been proposed.
- Several host defenses exist to prevent absorption of intact allergens from the GI tract, including effective digestion, intestinal peristalsis, an intact intestinal mucus layer, tight junctions between mucosal cells, and mucosal IgA. The small amounts of food proteins that do cross the intestinal mucosa activate T-suppressor cells and stimulate an immune response in the gut-associated lymphoid tissue that leads to tolerance. A defect in any of these defense mechanisms may lead to sensitization of the immune system and development of a food allergy.
- Idiosyncratic adverse reactions to food and food additives, such as erythema multiforme, are suspected to occur in animals (unproven).
- Some foods contain products that may directly produce a pharmacologic effect. Scombroid fish such as tuna, mackerel, skipjack, and bonito contain vasoactive amines such as histamine and have been reported to cause adverse reactions in cats and dogs. Cadaverine, another vasoactive amine, may exacerbate adverse food reactions by inhibiting histamine metabolism.

FOOD ALLERGY, DERMATOLOGIC Otitis externa in a dog with food allergy. Extensive erythema of the concave surface of the pinna was present.

FOOD ALLERGY, DERMATOLOGIC Facial erythema and excoriation in a Himalayan cat with food allergy.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The clinical presentation is similar to several other common dermatoses, and the diagnosis can only be confirmed through the completion of a strict elimination diet trial. Concurrent bacterial and yeast infections are common and should be identified and treated. Many differential diagnoses can be identified (and should be sought) prior to determining the need for a diet trial. Note that environmental allergy/atopic dermatitis is a diagnosis of exclusion and cannot be ruled out by testing.

DIFFERENTIAL DIAGNOSIS

- Ectoparasites (*Sarcoptes*, *Demodex*[uncommonly], *Cheyletiella*, *Notoedres*, *Otodectes*, fleas, lice)
- Bacterial folliculitis (*Staphylococcus pseudintermedius*[*S. intermedius* was reclassified in 2007])
- *Malassezia* dermatitis
- Other hypersensitivity disorders (environmental allergens, flea bite, other ectoparasites, intestinal parasite, contact, drug)
- Dermatophytosis (ringworm)
- Cornification disorders
- Behavioral disorders (feline psychogenic alopecia, flank sucking, tail-biting, self-nursing)
- Neoplasia (mast cell tumor, epitheliotropic lymphoma)

INITIAL DATABASE

- Cytologic evaluation: Secondary microbial infections with bacteria and yeast are common. Acetate tape, direct impression smears, and superficial skin scrapings are appropriate methods for obtaining cytologic samples. Ears and interdigital and intertriginous regions are commonly affected. The contribution of a confirmed secondary microbial infection to clinical signs is determined by assessing the patient's response to appropriate antimicrobial therapy.
- Skin scrapings: deep focal skin scrapes should be used for detecting *Demodex canis*, whereas broad superficial scrapes may be more beneficial in detecting *Sarcoptes*, *Cheyletiella*, and *Demodex gatoi*(cats). Note: *Sar-coptes*, *Cheyletiella*, and *D. gatoi*mites may not be detected on all skin scrapings; they require a trial course of appropriate therapy to be fully ruled out when the index of suspicion for infection is high.
- Examination for fleas/flea comb: presence of fleas, flea dirt, or tapeworms raises the index of suspicion for flea allergy dermatitis as a cause of clinical signs, but this entity should be fully ruled out by treatment with an appropriate adulticidal flea control product in patients presenting with pruritic skin disease.
- Elimination diet: only useful test for confirming the diagnosis of DAFR. Current serologic tests correlate poorly with the true offending allergen. The ideal diet should be nutritionally adequate and use a single highly digestible protein source or protein

hydrolysate, avoiding additives and vasoactive amines. The exact protein source is not important, but it should be one to which the animal has not been previously exposed. This diet should be fed exclusively for 8-12 weeks, ensuring that treats, flavored heartworm preventives, table scraps, and any other sources of food are also eliminated from the diet. A significant decrease in pruritus is typically seen within 4-6 weeks, but may take up to 12 weeks. Properly prepared home-cooked diets are an alternative to commercial products, although it may be challenging to ensure they are nutritionally balanced (this requirement may be waived for the duration of the diet trial so long as the patient is full grown, otherwise healthy, and appears to be maintaining body condition).

ADVANCED OR CONFIRMATORY TESTING

Dietary challenge: necessary step to confirm the diagnosis. The original diet is fed back to the animal for 10-14 days. In most cases of true DAFR, there is an exacerbation in pruritus within 3-7 days, but it may take up to 14 days. Once the pruritus is under control again, individual ingredients may be fed for 14 days each to determine which ingredients caused the adverse reaction. In most cases, only 1 or 2 substances are the cause of the adverse reaction.

TREATMENT

TREATMENT OVERVIEW

Treatment consists of the identification and permanent removal of the offending food from the patient's diet. Secondary infections require identification and treatment to achieve full resolution of clinical signs.

ACUTE GENERAL TREATMENT

- Manage any secondary microbial infections with appropriate antimicrobial therapy. A 3-4 week course of cephalexin, 22-30 mg/kg PO q 12 h, is appropriate for most superficial bacterial infections. Topical or oral azole antifungals can be used for *Malassezia*dermatitis.
- Systemic or topical antipruritic therapy, such as oral antihistamines or topical oatmeal-based shampoos, may be necessary initially to control self-trauma. Corticosteroid use should be avoided where possible, as it may mask other conditions and make it more difficult to assess response to the elimination diet trial. In cases of marked pruritus, corticosteroids may be necessary initially (e.g., prednisolone, 0.5-1 mg/kg PO q 24 h × 1-2 weeks maximum, to avoid masking effect of elimination diet).

NUTRITION/DIET

The patient may be maintained on a balanced home-cooked or commercial elimination (hypoallergenic) diet which avoids the offending food, or provocative testing with individual ingredients may be used for determining which dietary components can be tolerated.

PROGNOSIS AND OUTCOME

The prognosis is excellent with avoidance of offending foods.

PEARLS & CONSIDERATIONS

COMMENTS

- The first step when dealing with any suspect DAFR is to make sure other causes of pruritus have been ruled out.
- In some cases, a single elimination trial may be insufficient, and a second elimination trial using an alternative commercial novel protein or hydrolyzed protein source, or a novel-protein home-cooked diet, may be required to see improvement.
- Considering that canine atopic dermatitis is much more prevalent than food allergy, it is important to inform the owner that approximately 70%-80% of dogs will not show appreciable reduction in pruritus during the food trial. Doing so may help avoid owner frustration and ensure better compliance.

TECHNICIAN TIPS

- It is helpful to label the patient's file in a readily identifiable manner so that inappropriate treats or diets are not fed inadvertently if the patient is in hospital.
- Technicians can have an important role in informing/educating clients on the feeding changes and need of strict food intake

during the elimination diet trial in order to ascertain that food allergy is indeed confirmed or ruled out at the end of the trial period. Many owners do not understand that “just one treat” may invalidate the entire process, and hearing this reinforced by the technician can be extremely valuable.

EDITOR: MANON PARADIS

Follicular Dysplasia, Canine

Follicular Dysplasia, Canine Follicular dysplasia in a Portuguese water dog.

BASIC INFORMATION

DEFINITION

Follicular dysplasias are noninflammatory disorders of the haircoat that result in hair loss and altered coat quality. An underlying genetic predisposition for abnormal follicular development has been noted in specific breeds.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- These disorders affect dogs of either sex and any reproductive status.
- Color dilution alopecia (CDA) and black hair follicular dysplasia (BHFD) are disorders of early onset (usually <1 year of age).
- Non–color-linked follicular dysplasias usually start during adulthood.

GENETICS & BREED PREDISPOSITION

- CDA: seen in several breeds with dilute coat colors such as in blue Doberman pinscher, dachshund, Great Dane, Yorkshire terrier, and Chihuahua
- BHFD: recognized in several bi- or tri-colored breeds (e.g., saluki, basset hound) as well as mixed breeds but can also be seen in solid-colored (black) breeds

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Canine recurrent flank alopecia (see p. 966)
- Alopecia X (see p. 58)
- CDA
- BHFD
- Follicular dysplasia of specific breeds (Irish water spaniel, Portuguese water dog, red and black Doberman, Chesapeake Bay retriever, Pont Audemer spaniel dog, etc.)

HISTORY, CHIEF COMPLAINT

Dogs born with a normal haircoat are presented for evaluation of a gradual thinning of the haircoat.

PHYSICAL EXAM FINDINGS

- CDA: progressive alopecia involving exclusively hair follicles in the areas with diluted coat color, usually starting around 6 months of age (light blue) but as late as 2-3 years of age (steel blue Doberman). The rate of hair loss is variable, but most light-colored dogs are almost completely alopecic by 2-3 years of age. These dogs are prone to follicular plugging and secondary recurrent bacterial folliculitis that can aggravate the hair loss and may cause pruritus.
- BHFD: progressive alopecia and excessive scaling, exclusively involving the black-haired areas, seen as early as 4 weeks of age.

ETIOLOGY AND PATHOPHYSIOLOGY

- Follicular dysplasia can be divided histologically into categories in which the hair cycle is abnormal (canine recurrent flank alopecia, alopecia X) and those in which there are abnormalities in the process of melanization of the pilosebaceous units (CDA, BHFD).
- All known forms of follicular dysplasia appear to be genetically determined.
- In CDA, an inherited autosomal recessive disorder of melanosome transportation has been demonstrated.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is based on history, clinical findings, and ruling out other differentials. A diagnosis of follicular dysplasia is suspected based on breed predilection and in some cases an early onset of color-linked alopecia (CDA, BHFD).

DIFFERENTIAL DIAGNOSIS

- Endocrinopathies (hypothyroidism, hyperadrenocorticism, hyperestrogenism)
- Infectious process (pyoderma, demodicosis, dermatophytosis) in some clinical presentations

INITIAL DATABASE

- Trichogram: large melanin clumps along the hair shaft, causing distortion and fracture of the hair in CDA and BHFD

ADVANCED OR CONFIRMATORY TESTING

Skin biopsy and dermatohistopathologic evaluation: dilated and cystic hair follicles with melanin clumping in follicular basal cells, hair bulbs, hair shafts, follicular lumen in CDA and BHFD.

TREATMENT

TREATMENT OVERVIEW

The main goals are to attempt hair regrowth and control secondary bacterial folliculitis, seen commonly in CDA.

GENERAL TREATMENT

Anecdotal evidence exists for the efficacy of melatonin at 3-6 mg/dog PO q 8-12 h for 1-2 months to stimulate hair growth reported in CDA.

PROGNOSIS AND OUTCOME

- These entities are incurable, genetically based dermatoses.
- Affected dogs are healthy otherwise, with the exception of secondary pyoderma in CDA.

PEARLS & CONSIDERATIONS

COMMENTS

- The early onset, color link (CDA, BHFD), and/or breed predisposition make the diagnosis straightforward in many cases.
- The main impact of these disorders is cosmetic rather than medical, unless secondary infection or sunburn occurs.

Paradis M, Cerundolo R: An approach to symmetrical alopecia in the dog. In Foster A, Foil C, editors: BSAVA manual of small animal dermatology, ed 2, Gloucester, UK, 2003, British Small Animal Veterinary Association, pp 83–93.

AUTHOR & EDITOR: MANON PARADIS

Flea Bite Allergy

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Development of hypersensitivity reaction(s) and subsequent skin lesions accompanied by variable pruritus in response to exposure to flea salivary antigens. Very common in flea-endemic regions. Must be differentiated from flea infestation alone, where fleas are present on the animal or in the environment, but the animal does not develop clinical signs of skin disease.

SYNONYMS

Flea allergy dermatitis (FAD), flea bite hypersensitivity

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Dogs: develops at any age but is most common in 3- to 5-year-olds and uncommon if <6 months old
- Cats: no age predilection reported

GENETICS & BREED PREDISPOSITION

- Dogs: breed predilections not well established
- Cats: no breed predilections reported

RISK FACTORS

- Genetic predisposition to develop allergic dermatitis
- Dogs: intermittent flea exposure
- Cats: persistent flea exposure
- Atopic patients are at greater risk for flea bite allergy.

GEOGRAPHY AND SEASONALITY

- Diagnosed worldwide wherever fleas reside
- Seasonal in climates with cold winters
- Continuous in warm, humid climates
- Nonseasonal when indoor infestation is present

ASSOCIATED CONDITIONS & DISORDERS

- Infestation with *Dipylidium caninum*
- Gastric trichobezoars (hairballs) associated with excessive grooming
- Secondary bacterial pyoderma

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- Canine flea bite allergy:
  - Pruritic papular dermatitis
  - Acute moist dermatitis (“hot spot”)
  - Fibropruritic nodules in chronic cases
- Feline flea bite allergy:
  - Pruritic papulocrustous dermatitis (“miliary dermatitis”)
  - Symmetric self-induced alopecia
  - Eosinophilic granuloma complex

HISTORY, CHIEF COMPLAINT

- Dogs: acute onset of moderate-severe pruritus. Hair loss and malodor in longer-standing cases. Clients may report live fleas on their pet or experience flea bites themselves.
- Cats: hair loss, pruritus, excessive grooming, vomiting hairballs, or small crusted papules noted under the haircoat. Lip ulcers, raised plaques, or granulomas may be noted. Fleas are less commonly observed than in dogs.

PHYSICAL EXAM FINDINGS

Dogs:

- Papulocrustous lesions, varying degrees of alopecia, erythema, and excoriations. Most commonly affected regions: dorsal lumbosacral region, tailhead, and caudomedial thighs. Ventral abdomen, especially near the umbilical area, flanks, and neck may also be affected.
- Well-demarcated, moist, erythematous, exudative skin lesions with alopecia
- Lichenification, lattice pattern hyper-pigmentation, scaling
- Poor body condition, weight loss, worn incisor teeth
- ± Fleas, flea excreta (“flea dirt”)

Cats:

- Self-inflicted symmetrical hair loss on the ventral abdomen, lateral flanks, and caudomedial thighs
- Erythematous crusted papules around the neck and on the lumbosacral region (miliary dermatitis)
- Lesions consistent with eosinophilic granuloma complex (indolent ulcer, eosinophilic plaque, eosinophilic granuloma)
- Excoriations, crusts
- Weight loss, poor body condition, peripheral lymphadenopathy
- ± Fleas, flea excreta (“flea dirt”)

ETIOLOGY AND PATHOPHYSIOLOGY

- Repeated exposure to flea salivary antigens induces development of various hypersensitivity reactions (see p. 1399):
  - Type I (immediate/anaphylactic) hypersensitivity (dogs, cats)
  - Cutaneous basophil hypersensitivity (dogs)
  - Type IV (delayed/cell-mediated) hypersensitivity (dogs, cats)
  - Late-phase IgE-mediated reactions (dogs)
- Hypersensitivity reactions, when recurrent or persistent, may become more intense and be triggered with progressively less antigen (flea saliva).

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

The diagnosis of flea bite allergy is based almost entirely on history and physical exam findings. Even in the absence of live fleas or flea excreta, physical signs as described warrant empirical antiflea treatment before or while pursuing advanced diagnostic testing for other causes of pruritus.

DIFFERENTIAL DIAGNOSIS

- Dogs, cats:
  - Other hypersensitivities (atopic dermatitis, foods, intestinal parasites, drugs)
  - Ectoparasitic dermatoses
  - Bacterial folliculitis
- Dogs:
  - *Malassezia* dermatitis
- Cats:
  - Dermatophytosis
  - Anal sac disease (excessive grooming of ventral abdomen, lateral flanks and caudomedial thighs)

INITIAL DATABASE

- History
- Physical examination findings

- ± Observation of fleas, excreta

ADVANCED OR CONFIRMATORY TESTING

- Intradermal testing with 1 : 1000 w/v aqueous solution of whole flea antigen
- ELISA serologic allergen screening for flea saliva antigens
- Response to flea eradication—considered by many to be most definitive

TREATMENT

TREATMENT OVERVIEW

In flea infestation, the goals of treatment are focused on eradication of the flea population from the animal and its environment (i.e., integrated flea management). In flea bite allergy, the goals of treatment also include providing rapid relief of the clinical signs and discomfort.

ACUTE GENERAL TREATMENT

- Corticosteroids:
  - Dogs: prednisone/prednisolone, 1 mg/kg PO daily for 5-7 days, then taper; may also use 0.0584% hydrocortisone acetonate spray topically once daily as monotherapy or in addition to oral predniso(lo)ne
  - Cats: prednisolone, 2.2 mg/kg PO daily for 5-7 days, then taper. If daily oral drug administration is not possible, may substitute methylprednisolone injectable, 5 mg/kg or 20 mg per cat IM or SQ; however, multiple risks with use (diabetes mellitus, iatrogenic hyperadrenocorticism, iatrogenic congestive heart failure, etc.)
- Topical flea adulticide: several options
  - Permethrin sprays/spot applications (Active-3)
  - Imidacloprid (Advantage)
  - Fipronil (Frontline)
  - Selamectin (Revolution)
  - Dinotefuran, permethrin, pyriproxyfen (Vectra) for dogs, without permethrin for cats
  - Metaflumizone, amitraz (ProMeris) for dogs, without amitraz for cats
- Oral flea adulticide
  - Nitenpyram (Capstar)
  - Spinosad (Comfortis) for dogs
- Specific therapy of any secondary infections

CHRONIC TREATMENT

Integrated flea management: essential for eradication of the problem

- Ongoing use of topical flea adulticide
- Insect growth regulators: methoprene, pyriproxyfen, others. Note: some products are formulated for spraying the patient; others are for treating the environment.
- Insect development inhibitors: lufenuron (Program) oral, monthly
- Environmental control
  - Identify “point sources” of infestation.
  - Cleaning or frequent vacuuming
  - Organic debris removal outdoors
  - Use of an approved insect growth regulator premise spray
- Immunotherapy is experimental at this time.

POSSIBLE COMPLICATIONS

- Neurotoxicosis with the use of pyrethrins, permethrins in cats
- Diabetes mellitus, iatrogenic hyperadrenocorticism (glucocorticoids, especially sustained-release injections)

RECOMMENDED MONITORING

Routine flea combing

PROGNOSIS AND OUTCOME

Good with long-term management

PEARLS & CONSIDERATIONS

COMMENTS

- Clients may not recognize excessive grooming as a manifestation of pruritus.
- Trichograms (microscopic examination of hair plucks) confirm self-induced alopecia: broken ends of hair shafts.
- Excessive grooming decreases live flea population.

PREVENTION

- Avoidance of flea bites prevents disease recurrence in flea-allergic patients.
- Continued integrated flea control is mandatory.

CLIENT EDUCATION

- Progressive disease unless fleas are eradicated
- Preventable, not curable, disease
- Treatment of all in-contact pets is mandatory.

TECHNICIAN TIPS

- Clients are frequently in denial, and compliance with a treatment plan may be poor.
- Challenge the clients to follow through with the treatment plan and “disprove” the diagnosis.

SUGGESTED READING

Bevier DE: Flea allergy dermatitis. In Campbell KL, editor: Small animal dermatology secrets, Philadelphia, 2004, Hanley & Belfus, pp 208–213.

AUTHOR: STEPHANIE R. BRUNER

EDITOR: MANON PARADIS

Flatulence and Borborygmi

BASIC INFORMATION

DEFINITION

- Flatulence is the excessive formation of gas in the stomach or intestine, which is expelled via the anus.
- Borborygmus is the rumbling noise caused by the propulsion of gas through the intestine.

EPIDEMIOLOGY

SPECIES, AGE, SEX: More prevalent in dogs than cats

GENETICS & BREED PREDISPOSITION

- Borborygmus more prevalent in brachycephalic breeds and working/sporting dogs because of increased aerophagia
- Cats with flatulence will generally have underlying gastrointestinal (GI) tract disease: inflammatory bowel disease, food sensitivity

RISK FACTORS

- Diets high in nonabsorbable oligosaccharides, carbohydrates, fiber or poorly digestible protein
- GI tract disease
- Low activity or exercise level

ASSOCIATED CONDITIONS & DISORDERS: GI tract disease in dogs and especially cats

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Owner may describe flatulence, belching, borborygmus or abdominal distension.
- May be associated with other signs of GI disease: vomiting, diarrhea, weight loss

PHYSICAL EXAM FINDINGS

- Generally unremarkable
- Palpation of gas in the intestines is not in itself an abnormal finding.
- Mild abdominal discomfort may be caused from intestinal distension. If excessive, fermentation may be associated with severe distension of the GI tract and signs of colic and shock.

ETIOLOGY AND PATHOPHYSIOLOGY

- Gas occurs naturally in the GI tract and is caused by:
  - Aerophagia (the major cause: 17 mL of air accompanies 10 mL of swallowed water in humans).
  - Interaction of gastric acid and alkaline food
  - Diffusion from the bloodstream
  - Bacterial metabolism and fermentation, especially in the colon
- Gas is removed from the GI tract by passage through the esophagus (belching) or anus (flatus), diffusion into the blood, or utilization by bacteria. Intestinal transit time for gas is 15-35 minutes.
- Aerophagia and fermentation of dietary carbohydrates are major contributors to natural intestinal gas volume, of which 99% is odorless. The foul odor is caused by sulfur-containing gases that originate from bacterial metabolism of endogenous substances (mucin, bile acids) and dietary sources (onions, nuts, spices, cruciferous vegetables). Additional sources are ammonia, amines, indoles and phenols, originating mainly from dietary protein.
- Causes of excessive GI gas:
  - Excessive aerophagia: brachycephalic breeds, vigorous exercise, competitive eating habits
  - Excessive bacterial fermentation: dietary substances—nonabsorbable oligosaccharides such as soy beans, legumes, rapidly fermentable fibers [pectin]
  - Gastrointestinal disease: maldigestion and malabsorption—large amounts of malassimilated substances are available

for fermentation, especially with lactose-containing foods, as lactase is lost with adulthood. Adult dogs are lactose intolerant.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

A common disorder which is of no clinical significance unless associated with other GI tract signs

DIFFERENTIAL DIAGNOSIS

Abdominal distension (organomegaly, ascites)

INITIAL DATABASE

Laboratory testing is required only if additional GI signs are also present.

TREATMENT

TREATMENT OVERVIEW

Management is generally aimed at long-term modification of the dietary and exercise regimen of the dog. Aim: decrease the amount of gas passed, reduce the odor, encourage passage of gas outdoors while exercising, and finally, prescription of carminatives.

ACUTE GENERAL TREATMENT

If very severe gas accumulation occurs secondary to excessive intake of a fermentable substance, emergency decompression, pain control, and shock therapy may be indicated.

CHRONIC TREATMENT

- The condition is controlled using long-term management strategies affecting diet, feeding habits, and exercise.
- Treat any underlying GI tract disease.
- Surgically correct upper airway stenoses in brachycephalic dogs.
- Use of carminatives (preparations decreasing flatulence) should only be considered after surgical, dietary, and behavioral interventions are unsuccessful.
- Ingestion of activated charcoal has not been proven successful in humans.
- Bismuth subsalicylate has antibacterial and antiendotoxic properties. The efficacy is dose dependent, which needs to be frequent. High doses are contraindicated in cats.
- Zinc acetate, 1% of diet, reduces the malodor of flatus.
- Simethicone, an antifoaming agent has no effect.
- A combination of activated charcoal, zinc acetate, and *Yucca schidigera* showed a significant decrease in flatus.

NUTRITION/DIET

- Decrease intake of substances causing odiferous gas production.
    - Decrease and change dietary protein levels and sources.
    - Eliminate supplements and treats.
    - Avoid cruciferous vegetables.
    - Avoid canned foods containing carrageenan (an algal-based thickening agent).
- Decrease the volume of intestinal gas production.
- Diet must be highly digestible, thus limiting substances supporting bacterial fermentation.
- Avoid foods containing legumes, dairy products, and fruit.
- Use rice as the main carbohydrate source, although this does have a high glycemic index.

BEHAVIOR/EXERCISE

- Control aerophagia.
    - Feed at least twice a day.
    - Discourage rapid, competitive feeding.

- Increase exercise/activity.
    - Exercise dogs within 30 minutes of meals to encourage defecation and elimination of gas.
    - Active outdoor dogs have been shown to exhibit less flatulence while with the owners.

DRUG INTERACTIONS

Activated charcoal can alter the absorption of concurrently administered medication.

RECOMMENDED MONITORING

- Progression of clinical signs may warrant an evaluation for GI disease.
- Intermittent relapses usually indicate dietary indiscretion.

PROGNOSIS AND OUTCOME

Prognosis for control is good in most cases.

PEARLS & CONSIDERATIONS

COMMENTS

“After trying empirical therapy for pets with chronic flatulence, sound advice for the client is to always stand upwind of the patient and keep windows open.” (Roudebush, Lorenz)

SUGGESTED READING

Giffard C, et al: Administration of charcoal, *Yucca schidigera*, and zinc acetate to reduce malodorous flatulence in dogs. J Am Vet Med Assoc 218(6):892, 2001.

AUTHOR: LIESEL VAN DER MERWE

EDITOR: ETIENNE CÔTÉ

Flail Chest

BASIC INFORMATION

DEFINITION

Two or more adjacent rib fractures at two or more sites on each rib. The fractures result in chest wall segment instability and therefore in asynchronous chest wall movement during respiration.

SYNONYMS

Flail segment, multiple rib fractures

EPIDEMIOLOGY

SPECIES, AGE, SEX: Young male animals that roam are at increased risk for trauma.

RISK FACTORS: Unmonitored activity

ASSOCIATED CONDITIONS & DISORDERS

- Pulmonary contusions
- Diaphragmatic hernia
- Pneumothorax
- Hemothorax

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Trauma
  - Hit by car
  - Bite wound
- Increased respiratory rate and effort
- External thoracic skin wounds

PHYSICAL EXAM FINDINGS

- Increased respiratory rate and effort
- Paradoxical movement of the flail segment during respiration: pathognomonic
  - Flail segment moves inward during inspiration and outward during expiration.
- Concurrent injuries are common:
  - Skin lacerations
  - Other fractures

ETIOLOGY AND PATHOPHYSIOLOGY

- Trauma results in two or more fractures per rib on two or more adjacent ribs.
- Hypoxemia due to abnormal pulmonary airflow (traditional model). Air from the lung in proximity to the flail chest segment flows to the opposite lung during inspiration and then back to the lung in proximity to the flail chest during expiration. This abnormal airflow provides no effective contribution to ventilation and is essentially an increase in dead space.
- Recent evidence indicates that hypoxemia and respiratory distress arise primarily from pulmonary contusions associated with pneumothorax and not from abnormal airflow.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Flail chest is first suspected in any patient with thoracic trauma. Confirmation is on physical exam: observation of the paradoxical movement of the flail segment is diagnostic.

DIFFERENTIAL DIAGNOSIS

- Pathologic rib fractures due to neoplasia or osteomyelitis (very rare)
- Increased work of breathing leading to rib fractures (chronic bronchitis/asthma; also uncommon)

INITIAL DATABASE

- Thoracic radiographs:
  - Lateral and dorsoventral (much less stressful to the patient than ventrodorsal) views required, as fractures may be apparent on only one view
  - If respiratory distress is severe, horizontal beam technique may be preferable (less restraint of patient, recumbency not necessary); alternatively radiographs may be delayed until the patient is more stable.
- CBC, serum chemistry panel, urinalysis: generally unremarkable unless abdominal organs affected or preexisting illness

ADVANCED OR CONFIRMATORY TESTING

Arterial blood gas analysis:

- May help confirm a clinical suspicion of hypoxemia
- Serial analysis may be useful to monitor trends.
- Hypoxemia (Pao2 < 80 mm Hg) is common, warranting oxygen supplementation (see p. 1318).
- In severe cases, hypoventilation may develop (Pco2 > 50 mm Hg).

TREATMENT

TREATMENT OVERVIEW

Therapeutic goals are to:

- Normalize oxygenation and control pain.
- Provide surgical stabilization if required (rare).

ACUTE GENERAL TREATMENT

- Pain control is essential; hypoventilation otherwise contributes to decreased blood oxygenation.
- Local nerve blocks, systemic opioids (e.g., hydromorphone, 0.05-0.1 mg/kg IV q 4-6 h, or buprenorphine 0.005-0.02 mg/kg IV, SQ, or IM) and nonsteroidal antiinflammatory drugs (e.g., carprofen, 2-3 mg/kg PO or SQ q 12 h) may be used.
- Oxygen supplementation often necessary (nasal oxygen, oxygen mask, oxygen cage; see p. 1318)
- Pneumothorax management (see p. 889):
  - Intensity of treatment determined mainly by degree of patient distress
  - Treatment options, in increasing order of intensity, include: monitoring only, oxygen supplementation, thoracocentesis (see p. 1338), chest tube placement (see p. 1230), and thoracotomy (if large segments of rib are perforating the lung).
- Mechanical ventilation (see p. 1362) may be necessary with patients unresponsive to oxygen supplementation:
  - Response to oxygen supplementation is best assessed clinically by evaluating patient respiratory rate and effort.
  - However, pulse oximetry reading < 88%-90% or an arterial blood gas oxygen level (Pao^2) < 60 mm Hg with supplemental oxygen is an indication for mechanical ventilation.
- Surgery is rarely required:
  - Flail chest segments resulting from bite wounds may be stabilized when the bite wounds are repaired.
- Chest wraps are unlikely to be of benefit and may be detrimental.

POSSIBLE COMPLICATIONS

- Hypoventilation associated with pain
- Pneumothorax associated with rib segments piercing lung parenchyma

RECOMMENDED MONITORING

- Electrocardiogram if cardiac arrhythmias occur
- Monitor respiratory rate and effort closely; use this information to guide decisions regarding oxygen supplementation, thoracocentesis, or chest tube placement.
- Signs of pain may include restlessness, tachycardia, anorexia, and excessive vocalization.

PROGNOSIS AND OUTCOME

Good with adequate supportive care and if no other concurrent traumatic injuries

PEARLS & CONSIDERATIONS

COMMENTS

Hypoxemia surrounding flail chest more commonly reflects the underlying pulmonary contusion rather than chest wall instability.

PREVENTION

- Keep animals indoors and confined to a leash.
- Neutering may prevent roaming behavior.

CLIENT EDUCATION

Don't let animals roam; monitor dog-dog interactions.

SUGGESTED READING

Olsen D, et al: Clinical management of flail chest in dogs and cats: a retrospective study of 24-cases (1989-1999). J Am Anim Hosp Assoc 38:315–320, 2002.

AUTHOR: THOMAS J. WALKER

EDITOR: ELIZABETH ROZANSKI

Fibrosarcoma

BASIC INFORMATION

DEFINITION

A common primary, malignant neoplasm of fibrous tissue. Fibrosarcoma is most common in the skin, subcutaneous tissue, and the oral cavity but can occur anywhere, including the spleen.

EPIDEMIOLOGY

SPECIES, AGE, SEX: Fibrosarcomas are more common in middle-aged to older dogs and cats. Injection-site sarcomas have many similarities and are discussed separately (see p. 610).

GENETICS & BREED PREDISPOSITION: Genetic factors are not well defined in dogs or cats.

RISK FACTORS: Prior irradiation and metal implants have been implicated as a cause for fibrosarcomas. There are cases of a fibrosarcoma in cats developing at sites of microchips and surgical sponges.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- The most common form of fibrosarcoma in dogs is a solitary mass, typically found on the head, limbs, or oral cavity.
- Sarcomas that are histologically low grade but biologically high grade (malignant behavior) are an uncommon variant of fibrosarcoma found in the maxilla and mandible in large-breed dogs.

HISTORY, CHIEF COMPLAINT: Most animals present for a progressive mass noticed by the owner or clinical signs related to the location of the tumor (e.g., oral and splenic tumors).

PHYSICAL EXAM FINDINGS

- Fibrosarcoma often appears as a firm, palpable mass in the subcutaneous or deep tissues; occasionally hairless or ulcerated. Oral fibrosarcomas often appear as smooth, round masses. On the hard palate, fibrosarcomas are frequently a flat and ulcerated.
- Regional lymphadenomegaly may be present secondary to inflammation or (rarely) lymph node metastasis.
- Dogs with a splenic fibrosarcoma may present with abdominal mass, pain, or enlargement.

ETIOLOGY AND PATHOPHYSIOLOGY

- Fibrosarcomas are spontaneously occurring tumors in most cases in dogs.
- Specific dysfunction caused by fibro-sarcomas depends on the location of the primary tumor.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Definitive diagnosis can only be confirmed via histopathology although additional tests such as diagnostic imaging are often helpful in defining the extent of the tumor, especially for oral fibrosarcomas.

DIFFERENTIAL DIAGNOSIS

- Other soft-tissue sarcomas
- Other skin and subcutaneous tumors:
  - Mast cell tumors, etc.
- Other oral tumors (epulis, melanoma, squamous cell carcinoma)
- Benign or nonneoplastic masses:
  - Benign tumor (e.g., lipoma)

- Abscess

INITIAL DATABASE

- Fine-needle aspiration and cytologic evaluation may help identify the tumor type before other diagnostics.
- Three-view thoracic radiographs to rule out pulmonary metastases
- Radiographs of the affected area may reveal involvement of underlying bone.
- Abdominal ultrasound to identify splenic tumors and rule out metastasis
- Fine needle aspiration and cytologic examination of the regional/draining lymph node to assess for metastasis.

ADVANCED OR CONFIRMATORY TESTING

- Biopsy of mass:
  - The definitive diagnosis of fibrosarcoma is based on histopathologic evaluation of tumor tissue.
  - Special immunohistochemical stains may be necessary to differentiate fibrosarcoma from other soft-tissue sarcomas, especially poorly differentiated tumors.
- CT or MRI may be necessary to delineate the local extent of the tumor and to plan for surgery or radiation therapy.
- Histopathologic grade of the tumor is necessary for determining the prognosis and treatment of most soft-tissue sarcomas (see p. 1034).

TREATMENT

TREATMENT OVERVIEW

Definitive treatment is based on complete eradication of the primary tumor whenever possible. Since metastasis of this type of tumor is uncommon, additional treatment such as chemotherapy is rarely used but could be considered for high-grade tumors or tumors that have already metastasized. Palliative treatment options, such as palliative radiation, may help control pain or discomfort in patients with advanced tumors or in patients where definitive treatment cannot be tolerated.

ACUTE AND CHRONIC TREATMENT

- Aggressive surgical resection, radiation therapy, and/or chemotherapy may be used for treatment of fibrosarcoma (see for specific details).
- Chemotherapy may be indicated for tumors of the spleen or high-grade tumors (see p. 1034).

POSSIBLE COMPLICATIONS

Complications of treatment for fibrosarcomas depend on the types of treatments and the location of the primary tumor (see p. 1034).

RECOMMENDED MONITORING

After appropriate local treatment, follow-up examination should be done on a routine basis to monitor for recurrence and metastasis. High-grade tumors may require more frequent monitoring for metastases during and after chemotherapy administration.

- Dogs that are likely to develop metastasis (splenic tumors, high-grade tumors) should be monitored closely (every 2-3 months) with physical exam, lymph node palpation, and thoracic radiographs.
- Dogs with low- or intermediate-grade tumors that have adequate local treatment should have physical examinations every 2-3 months or more frequently depending on risk of side effects from treatment. Thoracic radiographs could be done less frequently (6 months and 1 year after therapy).

PROGNOSIS AND OUTCOME

- A combination of radiation therapy and surgery has resulted in long-term tumor control in 86% of dogs with fibrosarcoma in peripheral sites and 54% of fibrosarcomas from all sites including the oral cavity.
- Radiation alone has resulted in 1-year tumor control rates of 33% and therefore is not typically recommended for fibrosarcomas. However, this statistic may underestimate efficacy, as it is derived from studies that used suboptimal radiation dose schedules.
- In certain situations where surgery is not indicated (e.g., nonresectable tumors or metastatic disease), radiation may be used to provide some degree of tumor control.
- Prognosis is excellent for low- to intermediate-grade fibrosarcomas with appropriate local treatment. This includes either

surgical resection with clean histopathologic margins or incomplete resection combined with radiation therapy.
- Information is limited regarding prognosis for high-grade fibrosarcomas, but it is considered to be guarded based on the increased likelihood for metastases.
- Dogs with splenic fibrosarcomas are more likely to develop metastases and therefore have a poor prognosis.

PEARLS & CONSIDERATIONS 

COMMENTS

Many animals with fibrosarcoma are successfully treated with wide surgical excision of the tumor. Animals with tumors that are difficult to treat in this manner (oral sarcomas, grade 3 sarcomas, nonresectable tumors, etc.) should be referred for consultation with a specialist (surgeon, oncologist, or radiation oncologist) to develop a multimodality treatment approach.

CLIENT EDUCATION

Pet owners can be educated to monitor their pets for the occurrence of tissue masses such as fibrosarcomas. Early detection and treatment may allow for less aggressive treatments with fewer side effects.

SUGGESTED READING

Liptak JM, Forrest LJ: Soft tissue sarcomas. In Withrow SJ, Vail DM, editors: Small animal clinical oncology, Philadelphia, 2007, WB Saunders, pp 425–454.

AUTHOR: JOHN FARRELLY

EDITOR: KENNETH M. RASSNICK

Fibrocartilaginous Embolism

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Fibrocartilaginous embolism (FCE) is a syndrome of acute spinal cord, and rarely brainstem, infarction and subsequent necrosis secondary to embolization of arterial and/or venous vasculature within the central nervous system. Although it is unconfirmed at this time, it is suspected that the embolus originates from the nucleus pulposus of the intervertebral disk.

SYNONYMS

Fibrocartilaginous embolic encephalomyelopathy, fibrocartilaginous embolic myelopathy, ischemic myelopathy

EPIDEMIOLOGY

SPECIES, AGE, SEX: FCE has been described in dogs, cats, horses, pigs, sheep, turkeys, cattle, and humans. Male dogs may be at higher risk than females, and middle-aged dogs (3-6 years) are most commonly affected.

GENETICS & BREED PREDISPOSITION: FCE most commonly affects nonchondrodystrophoid, large to giant breeds of dogs. Breeds at risk include Labrador retrievers, German shepherds, golden retrievers, Great Danes, and Doberman pinschers. Miniature schnauzers and Shetland sheepdogs can also be affected. FCE has not been reported in chondrodystrophoid breeds with intervertebral disk disease, though it has been reported in chondrodystrophic breeds.

RISK FACTORS: There may be a history of mild trauma and/or vigorous exercise before the onset of clinical signs of FCE.

ASSOCIATED CONDITIONS & DISORDERS: Concurrent Hansen type II intervertebral disk disease (fibroid degeneration of the nucleus pulposus) may be present in the affected animal.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Dogs with FCE will present with neurologic deficits that reflect the severity of the infarction and ischemia, as well as the location of the lesion within the central nervous system. The onset of FCE is peracute to acute, and clinical signs generally stabilize within 24 hours, after which the disease is often nonprogressive. This disease is nonpainful, although the affected dog may yelp or cry out at the onset of signs.

PHYSICAL EXAM FINDINGS

- The patient's neurologic deficits depend on the level of spinal cord affected, and clinical findings are consistent with a focal myelopathy.
- If the brachial plexus or lumbosacral intumescence is involved, lower motor neuron signs will predominate; if the C1-C5 or T3-L3 segments are involved, upper motor neuron signs will prevail.
- Nociception and proprioception may also be affected.
- Brainstem involvement can occur, in which case cranial nerve deficits, change in the level of consciousness, and/or cardiorespiratory difficulty may be seen.
- Spinal hyperesthesia is not a consistent finding.
- FCE is often lateralizing and should be suspected in a patient with the peracute to acute onset of nonpainful, nonprogressive, lateralizing/asymmetric focal myelopathy.

ETIOLOGY AND PATHOPHYSIOLOGY

- FCE is thought to affect large, non-chondrodystrophoid dogs because their nucleus pulposus remains soft and gelatinous longer relative to chondrodystrophoid dogs and can extrude along tears or fissures in the annulus fibrosus. Histopathologically, the nature of the embolus is similar to that of the nucleus pulposus of the intervertebral disk. Several theories have been proposed to explain the presence of disk material in the vasculature:
  - Chronic inflammation (e.g., type II intervertebral disk disease) may induce neovascularization of the intervertebral disk. With increased intradiskal pressure, the nucleus pulposus could extrude into this arterial system and into the radicular artery.
  - Embryonic vasculature of the annulus fibrosus may persist, and the nucleus pulposus could herniate into this arterial system with an increase in intradiskal pressure.

- The fibrocartilaginous material could extrude directly into an artery (radicular, vertebral, or ventral spinal). However, these arteries have thick, muscular walls, and one would expect to see evidence of hemorrhage if such damage occurred (hemorrhage has not been documented consistently on postmortem examination of dogs with FCE).
- The disk material could herniate into the vertebral venous sinuses and enter the arterial system in a retrograde manner, induced by a Valsalva maneuver (trauma, exercise, coughing, straining) in which increased intraabdominal pressure would induce retrograde blood flow, despite the presence of valves in the radicular veins.

- Another theory postulates that the source of the fibrocartilage is endothelial metaplasia.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Clinically, this is generally a diagnosis of exclusion that is reached based on history, clinical presentation, and the exclusion of other disorders. Characteristic MRI findings for fibrocartilaginous embolism also support the diagnosis.

DIFFERENTIAL DIAGNOSIS

- Other causes of embolism:
  - Sepsis
  - Leukemia
  - Polycythemia
  - *Dirofilaria immitis* microfilaria
  - Hyperviscosity or hyperlipidemia
  - Fat embolism
- Nonpainful myelopathies
  - Intramedullary neoplasia
  - Focal myelitis
  - Intramedullary hemorrhage
- Painful myelopathies
  - Intervertebral disk disease
  - Spinal trauma
  - Extradural or intradural, extramedullary neoplasia
  - Diskospondylitis
  - Vertebral osteomyelitis

INITIAL DATABASE

- CBC, serum biochemistry profile, and urinalysis: results usually within normal limits
- Survey radiographs will usually be within normal limits.

ADVANCED OR CONFIRMATORY TESTING

- Cerebrospinal fluid (CSF) analysis may be within normal limits, or it may reveal mild, nonspecific changes, including pleocytosis and increased protein content, inflammatory changes which may be associated with secondary spinal cord necrosis (myelomalacia). CSF analysis is not sufficiently sensitive or specific for the diagnosis of FCE, but it can be useful to rule out other causes of focal myelopathy.
- Myelography may be within normal limits, or it may reveal focal intramedullary swelling. This can be useful to rule out causes of myelopathy that produce spinal cord compression (e.g., IVDD).
- MRI is the imaging modality of choice in FCE. Initially, evidence of intramedullary spinal cord ischemia and swelling may be seen (hyperintense signal on T2-weighted images, and hypo-or isointense signal on T1-weighted images. Later, the findings may be consistent with ischemia, with increased intensity noted at the infarcted level on T2-weighted images. Recent studies have shown that the addition of the gradient echo sequence in multiple planes may increase the MRI sensitivity of detecting intraparenchymal spinal cord changes.

TREATMENT

TREATMENT OVERVIEW

Treatment consists of supportive care and physical rehabilitation, as there is no definitive treatment for FCE.

ACUTE GENERAL TREATMENT

- Because FCE is not a compressive lesion, surgical decompression is not indicated. In addition, because the fibrocartilaginous material occludes microscopic blood vessels, surgical removal of the embolus should not be attempted.
- The embolus is composed of fibrocartilaginous material and not blood; thus attempts at medical dissolution with fibrinolytic therapy are unsuccessful.
- Good nursing care is crucial. For patients with urinary incontinence, it is important to prevent an atonic urinary bladder; bladder expression or catheterization is necessary. In addition, patients with urinary and/or fecal incontinence must be kept clean and dry. The recumbent patient needs to be placed on appropriate bedding and rotated frequently or placed in a sling to prevent the formation of pressure sores. Nutritional and intravenous fluid support may be indicated in a patient who cannot maintain adequate nutrition per os.
- Free-radical scavenger drugs may prevent secondary ischemic complications, including edema and hemorrhage. Although controversial, corticosteroids may be given only if the patient presents within 6 hours of the initial insult (see Intervertebral Disk Disease, p. 617, for protocols).

CHRONIC TREATMENT

The patient will likely benefit from physical rehabilitation (see p. 1329), though a recent study reported that such treatment was not significantly associated with clinical outcome. It can be instituted immediately, and modalities include passive range of motion exercises, massage, hydrotherapy, and electrical stimulation.

POSSIBLE COMPLICATIONS

Complications, including the development of decubital ulcers and pneumonia, can arise secondary to the patient's recumbency.

RECOMMENDED MONITORING

Observation of respiratory effort and onset of cough, pulse oximetry, and lung auscultation are recommended to monitor for the development of pneumonia.

PROGNOSIS AND OUTCOME

- The presence of unilateral spinal cord damage yields a better prognosis than a transverse myelopathy.
- Lower motor neuron deficits suggest destruction of the ventral gray matter of the cervicothoracic or lumbosacral intumescence and yield a guarded to poor prognosis; upper motor neuron deficits indicate a better prognosis.
- The absence of deep pain perception lends a poor prognosis.
- The length and cross-sectional area of a lesion on MRI is correlated with functional outcome.
- Animals that display a functional recovery within the first 1-2 weeks after insult have a better prognosis. After this time period, it is less likely for further improvements to appear.
- In the acute setting, the patient should be evaluated frequently with neurologic examinations to detect signs of ascending or descending myelomalacia. If evidence of myelomalacia is present (i.e., clearly progressive deterioration of spinal cord function over a period of hours), the prognosis is grave.
- The patient with nonprogressive lateralizing signs, intact deep pain perception, and no evidence of spinal cord swelling on diagnostic imaging has a relatively good prognosis compared with the patient with symmetric lower motor neuron deficits, absent deep pain perception, and CSF changes.

PEARLS & CONSIDERATIONS

COMMENTS

One should be highly suspicious of FCE in the patient with a peracute to acute onset of nonpainful, nonprogressive, lateralizing focal myelopathy.

CLIENT EDUCATION

Clients must be advised of the intensive nursing and supportive care required of animals with FCE. The client should also have a commitment to rehabilitation and physical therapy, which can be time consuming and costly.

Fever of Unknown Origin

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

- Fever is defined as a higher than normal body temperature >102.5°F [>39.1°C]) due to altered thermoregulatory mechanisms in the hypothalamus.
- Fever of unknown origin (FUO) is a fever that is documented repeatedly, lasts for 3 weeks or longer, and for which a cause is not identified initially (human medical definition).
- The normal range of body temperatures in calm, normal individuals in a cool environment is 100.2°F-102.5°F (37.8°C-39.1°C) in the dog and 100.5°F-102.5°F (38.0°C-39.1°C) in the cat.

SYNONYM

Pyrexia

Note: Fever is a subset of hyperthermia, not a synonym. Nonfebrile hyperthermia (e.g., physical exertion, heat stroke, muscle fasciculations) does not involve alterations in the hypothalamic thermoregulatory mechanisms and is not treated with antipyretic drugs.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Any age, breed, or sex
- Young dogs may be more likely to have infectious causes.
- Older dogs may be more likely to have neoplastic causes.

GENETICS & BREED PREDISPOSITION

- Shar-pei: idiopathic, possible cytokine abnormality
- Weimaraner: neutrophil function deficiency
- Irish setter: leukocyte adhesion deficiency

RISK FACTORS

- Immunosuppression
- Exposure to infectious agents or vectors
- Travel to endemic areas of disease

CONTAGION & ZOONOSIS: Risk varies, dependent on causative agent.

GEOGRAPHY AND SEASONALITY: Some regions are endemic for particular infectious diseases. See individual specific topics.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Will vary with organ systems involved and causative agent but usually associated with nonspecific clinical signs such as lethargy, depression, and anorexia

PHYSICAL EXAM FINDINGS

- A complete physical exam in all patients with FUO must include rectal exam (dog), fundic exam (dog, cat), oral exam (dog, cat), meticulous examination of the skin (dog, cat), orthopedic, and neurologic exam (dog, cat)
- Fever:
  - Individual (haircoat, anxiety) and environmental (ambient temperature) influences may raise the body temperature of normal, healthy dogs and cats and must be considered when interpreting a patient's temperature.
- Depression
- Lethargy
- Tachycardia

- Hyperpnea
- Dehydration
- Lymphadenopathy with infectious or neoplastic disease
- Neck or back pain or central signs with meningitis, meningoencephalitis, diskospondylitis
- Joint pain or swelling with monoarthritis or polyarthritis
- Heart murmur may indicate bacterial endocarditis
- Chorioretinitis or hemorrhage suggestive of infectious cause
- Localized swelling and/or pain with wounds or abscesses

ETIOLOGY AND PATHOPHYSIOLOGY

Etiology:

- Infectious:
  - Localized or systemic bacterial infections (dog, cat): diskospondylitis, osteomyelitis, bacterial endocarditis, septic arthritis, prostatitis, pyelonephritis, septic meningitis, cholangiohepatitis, abscesses, pyothorax, peritonitis, pneumonia, pyometra, catheter site infections
  - Specific bacterial infections: leptospirosis (dog), borreliosis (dog), brucellosis (dog), mycobacterial infections (dog, cat), bartonellosis (dog, cat), hemotropic *Mycoplasma (Haemobartonella)* (dog, cat), tularemia (dog, cat), salmonellosis (dog, cat)
  - Viral: canine influenza (dog), canine distemper virus (dog), parvovirus/panleukopenia (dog/ cat), feline leukemia (FeLV) (cat), feline immunodeficiency virus (FIV) (cat), feline infectious peritonitis (cat), systemic calicivirus (cat)
  - Rickettsial: ehrlichiosis/anaplasmosis (dog, cat), Rocky Mountain spotted fever *(Rickettsia rickettsii)* (dog)
  - Fungal (dog, cat): histoplasmosis, blastomycosis, coccidioidomycosis cryptococcosis, systemic aspergillosis
  - Protozoal: babesiosis (dog), leishmaniasis (dog), trypanosomiasis (dog), hepatozoonosis (dog), toxoplasmosis (dog, cat), cytauxzoonosis (cat)
- Immune mediated: immune-mediated polyarthritis (dog, cat), systemic lupus erythematosus (SLE) (dog, cat), rheumatoid arthritis (dog), vasculitis (dog, cat), meningitis (dog), pemphigus (dog, cat), immune-mediated hemolytic anemia (IMHA) (dog, cat), immune-mediated thrombocytopenia (ITP; dog, cat), transfusion reaction (dog, cat)
- Neoplastic (dog, cat): histiocytic sarcoma, lymphoma, leukemia, multiple myeloma, necrotic solid tumors
- Other (dog, cat):
  - Pancreatitis
- Drug induced (tetracyclines, penicillins, sulfas), toxins, metabolic bone disorders, hyperthyroidism, tissue necrosis

Pathophysiology:

- The hypothalamus is responsible for thermoregulation. Fever occurs when the hypothalamic setpoint is reset to higher than normal.
- Inflammation and bacterial endotoxins increase the hypothalamic set point by causing the release of endogenous pyrogens such as interleukin (IL)-1, IL-6, and tumor necrosis factor a.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of FUO is justified when an elevated body temperature has been documented on several occasions (typically over a period of several days) in the absence of confounding factors, which are common: anxiety in the hospital setting and warm ambient temperatures. Confirmation justifies testing to differentiate infectious from noninfectious causes.

DIFFERENTIAL DIAGNOSIS

Rule out nonpyrogenic causes of an elevated body temperature (heat stroke, overexertion, muscle fasciculations, etc.)

INITIAL DATABASE

- CBC, chemistry profile, urinalysis: results will vary with organ system involvement.
- Urine bacterial culture and sensitivity should be performed in all cases of FUO even if urine sediment is inactive. Helpful with detection of pyelonephritis or prostatitis.
- FeLV antigen and FIV antibody tests in all cats

ADVANCED OR CONFIRMATORY TESTING

Further laboratory testing depends on history, physical exam findings, and minimum database results.

- Laboratory tests:
  - Serial blood cultures: to detect bacteremia associated with diskospondylitis, endocarditis, or other foci of infection. A negative culture does not rule out bacteremia (intermittent bacterial showering).
  - Specific serologic tests: antibody titers or antigen tests are obtained for evidence of infectious disease. If infectious disease is suspected and initial titers are negative, repeat in 2-4 weeks.
  - PCR testing for specific infectious agents
  - Fungal cultures and/or serologic titers
  - Fungal antigen tests: blastomycosis (urine, blood), cryptococcosis (blood)
  - Cytology and cultures of cerebrospinal fluid (CSF) or synovial fluid
  - Immune tests: antinuclear antibody test if suspected SLE; Coombs' test if suspicion of IMHA or immune-mediated thrombocytopenia (ITP); serum protein electrophoresis
- Imaging:
  - Thoracic radiographs: to evaluate for evidence of neoplasia, effusions, or pulmonary infiltrates
  - Abdominal radiographs: evaluate for abdominal masses, effusions, free gas.
  - Spinal and long bone radiographs: examine for evidence of diskospondylitis, osteomyelitis, periosteal proliferation.
  - Abdominal ultrasound: rule out pyelonephritis, prostatitis, or pyometra; identify ± aspirate any enlarged abdominal organs or masses (unless highly vascular or bleeding disorder).
  - Echocardiogram: identify vegetative valvular lesions associated with bacterial endocarditis.
  - CT/MRI often indicated before CSF tap to rule out an intracranial mass and decrease risk of herniation
- Diagnostic procedures:
  - Arthrocentesis: polyarthritis
  - Cytologic study of enlarged lymph nodes or affected organs: neoplasia or identification of infectious agents
  - Bone marrow aspirates and/or biopsy: if CBC changes are reflective of bone marrow involvement or neoplasia is suspected
  - CSF tap if neurologic signs (± fundic exam) suggest meningoencephalitis or meningitis
  - Muscle biopsy: hepatozoonosis
  - Abdominocentesis: peritonitis and pancreatitis
  - Transtracheal wash or bronchoalveolar lavage if respiratory involvement

TREATMENT

TREATMENT OVERVIEW

- The goal in all cases of FUO is to obtain a specific diagnosis and treat accordingly.
- A therapeutic trial should be initiated only when a specific diagnosis cannot be ascertained.

ACUTE GENERAL TREATMENT

- Intravenous crystalloid fluid therapy at 1.5-2 times maintenance for fevers where temperature >103.5°F (>39.7°C)
- Mechanical cooling methods such as cool water baths or fans when patient's temperature >106°F (>41.1°C)
- Antipyretic agents (e.g., nonsteroidal antiinflammatories [NSAIDs], to be given only when animal is fully hydrated) may be considered if temperature exceeds 106°F (41.1°C) and does not respond to fluids and cooling.
  - Antipyretic drugs should be reserved only for patients with fevers >105°F (40.6°C) and have failed to respond to fluids and mechanical cooling, as such drugs can mask the effects of other therapies and can be associated with adverse effects such as gastrointestinal ulceration and hepatic and/or renal toxicity.
- Patients with persistent fevers <105°F (40.6°C) should be treated with supportive care, including IV fluids.

CHRONIC TREATMENT

- Antibiotic trials:
  - Broad-spectrum antibiotic therapy may be initiated after all culture specimens have been collected.
  - Therapy should be based on the agents most likely present, their known antibiotic sensitivity, and the organ or system affected.
  - Commonly used empirical antibiotics include amoxicillin-clavulanate, 10-20 mg/kg PO q 8-12 h; or cephalexin, 22 mg/kg PO q 8 h or 30 mg/kg PO q 12 h; or if tickborne diseases are suspected, doxycycline, 10 mg/kg PO q 24 h or 5 mg/kg PO q 12 h. The actual recommendation depends on the previously listed factors.
- Glucocorticoid trials (duration: 24-72 h):
  - Used when immune-mediated disease is suspected
  - Should be used only when infectious disease has been ruled out
  - A dramatic response (fever reduction) should be seen within 24-48 hours.

- Examples: prednisolone, 1 mg/kg PO q 12 h, or dexamethasone, 0.2 mg/kg IV q 24 h; doses for longer-term use are adjusted based on the specific underlying cause.

DRUG INTERACTIONS

The use of NSAIDs in combination with glucocorticoids should be avoided.

POSSIBLE COMPLICATIONS

- Drug therapy trials without a definitive diagnosis may interfere with future diagnosis and exacerbate an undiagnosed condition that may be life threatening.
- Glucocorticoids may lead to immunosuppression or may mask clinical signs due to their antiinflammatory effects.

RECOMMENDED MONITORING

Monitor temperature at least every 12 hours. Response to trial therapy may be nonspecific or coincidental, so monitoring should continue for a sufficient time to confirm that resolution of the fever can be attributed to selected therapy.

PROGNOSIS AND OUTCOME

Dependent on specific cause

PEARLS & CONSIDERATIONS

COMMENTS

- Infectious disease, immune-mediated conditions, and neoplasia account for more than 75% of FUO cases.
- With aggressive diagnostic testing, usually only 10% of FUO cases are considered idiopathic.
- Immune-mediated polyarthritis will frequently *not* be associated with detectable joint swelling; therefore arthrocentesis is indicated in all FUO cases where no underlying cause has been identified.

PREVENTION

- Ectoparasite prevention may reduce risk of vector-borne disease transmission.
- Indoor pets are less likely to be exposed to vector-borne diseases.
- Vaccination against specific disease agents for high-risk pets
- Yearly retroviral testing and vaccination in high-risk cats
- Routine screening of geriatric pets to facilitate early diagnosis and treatment of cancer

CLIENT EDUCATION

- Animals may serve as sentinels for infections or transmit some infections to humans (zoonoses).
- Exposure to vectors may increase risk of disease transmission.

Feline Lower Urinary Tract Signs, Idiopathic

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Lower urinary tract signs (LUTS) include stranguria, hematuria, dysuria (difficult or painful urination), pollakiuria (frequent passage of small amounts of urine), and periuria (urination in inappropriate locations). These signs can occur with lower urinary tract disease (LUTD) of any cause. Idiopathic feline LUTD refers to LUTS in the absence of a known cause and is a diagnosis of exclusion (see differential diagnosis) and the most common cause of LUTS in cats.

SYNONYMS

Feline lower urinary tract disease (FLUTD), feline idiopathic cystitis (FIC), feline urologic syndrome (FUS)

EPIDEMIOLOGY

SPECIES, AGE, SEX: Can affect cats of either sex at any age. Male cats develop lower urinary tract obstruction more than female cats (narrow penile urethra).

GENETICS & BREED PREDISPOSITION: Siamese cats at reduced risk of LUTS, whereas Persians and long-haired cats may be at increased risk. Epigenetic familial factors (e.g., quality of maternal care) may play a role.

RISK FACTORS: Stress (e.g., changes in feeding, litter boxes, human and animal family members, and owner schedule), neutering, indoor housing, increased weight, decreased activity, multicat households.

GEOGRAPHY AND SEASONALITY: None

ASSOCIATED CONDITIONS & DISORDERS: Cats with LUTS also may be at increased risk for separation anxiety disorder and other behavioral abnormalities (fear, nervousness, aggression), dilated cardiomyopathy, and obesity. Urethral obstruction may occur in male cats with LUTS.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Common history is abrupt onset of LUTS (e.g., hematuria, periuria) in an otherwise healthy young adult cat (2-6 years old).
- Often, affected cats are housed entirely indoors and are neutered.
- Male cats with obstructive LUTD have unproductive stranguria, may vocalize, vomit, and become progressively depressed/obtunded.

PHYSICAL EXAM FINDINGS

- Affected cats are often anxious and may be aggressive or shy.
- Unless urethral obstruction is present, the bladder is typically small and difficult to palpate.
- Male cats with urethral obstruction will have a large, painful, turgid, inexpressible bladder.

ETIOLOGY AND PATHOPHYSIOLOGY

- The etiology is not known, although a subset of patients appears to have a congenital disorder of the stress-response system that results in persistent sensitization of the system and reduced adrenocortical function. This sensitivity may be unmasked by cat-perceived threats in the environment, such as unpredictable owner schedules, conflict with other animals, and impoverished environments.
- The enhanced sympathetic drive may reduce epithelial tight-junction integrity, resulting in increased exposure of afferent neurons to environmental stimuli. When this occurs in the bladder of a cat with an activated stress-response system, LUTS may result.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

- Signalment, history, and physical examination often are sufficient to make the clinical diagnosis. Urinalysis with sediment examination can help rule out differential diagnoses such as urinary tract infection. Additional diagnostics are warranted in cats with atypical presentations, persistent or frequent episodes of LUTS, or urethral obstruction.

DIFFERENTIAL DIAGNOSIS

- Urolithiasis
- Behavioral disorder (e.g., territorial marking)
- Anatomic urinary tract defect (notably vesicourachal diverticula)
- Urinary tract infection
- Bladder neoplasia (uncommon; transitional cell carcinoma most often identified tumor type)

INITIAL DATABASE

- Urinalysis with sediment examination will often reveal hematuria, hypersthenuria (USG > 1.035), proteinuria +/− crystalluria.
- Urine culture and susceptibility: infection is rare in the United States, seemingly more common in European studies.
- For cats with a typical initial presentations, no additional diagnostic tests may be required.

ADVANCED OR CONFIRMATORY TESTING

- For cats with complicated initial presentations or recurrent episodes, diagnostic testing is aimed at ruling out the most common alternative diagnosis. With idiopathic LUTS, no abnormalities are expected.
    - Radiography of the entire lower urinary tract (including the distal urethra)
    - CBC, biochemical analysis and FIV/FeLV testing
- Other lower urinary tract imaging (e.g., ultrasonography, double contrast cystography) or cystoscopy are rarely indicated.

TREATMENT

TREATMENT OVERVIEW

Treatment focuses on stress reduction through owner education and environmental enrichment (EE). Lower urinary tract obstruction is a life-threatening condition requiring prompt attention to manage the associated metabolic derangements and reestablish urine flow.

ACUTE GENERAL TREATMENT

If the cat is obstructed, relieve the obstruction (see p. 1355), reestablish urine flow, and correct fluid, electrolyte, and acid-base imbalances.

Drugs Commonly Used for Cats With LUTS

Drug	Dose	Potential Side Effects
Acute Analgesic		
Butorphanol (Torbugesic)	0.2-0.4 mg/kg IV, IM, SQ q 8 h (IV: use lower end of dose range)	Sedation
Buprenorphine (Buprenex)	0.01-0.02 mg/kg IM, IV, or SQ q 8-12 h; 0.015 mg/kg PO or sublingual q 8-12 h (anecdotal)	
Fentanyl (Duragesic) patch	25 mcg/h	Respiratory depression, bradycardia
Bladder/Urethral Contractility		
Acepromazine (PromAce)	0.05 mg/kg SQ q 8 h	Sedation, hypotension
Prazosin (Minipress)	0.5 mg per cat PO q 12 h	
Phenoxybenzamine (Dibenzyline)	2.5 mg per cat PO q 12 h	Hypotension
Bethanechol (Urecholine)	2.5-5 mg per cat PO q 12 h	Salivation, vomiting, diarrhea
Chronic Analgesic/Anxiolytic		
Clomipramine (Anafranil)	0.5 mg/kg PO q 24 h	Sedation, anticholinergic effects
Amitriptyline (Elavil)	5-12.5 mg per cat PO q 12-24 h	Sedation, weight gain, urine retention; urolith formation

Drug	Dose	Potential Side Effects

- Establish IV access and provide appropriate analgesia.
- Submit samples for serum biochemical profile, CBC, and urinalysis. It is not necessary to evaluate the results before treating obstructed cats that present with urethral obstruction and severe systemic signs, with the exception of the potassium concentration.
- Resuscitate moribund cats with intravenous (IV) fluids, and correct serious electrolyte and acid-base disturbances before anesthesia for placement of a urinary catheter.
    - Obtain an electrocardiogram (ECG) of all systemically ill cats with urethral obstruction, as rescue from the cardiotoxic effects of severe hyper-kalemia may be necessary even before laboratory values for serum potassium (K^+) return if arrhythmias are present:
        - Slow IV administration of 2-10 mL of 10% calcium gluconate to effect will protect the myocardium from the deleterious effects of hyperkalemia, without lowering serum potassium concentration (monitor ECG for slowing of heart rate of 10% or more, warranting termination of calcium administration). Usually 0.2-0.5 mL/kg over 15 minutes is adequate (i.e., 1-2.5 mL/5 kg cat); can be repeated in 5 minutes if no improvement.
        - Administration of sodium bicarbonate (1-2 mEq/kg IV) or insulin (0.2-0.4 U regular insulin IV, while supplementing IV fluids to 2.5% dextrose and closely monitoring blood glucose concentration, owing to risk of hypoglycemia) may be used to drive potassium intracellularly and lower serum potassium concentrations prior to reestablishment of urine flow.
        - Consider decompressing the bladder by cystocentesis before attempting to pass a urinary (urethral) catheter. Insert a 22- or 23-gauge butterfly needle into the bladder wall midway between the apex and urethral outflow and directed caudoventrally. If a longer needle is necessary, it can be attached to an extension set and urine removed using a syringe. Palpate the bladder during drainage to empty it as completely as possible. Rare complications include extravasation of urine into the peritoneal cavity and damage to the bladder wall. This procedure may be sufficient to restore normal urine flow but remains controversial because of potential complications.
    - Pass a urinary catheter only if necessary. General anesthesia is needed to allow proper manipulation of the penis to pass the catheter. If the combination of IV ketamine and diazepam does not provide adequate relaxation, isoflurane gas in oxygen, or propofol infusion may provide both adequate sedation and urethral relaxation.
    - If a plug or urethrolith is retrieved, it should be submitted for quantitative analysis.
        - An indwelling urinary catheter (e.g., 3.5-Fr red rubber feeding tube–type) is placed in cats with pronounced azotemia or poor urinary stream after catheter placement. An indwelling urinary catheter also is used for cats with very large bladders at presentation, as they are more likely to develop detrusor atony.
- Manage cats medically unless future recurrent obstructions occur.
    - For most, analgesics (see table) and appropriate fluid therapy are indicated. Some α-blocking drugs (e.g., phenoxybenzamine) have not been shown to be effective. They act on the proximal feline urethra, whereas most obstructions in cats involve the distal urethra.
    - Monitor urine output frequently in severely ill cats. Those that recover from severe postrenal uremia generally undergo a substantial post-obstructive diuresis >2 mL/kg/h shortly after relief of obstruction and rehydration). During this period, it is essential to give sufficient IV fluids to replace the volume lost as urine. The diuresis declines to normal during 2-5 days.
- The role of glucocorticoids (e.g., prednisone), and nonsteroidal antiinflammatory drugs (e.g., aspirin, meloxicam) remains poorly defined, and none of these drugs has been shown to be an effective treatment for acute LUTS.

CHRONIC TREATMENT

- Step 1: Environmental enrichment (EE)/multimodal environmental modification (MEMO).
    - Provide at least one food bowl, one water bowl, and one litter box per cat, plus one. Locate these resources in quiet places where the cat is not startled during use.
    - Provide opportunities for the cat to hide safely and explore its environment. Placing “perches” at windows so the cat can look outside and structures the cat can climb on seem to be important parts of EE.
    - Provide a regularly scheduled time for petting, play, and/or trick-teaching, working toward at least 10 minutes a day.
    - Identify and resolve intercat conflict to the extent possible.
    - If ineffective, proceed to step 2.
- Step 2: step 1 plus consider use of pheromones (Feliway). If ineffective, proceed to step 3.
- Step 3: steps 1 and 2 plus consider use of a tricyclic agent such as clomipramine or amitriptyline at the lowest effective dose possible (see table). These drugs should be used only after steps 1 and 2 have been implemented and the cat is so severely affected he/she continues to have recurrences. Conclusive results regarding the efficacy of behavior-modifying drugs are lacking.
- A perineal urethrostomy may be needed in severe recurrent obstructive cases.
    - This surgery increases the risks of bacterial urinary tract infections, however, and postoperative strictures are a potential complication.
    - Clients should be made aware that this surgery does not correct the underlying problem, and recurrent episodes of

urolithiasis and LUTS still can occur.

NUTRITION/DIET

- Dietary therapy may be indicated if uroliths or crystals are identified and will depend on the type of urolith.
- Glycosaminoglycan (GAG) supplementation has been suggested, but its efficacy remains unproven in cats.

BEHAVIOR/EXERCISE

- See recommendations for environmental enrichment under Chronic Treatment.

POSSIBLE COMPLICATIONS

- When introducing EE, offer changes to the cat (e.g., new food in a separate bowl rather than in place of the familiar diet) to avoid precipitating a threat response. Make changes the client wants to make, if possible, to secure support and adherence to the EE effort. Make changes sequentially.
- When tricyclic drugs are used, they should be tapered slowly over at least 2 weeks to avoid adverse reactions.

RECOMMENDED MONITORING

Liver and kidney function should be assessed before use of tricyclic drugs and at least annually in young animals if therapy is extended.

PROGNOSIS AND OUTCOME

Most cases of idiopathic, nonobstructive, feline LUTS are self-limiting, usually resolving in 5-10 days. However, recurrent episodes of clinical signs, including urinary tract obstruction, occur with variable frequency. Overall prognosis depends on the cat, client, and environment:

- Cat:
  - Genetic predisposition
  - Duration of the problem
  - Frequency of occurrences
  - Number of areas and different types of surfaces soiled
- Client:
  - Ability to identify modifiable causes
  - Strength of bond to affected cat
  - Willingness to pay for treatment
  - Amount of time to devote to solution
  - Willingness to accept and use medications
- Environment:
  - Number of cats in the household
  - Number of affected cats
  - Practicality of allowing limited outdoor access
  - Ability to rearrange the environment

PEARLS & CONSIDERATIONS

COMMENTS

EE often is sufficient to suppress clinical signs and should be offered to all owners of cats exclusively housed indoors.

PREVENTION

EE recommendations should be provided to all owners of indoor cats, not just those with a clinical problem.

CLIENT EDUCATION

Client-oriented information is available at www.indoorcat.org.

Feline Leukemia Virus Infection

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Virus infection of cats that can result in immunosuppression, myelosuppression, and neoplasia

SYNONYM

FeLV

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Mainly domestic cats (rare examples in wild felids) are infected
- Young cats (<1 year old) are more likely to become persistently viremic. Male cats are slightly more commonly infected than female cats.

RISK FACTORS

- Free-roaming cats are more likely to be exposed to FeLV.

CONTAGION & ZOONOSIS

- FeLV is most commonly transmitted through saliva during grooming and playing and sharing food and water bowls. FeLV can also be transmitted through blood or transplacentally.
- Environmental contamination is of lesser concern, because the virus is highly sensitive to desiccation, disinfectants, and heat, although in experimental conditions, FeLV can be transmitted through feces.
- FeLV is not zoonotic.

GEOGRAPHY AND SEASONALITY: FeLV is found worldwide. However, there is a worldwide decrease in the prevalence (currently 2.3%-3.3% in the United States), possibly as a result of test and removal programs and vaccination.

ASSOCIATED CONDITIONS & DISORDERS: FeLV causes immunosuppression, which in turn is associated with op portunistic infectious diseases. It can also cause neoplasia.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: FeLV occurs in three major subgroups, A, B, and C. Subgroup A is present in all infected cats. Subgroup B and C are deletions and recombinations of the subtype A genome with host DNA. Subtype B is common in cats with neoplasia. Subgroup C is rare and can cause nonregenerative anemia.

HISTORY, CHIEF COMPLAINT

- FeLV infection can occur without overt clinical signs, as there is a long subclinical phase, and in these cats, infection is commonly discovered during routine screening.
- Persistent viremia may cause signs due to immunosuppression and secondary infections (e.g., weight loss, diarrhea, nasal or ocular discharge) or from non-specific signs attributable to anemia or tumors, such as weakness, lethargy, or inappetence.

PHYSICAL EXAM FINDINGS

- Signs are often nonspecific, including poor body condition, depression, weakness, or lymphadenopathy. Signs may be attributable to immunosuppression with secondary infection, myelosuppression (mainly nonregenerative anemia), or neoplasia (mainly lymphoma).
- Clinical signs of hematologic abnormalities may include pale mucous membranes due to anemia, sepsis secondary to neutropenia, or hemorrhage due to thrombocytopenia.
- The most common sign attributable to FeLV-associated lymphoma is dyspnea due to a mediastinal mass and pleural effusion.

Other signs include diarrhea (with intestinal lymphoma), vomiting (due to renal failure in cats with renal lymphoma), or icterus (hepatic lymphoma). The occurrence of other tumors may lead to various clinical abnormalities, including FeLV-associated osteochondromas (multiple cartilaginous exostoses) that may produce orthopedic abnormalities (palpable bony enlargements) or neurologic deficits, depending on site of involvement.

- FeLV may cause abortion and infertility.
- Newborn kittens may have “fading kitten syndrome” and die within the first 2 weeks of life.

ETIOLOGY AND PATHOPHYSIOLOGY

- FeLV is an oncornavirus (RNA virus) of the family *Retroviridae*.
- Infection occurs most commonly through exposure to saliva through the oral or nasal cavity. The virus replicates in the oropharyngeal lymphoid tissues.
- Cats can mount a full immune response and eliminate the infection, or mount an ineffective immune response resulting in viremia.
- Once the patient is viremic, the virus replicates within disseminated lymphoid tissues and later within the bone marrow. An effective immune response at this stage can result in elimination of the virus but more commonly results in the development of latent infection.
- With an ineffective immune response during viremia, the cat may become persistently viremic and is likely to develop FeLV-associated diseases (hematologic abnormality, malignancy, chronic infection, or other clinical signs).
- Latent infection may be reactivated, and cats may again become viremic after stress or immunosuppression.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Diagnosis is usually made by detecting FeLV antigen in ELISA or other immunochromatography tests (using a similar technique). Negative results are highly reliable (in an area with low prevalence), but positive results should be considered carefully because false-positive results occur. Thus, a positive test should always be confirmed.

DIFFERENTIAL DIAGNOSIS

Other immunosuppressive conditions, such as FIV infection

INITIAL DATABASE

- CBC, serum chemistry panel, urinalysis
  - Initial database that is routinely performed to rule out other illnesses or infections; changes are not specific to FeLV infection, and results are often normal in FeLV-infected cats.
  - CBC in cats with myelosuppression may show mild to marked abnormalities, including nonregenerative anemia, neutropenia, thrombocytopenia, or pancytopenia.
  - Serum biochemistry profile and urinalysis are usually normal, or changes may be nonspecific.
- Chest radiographs
  - Mediastinal mass and pleural effusion (mediastinal lymphoma)
- Screening tests of choice are fast in-house ELISA or other immunochromatography tests (using a similar technique) which detect free FeLV antigen in blood. In addition, IFAs are used that detect intracellular FeLV antigen in neutrophils and platelets in blood smears.
  - ELISA is more sensitive and detects viremia earlier than IFA, it is the diagnostic test of choice for general screening.
  - Positive results for both ELISA and IFA indicate that a cat has been infected for more than 3 weeks. Persistent viremia is likely in these cats.
  - Positive ELISA and negative IFA usually indicates early infection (<3 weeks). Therefore, cats with positive ELISA and negative IFA results should be retested with both tests 6 weeks later.
  - Latently infected cats are negative for both ELISA and IFA testing.
  - Vaccination (against FeLV) does not lead to positive ELISA, IFA, or PCR.
  - Saliva- or tear-based tests are not recommended (poor sensitivity due to intermittent shedding).

ADVANCED OR CONFIRMATORY TESTING

PCR testing is available for use in cats with a clinical suspicion of FeLV infection despite negative ELISA and IFA results, or discordant ELISA and IFA test results. PCR may also be used for detecting virus in latently infected cats (in blood, bone marrow, or tumor tissue).

TREATMENT

TREATMENT OVERVIEW

The most important advice is to keep FeLV-infected cats indoors only, away from the risk of secondary infections. In cats with no clinical signs, no other treatment is required. Secondary infections require prompt and thorough treatment. When overt clinical signs are present, antiviral treatment, e.g., with feline interferon-omega, is potentially beneficial.

ACUTE TREATMENT

May include intensive antibiotic therapy for secondary infections or blood transfusion in life-threatening anemia.

CHRONIC TREATMENT

- Management of FeLV-associated secondary infections
  - Any secondary infections should be treated intensively and with a prolonged course (e.g., antibiotics).
- Treatment of FeLV-associated lymphoma
  - Chemotherapy is used, but prognosis is worse than with non-FeLV-associated tumors
- Treatment of FeLV-associated myelosuppression
  - Severe nonregenerative anemia may be managed with blood transfusions.
  - Neutropenia may transiently respond to human granulocyte colony-stimulating factor (G-CSF 5 µg/kg q 12 h SQ). Antibody development eventually limits its use.
- Antiviral chemotherapy and immunomodulatory drugs
  - Antivirals such as AZT (zidovudine) are most effective when given within 96 hours of exposure to the virus, which is seldom clinically relevant.
  - Recombinant feline interferon-omega (Japan, Europe) showed some efficacy in reducing mortality.
  - The immunomodulator *Staphylococcus* protein A (SPA) may increase owners' perception of the cat's quality of life.

BEHAVIOR/EXERCISE

FeLV-infected cats should stay strictly indoors, both to prevent spread to other cats and reduce risk of exposure to secondary infections.

DRUG INTERACTIONS

All immunosuppressive and myelosuppressive drugs should be avoided.

POSSIBLE COMPLICATIONS

Treatment with AZT can result in reversible nonregenerative anemia.

RECOMMENDED MONITORING

Assess regularly for evidence of secondary infectious diseases, neoplasia, and progression of illness (e.g., recheck visits, with exam and CBC, every 6 months).

PROGNOSIS AND OUTCOME

- Historic findings of 3 years lifespan are likely outdated. Nowadays normal longevity is possible, though FeLV-associated syndromes require treatment.
- The prognosis for cats that develop lymphoma, leukemia, or myelosuppression is guarded to poor. Cats with lymphoma may experience a remission and an improved quality of life with chemotherapy for a median of 6 months. Cats with leukemia, severe anemia, and myelodysplasia respond poorly to therapy.

PEARLS & CONSIDERATIONS

COMMENTS

- The FeLV status of all cats should be known. Thus, every cat should be tested independent of age. Viremia can be detected

from birth onward.

- A diagnosis of FeLV is not a reason for euthanasia. Infected cats can live several years with a good quality of life. However, the diagnosis has certain implications.
    - The cats should only be kept indoors.
    - More intense and regular veterinary care is required in such a cat.
    - Vaccination programs to prevent common serious infectious diseases (using killed vaccine, since immune function may be compromised) should be maintained; revaccination on a more frequent basis should be considered given these cats' immunoincompetence.

PREVENTION

- Vaccination against FeLV is efficacious in cats at risk for exposure to the virus, but level of protection is not sufficient in the case of very high infectious pressure (e.g., if a naive cat lives together with a FeLV-shedding cat).
- The FeLV vaccine is associated with development of injection site–associated sarcomas (see p. 610) in cats. Thus, only cats at risk should be vaccinated (e.g., not cats that live indoors with no other cats). Cats should be vaccinated against FeLV distally in the left hind limb, to allow easy removal of injection-site sarcomas if they occur.

TECHNICIAN TIPS

- Technicians should be aware that the FeLV status of every cat should be known.
- As FeLV lives only minutes outside the host and is susceptible to all disinfectants including common soap, simple precautions and routine cleaning procedures will prevent transmission while in the hospital. FeLV-infected patients should not be placed in an “infectious disease ward” with cats with contagious diseases (e.g., upper respiratory infections).

CLIENT EDUCATION

Every cat should be tested for FeLV.

EDITOR: DOUGLASS K. MACINTIRE

Feline Infectious Peritonitis

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

A serious, often fatal disease that mainly occurs in young cats from multicat households and often is characterized by body cavity effusions or neurologic signs. Importantly, feline infectious peritonitis (FIP) is caused by a common feline coronavirus (FCoV) that, in affected cats, has spontaneously mutated from a benign, minimally pathogenic type to an aggressive, lethal type.

SYNONYMS

Feline coronaviral polyserositis (wet/effusive form), FIP, granulomatous feline infectious peritonitis (dry/noneffusive form), feline coronaviral vasculitis

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Young cats during postweaning periods are most susceptible; peak age 6 months to 2 years
- Males > females

GENETICS & BREED PREDISPOSITION: Purebred cats are most susceptible, especially Asian breeds (e.g., Birman, Himalayan).

RISK FACTORS

- Stress: vaccinations, elective surgery, placement in a new home
- Multicat households: catteries, pure breeds, shelters

CONTAGION & ZOONOSIS

- FCoVs are mainly transmitted by fecal-oral route or through saliva (e.g., mutual grooming).
- Can also be transmitted transplacentally
- FCoV infection is widespread or even ubiquitous in multicat environments.
- No two cats with FIP are infected with exactly the same virus. This fact suggests that horizontal transmission (cat to cat) is minimally important to the development of FIP. Rather, it is the ability of the virus to mutate inside the cat and the cat's immune response that determine whether a coronavirus infection remains innocuous or develops into FIP.
- No known zoonotic potential

ASSOCIATED CONDITIONS & DISORDERS: Feline enteric coronavirus causes mild, self-limiting diarrhea.

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES

- FCoV has a spectrum of pathogenicity, and its direct effects range from none (carrier individuals with no clinical signs) to life threatening (FIP).
- Two clinical forms of FIP: dry form (noneffusive) and wet form (effusive). Clinical signs are substantially different, but treatment options and outcome are equally poor.
- Two serotypes of feline coronavirus: type I and type II. Of no clinical importance, as each serotype can cause a range of clinical illnesses varying from benign infections with no clinical signs to fulminant FIP.

HISTORY, CHIEF COMPLAINT

- Nonspecific signs are most commonly reported by owners, including lethargy, inappetence, and weight loss.
- Cats with FIP may have a history of failure to grow, often having received multiple antibiotic therapies with no success.
- In cats with ascites due to effusive FIP, owners uncommonly notice the abdominal distension.
- Diarrhea is noted only occasionally in FIP; gastrointestinal signs suggesting intestinal obstruction are sometimes noted when the FIP lesion is confined to the intestine (colonic/intestinal FIP).

PHYSICAL EXAM FINDINGS

- Effusive form: abdominal distension with palpable fluid wave; dyspnea, muffled heart sounds, and muffled lung sounds due to pleural effusion; +/− palpable abdominal masses
- Noneffusive form: signs of central nervous system dysfunction, including ataxia, personality changes, nystagmus, seizures
  - Ocular abnormalities, including change in iris color due to iritis/uveitis, hyphema, aqueous flare, keratic precipitates, vitreous clouding, and vascular cuffing, manifesting as gray lines parallel to retinal vessels
  - Icterus
  - Palpable abdominal mass(es), usually due to organomegaly (e.g., enlarged mesenteric lymph nodes, nodules in other organs, intestinal thickening)
  - Raised intradermal pustules (nonpruritic cutaneous lesions)

ETIOLOGY AND PATHOPHYSIOLOGY

- FCoV related to transmissible gastroenteritis virus in pigs, canine, and human coronaviruses
- Largest known RNA genome; therefore, highly susceptible to mutation
- FIP virus is a mutation of the ubiquitous and otherwise benign FCoV.
  - Factors that allow or trigger mutation are not known; possibly breed susceptibility.
- Once mutated, the virus replicates within macrophages and regional lymph nodes.
- Virus pathogenicity and the cat's immune response then determine outcome:
  - Elimination
  - Complement-mediated pyogranulomatous vasculitis, causing effusive “wet” FIP
  - Partial cell-mediated response, causing the formation of “classic granulomas” and “dry” noneffusive FIP
  - Antibody-antigen complex formation and deposition in vascular endothelium, causing vasculitis

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The most reliable diagnostic test for FIP is biopsy of affected tissue (e.g., intestine), with or without immunohistochemical staining. Noninvasive clinical tests all have limitations, and an initial diagnosis of FIP generally relies on a combination of information:

- Compatible signalment and history
- Nonspecific (e.g., fever) and more specific (e.g., nonseptic exudative body cavity effusion, neurologic abnormalities, or characteristic ocular changes) physical exam findings
- Suggestive results on laboratory tests (e.g., with effusion: positive PCR result, presence of antibody titer, or immuno-fluorescent staining of antigen in macrophages)

DIFFERENTIAL DIAGNOSIS

- Neoplasia (lymphoma)
- Lymphocytic/nonsuppurative cholangitis
- Pyothorax/chylothorax
- Congestive heart failure
- Toxoplasmosis, FIV, FeLV, and systemic mycosis: ocular changes
- Lymphoma, multiple myeloma, chronic infection: hyperglobulinemia

INITIAL DATABASE

- CBC: lymphopenia, nonregenerative anemia, neutrophilic leukocytosis, higher number of Heinz bodies in RBCs (colonic FIP)
- Serum biochemistry profile
  - Hyperglobulinemia (and secondary low albumin/globulin ratio) are hallmarks of both effusive and noneffusive FIP.
  - Elevated liver enzymes: common
  - Elevated bilirubin: common, especially with noneffusive FIP
- Thoracic and abdominal radiographs: pleural effusion and ascites (effusive FIP)
- Abdominal ultrasound: abdominal mass, lymphadenopathy, ascites
- Ocular and neurologic examination
- Fluid analysis (ascites, pleural/pericardial effusion)
  - Clear, viscous (may contain clumped/precipitated protein), straw colored
  - Exudate: protein > 3.5 mg/dL and often much higher
  - Nonseptic: total cell count low (e.g., 2000/mcL); lymphocytes, nondegenerate neutrophils, macrophages predominate.
  - High globulin concentration (>32%) strongly suggests FIP. Effusion albumin/globulin ratio < 0.9 is 74% sensitive and

86% specific for FIP.

- Feline coronavirus serologic evaluation
  - Positive titer only represents exposure to FCoV, not specifically FIP.
  - Therefore, titer result must be interpreted jointly with remaining clinical and laboratory information.
  - Most cats with positive titers for feline coronavirus never develop FIP.
  - Titers > 1:16,000 are suggestive of FIP in cats showing signs of clinical disease.
  - Rarely, cats with FIP can have negative titers, especially in the terminal stages of disease.

ADVANCED OR CONFIRMATORY TESTING

- Serum protein electrophoresis in hyperglobulinemic patients:
  - To differentiate from neoplastic causes, which typically produce a monoclonal gammopathy
  - Polyclonal gammopathy with FIP (effusive and noneffusive forms), elevated globulins (usually a^2 and γ globulins)
- Cerebrospinal fluid (CSF) analysis:
  - High protein content>20 mg/dL, often markedly higher) and cell count >5 cells/µL, often much higher; mononuclear pleocytosis with some neutrophils)
  - Caution: patient may be at increased risk of cerebellar/medullary herniation after CSF tap
- a^1 Acid glycoprotein (AGP):
  - Acute phase protein that is often elevated in different infectious diseases of cats
  - AGP measurement on plasma or effusion >1500 µg/dL consistent with FIP
- CT:
  - Hydrocephalus detected grossly/histologically in 75% of cats in one study of CNS FIP
  - May be suggestive of FIPif documented on CT
- PCR:
  - Must involve reverse transcription, because test amplifies DNA, but coronavirus is an RNAvirus.
  - Blood test: interpret results with caution; cannot differentiate between enteric coronavirus and FIP.
  - Effusion test: sensitive and specific, as are conventional means (fluid analysis, serology)
  - Note: Handle all PCR samples carefully, keep frozen, and analyze as soon as possible after collection.
- FIP mRNA PCR Multi Test:
  - Test detects mRNA of M gene for feline coronavirus (only expressed during replication).
  - Relies on fact that FCoV can enter the bloodstream but cannot replicate outside the intestinal epithelium
  - FIP virus, however, replicates in mononuclear cells. This test detects replicating virus particles in the blood in cats with FIP. Cats with enteric coronavirus have replicating virus in the stool but not in the blood.
  - Use EDTA whole blood. Assay performed at Auburn University Molecular Diagnostics Lab (www.vetmed.auburn.edu).
  - Use in combination with clinical suspicion and other diagnostic tests.
- Definitive diagnosis only by histopathologic examination of suspected affected tissues: pyogranulomatous inflammation with vasculitis and perivascular cuffing. Immunohistochemical staining of tissues can confirm FIP.

TREATMENT

TREATMENT OVERVIEW

FIP is an incurable disease, so the goal is to provide comfort and supportive/palliative care.

ACUTE GENERAL TREATMENT

- See Thoracocentesis, p. 1338 .
- Oxygen therapy (see p. 1318)
- Fluid therapy

CHRONIC TREATMENT

Various drugs have been used. None has been shown effective, and the possibility of adverse effects often contraindicates use.

- Antiviral drugs: ribavirin (severely toxic in cats)
- Immunomodulating drugs:
  - α-Interferon (human): 30 U PO q 24 h on alternating weeks; few to no adverse effects
  - Recombinant feline interferon (may be combined with corticosteroids for better efficacy)
  - Acemannan
- Immune suppression: prednisolone (2-4 mg/kg PO q 24 h, tapering over 10-14 days) ± cyclophosphamide (2-4 mg/kg PO q 24 h for 4 days a week)
- Thalidomide: 50-100 mg PO given at night. Must get owners consent to use, teratogenic.

- Supportive therapy as indicated by clinical condition:
  - Environmental management: reduction of stress, including providing place to nest/hide, reducing conflicting cat-cat interactions
  - Intravenous fluids
  - Broad-spectrum antibiotics for secondary bacterial infections (uncommon)
  - Vitamins (A, C, B complex, B1, E)

NUTRITION/DIET

Nutritional support, including warming of food, offering multiple types of dry and moist food, and hand feeding if ill cats are unwilling to eat, can be an important cornerstone of supportive care.

PROGNOSIS AND OUTCOME

Poor irrespective of treatment:

- Cats with the effusive form generally die within 2 months of onset of clinical signs.
- Cats with the noneffusive form tend to have a more chronic disease course that is also generally fatal.

PEARLS & CONSIDERATIONS

COMMENTS

A "feline infectious peritonitis titer" does not exist. A positive FCoV titer indicates only exposure to a feline coronavirus, which may be pathogenic (e.g., FIP) or benign.

TECHNICIAN TIP

A patient with overt FIP does not need to be handled with supplemental precautions regarding contagion, because the risk of transmission of FIP is essentially zero.

PREVENTION

- Intranasal FIP vaccination:
  - Replicates only in respiratory epithelium; does not cause systemic infection
  - Protects 50%-75% of cats from exposure to virulent FIP virus
  - Not recommended for routine use in low-risk cats
- Optimize husbandry practices:
  - A minority of cats are seronegative to FCoV. In catteries, these cats should be kept apart from other cats, as they can be used for breeding and raising litters with a low risk of any coronavirus.
  - In catteries, remove kittens from positive queens and other adult cats in the cattery at 5-6 weeks old to reduce risk of acquisition of coronavirus.
  - When possible, only seronegative cats should be added to the cattery. Otherwise, seropositive cats may be kept with other seropositive cats.

CLIENT EDUCATION

- Select new cats from reputable breeder with low numbers of cats.
- See Cornell Feline Health Center brochure on FIP: http://www.vet.cornell.edu/fhc/brochures/fip.html

AUTHOR: KHRISTEN J. CARLSON

EDITOR: DOUGLASS K. MACINTIRE

Feline Immunodeficiency Virus Infection

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Virus infection of cats that may result in chronic immunosuppression after a long clinically latent stage

SYNONYM

Feline acquired immunodeficiency syndrome (AIDS)

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Feline immunodeficiency virus (FIV) and related viruses can infect all Felidae.
- Male cats are at least twice as likely to be infected as female cats, and adult cats are more commonly infected than kittens.
- Adult male sexually intact free-roaming cats ("fighting cats") are at higher risk for infection.

CONTAGION & ZOONOSIS

- FIV is transmissible through cell-containing saliva and blood inoculated parenterally, most commonly through bite wounds and mating. Experimental evidence has shown that FIV may be transmitted in utero or in milk (not common under natural circumstances).
- FIV is not zoonotic.

GEOGRAPHY AND SEASONALITY

- FIV is common worldwide, with a higher prevalence in regions with larger numbers of free-roaming cats (e.g., Italy, Japan). In the United States, the prevalence is 2.5%-6% (client-owned cats) and 3.5%-23% (stray cats).

ASSOCIATED CONDITIONS & DISORDERS

Immunosuppression caused by FIV infection can result in opportunistic infections. Cats with FIV may be more susceptible to stomatitis, upper respiratory infections, feline leukemia virus (FeLV) infection, feline infectious peritonitis (FIP), fungal infections, and toxoplasmosis.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- FIV infection most often occurs without overt clinical signs, and the infection is most commonly discovered incidentally during routine screening or when evaluating a cat for other illness.
- When clinical manifestations occur, history and complaints are usually associated with secondary infections that develop due to immunosuppression, with signs due to neoplasia (increased risk of lymphoma), or with FIV-associated neurologic dysfunction.

PHYSICAL EXAM FINDINGS

- The acute phase of infection is usually unnoticed but may cause fever, lethargy, or lymphadenopathy.
- In the ensuing clinically latent ("asymptomatic") phase, cats show no clinical signs.
- Conversion to the terminal phase of infection cannot be predicted. Clinical signs of the terminal phase are related to secondary infections, tumors, and FIV infection of the CNS, leading to behavioral changes, seizures, and paresis.

ETIOLOGY AND PATHOPHYSIOLOGY

- FIV is a lentivirus (RNA virus) of the family *Retroviridae*.
- It is most commonly spread through bite wounds and blood contamination. Vertical transmission from queen to offspring has

been reported in experimental infection but is unlikely in the field.
- At least five subtypes (or clades) worldwide, based on sequence differences in a hypervariable region of the *env* gene: clades subtypes A, B, C, D, and E. Routine diagnostic testing does not differentiate them.
- FIV infection has three clinical phases:
    - Acute phase
        - Viral replication begins in the salivary glands, peripheral lymphoid tissues, and thymus, then spreads to infect mononuclear cells throughout nonlymphoid tissues. Lasts days to a few weeks; usually unnoticed.
    - Clinically latent ("asymptomatic") phase
        - Most common phase during which cats with FIV infection are usually presented in veterinary practice
        - Host immune response contains, but does not eliminate, the virus.
        - No clinical signs are present.
        - Cats are transmitting the infection (through bites, blood).
        - Generally lasts for months to several years
    - Terminal phase
        - Organism replication eventually overwhelms host's immune response.
        - Overt signs of immune deficiency, manifesting with refractory opportunistic infections (enteric, respiratory, cutaneous, or other), neoplasia, or neurologic disorders

DIAGNOSIS

DIAGNOSTIC OVERVIEW

Two diagnostic contexts exist: routine screening of healthy pets, and suspicion of FIV underlying signs of infection, neoplasia, or neurologic dysfunction. In either context, diagnosis is usually made by detecting FIV-specific antibodies in ELISA or similar tests. Negative results are highly reliable (in an area with low prevalence), but positive results should be considered carefully, because vaccination causes antibody development that leads to a positive result, and false-positive results are possible. Thus, a positive test should always be confirmed.

DIFFERENTIAL DIAGNOSIS

- Other immunosuppressive conditions, such as FeLV infection
- Primary neurologic disease or systemic causes of encephalopathy

INITIAL DATABASE

- CBC, serum chemistry panel, urinalysis
    - Rarely suggestive of FIV infection; rules out other illnesses
    - CBC, serum biochemistry profile, urinalysis results often normal in the latent stage
        - FIV may sometimes cause lymphopenia (because FIV replicates mainly in lymphocytes and macrophages) or hyperglobulinemia (because of an immune-mediated response).
- The screening tests of choice are fast in-house ELISA or other immunochromatography tests (using a similar technique) which detect anti-FIV antibodies in blood.
    - The presence of anti-FIV antibody is considered consistent with infection, because a cat, once infected, will never clear infection.
    - There are two exceptions in which a cat not infected still may have antibodies:
        - FIV vaccination (no commercially available antibody test can distinguish between vaccine-induced and infection-induced antibodies.)
        - Presences of maternal antibodies (if the queen was infected or vaccinated) that can be detected up to age 6 months
    - There are also two conditions in which an infected cat may have no detectable antibodies:
        - Acute infection: up to 8 weeks required to produce antibody
        - Terminally ill cats, owing to loss of detectible antibodies secondary to severe immunodeficiency (very rare)
    - False-positive result more likely than false-negative in countries with lower prevalence of FIV (e.g., United States)
    - Positive results always should be retested (preferentially using a different test system, e.g., Western blot) before communication of the result to the owner.

ADVANCED OR CONFIRMATORY TESTING

- Western blot (detects antibodies)
    - Confirmatory antibody test of choice (in cats not vaccinated against FIV)
    - Has a higher sensitivity and specificity than ELISA and related tests, but ELISA is used more commonly for initial testing because it is technically easier

- PCR test (detects viral DNA)
    - Especially if a cat is vaccinated against FIV or has an unknown vaccination history, PCR is currently the only test that accurately confirms infection.
    - However, up to 50% false-negative results occur, and the test requires meticulous lab conditions to avoid false-positive results

TREATMENT

TREATMENT OVERVIEW

Lifestyle management is a cornerstone of treatment and prevention. The FIV-infected cat should stay indoors only, away from the risk of secondary infections. In cats with no clinical signs, no other treatment is required. If cats have secondary infections, these should be treated comprehensively. In FIV-infected cats with stomatitis or neurologic signs, azidothymidine (AZT) can be considered.

ACUTE AND CHRONIC TREATMENT

- Any secondary infections should be treated immediately and with a prolonged course as appropriate (e.g., antibiotics).
- Antiviral treatment with AZT has been associated with an improvement in clinical signs, immune signs, and quality of life, especially in cats with stomatitis and neurologic signs. Doses of 5 mg/kg PO q 12 h have been given without side effects.

BEHAVIOR/EXERCISE

The most important life-prolonging advice is to keep FIV-infected cats strictly indoors: doing so prevents contagion with FIV to other cats and reduces exposure of the immunosuppressed cat to infection.

DRUG INTERACTIONS

- Griseofulvin should not be used for treating dermatophyte infections in FIV-positive cats (risk of severe neutropenia).
- All immunosuppressive drugs should be avoided.

POSSIBLE COMPLICATIONS

- AZT can cause a reversible regenerative anemia.

RECOMMENDED MONITORING

FIV-infected cats should be monitored regularly for evidence of secondary infectious diseases, neoplasia, and progression of illness. Recheck visits are recommended q 6 mos.

PROGNOSIS AND OUTCOME

FIV-positive cats may have an excellent quality of life for many years. FIV infection is not a reason for euthanasia.

PEARLS & CONSIDERATIONS

COMMENTS

- The FIV status of all cats should be known. Thus, every cat should be tested independent of age. If a young cat (<6 months old) is FIV antibody-positive, it should be retested when >6 months. In vaccinated cats, antibody tests are useless, and other tests (e.g., PCR) have to be used.
- A diagnosis of FIV infection is not a reason for euthanasia. Infected cats can live many years with an excellent quality of life. However, the diagnosis has certain implications.
    - The cats should only be kept indoors.
    - More intense veterinary care is generally required in such a cat.
    - Vaccination for other infectious diseases is recommended (as it may lead to progression of FIV infection) only for those cats at high risk of developing an infectious disease (e.g., open multicat households). When vaccinating an FIV-positive cat against other infectious diseases, only inactivated vaccines should be used.

PREVENTION

- FIV vaccination is controversial. The incidence of FIV is low in household pets, and infection may be prevented (without vaccination) by inhibiting FIV-negative cats from interacting with unfamiliar and unowned cats.
- FIV vaccination interferes with routine testing methods. FIV vaccination will result in antibody production that cross-reacts with routine testing (e.g., ELISA) for at least 1 year after vaccination. Additionally, kittens born to vaccinated queens will have positive test results due to passive transfer of antibodies.
- For high-risk cats with a known FIV-negative status, FIV vaccination may be considered.

TECHNICIAN TIPS

- Clients should be aware that the FIV status of every cat should be known.
- As FIV lives only minutes outside the host and is susceptible to all disinfectants including common soap, simple precautions and routine cleaning procedures will prevent transmission while in the hospital. FIV infection does not justify being housed in an “infectious disease ward” in which cats with contagious diseases (e.g., upper respiratory infections) are kept.

CLIENT EDUCATION

- Every cat should be tested for FIV.
- The importance of neutering cats should be emphasized.

Fear Due to Veterinary Visits/Treatments

BASIC INFORMATION

DEFINITION

Extremely common, truly iatrogenic condition in which the animal learns to avoid the veterinarian, the practice, and/or all veterinary experiences because these engender fear and behavioral distress.

EPIDEMIOLOGY

SPECIES, AGE, SEX

- All species are affected, more so those not wholly domesticated (e.g., cats).
- Dogs, which may have coevolved with humans, are least affected before 2 years of age but may worsen with exposure. Females > males.
- At least 60% of all veterinary patients may be affected.

GENETICS & BREED PREDISPOSITION: Onset/worsening: possibly worse in breeds with apparent familial behavioral concerns associated with social anxieties (e.g., Bernese mountain dogs: generalized anxiety disorder), fear (e.g., German shepherd dogs), phobias (e.g., German shepherd dogs, Australian shepherds, Border collies for noise phobia) and/or panic (many herding and coursing breeds)

RISK FACTORS

- +/− Social maturity (occurring during age 12-18 [up to 36] months in dogs, 24-48 months in cats)
- Dogs/cats who appear developmentally delayed and/or overly fearful within their first few months of life may be more susceptible to this form of learned fear.

CONTAGION & ZOONOSIS: This condition is the result of learning about environments viewed as threatening or uncertain from behavioral cues given by other animals and people. Affected animals often bite veterinary professionals.

ASSOCIATED CONDITIONS & DISORDERS

- Generalized anxiety disorder
- Noise phobia
- Fear (generalized or specific)
- Fear aggression

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT: Clients recognize that their pets “do not like to go to the vet.” Physical and behavioral signs of stress, distress, and anxiety are generally recognized by most people present but ignored because they are considered “normal” for veterinary patients.

PHYSICAL EXAM FINDINGS: Physical exam findings are those associated with the physical and behavioral signs of stress, distress, and anxiety. These may include but are not restricted to:

- Social withdrawal with or without complete freezing (no interaction with anyone)
- Physical freezing and rigidity
- Salivation and/or clear nasal discharge
- Panting
- Shaking/trembling
- Increased shedding of hair/exfoliation of dry skin
- Avoidance of stimulus or stimulus modality that triggers response (e.g., metal table, smell of alcohol, all flooring that is not nonslip)
- Vocalization including whining, barking, growling, hissing, whimpering
- Mydriasis
- Escape behaviors
- Grabbing with mouth or paws

- Yawning/licking lips
- Scratching
- Chewing through restraints (e.g., leads)
- Hiding
- Crouching
- Tucking tail
- Tachypnea
- Tachycardia
- Hyperthermia
- Increased or decreased sensitivity to pain
- Increased or decreased reactivity to touch or approach
- Hyperemic mucous membranes
- Dehydration
- Exacerbation of any cardiac, respiratory, or skeletal condition that may be comorbid

ETIOLOGY AND PATHOPHYSIOLOGY

- The etiology is exposure to stimuli and environments animals feel are worrisome, threatening, or uncertain and from which they cannot escape in time or space, despite signaling their need to do so. Regardless of whether the humans feel the environment is not threatening, what matters is the animal's perception and response.
- The pathophysiology is as for any condition involving behavioral stress, distress, and/or anxiety and appears to be rooted in neurochemical encoding of information in the amygdala.
- Rodent studies show that fear is most easily erased in very young animals whose brains are still developing. After this period (which is undefined for cats and dogs), perineuronal nets protect memories of fear from modification. This is why it is so important not to learn to fear.

DIAGNOSIS 

DIAGNOSTIC OVERVIEW

The diagnosis is made based on visual observation of signs of stress, distress, and/or anxiety in association with veterinary premises or activities. Since this problem is highly prevalent, such signs are at risk of being downplayed or ignored, and the diagnosis missed.

DIFFERENTIAL DIAGNOSIS

All signs of this iatrogenic condition are shared by other behavioral conditions and by many physical conditions including various neuropathies and toxicoses. The key to assigning a cause to the signs is to ask whether the signs are manifest only under physical and behavioral environmental conditions involving veterinary care.

INITIAL DATABASE

- No diagnostic testing is required to make the diagnosis.
- Many laboratory databases can be skewed by the condition. Examples include but are not restricted to:
  - Altered lymphocyte/neutrophil ratios and leukocytosis, often with a left shift (stress leukogram)
  - Increased cortisol
  - Hyperglycemia (especially cats)
  - Increased creatine phosphokinase
  - Increased hematocrit due to splenic pooling and/or margination associated with mild dehydration

TREATMENT 

TREATMENT OVERVIEW

- Treatment should be focused on ameliorating any signs of stress, distress, or anxiety as they appear, and at preventing them from worsening by learning in the future. This means specific triggers must be identified and addressed for the patient population as a whole and for each animal as an individual.
- A list of potential triggers of stress, distress, or anxiety should be compiled at each visit and long-term and short-term plans made for how to address the triggers (e.g., replace slippery tile flooring with nonslip flooring; vaccinate outside while dog is watching other dogs).

ACUTE AND CHRONIC TREATMENT

- Cease exposure to or engagement in whatever environments or behaviors are provoking the animal (e.g., if animals are resistant to getting on the table, let them sit on the floor; if they slip on the table, give them a nonslip mat).
- If the animal continues to manifest distress, consider panicolytic medication to abort the distress while the animal is with the veterinarian. The first drug of choice is alprazolam (dogs, 0.01-0.1 mg/kg [likely most effective range: 0.02-0.04 mg/kg] PO q 4-6 h PRN; cats, 0.0125-0.025 mg/kg PO q 12-24 h PRN; some published sources mistakenly recommend a tenfold higher dose). May also be used as a preventive: 0.5-1 dose given 2 hours before the expected provocative event and repeated 30 minutes beforehand. Alternatively, clonidine (dogs: 0.01 mg/kg PO q 12-24 h increased stepwise up to 0.05 mg/kg PO q 12-24 h (maximum dose 0.9 mg/day) or gabapentin (dogs: 10-20 mg/kg PO q 8-12 h) may be useful.
- Have all staff work to reward the dog for calm and comfortable behaviors.
- Integrate Certified Pet Dog Trainers (CPDTs) with extensive experience in behavior modification into the practice (www.ccpdt.org).
- Treatment of phobias (see p. 875) and separation anxiety (see p. 1012) as needed.

BEHAVIOR/EXERCISE

- Prophylactic veterinary visits should be fun. Interventional veterinary visits should be nonthreatening, calming, reassuring, and as stress free as possible.
- Animals learn fear as they age, so early appointments should involve treats, play, massage, and lots of fun activities before anything threatening (e.g., a vaccination) should be attempted. Therefore, puppy and kitten visits should be longer, and the animals should be allowed to interact with the staff and explore the hospital.
- On-site puppy/kitten and young dogs manners classes are an excellent vehicle for these exposures.
- Environments should be friendly to animals. This means that practices should attempt to do the following:
    - Modulate the noise environment by using acoustic tiles, plexiglass cage doors/walls when possible. Consider Muttmuffs (www.muttmuffs.com) for hospitalized/anesthetized animals.
    - Modulate the visual environment by the use of movable barriers and flexible and non-harsh lighting conditions. Consider calming caps (www.premier.com), Doggles (www.doggles.com), or eye shades as needed, especially when recovering from anesthesia.
    - Modulate the olfactory environment by allowing animals to have T-shirts or gloves worn by their humans with them in cages and during manipulations or anesthetic inductions. Rinse common areas with plain water. Spraying hands with pheromonal analog products (e.g., Feliway) has been anecdotally reported to decrease locomotor behavior/increase calm behaviors in cats.
    - Provide hiding and perching boxes/containers for caged cats.
    - Change tactile environments through nonskid flooring, yoga mats, and covering tables and scales with nonslip surfaces.
    - Use treats to reward good behaviors, and teach animals to participate in the exam process by offering body parts.

POSSIBLE COMPLICATIONS

Left untreated, these animals are more at risk for relinquishment, euthanasia, or absence of any preventative veterinary care.

RECOMMENDED MONITORING

Screen each animal at every visit for behavioral concerns manifest at home or during examinations/interventions.

PEARLS & CONSIDERATIONS

COMMENTS

- Iatrogenic fear conditioned by veterinary visits and care may trigger otherwise latent pathologic behavioral conditions.
- Because manifestations of fear are commonly cited as reasons for relinquishment, euthanasia, or avoidance of veterinary visits, the single most important welfare concern for pet animals may be how they react to veterinary care and visits.
- Everyone can recognize the signs associated with this condition. Only if we begin to find it unacceptable to scare animals will we stop doing it.

PREVENTION

- This condition is completely preventable.
- Cats should be exposed to humane interactions with people between 2-9 weeks of age, and dogs should be exposed to nonterrifying interactions with people and other animals and to new environmental experiences between 3 weeks and 16 weeks of age. Any profoundly fearful or distressed reactions during this period should trigger a behavioral consult and inform

the quality and quantity of future interactions/exposure.

TECHNICIAN TIPS

- This is one condition where technicians, particularly those with an interest in behavior modification, can make a huge change for the better in an animal's life. Technicians should be comfortable with how to examine cats in carriers using towels, how to use head collars and no-pull harnesses, how to trim toenails and draw blood without restraints, how to teach dogs and cats to offer body parts for examination, and how to modify the environment according to the pet's needs.
- Many practices have one or a few technicians who are very adept at deciphering and acting favorably and appropriately on cues of stress (the “pet whisperers”), and much can be learned by example from these individuals.

CLIENT EDUCATION

- Clients should be taught that this condition need never develop and that it need not be normal for pets to fear veterinary visits or care. Working with a good CPDT, they can teach their pets to willingly participate in the physical exam.

AUTHOR & EDITOR: KAREN OVERALL

Fanconi Syndrome

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

Uncommon constellation of renal tubular resorptive defects (including amino acids, phosphates, glucose, bicarbonate, calcium, and potassium) with renal tubular acidosis and antidiuretic hormone (ADH)-resistant polyuria

EPIDEMIOLOGY

SPECIES, AGE, SEX

- Primarily affects dogs; has been seen in cats
- No sex predilection
- Onset of phosphaturia and renal sodium loss around 3 years of age, with glucosuria and aminoaciduria at 4 years of age in inherited forms

GENETICS & BREED PREDISPOSITION

- Inherited form in basenji; mode of inheritance unknown; affects 10%-30% of basenji dogs in United States
- Documented disease in other breeds (not necessarily inherited): border terriers, Norwegian elkhounds, single reports in a Yorkshire terrier, Labrador retriever, cocker spaniel, dachshund, whippet, Shetland sheepdog, and mixed breed
- Bedlington terrier, West Highland white terrier, Skye terrier, Dobermanpinscher, Labrador retriever, and dalmatian dogs are predisposed to copper storage diseases; West Highland white terriers and other breeds with copper storage disease have been noted to have a reversible Fanconi syndrome.

RISK FACTORS

- Copper storage hepatopathy has been associated with transient Fanconi syndrome, similar to Wilson's disease in humans.
- Newly recognized form of acquired Fanconi syndrome is suspected but not proven to be caused by ingestion of contaminated jerky treats (pathophysiology unknown).

ASSOCIATED DISEASES & CONDITIONS: Metabolic acidosis, electrolyte disorders, urinary tract infection; bone abnormalities are uncommon in adult dogs (rickets common in children with Fanconi syndrome).

CLINICAL PRESENTATION

DISEASE FORMS/SUBTYPES: Not all dogs have all components of tubular resorptive defects, and the degree of each defect varies from dog to dog.

HISTORY, CHIEF COMPLAINT

- Polyuria
- Polydipsia
- Weight loss
- Poor haircoat
- None (routine screening/incidental finding)
- Severe GI signs (vomiting, diarrhea, anorexia) if associated with jerky treat ingestion

PHYSICAL EXAM FINDINGS

- Dehydration
- Muscle weakness
- Exam may be unremarkable

ETIOLOGY AND PATHOPHYSIOLOGY

Can be acquired or inherited. Acquired disease can be due to heavy metal intoxication (lead, copper, mercury, organomercurials),

maleic acid, Lysol, drugs (outdated tetracycline, gentamicin, cephalosporins, cisplatin, salicylate), contaminated jerky treats (presumptive), copper storage hepatopathy, nephrotic syndrome, amyloidosis, neoplasia (multiple myeloma), hyperglobulinemia, hyperparathyroidism, vitamin D deficiency, hypokalemia, or interstitial nephritis associated with antibodies to the glomerular basement membrane or transplantation.

- Defects are primarily proximal tubular resorptive defects.
  - Filtered glucose is normally completely reabsorbed in the proximal tubule, so long as tubular concentration (similar to plasma concentration) does not exceed the transport maximum (about 180 mg/dL). A defect in the transport mechanism can lead to renal glucosuria despite normoglycemia.
  - Aminoaciduria may be generalized or involve only certain groups of amino acids, because different carrier molecules are involved in transport of acidic, basic, and neutral amino acids. Some dogs have cystinuria with minor defects in resorption of methionine, glycine, and dibasic amino acids.
  - Phosphate is reabsorbed primarily in the proximal tubule, with very little reabsorbed in the distal tubule. Excessive phosphaturia due to tubular defects may lead to hypophosphatemia.
  - Hyperchloremic metabolic acidosis may develop secondary to severe bicarbonaturia.
  - Hypokalemia may result from excess renal potassium loss associated with bicarbonaturia.
- In addition to proximal tubular defects, dogs with Fanconi syndrome are resistant to ADH, creating a form of nephrogenic diabetes insipidus. This results in urinary concentrating defects. Before the onset of renal failure, urine specific gravity is frequently less than 1.008.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The presence of glucosuria and ketonuria in the absence of hyperglycemia is a hallmark of Fanconi syndrome, but other tubular defects will be present in addition.

DIFFERENTIAL DIAGNOSIS

- Diabetes mellitus
- Central diabetes insipidus
- Any cause of nephrogenic diabetes insipidus
- Renal failure
- Primary renal glucosuria (glucosuria only without aminoaciduria, etc.)

INITIAL DATABASE

- Urinalysis: isosthenuria or minimally concentrated urine, glucosuria and proteinuria common, +/− ketonuria
- Urine culture: glucosuria leads to increased risk of UTI.
- CBC: anemia occurs late in disease secondary to kidney failure.
- Serum biochemistry panel: normoglycemia; hyperchloremic metabolic acidosis, and azotemia occur late in disease process.
- Venous blood gas (preferred to total CO2 from serum biochemistry panel because of artifactual changes associated with storage and handling): metabolic acidosis

ADVANCED OR CONFIRMATORY TESTING

- In a basenji with glucosuria and normoglycemia, no further confirmation necessary
- For other breeds:
  - Amino acids
    - Cyanide nitroprusside-based array for cystinuria
    - Urine amino acid excretion: either 24-hour excretion or fractional excretion compared to creatinine excretion; normally 98%-100% resorption (available from http://research.vet.upenn.edu/penngen)
  - Fractional excretion of electrolytes: (Ux/Sx)× (Scr/Ucr) × 100, where Ux is urine concentration of electrolyte, Sxis serum concentration of electrolyte, Scr is serum creatinine, and Ucris urine creatinine
    - Expect elevated fractional excretion values (normal values in parentheses): Na^+ (0.31 ± 0.2), Cl^- (0.31 ± 0.25), K^+ (9.3 ± 5.9), Phos (21 ± 9), Ca^{++} (0.15 ± 0.13)
  - Parathyroid hormone level if suspicion of hypoparathyroidism (hypocalcemia)
  - Heavy metal testing if indicated

TREATMENT

TREATMENT OVERVIEW

One treatment protocol (www.basenji.org/fanconi.pdf) replaces nutrients excreted in urine to maintain plasma concentrations. This protocol has not been compared to other (potentially simpler) protocols to determine whether it improves survival or quality of life, but it is used by many owners of basenji dogs with Fanconi syndrome.

ACUTE GENERAL TREATMENT

- If acute uremic crisis, hospitalize for intravenous fluid therapy and other management appropriate for decompensated chronic renal failure (see p. 207)
- Electrolyte and acid base disorders treated as appropriate
- If severe GI signs associated with jerky treats, hospitalization for IV fluid therapy and potentially feeding tube placement may be appropriate.

CHRONIC TREATMENT

- Acidosis: sodium bicarbonate titrated to keep venous pH normal. Doses may exceed 11 mEq/kg per day (650 mg = 10 grain = 7.8 mEq). Starting dose can be based on pH and Pco^2 using a chart in the basenji club website protocol, or if immediate blood gas monitoring not available, 30 grains q 12 h.
- Hypokalemia: supplement 5-15 mEq per day, depending on severity of hypokalemia. Potassium gluconate has 8 mEq K^+ per tsp. Potassium citrate provides 5 mEq K^+ per 540 mg tablet; the citrate is metabolized to 5 mEq bicarbonate, which may help control acidosis.
- Chelation therapy if copper storage hepatopathy

NUTRITION/DIET

- Vitamin and mineral replacement: 1-2 canine multivitamins per day (e.g., Pet-Tab Plus), 1-2 Pet-Cal (calcium, phosphorus, and vitamin d supplement) per day, and 1 human multivitamin with trace minerals (i.e., Centrum) per week in dogs with polyuria and polydipsia. Do not give Pet-Cal if dog is in renal failure.
- Amino acid replacement: 1 AminoFuel tablet per week

POSSIBLE COMPLICATIONS

- Neurologic signs (seizures, ataxia, dementia, or central blindness) of unknown cause are seen in up to 20% of dogs.
- Manipulation of electrolyte and acid-base balance can lead to overcorrection of deficiencies.

RECOMMENDED MONITORING

- Recheck chemistry panel and venous blood gas 8-10 weeks after starting therapy, then in 6 months. Recheck annually if animal remains stable and requires no dose adjustments.
- Recheck potassium 1 week after any dose adjustment.
- Culture urine at least every 6 months.

PROGNOSIS AND OUTCOME

Lifespan is not substantially reduced from normal (median survival time 5.25 years from diagnosis). Renal failure is the most common cause of death (40%).

PEARLS & CONSIDERATIONS

COMMENTS

Overall, this is a rarely encountered disease.

PREVENTION

Inherited disease in basenji dogs. Dogs with this disease should not be bred, although late onset of disease (3-8 years) complicates reproductive planning.

SUGGESTED READING

The Basenji Club of America: www.basenji.org/fanconi.pdf. Yearley JH, et al: Survival time, lifespan, and quality of life in dogs with idiopathic Fanconi syndrome. J Am Vet Med Assoc 225:377–383, 2004.

AUTHOR: CATHY LANGSTON

EDITOR: LEAH A. COHN

Facial Paralysis, Idiopathic

Client Education Sheet Available on Website

BASIC INFORMATION

DEFINITION

An acute neuropathy of unknown etiology affecting one or both facial nerves

EPIDEMIOLOGY

SPECIES, AGE, SEX: Mature (>5 years) dogs and cats may be affected.

GENETICS & BREED PREDISPOSITION: Cocker spaniels, golden retrievers, beagles, and domestic long-haired cats are overrepresented.

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Rapid onset of drooling from one side of the mouth
- Inability to blink:
  - This deficit may be somewhat inapparent to owners, since dogs and cats with facial paralysis retain the ability to periodically retract the globe, which may give the appearance of a blink, owing to passive motion of the third eyelid.
- Dogs usually have an apparent ear droop and occasionally will have deviation of the nose away from the affected side. Food may collect in the affected commissure of the lips, and there may be associated halitosis.
- Occasionally clinical signs are bilateral, but they may begin on one side and take several days or weeks to affect the contralateral side.

PHYSICAL EXAM FINDINGS

- The menace response and palpebral reflex on the affected side are absent.
- Facial drooping, ptyalism, and ptosis may be evident.
- When a noxious stimulus is applied to the upper lip, the muscles of facial expression will fail to contract (trigeminofacial reflex); sensation of the face remains unaffected.
- In chronic cases, there may be permanent lip contracture.
- Corneal ulceration may be evident as a result of damage to the parasympathetic fibers responsible for tear production and/or exposure keratitis from the inability to blink.

ETIOLOGY AND PATHOPHYSIOLOGY

- The pathogenesis in domestic animals is unknown, but in humans, a similar condition (Bell's palsy) is associated with herpes simplex virus infection.
- Histopathologic studies reveal active degeneration of large- and small-caliber myelinated fibers. Inflammation is absent.

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The diagnosis of idiopathic facial paralysis requires a complete neurologic exam and eliminating structural or metabolic causes of facial nerve dysfunction.

DIFFERENTIAL DIAGNOSIS

- Idiopathic facial paralysis must be differentiated from other conditions involving the peripheral aspect of the facial nerve (e.g., otitis media interna, hypothyroidism, ear polyps, and polyneuropathies).
- When they cause facial paralysis, disorders of the central nervous system such as neoplasia, encephalitis, congenital malformations, and trauma are usually accompanied by additional neurologic deficits.

INITIAL DATABASE

- Complete neurologic and otoscopic examination (see p. 1311 and p. 1316, respectively)
- Serum chemistry panel and CBC: un remarkable with idiopathic facial paralysis
- Thyroid panel
- Schirmer tear test

ADVANCED OR CONFIRMATORY TESTING

Advanced imaging (e.g., CT, MRI) may be indicated for evaluation of the tympanic bullae and brainstem. Enhancement patterns in the intratemporal segment of the facial nerve as seen on MRI may be used for predicting recovery times.

TREATMENT

TREATMENT OVERVIEW

The main goal is prevention of corneal ulceration. No specific therapy is indicated for the remaining manifestations of facial paralysis.

ACUTE GENERAL TREATMENT

- Treatment is primarily supportive. Sterile lubricant ophthalmic ointment should be applied to the affected eye(s) at least q 6-8 h to prevent exposure keratitis and corneal ulceration.
- The use of corticosteroids is controversial and unlikely to be of benefit, given the paucity of inflammation. However, in people with Bell's palsy, such drugs may be efficacious in hastening recovery.

CHRONIC TREATMENT

Some animals require lifelong eye lubrication. Others will eventually begin to reflexively use the third eyelid to moisten the cornea and will no longer need topical medication.

PROGNOSIS AND OUTCOME

Prognosis for complete recovery is guarded. Some animals will regain variable levels of function to the facial nerve, but many have some degree of residual deficit.

PEARLS & CONSIDERATIONS

COMMENTS

Facial paralysis was reported to be idiopathic in 75% of dogs and 25% of cats in one study. Therefore it is imperative that practitioners do a complete neurologic evaluation to rule out other common causes of facial nerve dysfunction (see Differential Diagnosis above).

AUTHOR: GEORGINA BARONE

EDITOR: CURTIS W. DEWEY

Facial Muscle Wasting

BASIC INFORMATION

DEFINITION

Atrophy of the muscles of mastication, mainly the temporal and masseter muscles

SYNONYM

Masticatory muscle atrophy

EPIDEMIOLOGY

SPECIES, AGE, SEX: Dogs (most commonly) and cats (rarely), any age, any sex; with muscular dystrophy (MD), only males affected; with hereditary Labrador retriever myopathy (HLRM), males and females affected.

GENETICS & BREED PREDISPOSITION

- German shepherd, retrievers, Doberman pinscher, spaniels: masticatory myositis (MM)
- Shetland sheepdogs, rough- and smooth-coated collies: dermatomyositis
- German shepherds, other large breeds: idiopathic polymyositis (IP)
- Large-breed dogs: glucocorticoid-induced muscle atrophy
- Young male golden retriever: muscular dystrophy
- Labrador retriever: HLRM
- Bassett hounds: temporomandibular joint (TMJ) dysplasia

ASSOCIATED CONDITIONS & DISORDERS

- Submandibular and prescapular lymphadenopathy (see p. 662)
- Generalized muscle atrophy

CLINICAL PRESENTATION

HISTORY, CHIEF COMPLAINT

- Detailed history to include inquiries regarding previous bouts of painful mastication or chronic corticosteroid use
- History may reflect abnormalities isolated to facial musculature or reflective of generalized myopathy.
    - Facial:
        - Prominence of external occipital protuberance noticed by owner
        - Difficulty or inability to prehend food (less common)
        - Reflects either weakness (decreased jaw tone) or masticatory muscle fibrosis (increased jaw tone or trismus [inability to open the mouth])
        - Prior episode(s) of painful mastication and crying while chewing: MM
    - Generalized:
        - Concomitant mild to severe weakness, exacerbated by exercise; generalized muscle atrophy: IP
        - Bunny hopping gait, progressing to a more stilted gait with a plantigrade stance: MD

PHYSICAL EXAM FINDINGS

- Full physical examination, paying particular attention to the head, the condition of other muscle groups, and the skin
- Bilateral atrophy of the temporal and masseter muscles; skull-like appearance of the head
    - Dogs with MM can show salivation, dysphagia, and difficulty in opening their mouths, progressing to trismus.
    - Dogs with dermatomyositis can show generalized muscle atrophy, decreased jaw tone, facial nerve paralysis, stiff gait, dysphagia, regurgitation, and skin lesions.
- Enophthalmos, with third eyelid protrusion and small palpebral fissure due to dramatic loss of retrobulbar muscular support
- Unilateral temporal muscle atrophy: ipsilateral denervation of the mandibular branch of the trigeminal nerve

ETIOLOGY AND PATHOPHYSIOLOGY

- Developmental
  - MD
  - HLRM
  - Dermatomyositis
- Idiopathic
  - Trigeminal neuropathy
- Infectious
  - Toxoplasmosis (rare)
  - Neosporosis (rare)
- Immune-mediated
  - Systemic lupus erythematosus
  - Idiopathic polymyositis
  - MMM
- Iatrogenic
  - Glucocorticoid administration
- Metabolic
  - Hyperadrenocorticism
  - Cardiac cachexia
- Neoplastic
  - Cachexia and protein energy malnutrition resulting in muscle atrophy are features of many chronic neoplastic and inflammatory conditions.
- Disuse atrophy
  - TMJ dysplasia
  - Traumatic luxation of the TMJ (cats)
  - TMJ ankylosis (cats)

DIAGNOSIS

DIAGNOSTIC OVERVIEW

The specific diagnosis is often made histopathologically, with the exception of serologic titers for infectious causes or for the detection of antibodies against type 2M muscle fibers.

DIFFERENTIAL DIAGNOSIS

As for Etiology, above

INITIAL DATABASE

- CBC usually normal by the time the muscles are atrophied
- Serum biochemistry profile
  - Elevated muscle enzyme levels (creatine kinase and aspartate aminotransferase): IP, MM, DM, MD, HLRM
  - Hyperglobulinemia: IP

ADVANCED OR CONFIRMATORY TESTING

- Muscle biopsies and histopathology (see p. 1305):
  - Immunohistochemistry shows lack of dystrophin (MD).
  - Paucity of type 2 myofibers (HLRM)
  - Antibodies against type 2 myofibers on frozen sections of muscle (MM)
  - Myofiber necrosis with mononuclear cell infiltrates, atrophy, and fibrosis (dermatomyositis)
  - Multifocal necrosis and phagocytosis of type 1 and type 2 myofibers (IP)
- Circulating serum antibodies against type 2 myofiber muscle fibers: MM
- Serology for *Toxoplasma* and *Neospora:* protozoal myositis
- Electromyography is more useful in determining neurologic rather than muscular etiology of the atrophy.

TREATMENT

TREATMENT OVERVIEW

Immunosuppressive drugs are the mainstay of treatment and have to be instituted early to halt the process of muscle inflammation

and atrophy. Antibiotics should be used for protozoal myositis.

CHRONIC TREATMENT

- Glucocorticoid therapy
  - Masticatory myositis (see p. 704)
  - Idiopathic polymyositis (prednisone, 1-2 mg/kg q 12 h for 14 days, then tapering over at least 4 weeks to 12 months or longer)
  - Dermatomyositis (variable response)
- Upright feeding of dogs with concomitant megaesophagus
- Clindamycin (12-25 mg/kg PO q 12 h): protozoal myositis

POSSIBLE COMPLICATIONS

Corticosteroid side effects

RECOMMENDED MONITORING
