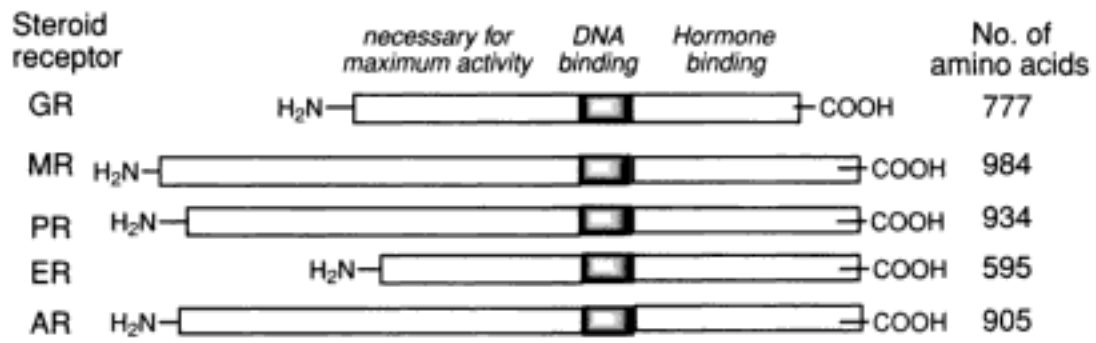
Steroid chemists often refer to the series of carbon–carbon bonds shown with heavy lines as the backbone of the steroid (Fig. 33.1). The *cis* or *trans* relationship of the four rings may be expressed in terms of the backbone. The compound 5α-cholestane (Fig. 33.2) is said to have a *trans-anti-trans-anti-trans* backbone. In this structure, all the fused rings have *trans* (diequatorial) stereochemistry; in other words, the A/B fused ring, the B/C fused ring, and the C/D fused ring are *trans*. The term *anti* is used in backbone notation to define the orientation of rings that are connected to each other and have a *trans*-type relationship. For example, the bond equatorial to ring B, at position 9, which forms part of ring C, is *anti* to the bond equatorial to ring B, at position 10, which forms part of ring A. 5β-Cholestane (Fig. 33.3) has a *cis-anti-trans-anti-trans* backbone in which the A/B rings are fused *cis*. The term *syn* is used in a similar fashion as *anti* to define a *cis*-type relationship. No natural steroids exist with a *syn*-type geometry, although such compounds can be chemically synthesized. Thus, the conventional drawing of the steroid nucleus is the natural configuration and does not show the hydrogens at 8β, 9α, or 14β positions. If the carbon at position 5 is saturated, the hydrogen is always drawn as either 5α or 5β. Also, the conventional drawing of a steroid molecule has the C18 and C19 methyl groups shown only as solid lines (no $CH_3$ drawn).



The stereochemistry of the rings markedly affects the biological activity of a given class of steroids. Nearly all biologically active steroids have the cholestane-type backbone. In most of the important steroids discussed in this chapter, a double bond is present between positions 4 and 5 or 5 and 6; consequently, there is no *cis* or *trans* relationship between rings A and B. The symbol Δ often is used to designate a carbon–carbon double bond (C═C) in a steroid. If the C═C is between positions 4 and 5, the compound is referred to as a $\Delta^4$-steroid. If the C═C is between positions 5 and 10, the compound is designated a $\Delta^{5(10)}$-steroid.

Cholesterol (cholest-5-en-3α-ol) is a $\Delta^5$-steroid or, more specifically, a $\Delta^5$-sterol, because it is an unsaturated alcohol. Biologically active compounds include members of the 5α-pregnane, 5α-androstane, and 5α-estrane steroid classes (Fig. 33.4). Pregnanes are steroids with 21 carbon atoms, androstanes 19 carbon atoms, and estranes 18 carbon atoms, with the C19 angular methyl group at C10 replaced by hydrogen. Numbering is the same as in 5α-cholestane.

The adrenocorticoids (adrenal cortex hormones) are pregnanes and are exemplified by cortisone, which is a 17α,21-dihydroxypregn-4-ene-3,11,20-trione. The acetate ester is named 17α,21-dihydroxypregn-4-ene-3,11,20-trione 21-acetate (cortisone acetate) (Fig. 33.4). Progesterone (pregn-4-ene-3,20-dione), a female sex hormone synthesized by the corpus luteum, also is a pregnane analogue. The male sex hormones (androgens) are based on the structure of 5α-androstane. Testosterone, an important and naturally occurring androgen, is named 17β-hydroxyandrost-4-en-3-one. Dehydroepiandrosterone (DHEA) is the major adrenal androgen and is named 3β-hydroxyandrost-5-en-17-one (Fig. 33.4). The estrogens, which are female sex hormones synthesized by the graafian follicle of the ovaries, are estrane analogues containing an aromatic A ring. Although the A ring does not contain isolated C═C groups, these analogues are named as if the bonds were in the positions shown in 17β-estradiol. Hence, 17β-estradiol, a typical member of this class of

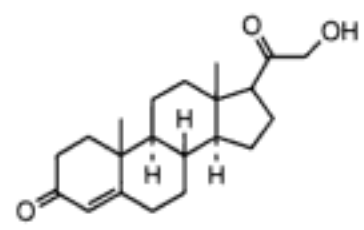
## HISTORY AND DISEASE STATES

The importance of the adrenal glands was recognized long ago. Addison's disease, Cushing's disease, and Conn's syndrome are pathological conditions related to the adrenal cortex and the hormones produced by the gland.

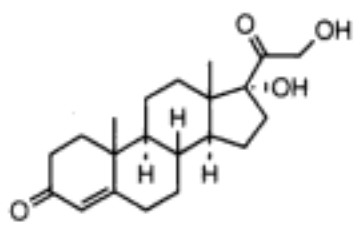
Addison's disease was named after Thomas Addison. In 1855, Addison described a syndrome in which the physiologic significance of the adrenal cortex was emphasized (11). This disease is characterized by extreme weakness, anorexia, anemia, nausea and vomiting, low blood pressure, hyperpigmentation of the skin, and mental depression resulting from decreased secretion of steroid hormones by the adrenal cortex. Addison's disease is a rare affliction that affects roughly 1 in 100,000 people and is seen equally in both sexes and in all age groups.

Conditions of this type, generally referred to as hypoadrenalism, may result from several causes, including destruction of the cortex by tuberculosis or atrophy or decreased secretion of adrenocorticotropin (adenocorticotropic hormone [ACTH]) because of diseases of the anterior pituitary (adenohypophysis). Cushing's disease, or hyperadrenalism, on the other hand, may result from adrenal cortex tumors or increased production of ACTH caused by pituitary carcinoma. Cushing's syndrome also is rare, occurring in only two to five people for every 1 million people each year. Approximately 10 percent of newly diagnosed cases are observed in children and teenagers.



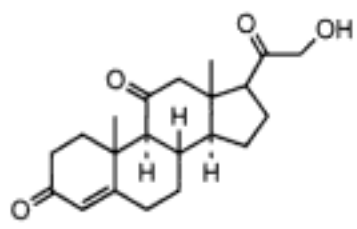
Conn's syndrome is apparently caused by an inability of the adrenal cortex to carry out 17α-hydroxylation during the biosynthesis of the hormones from cholesterol. Consequently, the disease is characterized by a high secretory level of aldosterone, which lacks a 17α-hydroxyl functional group. In addition, hypernatremia, polyuria, alkalosis, and hypertension are observed (12).

The importance of the adrenocorticoids is most dramatically observed in adrenalectomized animals. There is an increase of urea in the blood, muscle weakness (asthenia), decreased liver glycogen, decreased resistance to insulin, lowered resistance to trauma (e.g., cold and mechanical or chemical shock), and electrolyte disturbances. Potassium ions are retained, and excretion of $Na^+$, $Cl^-$, and water is increased. Adrenalectomy in small animals causes death in a few days.



After Addison's observations in 1855, physiologists, pharmacologists, and chemists from many countries contributed to our understanding of adrenocorticoids. It was not until 1927, however, that Rogoff and Stewart found that extracts of adrenal glands, administered by intravenous (IV) injection, kept adrenalectomized dogs alive.

Copyrighted material



Since that discovery, similar experiments have been repeated many times. Originally, the biological activity of the extract was thought to result from a single compound. Later, 47 compounds were isolated from such extracts, and some were highly active. Among the biologically active corticoids isolated, hydrocortisone, corticosterone, aldosterone, cortisone, 11-desoxycorticosterone (17α-hydroxyprogesterone), 11-dehydrocorticosterone (11-desoxycortisol), and 17α-hydroxy-11-desoxycorticosterone were found to be most potent (13). The biosynthesis of these steroids is described below.

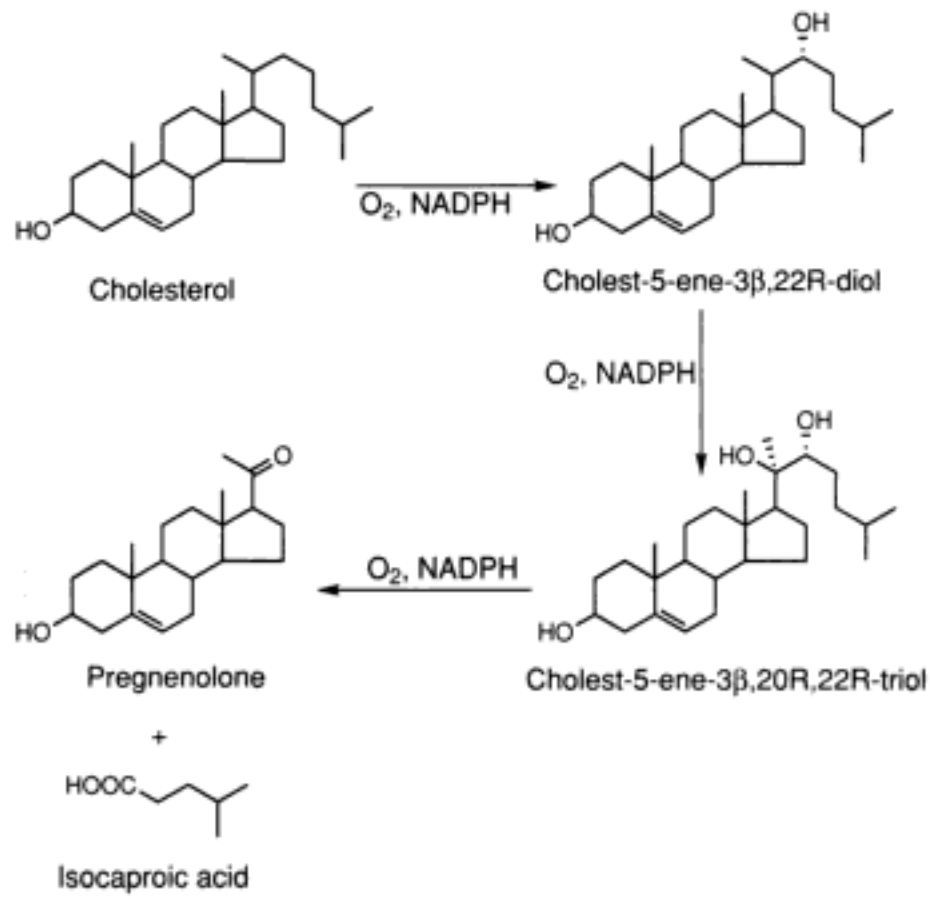

**Fig. 33.7.** Biosynthesis of pregnenolone from cholesterol.

## BIOSYNTHESIS

### Pregnenolone Formation

In the adrenal glands, cholesterol is converted by enzymatic cleavage of its side chain to pregnenolone (3β-hydroxypregn-5-en-20-one), which serves as the biosynthetic precursor of the adrenocorticoids (Fig. 33.7).This biotransformation is performed by a mitochondrial cytochrome P450 enzyme complex. This enzyme complex found in the mitochondrial membrane consists of three proteins: cytochrome P450 11A1 (CYP11A1; also known as $P450_{SCC}$), adrenodoxin, and adrenodoxin reductase (14). Defects in CYP11A1 lead to a lack of glucocorticoids, feminization, and hypertension. Three oxidation steps are involved in the conversion, and three moles of NADPH and molecular oxygen are consumed for each mole of cholesterol converted to pregnenolone. The first oxidation results in the formation of cholest-5-ene-3β,22R-diol (step a), followed by the second oxidation yielding cholest-5-ene-3β,20R,22R-triol (step b). The third oxidation step catalyzes the cleavage of the C20-C22 bond to release pregnenolone and isocaproic aldehyde (step c).

Pregnenolone serves as the common precursor in the formation of the adrenocorticoids and other steroid hormones. This C21 steroid is converted via enzymatic oxidations and isomerization of the double bond to a number of physiologically active C21 steroids, including the female sex hormone progesterone and the adrenocorticoids hydrocortisone (cortisol), corticosterone, and aldosterone. Oxidative cleavage of the two-carbon side chain of pregnenolone and subsequent enzymatic oxidations and isomerization lead to C19 steroids, including the androgens testosterone and dihydrotestosterone. The final group of steroids, the C18 female sex hormones, are derived from oxidative aromatization of the A ring of androgens to produce estrogens. More detailed information regarding these biosynthetic pathways are described in this and the following chapters under the particular class of steroid hormones.

### Pregnenolone to Glucocorticoids and Mineralocorticoids

The biosynthesis of the glucocorticoids and mineralocorticoids are regulated by independent mechanisms. The glucocorticoids, such as cortisol, are biosynthesized and released under the influence of peptide hormones secreted by the hypothalamus and anterior pituitary (adenohypophysis) to activate the adrenal cortex (the hypothalamic-pituitary-adrenal [HPA] axis). Removal of the pituitary results in atrophy of the adrenal cortex and a marked decrease in the rate of glucocorticoid formation and secretion. On the other hand, the secretion of the mineralocorticoids, corticosterone and aldosterone, are under the influence of the octapeptide, angiotensin II. Angiotensin II is the active metabolite resulting from the renin-catalyzed proteolytic hydrolysis of plasma angiotensinogen to angiotensin I in the blood. In hypophysectomized animals, the rate of secretion of aldosterone is only slightly decreased or remains

Copyrighted material

unchanged. Consequently, the electrolyte balance remains nearly normal.

The peptide hormone in the anterior pituitary that influences glucocorticoid biosynthesis is ACTH (corticotropin), whereas the peptide hormone in the hypothalamus is corticotropin-releasing factor (CRF). The production of both ACTH and CRF is regulated by the central nervous system and by a negative corticoid feedback mechanism. The CRF is released by the hypothalamus and is transported to the anterior pituitary, where it stimulates the release of ACTH into the bloodstream. Then, ACTH is transported to the adrenal glands, where it stimulates the biosynthesis and secretion of the glucocorticoids. The circulating levels of glucocorticoids act on the hypothalamus and anterior pituitary to regulate the release of both CRF and ACTH. As the levels of glucocorticoids rise, smaller amounts of CRF and ACTH are secreted, and a negative feedback is observed (HPA suppression). Stimuli, such as pain, noise, and emotional reactions, increase the secretion of CRF, ACTH, and consequently, the glucocorticoids. Once the stimulus is alleviated or removed, the negative feedback mechanism inhibits further production and helps to return the body to a normal hormonal balance (15,16).

Adrenocorticotropic hormone acts at the adrenal gland by binding to a receptor protein on the surface of the adrenal cortex cell to stimulate the biosynthesis and secretion of glucocorticoids. The only steroid stored in the adrenal gland is cholesterol, found in the form of cholesterol esters stored in lipid droplets. Adrenocorticotropic hormone stimulates the conversion of cholesterol esters to glucorticoids by initiating a series of biochemical events through its surface receptor. The ACTH receptor protein is coupled to a G protein and to adenylate cyclase. Binding of ACTH to its receptor leads to activation of adenylate cyclase via the G protein. The result is an increase in intracellular cyclic adenosine monophosphate (cAMP) levels. One of the processes influenced by elevated cAMP levels is the activation of cholesterol esterase, which cleaves cholesterol esters and liberates free cholesterol.

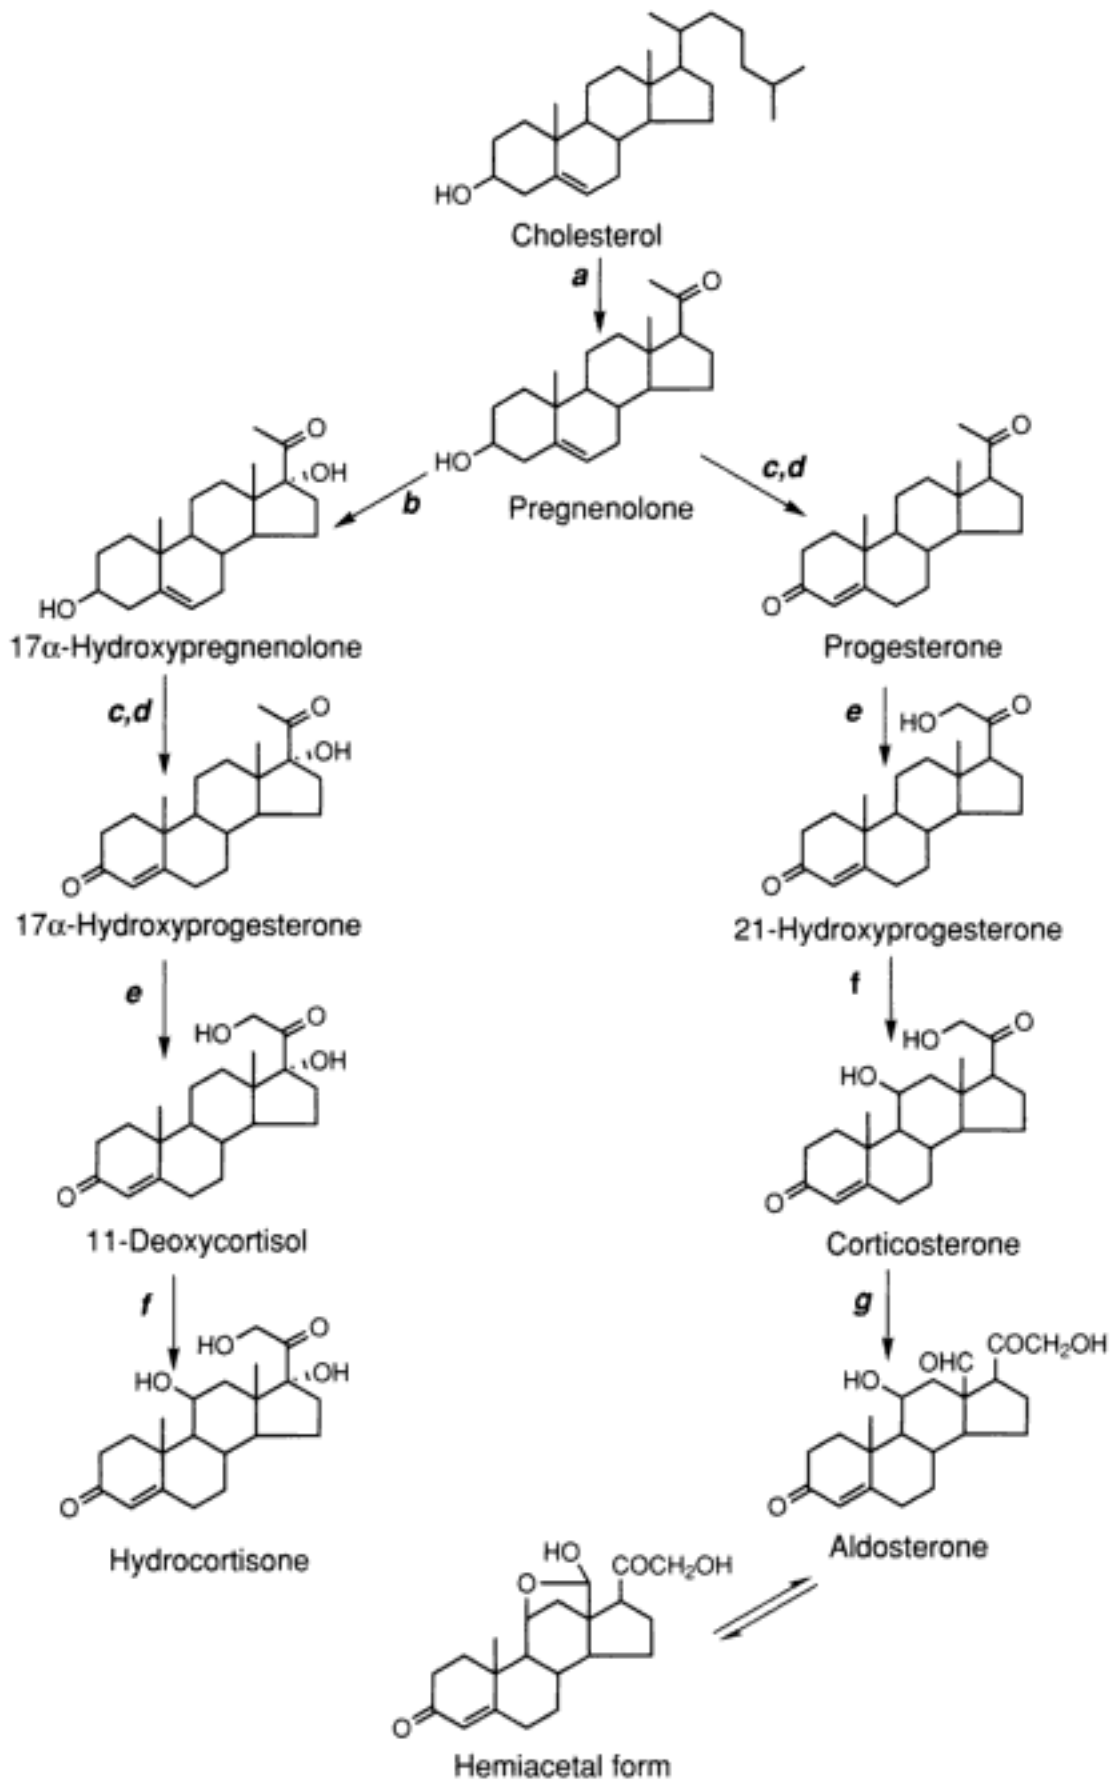
Free cholesterol is then converted within mitochondria to pregnenolone via the side-chain cleavage reaction described earlier (Fig. 33.7). Pregnenolone is converted to adrenocorticoids by a series of enzymatic oxidations and isomerization of the double bond (Fig. 33.8). The next several enzymatic steps in the biosynthesis of glucocorticoids occur in the endoplasmic reticulum of the adrenal cortex cell. Hydroxylation of pregnenolone at position 17 by the enzyme 17α-hydroxylase (CYP17) produces 17α-hydroxypregnenolone (step b). The 17α-hydroxyl group is important for adrenocorticoid hormone action. In one step, 17α-hydroxypregnenolone is oxidized to a 3-keto intermediate by the action of the enzyme 5-ene-3β-hydroxysteroid dehydrogenase (3β-HSD) and isomerized to 17α-hydroxyprogesterone by the enzyme 3-oxosteroid-4,5-isomerase (steps c and d). Another hydroxylation occurs by the action of 21-hydroxylase (CYP21) to give rise to 11-deoxycortisol, which contains the physiologically important ketol (—$COCH_2OH$) side chain at the 17β position (step e). A lack of CYP21 prevents cortisol biosynthesis, diverting excess 17α-hydroxypregnenolone and 17α-hydroxyprogesterone into overproduction of C19 androgens. The final step in the biosynthesis of hydrocortisone is catalyzed by the enzyme 11β-hydroxylase, a mitochondrial cytochrome P450 enzyme complex (CYP11B2). This last enzymatic step (step f) results in the formation of hydrocortisone (cortisol), the most potent endogenous glucocorticoid secreted by the adrenal cortex. Approximately 15 to 20 mg of hydrocortisone are biosynthesized daily. Several reviews (14,15,17–19) provide more detailed discussions about the enzymology and regulation of adrenal steroidogenesis.

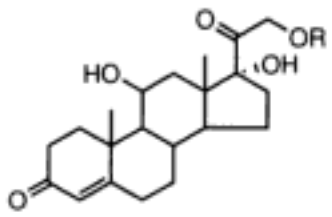
The pathway for the formation of the potent mineralocorticoid molecule, aldosterone, is similar to that for hydrocortisone and uses several of the same enzymes (Fig. 33.8). The preferred pathway involves the conversion of pregnenolone to progesterone by 5-ene-3β-hydroxysteroid dehydrogenase and 3-oxosteroid-4, 5-isomerase (steps c and d). Hydroxylation at position 21 of progesterone by 21-hydroxylase results in 21-hydroxyprogesterone (11-deoxycorticosterone) (step e). Again, these first conversions occur in the endoplasmic reticulum of the cell, whereas the next enzymatic steps occur in the mitochondria. 11β-Hydroxylase (CYP11B2) catalyzes the conversion of 21-hydroxyprogesterone to corticosterone (step f), which exhibits mineralocorticoid activity. The final two oxidations involve hydroxylations at the C18 methyl group and are catalyzed by 18-hydroxylase (step g). These reactions produce first 18-hydroxycorticosterone (not shown) and then aldosterone, the most powerful endogenous mineralocorticoid secretion of the adrenal cortex. The aldehyde at C18 of aldosterone exists in equilibrium with its hemiacetal form.

## METABOLISM

Hydrocortisone (hormonally active) and cortisone (the inactive metabolite of hydrocortisone) are biochemically interconvertible by the enzyme 11β-hydroxysteroid dehydrogenase (Fig. 33.9). Two isozymes of 11β-hydroxysteroid dehydrogenase are present, type 1 11β-hydroxysteroid dehydrogenase (11β-HSD1), referred to as the "liver" isozyme, and type 2 11β-hydroxysteroid dehydrogenase (11β-HSD2), referred to as the "kidney" isozyme (20–22). The 11β-HSD1 isozyme is a bidirectional enzyme, readily interconverts hydrocortisone and cortisone, and is found in many tissues in the body. This isozyme plays an important role in the regulation of hepatic gluconeogenesis in the liver and in fat production in adipose tissues. By contrast, the 11β-HSD2 isozyme is only unidirectional, catalyzing the 11β-dehydrogenation of hydrocortisone to give cortisone. The 11β-HSD2 is present in placenta and in kidney, specifically the distal convoluted tubules and cortical collecting ducts in the kidney. The 11β-HSD2 isozyme plays an important role in the rapid metabolism

Copyrighted material





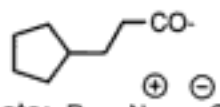


**Fig. 33.8.** Biosynthesis of the adrenocorticoids from cholesterol.

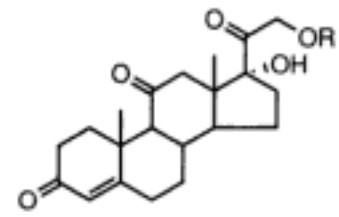

of hydrocortisone, thus preventing hydrocortisone from binding to the mineralocorticoid receptors present in the same kidney tissues. A deficiency of 11β-HSD2 is associated with the inherited genetic disease, apparent mineralocorticoid excess, which is characterized by hypertension, excessive salt retention, and hypokalemia caused by the elevated hydrocortisone levels in the kidney.

Hydrocortisone is metabolized by the liver following administration by any route, with a half-life of approximately 1.0 to 1.5 hours (23). Hydrocortisone is mainly excreted in the urine as inactive O-glucuronide conjugates and minor O-sulfate conjugates of urocortisol, 5β-dihydrocortisol, and urocortisone (Fig. 33.9). The tetrahydro metabolite urocortisol is the major metabolite formed and has the 5β-pregnane geometry and 3α-hydroxyl function. The 5β configuration is similar to the ring geometry for the nonhormonal bile acids. Several compounds of this type have been isolated (24,25). All of the biologically active adrenocorticoids contain a ketone at the 3-position and a double bond in the 4,5-position. The formation of 5β-metabolites from hydrocortisone is characterized by reduction of the 4,5-double bond to a 5β geometry for rings A and B (a *cis* configuration) by 5β-reductase or reduction of the 3-ketone by 3α-hydroxysteroid dehydrogenase (3α-hydroxyl configuration) or 3β-hydroxysteroid dehydrogenase (3β-hydroxyl configuration). corticosteroids are used clinically by the oral route, including hydrocortisone, prednisone, prednisolone, methylprednisolone, and dexamethasone (Fig. 33.10). These corticosteroids often are described as short-acting, intermediate-acting, or long-acting according to their biological half-life and duration of action (Table 33.2). They are well-absorbed, undergo little first-pass metabolism in the liver, and demonstrate oral bioavailabilities of 70 to 80%, except for triamcinolone (Table 33.3). The larger volume of distribution for methylprednisolone compared to prednisolone is thought to result from a combination of increased lipophilicity, decrease in metabolism, and better tissue penetration. Glucocorticoids vary in the extent to which they are bound to the plasma proteins, albumin, and corticosteroid-binding globulin (transcortin) (Table 33.3) (27).

Hydrocortisone is extensively bound to the plasma proteins, primarily to transcortin (corticosteroid-binding globulin), with only 5 to 10% of plasma hydrocortisone unbound. Prednisolone and methylprednisolone, but not the 9α-fluoro analogues betamethasone, dexamethasone, or triamcinolone, have a high affinity for transcortin and, thus, compete with hydrocortisone for this binding protein. The 9α-halo analogues bind primarily to albumin.

Table 33.3. Pharmacokinetics of Commonly Used Oral Adrenocorticoids

Copyrighted material

Only the unbound fraction of hydrocortisone and the synthetic corticosteroids are biologically active. Generally, the amount of transcortin in the plasma determines the distribution of glucocorticoids between free and bound forms, and free glucocorticoid concentrations determine the drug's half-life. Glucocorticoids cross the placenta and may be distributed into milk.

The degree of systemic side effects is dose-dependent, related to the half-life of the drug, frequency of administration, time of day when administered, and route of administration. In other words, the higher the plasma corticosteroid concentration and longer the half-life, the greater the systemic side effects will be (Table 33.3).

Regardless of the route of administration, all the synthetic adrenocorticoids are excreted from the body in a manner similar to the endogenous adrenocorticoids (i.e., they are metabolized in the liver and excreted into the urine primarily as glucuronide conjugates but also as sulfate conjugates) (28). In fact, hepatic oxidative metabolism rapidly converts many of the systemic and topical corticosteroids to inactive metabolites and, thus, serves to protect patients from the HPA-suppressive effects of these drugs on endogenous steroid production. The corticosteroids are metabolized in many tissues, including the liver, muscles, and red blood cells (15,18,29); however, the liver metabolizes them most rapidly. The fact that many of the endogenous corticosteroids are rapidly metabolized by the liver precludes their administration by the oral route. Catabolic products can be isolated from the urine and bile and can be formed in tissue preparations in vitro (30,31).

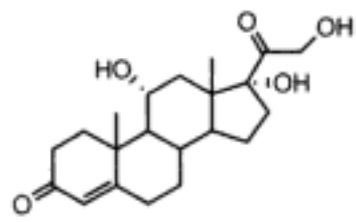
### Specific Drugs

11-Desoxycorticosterone was the first naturally occurring corticoid to be synthesized. It was prepared, before its isolation from the adrenal cortex, by Steiger and Reichstein (32). As a result of his synthesis of 11-desoxycorticosterone and other early work with corticoids, Reichstein later shared the Nobel Prize with Kendall, another chemist who was instrumental in carrying out early steroid syntheses, and with Hench, a rheumatologist who in 1929 discovered that cortisone is effective in the treatment of rheumatoid arthritis. Kendall's basic research ultimately led to the synthesis of cortisone from naturally occurring bile acids (33).

**CORTISONE, HYDROCORTISONE, AND THEIR DERIVATIVES.** After the synthesis of 11-desoxycorticosterone in 1937, all the corticoids were synthesized and their structures confirmed. The first synthesis of cortisone from methyl 3α-hydroxy-11-ketobisnorcholanate was reported by Sarett (34) in 1946. Earlier work of Kendall and coworkers involving its preparation from the methyl ester of desoxycholic acid was used in his research (35). Later, several chemists, including Sarett (36), Kendall, and Tishler, found ways to improve the yields and to decrease the labor involved in the multistep conversion of bile acids to cortisone acetate. In 1949, Merck sold limited quantities of this glucocorticoid to physicians at $200 per gram for treating rheumatoid arthritis. Subsequent improvements in the methods of synthesis reduced the price to $10 per gram by 1951. In 1955, Upjohn used an efficient process involving the synthesis of cortisone acetate from progesterone, with the latter steroid being prepared from diosgenin. This further reduced the price to $3.50 per gram. In 2005, the cost was $8 per gram. Other pharmaceutical companies also began to sell cortisone synthesized from bile acids by a well-developed but lengthy procedure (33).

Cortisone is administered orally or by intramuscular (IM) injection as its 21-acetate (cortisone acetate). Cortisone acetate or hydrocortisone usually is the corticosteroid of choice for replacement therapy in patients with adrenocortical insufficiency, because these drugs have both glucocorticoid and mineralocorticoid properties. Following oral administration, cortisone acetate and hydrocortisone acetate are completely and rapidly deacetylated by first-pass metabolism (37). Much of the oral cortisone, however, is inactivated by oxidative metabolism (Fig. 33.9) before it can be converted to hydrocortisone in the liver. The pharmacokinetics for hydrocortisone acetate is indistinguishable from that of orally administered hydrocortisone. Oral hydrocortisone is completely absorbed, with a bioavailability of greater than 95% and a half-life of 1 to 2 hours (23). The metabolism of hydrocortisone (Fig. 33.9) has been previously described. Cortisone acetate is slowly absorbed from IM injection sites over a period of 24 to 48 hours and is reserved for patients who are unable to take the drug orally. The acetate ester derivative demonstrates increased stability and has a longer duration of action when administered by IM injection. Thus, smaller doses can be used. Similarly, hydrocortisone may be dispensed as its 21-acetate (hydrocortisone acetate), which is superior to cortisone acetate when injected intra-articularly. Systemic absorption of hydrocortisone acetate from intra-articular injection sites usually is complete within 24 to 48 hours. When administered intrarectally, hydrocortisone is poorly absorbed (38,39).

Other ester derivatives that are available include hydrocortisone cypionate [21-(3-cyclopentylpropionate) ester], hydrocortisone butyrate (17α-butyrate ester), hydrocortisone buteprate (17α-butyrate, 21-propionate esters), hydrocortisone valerate (17α-valerate ester), hydrocortisone sodium succinate (21-sodium succinate ester), and hydrocortisone sodium phosphate (the 21-sodium phosphate ester) (Fig. 33.10). The water-insoluble hydrocortisone cypionate is used orally in doses expressed in terms of hydrocortisone for slower absorption from the gastrointestinal (GI) tract. The extremely water-soluble 21-sodium succinate and 21-sodium phosphate esters are used for IV or IM injection in the management of emergency conditions that can be treated with anti-inflammatory steroids. The phosphate ester is completely



Copyrighted material

and rapidly metabolized by phosphatases, with a half-life of less than 5 minutes (38). Peak hydrocortisone levels are reached in approximately 10 minutes. The sodium succinate ester is slowly and incompletely hydrolyzed, and peak hydrocortisone levels are attained in 30 to 45 minutes (38). Hydrocortisone butyrate, hydrocortisone buteprate, and hydrocortisone valerate are used topically.

After the introduction of cortisone (1948) and, later, hydrocortisone (1951) for the treatment of rheumatoid arthritis, many investigators began to search for superior agents having fewer side effects. When these drugs are used in doses necessary to suppress symptoms of rheumatoid arthritis, they also affect other metabolic processes. Side effects, such as excessive sodium retention and potassium excretion, negative nitrogen balance, increased gastric acidity, edema, and psychosis, are exaggerated manifestations of the normal metabolic functions of the hormones.

It was hoped that a compound with high glucocorticoid and low mineralocorticoid activity could be synthesized. Because it was recognized early that a carbonyl group at C3, a double bond between carbons 4 and 5, an oxygen (C=O or β-OH) at carbon 11, and a β-ketol side chain at position 17 are necessary for superior glucocorticoid activity, investigators began to synthesize analogues containing these functions. Additional groups were inserted into other positions of the basic steroid structure, with the expectation that these new substituents might modify the glucocorticoid and mineralocorticoid activities of the parent drugs.

The first potent analogues discovered, however, did not result from a concentrated effort to find a better drug but, rather, from basic chemical research concerned with the preparation of hydrocortisone from 11-epicortisol (11α-hydrocortisone).

11-Epicortisol

**FLUDROCORTISONE.** A 9α-bromo analogue was prepared that had one-third the glucocorticoid activity of cortisone acetate (40). Other halogens were introduced into the 9α-position, and it was soon observed that glucocorticoid activity is inversely proportional to the size of the halogen at carbon 9. The 9α-fluoro analogue (fludrocortisone) is approximately 11 times as potent as cortisone acetate (Fig. 33.10). Fludrocortisone is orally administered as its 21-acetate derivative. When tested clinically in patients with rheumatoid arthritis, it was found to be effective at approximately one-tenth the dose of cortisone acetate. Although glucocorticoid activity is increased 11 times by insertion of the 9α-fluoro substituent, mineralocorticoid activity is increased 300 to 800 times (27). Because of its intense sodium-retaining activity, fludrocortisone is contraindicated in all conditions except those that require a high degree of mineralocorticoid activity, because it leads to edema. Fludrocortisone acetate is used orally for mineralocorticoid replacement therapy in patients with adrenocortical insufficiency, such as Addison's disease. This drug, introduced in 1954, helped to provide the impetus for the synthesis and biological evaluation of newer halogenated analogues.

**PREDNISONE, PREDNISOLONE, AND ITS DERIVATIVES.** One year after the introduction of fludrocortisone, the Δ-corticoids were brought forth into clinical medicine. Investigators at Schering observed that the 1-dehydro derivatives of cortisone and hydrocortisone—namely, prednisone and prednisolone—are more potent antirheumatic and antiallergenic agents than the parent compounds and produced fewer undesirable side effects. These compounds are known as $\Delta^1$-corticoids, because they contain an additional double bond between positions 1 and 2 (Fig. 33.10).

The $\Delta^1$-corticoids, which can be prepared by microbial dehydrogenation of cortisone or hydrocortisone with *Corynebacterium simplex* (41) and by several synthetic methods (33), represent the first chemical innovation leading to the creation of a modified compound that could be prescribed for rheumatoid arthritis. One high-yield route involves oxidation of 5α- or 5β-pregnane precursors that have appropriate oxygen substitutions with selenium dioxide (42).

Both prednisone and prednisolone were found to have adrenocortical activity (measured by eosinopenic response, liver glycogen decomposition, and thymus involution in adrenalectomized mice). In these tests, prednisone and prednisolone were found to be three- or fourfold more potent than cortisone and hydrocortisone. Antiphlogistic strengths in human subjects were similarly augmented, but their electrolyte activities were not proportionately increased.

The increased potency reflects the effect in the change in geometry of ring A caused by the introduction of C1=C2 function on glucocorticoid receptor (GR) affinity and altered pharmacokinetics (primarily metabolism). Although the remaining portions of the steroid are essentially unchanged (except for less easily visualized molecular perturbations), the conformation of ring A changes from a chair, as in 5α-pregnan-3-one, to a half-chair (pregn-4-en-3-one) and to a flattened boat (pregna-1,4-dien-3-one) on introduction of unsaturation (Fig. 33.11). The order of GR affinity is dexamethasone (10×) > triamcinolone (5×) > methylprednisolone (4×) > prednisolone (2×) > hydrocortisone (1×) (43).

When orally administered, prednisone and prednisolone are almost completely absorbed, with a bioavailability of greater than 80% (Table 33.3) (44,45). As with

Copyrighted material

plasma levels for methylprednisolone is attained in approximately 30 to 60 minutes following its IV administration, and approximately 15% of its IV dose is recovered unchanged in urine (45,46). CYP3A4 inhibitors such as the antifungals, ketoconazole, and itraconazole can potentiate the effects of prednisolone.

**TRIAMCINOLONE.** A natural extension of corticoid research involved examination of compounds containing both a 9α-fluoro group and a double bond between positions 1 and 2. Triamcinolone (9-fluoro-11β, 16α, 17, 21-tetrahydroxypregna-1,4-diene-3,20-dione), introduced in 1958, combines the structural features of a $\Delta^1$-corticoid and a 9α-fluoro corticoid (Fig. 33.10). As mentioned previously, the 9α-fluoro group increases the anti-inflammatory potency, but it also markedly increases the mineralocorticoid potency. This is undesirable if the drug is to be used internally for the treatment of rheumatoid arthritis. By inserting a 16α-hydroxy group into the molecule, one can decrease the mineralocorticoid activity.

The original interest in 16α-hydroxycorticosteroids stemmed from their isolation from the urine of a boy with an adrenal tumor. The desire of chemists to synthesize these corticoids, and the hope that such analogues might have potent biological activity furthered their development (50–52). Therefore, inserting a 16α-hydroxy group into 9α-fluoroprednisolone resulted in triamcinolone with glucocorticoid activity equivalent to prednisolone but decreased mineralocorticoid activity. In fact, 16α-hydroxy analogues of natural corticoids retain glucocorticoid activity and have a considerably reduced mineralocorticoid activity. The lower-than-expected oral anti-inflammatory potency for triamcinolone (Table 33.2) has been attributed to its low oral bioavailability (Table 33.3), in part because of increased hydrophilicity from the 16α-hydroxy group and first-pass metabolism, primarily to its 6β-hydroxy metabolite. These glucocorticoids actually may cause sodium excretion rather than sodium retention. Triamcinolone diacetate (17,21-diacetate) and its hexacetonide [16α, 17α-methylenedioxy-21-(3,3-dimethylbutyrate)] esters are administered IM or intra-articularly for a prolonged release of triamcinolone. Triamcinolone diacetate has a duration of action depending on its route of administration from 1 to 8 weeks, and triamcinolone hexacetonide has a duration of action of 3 to 4 weeks (53,54).

On a weight-for-weight basis, the antirheumatic potency of triamcinolone is greater than that of prednisolone (~20%) and approximately the same as that of methylprednisolone. Initial improvement following administration of triamcinolone is similar to that noted with other compounds. Reports in the literature, however, indicate that the percentage of patients maintained satisfactorily for long periods has been distinctly smaller than that with prednisolone.

Even though triamcinolone has an apparently decreased tendency to cause salt and water retention and edema and may induce sodium and water diuresis, it causes other unwanted side effects, including anorexia, weight loss, muscle weakness, leg cramps, nausea, dizziness, and a general toxic feeling (55). Intramuscular triamcinolone is reportedly effective and safe in the treatment of dermatoses, and in combination with folic acid antagonists, it is effective in the treatment of psoriasis (56,57).

**DEXAMETHASONE.** Research with 16-methyl substituted corticoids was initiated in part because investigators hoped to stabilize the 17β-ketol side chain to metabolism in vivo and improve bioavailability (Fig. 33.10). These studies led to the development of dexamethasone (9-fluoro-16α-methyl-11β,17,21-trihydroxypregna-1,4-diene-3,20-dione), which was introduced for clinical trial. A 16α-methyl group does decrease the reactivity of the 20-keto group to carbonyl reagents and increases the stability of the drug in human plasma in vitro (58,59). Unlike 16α-hydroxylation, a methyl group increases the anti-inflammatory activity by increasing lipophilicity and, consequently, receptor affinity. Like the 16α-hydroxyl group, the methyl group appears to reduce markedly the salt-retaining properties of the corticosteroids (Table 33.2) (60–62). The activity of dexamethasone, as measured by glycogen deposition, is 20 times greater than that of hydrocortisone. It has five times the anti-inflammatory activity of prednisolone. Clinical data indicate that this compound has seven times the antirheumatic potency of prednisolone. It is roughly 30 times more potent than hydrocortisone. Its pharmacokinetics are presented in Table 33.3. Routes of metabolism for dexamethasone are similar to those for prednisolone, with its primary 6β-hydroxy metabolite being recovered in urine (63). Dexamethasone sodium phosphate is the water-soluble sodium salt of the 21-phosphate ester, with an IV half-life of less than 10 minutes because of rapid hydrolysis by plasma phosphatases (64). Peak plasma levels for dexamethasone usually are attained in approximately 10 to 20 minutes following its IV administered dose. A similar reaction occurs when the phosphate ester is applied topically or by inhalation.

In practical management, 0.75 mg of dexamethasone promotes a therapeutic response equivalent to that from 4 mg of triamcinolone or methylprednisolone, 5 mg of prednisolone, and 20 mg of hydrocortisone. Clinical investigations with small groups of patients indicate that this compound could control patients who did not respond well to prednisolone. Over long periods, the improved status of some patients deteriorated.

In summarizing the biological properties of this drug, it seems clear that with doses of corresponding antirheumatic strength, this steroid has approximately the same tendency as prednisolone to produce facial mooning, acne, and nervous excitation. Peripheral edema is uncommon (7%) and mild. The more common and most objectionable side effects are excessive appetite and weight gain, abdominal bloating, and distention. The frequency and severity of

Copyrighted material

these symptoms vary with the dose (1 mg maximum for females, and 1.5 mg maximum for males). The longer biological half-life for dexamethasone significantly increases the potential for glucocorticoid-induced adrenal insufficiency (see *Adverse Effects*).

The striking increase in potency does not confer a general therapeutic index on dexamethasone that is higher than that of prednisolone. Again, this drug probably is best employed as a special-purpose corticoid. It may be useful when other steroids are no longer effective or when increased appetite and weight gain are desirable (64–69). Its efficacy may be increased when it is used in combination with cyproheptadine as an antiallergenic, antipyretic, and anti-inflammatory agent (60).

**BETAMETHASONE.** Shortly after the introduction of dexamethasone, betamethasone, which differs from dexamethasone only in configuration of the 16-methyl group (Fig. 33.10), was made available for the treatment of rheumatic diseases and dermatologic disorders. This analogue, which contains a 16β-methyl group, has received sufficient clinical trial examination to indicate that it is as effective as dexamethasone or, perhaps, even slightly more active. Although this drug has been reported to be less toxic than other steroids, some clinical investigators suggest that it is best used for short-term therapy. Toxic side effects, such as increased appetite, weight gain, and facial mooning, occur with prolonged use. Generally, a 0.5-mg tablet of betamethasone is equivalent to a 5.0-mg tablet of prednisolone, and except for isolated instances, this drug is apparently on a par with dexamethasone (70).

**SELECTIVE GLUCOCORTICOID RECEPTOR MODULATORS.** The long-term use of glucocorticoids is associated with severe adverse effects (see *Adverse Effects*), including osteoporosis, hyperglycemia, muscle wasting, hypertension, and impaired wound healing. Improved glucocorticoids that demonstrate potent anti-inflammatory activity without these serious side effects would provide a significant therapeutic advance and are the focus of intense research efforts by the pharmaceutical industry. The molecular mechanism of the GR makes it a particularly suitable target for this effort. The majority of unwanted side effects of the glucocorticoids arise from the interaction of the GR with DNA (i.e., GR-mediated transcription), whereas the anti-inflammatory effects are mediated via protein–protein interactions between the GR and pro-inflammatory transcription factors (i.e., AP-1 and NFκB) that results in repression of the inflammatory response. A variety of selective GR modulators with the ability to repress inflammation but with lesser ability to elicit GR-mediated transcription have been reported (71–73). Early investigations indicate that a variety of different nonsteroidal pharmacophores (e.g., spirocyclic dihydropyridines, triphenylmethanes, and benzoindazoles) bind with high affinity and selectivity to the GR. Importantly, some of these analogues demonstrate preferential ability to repress pro-inflammatory genes and a lesser ability to induce GR-mediated transcription. Although these nonsteroidal ligands have yet to be evaluated in clinical studies, these drugs may someday prove to be the first members of an improved class of anti-inflammatory drugs.

**DISCONTINUED ORAL GLUCOCORTICOIDS.** Paramethasone acetate (6α-fluoro-16α-methyl-11β-17,21-trihydroxypregna-1,4-diene-3,20-dione 21-acetate), synthesized in 1960, retains the 16α-methyl group, but the 9α-fluoro substituent has been moved to the 6α position. It was thought that this manipulation would reduce the electrolyte loss associated with dexamethasone. Reports in the literature indicate that paramethasone causes a slight loss of sodium and chloride with little or no loss of potassium (with doses as large as 15 mg). An analysis of continuous therapy over 9 months, however, showed that the therapeutic efficacy of paramethasone did not differ greatly from that of fluprednisolone (74).

Fluprednisolone (6α-fluoro-11β,17,21-trihydroxypregna-1,4-diene-3,20-dione) is the 16-desmethyl analogue of paramethasone. Its activity is similar to that of paramethasone, and it has approximately 2.5 times the antirheumatic potency of prednisolone. With doses of 2 to 7 mg, evidence of salt and water retention has not been noted. The therapeutic index, however, probably is the same or only a little greater than that for prednisolone. Because no new adverse reactions have been noted during the administration of this drug on a short-term basis, it seems that a 6α-fluoro group does not deleteriously affect the activity of prednisolone (49,75).

## Topical Glucocorticoids

Topically applied glucocorticoids are also capable of being systemically absorbed, although to a much smaller extent. The extent of absorption of topical adrenocorticoids is determined by several factors, including the type of cream or ointment, the condition of the skin to which it is being applied, and the use of occlusive dressings. Previous studies with halobetasol propionate showed that approximately 6% of the drug was systemically absorbed after topical application. Although this is a small fraction of the dose, the very high potency of halobetasol propionate contributed to its ability to cause mild adrenal suppression in some patients. The relative potency of the topical glucocorticoids is commonly determined using topical vasoconstriction assays and is dependent on the intrinsic activity of the drug, its concentration in the formulation, and the vehicle in which it is applied (Table 33.4).

Once absorbed through the skin, topical corticosteroids are handled through metabolic pathways similar to the systemically administered corticosteroids. They are metabolized, primarily in the liver, and are then excreted into the urine or in the bile (76). The fact that circulating

BMP, beclomethasone IV, intravenous.
Data from McEvoy GK ed. AHFS 2001 Drug Information. Bethesda, MD: American Society of Health-System Pharmacists, 2001.
[a]Nasarel and Nasalide are not bioequivalent. Total absorption of Nasarel was 25% less, and the peak plasma concentration was 30% lower, than that of Nasalide. The clinical significance of this is likely to be small, however, because clinical efficacy is dependent on local effects on the nasal mucosa.
[b]Binding affinity to human glucocorticoid receptors in vitro relative to dexamethasone. Data from Kelly HW. Establishing a therapeutic index for the inhaled corticosteroids. Part 1: Pharmacokinetic pharmacodynamic comparison of the inhaled corticosteroids. J Allergy Clin Immunol 1998;102:S36–S51.

[e]Calculated log P for mometasone furoate = 4.7.
[f]Estimated for inhaled beclomethasone aerosol.
[g]Data from oral inhalation administration.

the older glucocorticosteroids (e.g., dexamethasone). Beclomethasone dipropionate was discovered to be a prodrug, and this discovery led to the reexamination of other 17α-monoesters as the active form of the corticosteroid esters. The absorption of budesonide, fluticasone propionate, and BDP into the airway tissue was 25 to 130 times greater than that for dexamethasone and hydrocortisone (86). The GR affinity and the pharmacokinetic properties for the inhaled and intranasal corticosteroids are listed in Table 33.5.

It is generally recognized that when administered by oral inhalation, 10 to 30% of a dose of the corticosteroid is deposited in the respiratory tract depending on type of inhaler (metered dose inhaler or dry powder inhaler [DPI]) and spacer used (87,88). The remainder of the dose is deposited primarily in the mouth and throat to be swallowed into the GI tract, where the drug may be absorbed, metabolized, and eliminated unchanged in the feces. Thus, systemic bioavailability of the inhaled/intranasal steroids is determined by the fraction of the dose absorbed from the lungs/nasal mucosa and the GI tract into systemic circulation and the degree of first-pass metabolism. Although these corticosteroids are very lipid soluble, they display variable degrees of absorption from respiratory and GI tissues, in part because of dissolution problems. When systemically absorbed, they are capable of suppressing the HPA and adrenal function with high and chronic dosing regimens (88,89). Although as much as 40% of the dose for the high-potency adrenocorticoids flunisolide, mometasone furoate, or fluticasone propionate is absorbed into airway and nasal tissues during oral inhalation, the remainder of the drug is swallowed to undergo extensive first-pass metabolism in the liver to essentially inactive metabolites, with no apparent suppression effects on adrenal function with long-term therapy.

Copyrighted material

potency for fluticasone propionate is approximately equal to that for mometasone furoate, 13-fold greater than that for triamcinolone acetonide, ninefold greater than that for fluocinolone acetonide, threefold greater than that for betamethasone 17-valerate, and twofold greater than that for BDP (111). Because of its low systemic bioavailability when administered intranasally or by inhalation and nondetectability in plasma, most pharmacokinetic data for fluticasone propionate are based on IV or oral administration (Table 33.5). Its rate of topical uptake into epithelial tissue is more than 100-fold faster than that for hydrocortisone and dexamethasone but is similar to BDP and budesonide.

As a consequence of its high lipophilicity (Table 33.5), fluticasone propionate is very insoluble and, therefore, is poorly absorbed from the respiratory (10–13%) and GI tract following nasal inhalation of the drug (112–114). The majority of the intranasal dose for fluticasone propionate is deposited in the nasal mucosa and swallowed into the GI tract until eliminated in the feces (~80–90% of the intranasal dose is recovered metabolized and unchanged in the feces). After administration of an IV suspension, fluticasone propionate displayed a systemic bioavailability of less than 2% and underwent extensive hydrolysis and CYP3A4 first-pass metabolism in the liver, with an elimination half-life of approximately 3 hours. Its primary hydrolysis product is 17β-carboxylate metabolite, which has 1/2,000 the affinity for the GR, can be recovered from the urine along with other unidentified hydroxy metabolites and their conjugates. Following oral administration of 1 to 40 mg, fluticasone propionate is poorly absorbed from the GI tract because of hydrolysis and its insolubility, with an oral bioavailability of less than 1%. Less than 5% of the oral dose is excreted unchanged in the urine. Fluticasone propionate was not detected in plasma for up to 6 hours after IV or oral administration (113). Approximately 80 to 90% of the oral dose is excreted unchanged in the feces, of which approximately 3 to 40% is the hydrolyzed 17β-carboxylate metabolite. Pulmonary bioavailability ranges between 16 and 30% depending on the inhalation device used, with an elimination half-life of approximately 14 hours, increasing its potential for drug accumulation with repeated dosing (114). The long elimination half-life for fluticasone propionate results, in part, from its very high lipophilicity and very poor water solubility and, consequently, slow dissolution into lung tissue. Some suppression of overnight hydrocortisone levels has been reported with inhaled fluticasone propionate at higher dosages (indicative of HPA-axis suppression) (115).

Fluticasone propionate nasal suspension and inhalation aerosol are both available as micronized suspensions in a chlorofluorocarbon propellant that delivers 50 μg per metered spray. The total daily adult dose for fluticasone propionate is 200 μg for the nasal suspension and 880 μg for the inhalation aerosol.

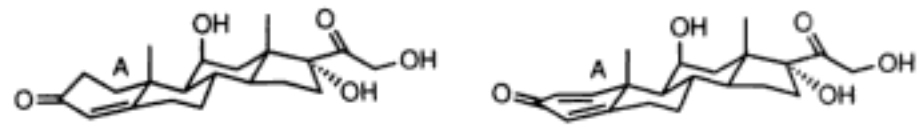

**Fig. 33.15.** Conformations of hydrocortisone and prednisolone.

## SUMMARY OF STRUCTURE–ACTIVITY RELATIONSHIPS

The structure in Figure 33.15 depicts the ring conformation and the absolute configuration of hydrocortisone and prednisolone. The all-*trans* (B/C and C/D) backbone that is necessary for activity is very evident.

As previously pointed out, the adrenocorticoids generally are classified as either glucocorticoids, which affect intermediary metabolism and are associated with inhibition of the inflammatory process, or mineralocorticoids. In fact, most naturally occurring and semisynthetic analogues exhibit both of these actions. The 17β-ketol (—$COCH_2OH$) side chain and the $\Delta^4$-3-ketone functions are found in clinically used adrenocorticoids, and these groups do contribute to the potency of the agents. Modifications of these groups may result in derivatives that retain biological activity. For example, replacement of the 21-OH group with fluorine increases glucocorticoid and sodium-retaining activities, whereas substitution with chlorine or bromine abolishes activity. Some compounds that do not contain the $\Delta^4$-3-ketone system have appreciable activity. It has been suggested that this group makes only a minor contribution to the specificity of action by these drugs or to the steroid–receptor association constant (116).

Based on structure–activity studies, the C and D rings, involving positions 11, 12, 13, 16, 17, 18, 20, and 21, are more important for receptor binding than the A and B rings. Generally, insertion of bulky substituents on the β-side of the molecule abolishes glycogenic activity, whereas insertion on the α-side does not. It has been suggested that association of these steroids with receptors involves β-surfaces of rings C and D and the 17β-ketol side chain (116). It is possible, however, that association with the α-surface of rings A, C, and D, as well as with the ketol side chain, is essential for sodium-retaining activity. Many functional groups, such as 17α-OH, 17α-$CH_3$, 16α-$CH_3$, 16β-$CH_3$, 16α-$CH_3O$, and 16α-OH substituents, abolish or reverse this activity in 11-desoxycorticosterone and 11-oxygenated steroids. Discussions of exceptions of these generalities are found in the literature (116).

Although some steroids cause sodium retention, many have glucocorticoid and either sodium-retaining or sodium-excreting action. Difficulties in correlating the structures of adrenocorticoids with biological action are compounded because of differences in assay methods, species variation, and mode of drug administration. For

## PHARMACOLOGICAL EFFECTS AND CLINICAL APPLICATIONS

In addition to their natural hormonal actions, the adrenocorticoids have many clinical uses. Glucocorticoids and mineralocorticoids may be used for the treatment of adrenal insufficiency (hypoadrenalism), which results from failure of the adrenal glands to synthesize adequate amounts of the hormones. Adrenocorticoids also are used to maintain patients who have had partial or complete removal of their adrenal glands or adenohypophysis (adrenalectomy and hypophysectomy, respectively). Glucocorticoids can cross the placenta and can be distributed into milk.

Two major uses of glucocorticoids are in the treatment of rheumatoid diseases and allergic manifestations. Their use in the treatment of severe asthma is well documented, as is the utility of glucocorticoids in sepsis and acute respiratory distress syndrome (157,158). They are effective in the treatment of rheumatoid arthritis, acute rheumatic fever, bursitis, spontaneous hypoglycemia in children, gout, rheumatoid carditis, sprue, allergy (including contact dermatitis), and other conditions. The treatment of chronic rheumatic diseases and allergic conditions with glucocorticoids is symptomatic and continuous. Symptoms return after withdrawal of the drug.

In addition, these drugs are moderately effective in the treatment of ulcerative colitis, dermatomyositis, periarteritis nodosa, idiopathic pulmonary fibrosis, idiopathic thrombocytopenic purpura, regional ileitis, acquired hemolytic anemia, nephrosis, cirrhotic ascites, neurodermatitis, and temporal arteritis. The newer analogues with medium to high potency rankings (Table 33.4), such as diflorasone diacetate, desoximetasone, flurandrenolide, and fluocinonide (Fig. 33.12), are effective topically in the treatment of psoriasis. Glucocorticoids may be combined with antibiotics to treat pneumonia, peritonitis, typhoid fever, and meningococcemia.

When dosages with equivalent antirheumatic potency are given to patients not treated with steroids, the $\Delta^1$-corticoids (prednisone and prednisolone) promote the same pattern of initial improvement as hydrocortisone. Statistical results of improvement during the first few months of therapy have been similar with prednisone, prednisolone, and hydrocortisone. The results of longer-term therapy have been significantly better with the modified compounds.

Satisfactory rheumatic control, lost after prolonged cortisone or hydrocortisone therapy, may be regained in an appreciable number of patients by changing to prednisone, prednisolone, or other modified drugs. Of patients whose conditions deteriorate below adequate levels during hydrocortisone administration, nearly half reach their previous level of improvement after $\Delta^1$-corticoids (in doses slightly larger in terms of antirheumatic strength) are used. With further prolongation of steroid therapy, improvement again wanes in some patients, but in other patients, such management is successful for longer than 2 years. In some instances, the improvement is attributed to increased effectiveness of the drug because of correction of salt and water retention; in other instances, there is no adequate explanation.

When these drugs are administered in doses that have similar antirheumatic strengths, the general incidence of adverse reactions with prednisone and prednisolone is about the same as that with hydrocortisone. The compounds differ, however, in their tendencies to induce individual side effects. The incidence and degree of salt and water retention and blood pressure elevation are less with the $\Delta^1$-corticoids. Conversely, these analogues are more likely to promote digestive complaints, peptic ulcer, vasomotor symptoms, and cutaneous ecchymosis.

Although these analogues have unwanted side effects, most clinical investigators prefer the $\Delta^1$-corticoids to cortisone and hydrocortisone for rheumatoid patients who require steroid therapy. The reasons are that these drugs have less tendency to cause salt and water retention and potassium loss and that they restore improvement in a significant percentage of patients whose therapeutic control has been lost during cortisone and hydrocortisone therapy.

It seems desirable to administer prednisone and prednisolone in conjunction with nonabsorbable antacids. This affords improvement of long-term therapy. It appears that the therapeutic indices of these two analogues, especially when used in conjunction with nonabsorbable antacids, are higher than those for the naturally occurring glucocorticoids.

Most important, glucocorticoids should not be withdrawn abruptly in cases of acute infections or severe stress, such as surgery or trauma. Myasthenia gravis, peptic ulcer, diabetes mellitus, hyperthyroidism, hypertension, psychological disturbances, pregnancy (first trimester), and infections may be aggravated by glucocorticoid administration. Hormone therapy is contraindicated in these conditions and should be used only with the utmost precaution.

Semisynthetic analogues exhibiting high mineralocorticoid activity are not employed in the treatment of rheumatic disorders because of toxic side effects resulting from a disturbance of electrolyte and water balance. Some newer synthetic steroids (Table 33.2) are relatively free of sodium-retaining activity. They may show other toxic manifestations, however, and eventually need to be withdrawn.

Glucocorticoids sometimes are used in the treatment of scleroderma, discoid lupus, acute nephritis, osteoarthritis, acute hepatitis, hepatic coma, Hodgkin's disease, multiple myeloma, lymphoid tumors, acute leukemia, metastatic carcinoma of the breast, and

Copyrighted material

Table 33.7. Effect of an Oral Single Dose on the Duration of HPA Suppression

| Adrenocorticoid | Duration of Suppression (days) |
|---|---|
| Hydrocortisone (250 mg) | 1.25–1.5 |
| Cortisone (250 mg) | 1.25–1.5 |
| Methylprednisolone (40 mg) | 1.25–1.5 |
| Prednisone (50 mg) | 1.25–1.5 |
| Prednisolone (50 mg) | 1.25–1.5 |
| Triamcinolone (40 mg) | 2.25 |
| Dexamethasone (5 mg) | 2.75 |
| Betamethasone (6 mg) | 3.25 |

induced osteoporosis, and generalized protein depletion (16,27). The duration of anti-inflammatory activity of glucocorticoids approximately equals the duration of HPA-axis suppression. The duration of HPA-axis suppression after a single oral dose of glucocorticoids in one study is shown in Table 33.7. When given for prolonged periods, glucocorticoids suppress the HPA axis, thereby decreasing secretion of endogenous corticosteroids and adrenal atrophy. Glucocorticoids inhibit ACTH production by the adenohypophysis, and in turn, this reduces endogenous glucocorticoid production. With time, atrophy of the adrenal glands takes place. The degree and duration of adrenocortical insufficiency produced by the synthetic glucocorticoids is highly variable among patients and depends on the dose, frequency and time of administration, and duration of glucocorticoid therapy. This effect may be minimized by use of alternate-day therapy.

Patients who develop drug-induced adrenocortical insufficiency may require higher corticosteroid dosage when they are subjected to stress (e.g., infection, surgery, or trauma). In addition, acute adrenal insufficiency (even death) may occur if the drugs are withdrawn abruptly or if patients are transferred from systemic glucocorticoid therapy to oral inhalation therapy. Therefore, the drugs should be withdrawn very gradually following long-term therapy with pharmacological dosages. Adrenal suppression may persist up to 12 months in patients who receive large dosages for prolonged periods. Until recovery occurs, patients may show signs and symptoms of adrenal insufficiency when they are subjected to stress, and replacement therapy may be required. Because mineralocorticoid secretion may be impaired, sodium chloride or a mineralocorticoid also should be administered.

Although side effects and toxicities vary with the drug and, sometimes, with the patient, facial mooning, flushing, sweating, acne, thinning of the scalp hair, abdominal distention, and weight gain are observed with most glucocorticoids. Protein depletion (with osteoporosis and spontaneous fractures), myopathy (with weakness of muscles of the thighs, pelvis, and lower back), and aseptic necrosis of the hip and humerus are other side effects. These drugs may cause psychological disturbances, headache, vertigo, and peptic ulcer, and they may suppress growth in children.

Patients with well-controlled diabetes must be closely monitored and their insulin dosage increased if glycosuria or hyperglycemia ensues either during or following glucocorticoid administration. Patients should also be watched for signs of adrenocorticoid insufficiency after discontinuation of glucocorticoid therapy. Individuals with a history of tuberculosis should receive prophylactic doses of antituberculosis drugs.

Osteoporosis is one of the most serious adverse effects of long-term glucocorticoid therapy. Moderate- to high-dose glucocorticoid therapy is associated with loss of bone and an increased risk of fracture that is most rapid during the initial 6 months of therapy. These adverse effects of glucocorticoids appear to be both dose- and duration-dependent, with oral prednisone dosages of 7.5 mg or more daily for 6 months or longer often resulting in clinically important bone loss and increased fracture risk. Bone loss has even been associated with oral inhalation of glucocorticoids and is of great concern in children. Most patients receiving long-term glucocorticoid therapy will develop some degree of bone loss, and more than 25% will develop osteoporotic fractures. Vertebral fractures have been reported in 11% of patients with asthma who are receiving systemic glucocorticoids for at least 1 year, and glucocorticoid-treated patients with rheumatoid arthritis are at increased risk of fractures of the hip, rib, spine, leg, ankle, and foot. Muscle wasting or weakness and atrophy of the protein matrix of the bone resulting in osteoporosis are manifestations of protein catabolism, which may occur during prolonged therapy with glucocorticoids. These adverse effects may be especially serious in debilitated patients, in geriatric populations, and in postmenopausal women who are especially prone to osteoporosis.

To minimize the risk of glucocorticoid-induced bone loss (osteoporosis) and those with low mineral bone density, the smallest possible effective dosage and duration should be used. Topical and inhaled preparations should be used whenever possible. The immunosuppressive effects of glucocorticoids increase the susceptibility to and mask the symptoms of infections and may result in activation of latent infection or exacerbation of intercurrent infections. The most common adverse effect of oral inhalation therapy with glucocorticoids is fungal infections of the mouth, pharynx, and occasionally, the larynx. The mineralocorticoid effects are less frequent with synthetic glucocorticoids (except fludrocortisone) than with hydrocortisone or cortisone but may occur, especially when synthetic glucocorticoids are given in high dosage for prolonged periods.

# 34. *Thyroid Function and Thyroid Drugs*

ALI R. BANIJAMALI

**DRUGS COVERED IN THIS CHAPTER:**

DRUG FOR TREATMENT OF HYPOTHYROIDISM
- Thyroid gland products
- Levothyroxine
- Liotyronine
- Liotrix

DRUGS FOR TREATMENT OF HYPERTHYROIDISM
- Iodide
- Perchlorate
- Radioiodine
- Methimazole
- Propylthiouracil

## INTRODUCTION

The thyroid gland is a highly vascular, flat structure located at the upper portion of the trachea, just below the larynx. It is composed of two lateral lobes joined by an isthmus across the ventral surface of the trachea. The gland is the source of two fundamentally different types of hormones, thyroxine ($T_4$) and triiodothyronine ($T_3$). Both hormones are vital for normal growth and development and control essential functions, such as energy metabolism and protein synthesis.

The word thyroid, meaning shield-shaped, was introduced by Wharton in his description of the gland (1). Like many before him, he attributed a solely cosmetic function to it because of the more frequent presence of enlarged glands in women, giving the throat region a more beautiful roundness. Later, however, it was observed that some characteristic symptoms for diseases always were accompanied by an obvious change in the size of the thyroid. This change was correctly interpreted as evidence that this structure plays a major role in normal body function.

An important step in the understanding of thyroid function was taken by Baumann (2), who discovered that the thyroid gland was the only organ in mammals that had the capability to incorporate iodine into organic substances. That discovery was important in research concerning the phylogeny of the thyroid.

Major clues to the physiological roles of thyroid hormones were provided when normal and abnormal thyroid function were related to oxygen uptake (3) and when thyroid hormones were found to induce metamorphosis in tadpoles (4). The first discovery led to investigations regarding the role of thyroid hormone in metabolism and calorigenesis, and the second inspired research concerning specific receptors as points of initiation of thyroid hormone expression. A patient lacking thyroid hormones may be treated with synthetic hormones or natural preparations. Better agents to treat hyperthyroidism are still being sought. Presently available drugs, other compounds affecting thyroid function, and current approaches in the search for new drugs are presented in this chapter within the context of thyroid biochemistry and physiology.

## NORMAL BIOCHEMISTRY AND PHYSIOLOGY

### Thyroid Follicular Cells

All vertebrates have a thyroid gland consisting of functional units, the follicles. The morphological and functional characteristics of the follicles are essentially similar in all vertebrate groups.

The follicle is a spherical, cyst-like structure approximately 300 μm in diameter, and it consists of a luminal cavity surrounded by a one-cell-deep layer of cells called follicular or acinar cells. The center of the follicles is filled with a gelatinous colloid, the main component of which is a glycoprotein called thyroglobulin. The follicular cells contain an extensive network of rough endoplasmic reticulum, a well-developed Golgi apparatus, and lysosomes of various sizes (5). Thyroglobulin is synthesized in the rough endoplasmic reticulum of the follicular cells and transported by way of the Golgi complex to the apical membrane and then secreted into the follicle lumen.

The follicular cell contains two major assembly lines operating in opposite directions (6). One line moves in an apical direction and produces thyroglobulin that is delivered to the follicle lumen; the other line begins at the apical cell surface with endocytosis of thyroglobulin and ends by delivering hormones at the basolateral cell membrane. The follicular cell seems, therefore, to fulfill the functions of secretory and absorptive cells simultaneously. In addition to the functions associated with these two lines, the follicle has the specific ability to metabolize iodine, comprising the accumulation of iodide, iodination of tryosyl residues in thyroglobulin, and coupling of the iodinated tyrosyls to form thyroid hormones.

Parafollicular cells, also called light cells or C cells, are located individually or in clusters between follicular cells but do not border on the colloid. These cells produce

Thyroid hormones at the levels present in hyperthyroidism are catabolic; they lead to the mobilization of tissue protein and, especially, of muscle tissue protein for gluconeogenetic processes (20). Thus, the depletion of liver glycogen, the increased breakdown of lipids, and the negative nitrogen balance observed in hyperthyroidism represent toxic effects. The metabolic processes of hypermetabolism are wasteful. In hyperthyroidism, a smaller-than-normal amount of liberated energy is available for useful work, and an excessive amount is wasted as heat.

Because of the role of mitochondria in cellular respiration and energy production, efforts to elucidate the mechanism of thyroid hormone action in metabolism and calorigenesis have focused on mitochondrial studies. Thyroid hormones in vitro are known to uncouple oxidative phosphorylation in isolated mitochondria, but these effects occur at unphysiological doses of $T_4$. In physiological concentrations, $T_4$ increases adenosine triphosphate (ATP) formation and the number and inner membrane surface area of mitochondria (21), but $T_4$ does not reduce the efficiency of oxidative phosphorylation. Furthermore, 2,4-dinitrophenol, a classic uncoupler of oxidative phosphorylation, can neither relieve hypothyroidism nor duplicate other physiological effects of thyroid hormones.

Because in most physiological circumstances oxygen consumption is controlled by energy metabolism, Ismail-Beigi and Edelman (22) proposed that the primary effect of thyroid hormones is to increase the amount of energy expended in translocating cations across cell membranes, probably as a response to an increased passive leak of sodium into, and potassium out of, cells. The extent to which this transport contributes to heat production and ATP utilization is uncertain. The stimulation of futile cycles by thyroid hormones (23) has been suggested to be an additional component of ATP disposal.

The effectiveness of β-blocking agents in treating the symptoms of thyrotoxicosis has led to investigations that have indicated thyroid hormones modulate adrenergic effects by increasing the number of β-adrenergic receptors (24) and, at least in cardiac tissue (25), by increasing the adrenergic receptors that are coupled with a membrane-bound adenylate cyclase (also known as adenyl cyclase) (26); both observations appear to be mutually consistent. The role of thyroid hormones in adaptive thermogenesis (17) could be affected by stimulating an increase in brown adipose tissue β-adrenergic receptors; catecholamines, which are known to activate the β receptor-linked adenylate cyclase in that tissue (23), would then start the lipolysis cascade resulting in heat production.

### Differentiation and Protein Synthesis

Stimulation of amphibian metamorphosis by thyroid hormones has been known for a long time (4). Changes in amphibian morphogenesis, such as involution of the tail of *Xenopus* (toads) and metamorphosis of the axolotl (salamanders) and of *Rana* (frogs), have been repeatedly used as end points for the bioassay of thyroid analogues. In young mammals, thyroid hormone is necessary not only for general growth but also for proper differentiation of the central nervous system. The counterpart of amphibian metamorphosis in the developing mammalian brain is myelogenesis and the formation of axons and dendrites (27). Behavioral studies in neonate hypothyroid mammals show that impairment in learning capacity (27) paralleled impairment of proper anatomic development in the brain. A deficiency of thyroid hormone during the critical period when the developing human brain is sensitive to thyroid hormone results in an irreversible clinical entity termed cretinism, which is characterized by stunted growth and mental retardation.

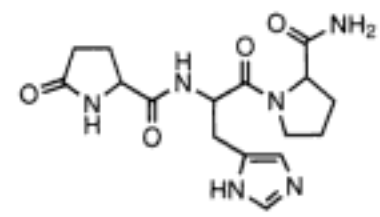
A great deal of attention has been devoted to the events taking place in the roughly 48-hour interval between the administration of thyroid hormone and the manifestation of certain effects caused by that administration. After Tata (28) had observed that the anabolic effects observed in rats given $T_4$ could be blocked by inhibitors of protein synthesis, further investigations led Tata and Widnell (29) to the conclusion that thyroid hormones were activating protein synthesis at the ribosomal level. Subsequently, Dillmann et al. (30) showed that the $T_3$-induced formation of α-glycerophosphate dehydrogenase (E.C. 1.1.99.5) could be blocked by α-amanitin, an inhibitor of RNA polymerase II, inferring that thyroid hormones affected the transcription process. In 1972, when the partition of thyroid hormones between plasma and a number of tissues was investigated, Schadlow et al. (31) demonstrated that the uptake of $T_3$ by unfractionated pituitary tissue was inverse to the dose, suggesting that the pituitary was limited in its capacity to bind $T_3$. This finding prompted efforts to find the subcellular location of the binding sites and to search for the presence of specific binding sites in other tissues (32). The research revealed that the binding sites were located in cell nuclei and were also present in liver and kidney (32). Eventually, receptors were located in all mammalian tissues and also in tadpole erythrocytes (33). In cultured pituitary cells, the receptor was described as an acidic, nonhistone, 50,000-Da protein (34) with an equilibrium dissociation ($K_d$) constant of $2.9 \times 10^{-11}$ for $T_3$ and of $2.6 \times 10^{-10}$ for $T_4$, indicating that $T_3$ had a 10 times greater affinity than $T_4$ for the receptor. There were 6,000 nuclear binding sites in the pituitary, 4,000 in the liver, but only 16 in the testis, a tissue that is not responsive to thyroid hormone (35). The findings by Tata and Widnell (29) of the activation of one RNA polymerase were extended to all RNA polymerases, suggesting that thyroid hormones were involved in all phases of gene activation.

Receptors located on the plasma membrane, in the cytoplasm, and in mitochondria have been described as well (36). Plasma membrane receptors are believed to mediate the transport of hormone into the cell and, possibly, to mediate nonnuclear, immediate effects of thyroid hormone (36). The presence of a large number of low-affinity cytosol binding proteins has been known for

Copyrighted material

some time (37), but these proteins have not been assigned a specific physiological role. The cytosolic binding proteins have been proposed as a large intracellular thyroid hormone reservoir, delaying the metabolic disposition of thyroid hormone.

Because thyroid hormones immediately increase oxygen uptake and ATP formation and, eventually, lead to an increase in the number, size, and inner membrane surface area of mitochondria as well as to the induction of many mitochondrial enzymes, many efforts to characterize mitochondrial thyroid hormone receptors have been made. Sterling et al. (38) have reported the presence of very high affinity receptors in mitochondria, but their work has not been duplicated. Additionally, many authors believe that most mitochondrial enzymes are synthesized on cytoplasmic ribosomes and then transferred into mitochondria (39).



## Control of Thyroid Hormone Biosynthesis

The primary role of thyroid is to produce thyroid hormones. The primary regulator of thyroid, both its function and growth, is the pituitary hormone, thyrotropin (TSH). Thyrotropin is a glycoprotein with a molecular weight of approximately 28,000 daltons, which can dissociate into two equally large polypeptide chains: an α-chain, which is also present in other pituitary peptides, and a β-chain, which is present in TSH only. The TSH is produced by and released from the anterior pituitary gland, causing the thyroid hormone to initiate new thyroid hormone synthesis. Increases in iodide uptake, the iodination of thyroglobulin, and endocytosis of colloid are all observed in response to stimulation of TSH. The effects of TSH on the thyroid appear to be the consequence of binding to high-affinity receptors on the capillary membrane of follicular cells and activation of adenylate cyclase and protein kinase enzymes, found on the inner side of the membrane, with subsequent phosphorylation of cellular proteins. It is believed that most, if not all, effects of TSH are mediated through the cyclic adenosine monophosphate (cAMP) formed by adenylate cyclase and, possibly, also by cAMP-activated intracellular phosphokinases.

The amount of thyroid hormone circulating in body fluids and present in tissues remains fairly constant. Accounting for this constancy are the relatively long biological half-life of the thyroid hormones, the regulation of gland activity by the pituitary-hypothalamic system, and the availability of iodide. Thyroid hormone research points toward $T_3$ as the thyroid hormone; therefore, factors affecting peripheral $T_3$ formation by the 5′-D enzymes are highly relevant.

The relation of biological half-life to protein binding has already been alluded to. The $T_4$ is firmly bound to plasma proteins. Only 0.05% of $T_4$ is not protein bound, and $T_4$ has a biological half-life of 1 week, as compared to 1 day for the less firmly bound $T_3$.

The biosynthesis and secretion of TSH is, in turn, regulated by thyrotropin-releasing hormone (TRH) and the quantity of thyroid hormone in circulation through feedback control. The tripeptide pyroglutamylhistidylprolylamide, TRH is formed in the hypothalamus, reaches the thyrotrophs (i.e., the TSH-producing pituitary cells) by way of the hypophyseal portal system, and stimulates TSH release by binding to the TRH receptors of the thyrotrophs (40). The ability of thyroid hormones to prevent the release of TSH is referred to as feedback regulation. It is believed that $T_3$ prevents the TRH-stimulated release of TSH by stimulating the synthesis of a peptide that would compete with TRH for the TRH receptor sites on the thyrotroph (41). Inhibition of the transcription of the α and β subunits of TSH by thyroid hormone (42) also may contribute to the feedback effect.

TRH

The amount of iodide available to the gland for hormone synthesis also is an important regulator of thyroid function. The efficiency of the thyroid pump mechanism and the rate of thyroglobulin and TPO synthesis are all TSH-dependent. In cases of iodide deficiency, the production of thyroid hormone is lowered, and TSH rises through the pituitary feedback mechanism described previously. The effect of the increased TSH is to produce more thyroid hormone by increasing efficiency of the iodide pump and increasing thyroglobulin and TPO synthesis. Thus, in iodide deficiency, there is an increased uptake of iodide (43) are larger MIT-to-DIT ratios, which leads to larger $T_3$-to-$T_4$ ratio. The $T_3$ is the more rapidly acting hormone, mitigating the effect of iodide deficiency. When iodide deficiency is severe, a persistent rise in TSH is observed. This then results in thyroid growth.

In the presence of an excess of circulating iodide, the absolute amount of iodide taken up remains approximately constant. There is a decrease in the fraction of the total iodide taken up and an increase in the amount of iodide leaked from the thyroid gland. In addition, there may be a decrease in organification (i.e., in the formation of iodinated thyroglobulin residues) and in the release of hormones from the gland. The decrease in organification that occurs at excessive physiological doses of iodide has been called the Wolff-Chaikoff block (44). This block may be caused by an interaction of iodide with NADPH (45), which depletes follicular NADPH and, in turn, depletes the $H_2O_2$ necessary for TPO activity. The decrease in hormone release occurs when iodide is given in pharmacological (mg) quantities; it may last for a few weeks.

The activity of deiodinases reflects thyroid status, general health, and food intake. In hypothyroidism, there is a decrease in hepatic 5′ D-I but an increase in 5′ D-II activity (46). There is a decrease in $T_3$ and an increase in $rT_3$ after hepatic disease (47), renal damage (48), chronic

Copyrighted material

illness (49), and starvation (50), indicating a decrease in the activity of the quantitatively more important 5′ D-I. An increase in deiodinase activity has been observed after overfeeding subjects or after administering a high-carbohydrate or high-fat diet (51) to experimental animals. The mechanism of deiodinase control is presumably intricate, but the inhibiting effects of propranolol on 5′ D-I (52) and of prazosin on the 5′ D-II of BAT (53) infer the involvement of adrenergic components in the regulation. In addition, the rapid change in activity observed after asphyxia points toward a rapid, possibly cAMP-related control (54).

## DISEASES INVOLVING THE THYROID GLAND

### Hypothyroidism

#### Goiter

An enlarged, palpable thyroid gland is referred to as a goiter. When insufficient thyroid hormone is liberated from the thyroid gland, the breakdown of the thyroid-pituitary-hypothalamic feedback mechanism results in the release of excess TSH and in the formation of a thyroid hypertrophy referred to as a nontoxic goiter. The gland enlarges as it tries to take up more iodine, leading to goiter. Endemic goiters are those that occur in a significant segment of a given population. Goiters most frequently are caused by inadequate intake of dietary iodide in regions not reached by iodide-providing sea mists and, occasionally, by the prolonged intake of goitrogens derived from plant sources or aquifers. This condition can be prevented with iodine supplements, and many industrialized countries now iodize salt.

A characteristic sign of hypothyroidism is a decrease in metabolic rate, with a reduction in calorigenic effect and defective thermoregulation. The elevated serum cholesterol level seen in hypothyroidism is the result of a decrease in cholesterol degradation that exceeds the decrease in cholesterol biosynthesis; it reflects a general slowdown in catabolic processes. Shared symptoms of hypothyroidism and cognitive disorders include fatigue, mental dullness, lethargy, and inattention. Treatment of hypothyroidism includes supplementation of $T_4$ with the goal of returning TSH levels to normal.

#### Cretinism

Cretinism, the irreversible clinical entity characterized by defective physical and mental development, appears when thyroid hormone is not available during early childhood for normal bone formation and normal brain growth and differentiation.

#### Myxedema

Myxedema is used either as a specific term to describe the infiltration of the intercellular spaces of skin and muscle with mucopolysaccharide or as a general term, as in adult myxedema or pituitary myxedema, to denote hypothyroid status.

### Hyperthyroidism

The increased metabolic rate of hyperthyroidism results in symptoms opposite to those seen in hypothyroidism. The increased oxygen demand in hyperthyroidism leads to an increased heart rate and increased cardiac output and, thereby, places strain on the heart. Exaggerated catabolic processes lead to decreased serum cholesterol and, possibly, to poor glucose tolerance and glucosuria as well, and the excessive calorigenic effect produced by catabolic processes causes anorexia and poor thermoregulation. Excessive hormone function is expressed by the word "toxic," as in toxic goiter, toxic adenoma, and thyrotoxicosis. Thyrotoxic crisis or thyroid storm is an emergency caused by a stress-triggered augmentation of the symptoms of thyrotoxicosis (55). Treatment models aim to decrease the overproduction of thyroid hormones using antithyroid medication or radioactive iodine ablation or surgery.

#### Graves' Disease

Graves' disease is the most frequently encountered form of hyperthyroidism and is caused by a generalized overactivity of the entire thyroid gland. Named after the physician who first described it, Graves' disease is an autoimmune condition in which the body's immune system tricks the thyroid into producing too much thyroid hormone. It is also called diffuse toxic goiter: "diffuse" because the entire thyroid gland is involved in the disease process; "toxic" because the patient appears hot and flushed, as if feverish due to an infection; and "goiter" because the thyroid gland enlarges in this condition. Signs of this disease may include goiter, a protrusion of the eyeballs called exophthalmos, and pretibial myxedema. Hyperthyroidism from Graves' disease is, in general, easily controlled and safely treated.

In the serum of most patients suffering from Graves' disease, an immunoglobulin (IgC) is present that, after a slow onset, elicits a long-lasting stimulation of the thyroid gland. Because the release of the long-acting thyroid stimulator is not controlled by thyroid hormone levels as is TSH, patients with long-acting thyroid stimulator have a hyperplastic, hypertrophied gland that produces and releases an excessive amount of hormone.

The indications are that the exophthalmos is caused by a substance produced by a distinct autoimmune system (56), possibly in response to a modified TSH of pituitary origin.

#### Hashimoto's Disease

Hashimoto's disease, named after the physician who first described it, is an autoimmune disorder in which plasma cells, lymphocytes, and fibrous tissue attack and destroy the thyroid gland. Pitt-Rivers and Tata (57) suggested that the sequence of events in Hashimoto's disease was initiated by injury to some thyroid structure, following which the normally sequestered thyroglobulin would be released and exposed to immunological mechanisms, thus setting into motion a progressive interaction between

Copyrighted material

thyroglobulin and circulating autoantibodies. Hashimoto antibodies are present in adult-onset myxedema and in most persons with Graves' disease, but it is recognized that other antigenic factors are involved in these and other autoimmune diseases of the thyroid. Hypothyroidism resulting from Hashimoto's disease requires lifelong treatment with thyroid hormone replacement.

### Generalized Resistance to Thyroid Hormone

Generalized resistance to thyroid hormone (GRTH) is a rare form of thyroid disorder and may be a heritable disorder characterized by reduced responsiveness of the pituitary and peripheral tissues to the action of thyroid hormones. Behavioral manifestations include hyperactivity, behavioral problems, and cognitive deficits. Physical traits representative of GRTH are small goiters, and GRTH is marked by genetic mutation of the thyroid receptor β gene on chromosome 3 (58).

Many have evaluated the association of GRTH to attention-deficit hyperactivity disorder and suggested that similar mechanistic pathways are shared between the two conditions (59,60). In GRTH, $T_4$ fails to block TSH production, leading to excess levels of $T_3$ and $T_4$ with either normal or elevated levels of TSH. In conditions of an improperly functioning thyroid, TH and TSH ratios are unregulated, producing symptoms that are characteristic of attention-deficit hyperactivity disorder.

### Thyroid Cancer

Thyroid cancer is a disease in which malignant cells are found in the tissues of the thyroid gland. Four main types of cancer of the thyroid are differentiated based on how the cancer cells look under a microscope: papillary, follicular, medullary, and anaplastic. Follicular and papillary carcinomas have the highest incidence in young women but have low mortality; they represent a different disease than anaplastic types or undifferentiated carcinomas, both of which occur among the older patients and have high death rates. Each year in the United States, approximately 20,000 people are diagnosed with thyroid cancer, and it is more common in women than in men. A study published in Journal of National Cancer Institute (61) predicts that these numbers may rise as individuals who were exposed to radioactive iodine ($^{131}I$) from nuclear testing in the western states in the 1950s and 1960s reach middle age: A strong dose–response relationship was observed between radiation dose to the thyroid received in childhood and thyroid cancer risk. The risk of radiation-related thyroid cancer was threefold higher in iodine-deficient areas than elsewhere. Administration of potassium iodide as a dietary supplement appear to modify this risk. Treatment of thyroid cancer is straightforward and effective. Follow-up testing can be uncomfortable, however, because it requires a hypothyroid state. Follow-up takes two forms: serum thyroglobulin measurement, and a radioiodine whole-body scan, as described later.

## THERAPEUTIC AGENTS

### Thyroid Replacement Therapy

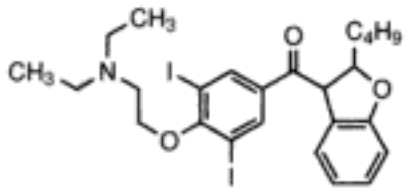
Hormone replacement appears to be the established therapy in the treatment of various forms of hypothyroidism, from the complete absence of thyroid function seen in myxedema to simple goiter and cretinism. Thyroid hormone drugs are natural or synthetic preparations containing $T_4$ sodium, $T_3$ sodium, or both. A large number of organic and some inorganic compounds stimulate or prevent thyroid hormone formation by interfering with iodide uptake into follicular cells, inhibiting TPO, preventing thyroid hormone binding to plasma proteins, or acting as effectors of thyroid deiodinases. Some of the agents described in this section are of therapeutic or diagnostic value, some illustrate potential side effects of drugs, and some are experimental compounds designed to achieve unmet therapeutic goals or to define structural parameters necessary for thyroid hormone actions.

Thyroid hormone preparations belong to two categories: natural hormone preparations derived from animal thyroid, and synthetic preparations.

### Natural Thyroid Hormone Preparations

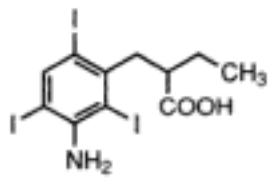
Natural preparations include desiccated thyroid and thyroglobulin. Desiccated thyroid and thyroglobulin are derived from thyroid glands of domesticated animals that are used for food by human. The hormones were released from the proteolytic activity of gut enzymes. Potency is based on total iodine content or bioassay and is somewhat variable with different preparations.

Desiccated thyroid preparations (Thyroid USP) are essentially acetone powders of bovine or porcine thyroid glands compressed into oral tablets. A diluent usually is present, because the preparations (especially those of porcine origin) commonly exceed the 0.17 to 0.23% iodine content required by the U.S. Pharmacopeia (USP). Because the iodine of desiccated thyroid is in the form of iodinated tyrosyl and thyronyl residues of the precipitated thyroglobulin, the preparation owes its efficacy to the hormones that eventually are liberated by intestinal proteases. In desiccated preparations, $T_3$ and $T_4$ may be present in a ratio of approximately the same as found in humans. Desiccated preparations are less expensive than synthetic hormones but have been shown to produce variable $T_4/T_3$ blood levels because of inconsistencies both between and within animal sources of the thyroid gland. Most comments regarding desiccated thyroid also apply to partially purified thyroglobulin, because the two preparations differ in their total and their relative amounts of $T_4$ and $T_3$.



### Synthetic Thyroid Hormones

Synthetic, crystalline thyroid hormones are more uniformly absorbed than biological preparations and contain more precisely measured amounts of active ingredient in their dosage forms. Of present interest are $T_4$ (levothyroxine), $T_3$ (liothyronine), $dT_4$ (dextrothyroxine), and $T_4$-$T_3$ mixtures (Liotrix).

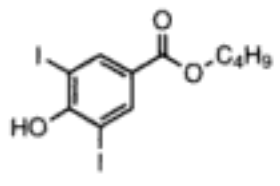


Copyrighted material

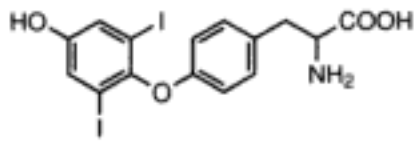
thyroid membranes (84) suggests that other oxygenated phenols may interfere with thyroid hormone function in more than one way. Examples of iodinated drugs affecting thyroid function are the antiarrhythmic agent amiodarone and the radiocontrasting agents iopanoic acid and ipodoic acid. All of these compounds interfere with the peripheral deiodination of $T_4$ and are being tested as adjuncts in the treatment of hyperthyroidism.

The binding of thyroid hormones to plasma carrier proteins is affected by endogenous agents or by drugs that can change the concentration of these proteins or compete with thyroid hormones for binding sites. Examples of the first group are testosterone (and related anabolic agents) that are able to decrease and estrogens (and related contraceptive agents) that are able to increase the concentration of $T_4$ binding globulin. Salicylates, diphenylhydantoin, and heparin are members of the large group competing with thyroid hormones for binding sites. Alterations in the binding of $T_3$ and $T_4$ are of no large physiological consequence, because the steady-state concentrations of free hormone are rapidly restored by homeostatic mechanisms. Knowledge regarding the presence of agents affecting thyroid hormone binding, however, is important for the interpretation of diagnostic tests assessing the presence of free or total hormone in plasma.

Amiodarone



Iopanoic acid



## THYROID HORMONE ANALOGUES

The search for thyroid hormone analogues was prompted by the desire to establish SARs for the hormone and by the need for a safe, specific antagonist able to block thyroid action without delay at a peripheral site. The reader will recall that TPO inhibitors, such as PTU, do not affect the extensive amount of hormone stored in thyroidal thyroglobulin.

Some early analogues designed as antagonists were butyl-3,5-diiodo-4-hydroxybenzoate (BHDB), which was designed as a deiodinase inhibitor and is, to a degree, effective as such, and 2′6′-diiodothyronine, which has a small antithyroid effect.

DHDB

2′,6′-Diiodothyronine

When the activity of $T_3$ was discovered in 1955, and when none of the many analogues tabulated by Selenkow and Asper (85) demonstrated significant antithyroid activity, efforts were made to redefine the structural requirements for thyroid-like activity to provide a better rationale for the design of a peripheral thyroid antagonist. The biological assay methods used for the newer compounds included measurements of in vivo oxygen uptake, of hepatic lipogenic enzyme activity, of goiter formation, of the rate of amphibian metamorphosis, and more recently, of the binding to nuclear receptors.

The measurement of oxygen uptake provides a direct index of metabolic rate; this measurement can be done simply by placing experimental animals in a calibrated vessel maintained at constant temperature and connected to an oxygen analyzer (86). Repeatedly used as an index of thyromimetic activity have been the in vitro assay of oxygen uptake by suspended mitochondria and the spectrophotometric assays of rat liver mitochondrial α-glycerophosphate dehydrogenase (87) and of cytoplasmic malic enzyme (88).

In the "goiter" or "antigoiter" assay, goiter formation is induced by the administration of a TPO inhibitor, such as thiouracil. The inhibitor is blended with the food or added to the drinking water and given to experimental animals for 10 to 14 days. The increase in gland weight caused by the TPO inhibitor can be reversed by $T_4$ or by a test compound with thyromimetic activity. The effect of a given dose of thyromimetic agent compared with that of a given dose of $T_4$ yields the "antigoitrogenic effect" of the compound. Furthermore, when both a test compound and $T_4$ are given to an animal receiving a TPO inhibitor, the ability of the test compound to antagonize $T_4$, or the "antithyroid effect" of the test compound, can be assessed.

Discrepancies have been seen between the results obtained with amphibian metamorphosis and those obtained with other assays. These discrepancies have been attributed to the ability of test animals, such as tadpoles, to concentrate test compounds and, especially, lipophilic test compounds from the medium (89). The binding affinity of thyroid analogues to nuclear receptors correlates well with the effectiveness of these analogues in the antigoiter assay, provided that the metabolism of the analogues is taken into consideration (89).

### Structure–Activity Relationships of Thyroid Analogues

The synthesis and biological evaluation of a wide variety of $T_4$ and $T_3$ analogues allowed a significant correlation of structural features with their relative importance in the production of hormonal responses. The key findings are summarized in Table 34.2. In general, only compounds with the appropriately substituted phenyl-X-phenyl nucleus (as depicted at the top of Table 34.2) have shown significant thyroid hormonal activities. Both single ring compounds such as DIT and a variety of its aliphatic and alicyclic ether derivatives showed no $T_4$-like activity in the rat antigoiter test (90), the method most often used in determining thyromimetic activity in vivo (91). The SARs

are discussed in terms of single structural variations of $T_4$ in the 1) alanine side chain, 2) 3- and 5-positions of the inner ring, 3) the bridging atom, 4) 3′- and 5′-positions of the outer ring, and 5) the 4′-phenolic hydroxyl group.

### Aliphatic Side Chain

The naturally occurring hormones are biosynthesized from L-tyrosine and possess the L-alanine side chain. The L-isomers of $T_4$ and $T_3$ (compounds 1 and 3 in Table 34.2) are more active than the D-isomers (compounds 2 and 4) (Table 34.2). The carboxylate ion and the number of atoms connecting it to the ring are more important for activity than is the intact zwitterionic alanine side chain. In the carboxylate series, the activity is maximum with the two-carbon acetic acid side chain (compounds 7 and 8) but decreases with either the shorter formic acid (compounds 5 and 6) or the longer propionic and butyric acid analogues (compounds 9-12). The ethylamine side chain analogues of $T_4$ and $T_3$ (compounds 13 and 14) are less active than the corresponding carboxylic acid analogues. In addition, isomers of $T_3$ in which the alanine side chain is transposed with the 3-iodine or occupies the 2-position were inactive in the rat antigoiter test (92), indicating a critical location for the side chain in the 1-position of the inner ring.

### Alanine-Bearing Ring

The phenyl ring bearing the alanine side chain, called the inner ring or α-ring, is substituted with iodine in the 3- and 5-positions in $T_4$ and $T_3$. As shown in Table 34.2, removal of both iodine atoms from the inner ring to form 3′,5′-$T_2$ (compound 15) or 3′-$T_1$ (compound 16) produces analogues devoid of $T_4$-like activity, primarily because of the loss of the perpendicular orientation of diphenyl ether conformation. Retention of activity observed on replacement of the 3- and 5-iodine atoms with bromine (compounds 17 and 18) implies that iodine does not play a unique role in thyroid hormone activity. Moreover, a broad range of hormone activity found with halogen free analogues (compounds 19 and 20) indicates that a halogen atom is not essential for activity. In contrast to $T_3$, 3′-isopropyl-3,6-dimethyl-L-thyronine (compound 20) has the capacity to cross the placental membrane and exerts thyromimetic effects in the fetus after administration to the mother. This could prove to be useful in treating fetal thyroid hormone deficiencies or in stimulating lung development (by stimulating lung to synthesize special phospholipids [surfactant], which ensure sufficient functioning of the infant's lungs at birth) immediately before premature birth (93). Substitution in the 3- and 5-positions by alkyl groups significantly larger and less symmetric than methyl groups, such as isopropyl and secondary butyl moieties, produces inactive analogues (compounds 21 and 22). These results show that 3,5-disubstitution by symmetric, lipophilic groups not exceeding the size of iodine is required for activity.

### Bridging Atom

Several analogues have been synthesized in which the ether oxygen bridge has been removed or replaced by other atoms. The biphenyl analogue of $T_4$ (compound 23 in Table 34.2), formed by removal of the oxygen bridge, is inactive in the rat antigoiter test. The linear biphenyl structure is a drastic change from the normal diphenyl ether conformation found in the naturally occurring hormones. Replacement of the bridging oxygen atom by sulfur (compound 24) or by a methylene group (compound 25) produces highly active analogues. This provides evidence against the Niemann quinoid theory, which postulates that the ability of a compound to form a quinoid structure in the phenolic ring is essential for thyromimetic activity, and emphasizes the importance of the three-dimensional structure and receptor fit of the hormones. Attempts to prepare amino- and carbonyl-bridged analogues of $T_3$ and $T_4$ have been unsuccessful (94,95).

### Phenolic Ring

The phenolic ring, also called the outer or β-ring, of the thyronine nucleus is required for hormonal activity. Variations in 3′- or 3′,5′-substituents on the phenolic ring have dramatic effects on biological activity and affinity for the nuclear receptor. The unsubstituted parent structure of this series L-$T_2$ (compound 26 in Table 34.2) possesses low activity. Substitution at the 3′-position by polar hydroxyl or nitro groups (compounds 27 and 28) causes a decrease in activity as a consequence of both lowered lipophilicity and intramolecular hydrogen bonding with the 4′-hydroxyl (96). Conversely, substitution by nonpolar halogen or alkyl groups results in an increase in activity in direct relation to the bulk and lipophilicity of the substituent—for example, $F < Cl < Br < I$ (compounds 29-31) and $CH_3 < CH_2CH_3 < CH(CH_3)_2$ (compounds 32–34). Although 3′-isopropylthyronine (compound 34) is the most potent analogue

Copyrighted material

Table 34.2) results in a substantial decrease in activity, presumably as a result of the weak hydrogen bonding ability of the latter group. The retention of activity observed with the 4′-unsubstituted compound (compound 40) provides direct evidence for metabolic 4′-hydroxylation as an activating step. Introduction of a 4′-substituent that cannot mimic the functional role of a phenolic group, such as a methyl group (compound 41), and that is not metabolically converted into a functional residue results in complete loss of hormonal activity. The thyromimetic activity of the 4′-methyl ether (compound 42) was ascribed to the ready metabolic cleavage to form an active 4′-hydroxyl analogue. The $pK_a$ of 4′-phenolic hydroxyl group is 6.7 for $T_4$ (90% ionized at pH 7.4) and 8.5 for $T_3$ (~approximately 10% ionized). The greater acidity for $T_4$ is reflective of its stronger affinity for plasma proteins and, consequently, of its longer plasma half-life.

## Conformational Properties of Thyroid Hormones and Analogues

The importance of the diphenyl ether conformation for biological activity was first proposed by Zenker and Jorgensen (98,99). Through molecular models, they showed that a perpendicular orientation of the planes of the aromatic rings of 3,5-diiodothyronines would be favored to minimize interactions between the bulky 3,5-iodines and the 2′,6′-hydrogens. In this orientation, the 3′- and 5′-positions of the ring are not conformationally equivalent, and the 3′-iodine of $T_3$ could be oriented either distal (away from) or 5′ proximal (closer) to the side chain–bearing ring (Fig. 34.6). Because the activity of compounds such as 3′,5′-dimethyl-3,5-diiodothyronine had demonstrated that alkyl groups could replace the 3′- and 5′-iodine substituents, model compounds bearing alkyl groups in the 3′-position and alkyl or iodine substituents in the 5′-position (in addition to the blocking 2′-methyl group) were synthesized for biological evaluation (99).

Biological evaluation of 2′,3′- and 2′,5′-substituted diiodothyronines (100) revealed that 3′-substitution was favorable for thyromimetic activity but that 5′-substitution was not. The structures of representative distal analogues, 2′,3′-dimethyl-3,5-DL-diiodothyronine (compound I) and O-(4′-hydroxy-1′-naphthyl)-3,5-DL-diiodotyrosine (compound II), and of the proximal analogues, 2′,5′-dimethyl-3,5-DL-diiodothyronine (compound III) and 2′-methyl-3,5,5′-DL-triiodothyronine (compound IV), are given in Figure 34.6. The effectiveness of these compounds in rat antigoiter assay (101) is presented in Table 34.4. These

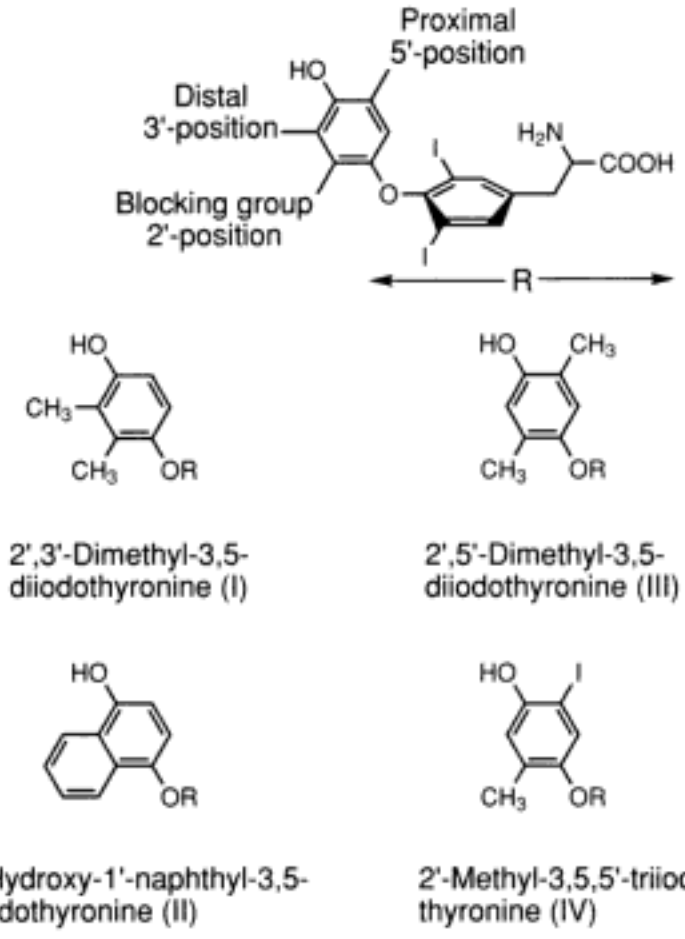

**Fig. 34.6.** Structures of representative distal and proximal compounds.

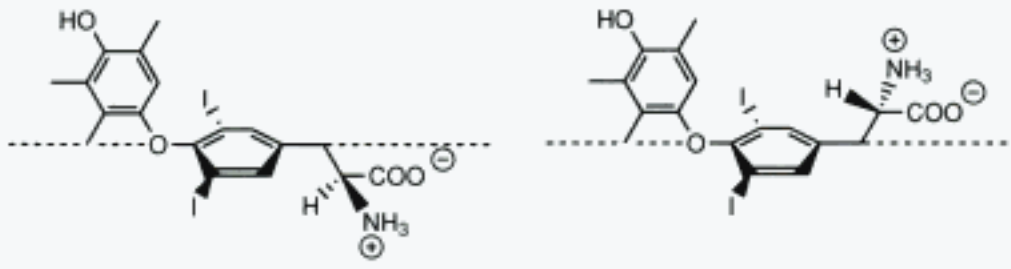
Table 34.4. Effectiveness of Distal and Proximal Compounds Antigoiter Assay

| Compound[a] | Dose (mg/kg/day) | % $T_4$ activity |
|---|---|---|
| I | 0.025 | 50 |
| II | 0.013 | >100 |
| III | 2.3 | <1 |
| IV | 0.5 | 2 |

[a]See text for specific descriptions of compounds I–IV.

results clearly indicate that in 2′-blocked analogues, a distal 3′-substitution is favorable for thyromimetic activity, but a proximal 5′-substitution is not.



The perpendicular orientation of the rings of 3,5-diiodothyronines, which was postulated from molecular models, has been confirmed by x-ray crystallographic studies (102), molecular orbital calculations (103), and nuclear magnetic resonance studies (104,105).

In addition to being perpendicular to the inner ring, the outer phenolic ring can adopt conformations relative to the alanine side chain, which would be *cis* or *trans*. In other words, the cisoid and transoid conformations result from the methine group in the alanine side chain being either *cis* or *trans* to the phenolic ring (Fig. 34.7). Although the bioactive conformation of the alanine side chain in thyroid hormone analogues has not yet been defined, these conformations appear to be similar in energy, because both are found in thyroactive structures as determined by x-ray crystallography (106). The synthesis of conformationally fixed cyclic or unsaturated analogues may allow evaluation of the bioactivity of the two conformers.

## Transthyretin Receptor Model

An additional tool in structural analysis and analogue design has been TTR (formerly called $T_4$ binding prealbumin), a plasma protein that binds as much as 27% of plasma $T_3$ (107). The amino acid sequence of the TTR $T_3$ binding site is known, and the protein has therefore served as a model, although admittedly an approximate model, for the $T_3$ receptor. The TTR model portrays the $T_3$ molecule as placed in an envelope near the axis of symmetry of the TTR dimer. In this envelope, hydrophobic

Transoid conformation Cisoid conformation

**Fig. 34.7.** Side-chain conformations of thyroid hormones: transoid (left), and cisoid (right).

residues, such as those of leucine, lysine, and alanine, are near pockets accommodating the 3,5,3′- and 5′-positions of $T_3$, whereas the hydrophilic groups of serine and threonine (hydrogen bonded to water), are between the 3′-substituent and the 4′-phenolic group. Taking this model into account, Ahmad et al. (108) suggested that 3′-acetyl-3,5-diiodothyronine might be a good analogue or a good inhibitor of $T_3$, because the carbonyl group of the 3′ acetyl substituent would form a strong hydrogen bond with the 4′ phenolic hydrogen, preventing thereby its bonding with the hydrated residue of the putative receptor.

This compound, prepared by Benson et al. (109), was found to be indistinguishable from $T_3$ in oxygen uptake and glycerophosphate activity tests and to be half as active as $T_3$ in displacing labeled $T_3$ from rat liver nuclei in specific in vivo conditions.

## Problems

### What organs and functions of the body are regulated by thyroid hormones?

Thyroid hormones regulate the body's metabolism and organ function, affecting heart rate, cholesterol level, body weight, energy level, muscle strength, skin condition, menstrual regularity, memory and many other conditions.

### List classes of drugs that interact (interfere) with thyroid hormones therapy.

- *Oral anticoagulants*—Thyroid hormones increase catabolism of vitamin K–dependent clotting factors.
- *Insulin or oral hypoglycemics*—Initiating thyroid replacement therapy causes increases in insulin or oral hypoglycemic requirements. The effects seen are poorly understood and depend on a variety of factors, such as endocrine status of the patient and type of thyroid preparations.
- *Cholestyramine*—Cholestyramine binds both $T_4$ and $T_3$ in the intestine, thus impairing absorption of these thyroid hormones.
- *Estrogen, oral contraceptives*—Estrogens tend to increase serum thyroxine-binding globulin (TBG), thus increasing thyroid requirements.
- Antidepressant drugs

### Why is the use of thyroid hormones in therapy for obesity unjustified?

Drugs with thyroid hormone activity, either alone or together with other therapeutic agents, have been used for treatment of obesity. In euthyroid patients, doses within the range of daily hormonal requirements are ineffective for weight reduction. Larger doses may produce serious or even life-threatening manifestation of toxicity, particularly when given in association with sympathomimetic amines, such as those used for their anorectic effects.

### What is the purpose of prescribing β-blockers along with thyroid drugs in treatment of hyperthyroidism?

β-Adrenergic blocking agents, such as atenolol, nadolol, metoprolol, or propranolol, block the action of circulating thyroid hormone on the body tissues, slowing heart rate and lessening nervousness. These drugs may be extremely helpful in reducing symptoms until one of the other forms of treatment have a chance to take effect. They are not used, however, in patients who have asthma or heart failure, which may be worsened with these drugs.

### Patients with hypothyroidism and organic depression may need both levothyroxine and antidepressant drug therapy. In levothyroxine-treated patients with hypothyroidism who were treated with sertraline, there was an elevated serum thyrotropin concentration, indicative of a decrease in the efficacy of levothyroxine. What is the possible mechanism of interaction between the two drugs?

Sertraline may interfere by increasing the clearance of thyroxine.

## What are the tests for checking the thyroid function?

1. *Total serum $T_4$*. This includes both bound and free $T_4$ concentration.
2. *$T_3$ resin uptake ($T_3RU$)*. The $T_3$ resin uptake test measures the amount of unsaturated binding sites on the thyroid hormone transport proteins. A proportion of the labeled $T_3$ will bind to available sites on the serum TBG; any excess will bind to the resin. Resin uptake is inversely proportional to the number of vacant binding sites and, therefore, inversely proportional to the total TBG.

   In thyrotoxicosis, fewer vacant binding sites are available on thyroxine binding globulin because of the high circulating levels of thyroid hormone. This means less radioactive $T_3$ will be able to bind to TBG and more will bind to the resin. Hence, resin uptake is higher in hyperthyroid patients than in normal patients. The converse is true in hypothyroid states. In high TBG states, such as pregnancy or estrogen therapy, the $T_3RU$ will be low; however, the physiologically active free $T_4$ level will still be normal.
3. *Free thyroxine Index ($FT_4I$)*. The $FT_4I$ is a reflection of the amount of free $T_4$ in most situations. It is a calculated value and corrects for changes in TBG concentrations by using the following formula:

   $$FTI = (\text{total } T_4) \times (T_3 \text{ resin uptake}/T_3RU \text{ control})$$

   Mean normal $T_3RU$ for the particular assay (normal range, 25–35%; mean normal, 30%). With extreme changes in TBG concentrations, acute medical illness, heparin therapy, or low protein states secondary to nephrotic syndrome, the $FT_4I$ may not accurately reflect the amount of free $T_4$ concentrations.
4. *TSH test*. Measuring the serum TSH has become the screen test of choice for thyroid disease. Primary hypothyroidism produces elevated TSH levels, whereas patients with primary hyperthyroidism (i.e., Graves' disease) should have undetectable TSH values. This relationship is true only in individuals with an intact hypothalamic-pituitary-thyroid axis. Patients who present with a normal or detectable TSH level and elevated thyroid hormone concentrations require further evaluation to exclude central causes of hyperthyroidism.
5. *TRH test*. The administration of TRH causes a rise in TSH concentration in normal subjects (TSH, 2-30 mU/L). An exaggerated response occurs in primary hypothyroid subjects (TSH often is >30 mU/L, depending on the baseline TSH elevation.) Hyperthyroid patients have a mild or absent TSH response (TSH, <2 mU/L), because the suppressed TSH cannot be stimulated by exogenous TRH. The introduction of sensitive TSH assays that can detect low suppressed TSH levels, identifying patients with primary hyperthyroidism, has made the TRH stimulation test virtually obsolete.
6. *Iodine test*. Plasma iodine in the form of iodide is concentrated (trapped) in the thyroid cells by an energy-requiring active transport mechanism, where it is incorporated into $T_3$ and $T_4$ via organification. Therefore, iodine measures both trapping and organification by the thyroid gland.

## What conditions are associated with decreased and increased levels of TBG?

TBG is synthesized by the liver under the influence of estrogen. An increase in TBG concentration in response to higher estrogen levels may result in higher measured total $T_4$ concentration. The amount of free $T_4$ concentration remains constant, however, and the patient remains clinically euthyroid.

Conditions associated with increased levels of TBG:

- *Estrogen effects*—pregnancy, oral contraceptives
- *Infectious hepatitis*
- *Biliary cirrhosis*
- *Genetic determination*

In contrast, factors that cause a decrease in TBG concentration or a lower affinity for $T_4$ binding to TBG may result in low measured total $T_4$ concentration without affecting free $T_4$ levels.

Conditions associated with decreased binding of $T_4$ by TBG:

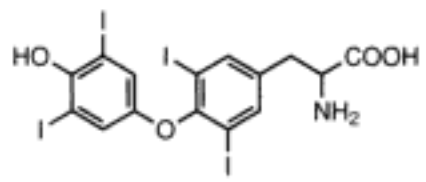
- *Androgens and anabolic steroids*
- *Large doses of glucocorticoids*
- *Nephrotic syndrome*
- *Major systemic nonthyroidal illness*
- *Active acromegaly*
- *Chronic liver disease*
- *Drugs*—dilantin, tegretol
- *Genetic determination*

## Considering that $T_3$ does not cross the placental membrane and, therefore, cannot be useful in treating fetal thyroid hormone deficiencies or in stimulating lung development immediately before premature birth, what would be your solution to overcome this problem?

(Refer to the *Structure-Activity Relationship of Thyroid Analogues* section)

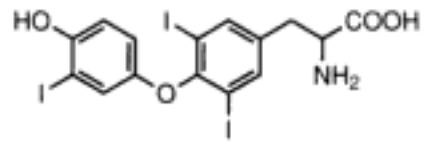
3′-Isopropyl-3,6-dimethyl-L-thyronine has the capacity to cross the placental membrane and exerts thyromimetic effects in the fetus after administration to the mother.

## List the major pathways for the metabolism of $T_4$.



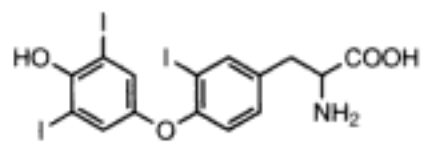
1. Outer ring deiodination by the enzyme 5′-D, which yields $T_3$.
2. Inner ring deiodination by the enzyme 5-D, which yields $rT_3$.
3. Glucuronide conjugation through the phenolic hydroxy group, which yields $T_4$-4′-O-glucuronide.
4. Sulfate conjugation through the phenolic hydroxy group, which yields $T_4$-4′-O-sulfate.
5. Side-chain oxidative deamination and decarboxylation, which yields thyroacetic acid and thyroethanediol.

## CASE STUDY



***Victoria F. Roche and S. William Zito***

GS is a 56-year-old women who, on her most recent visit to her physician, complains of always feeling cold. She says it is causing strife at home, because she always wants to turn up the thermostat and her husband wants to turn it down. In addition, she has been feeling tired for the last 6 months, and her skin has been dry and itchy. On further questioning, she reveals that she has been "grouchy" at work and finds it difficult to cope with the ordinary stresses of her job. Laboratory tests indicate elevated TSH (11 mIU/ml) and low levels of free $T_4$ (0.6 ng/dL). The physical and laboratory findings are consistent with a diagnosis of hypothyroidism. Her physician wants to treat the hypothyroidism with hormone replacement therapy. Evaluate the given structures for use in this case.



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented SAR analysis of all therapeutic alternatives provided in the case.
4. Evaluate the SAR findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

## Calcitonin

Human calcitonin

Human calcitonin is a 32-amino-acid peptide (molecular weight, 3,527 dalton) biosynthesized in the parafollicular "C" cells found within the thyroid gland. This hormone contains a critical disulfide bridge between residues 1 and 7, with the entire amino acid sequence required for biological activity. The carboxy terminal residue is a proline amide. "Pro-calcitonin," a precursor peptide, has been identified and proposed to facilitate intracellular transport and secretion. Calcitonin is secreted in response to elevated serum calcium concentrations (>9 mg/100 mL) and serves to oppose the hormonal effects of parathyroid hormone. In response to a hypercalcemic state (Fig. 35.1, B loops), increased calcitonin secretion drives serum calcium concentrations down via stimulation of urinary excretion of both calcium and phosphate (loop 3B), prevention of calcium resorption from the bone via inhibition of osteoclast activity (loop 1B), and inhibition of intestinal absorption of calcium (loop 2B). When serum calcium concentrations are low (hypocalcemia), the release of calcitonin is slowed, thereby activating loops 1A, 2A, and 3A.

## Parathyroid Hormone

Human pre-proparathyroid hormone with site of cleavage leading to proparathyroid ① and site of cleavage leading to PTH ② .

Parathyroid hormone (PTH) is biosynthesized as a 115-amino-acid preprohormone in the rough endoplasmic reticulum of the parathyroid gland and is cleaved to the prohormone (84 amino acids) in the cisternal space of the reticulum. The active hormone is finally produced (34 amino acids; molecular weight, 9,500 dalton) in the Golgi complex and is stored in secretory granules in the parathyroid gland. This gland is exquisitely sensitive to serum calcium concentrations and is able to monitor these levels via calcium-sensing receptors (CaSR). These cell surface receptors help cells to react to micromolar changes in the concentration of ionized calcium in the serum (8). Binding of calcium to these receptors facilitates activation of phospholipase C and, ultimately, inhibition of PTH secretion. The relatively short-acting PTH is secreted from the parathyroid gland chief cells in response to a hypocalcemic state and serves to oppose the hormonal effects of calcitonin (1). Unlike calcitonin, the biological activity of PTH resides solely in residues 1 to 34 in the amino terminus. Parathyroid hormone decreases renal excretion of calcium (Fig. 35.1, loop 3A), indirectly stimulates intestinal absorption of calcium (Fig. 35.1, loop 2A), and in combination with active vitamin D, promotes bone resorption (Fig. 35.1, loop 1A) by a complex, unknown mechanism, thereby elevating serum calcium concentrations. In addition, the secretion of PTH stimulates the biosynthesis and release of the third hormone associated with calcium homeostasis, vitamin D. When serum calcium concentrations are high, the release of PTH is inhibited.

## Vitamin D

Derived from cholesterol, vitamin D is biosynthesized from its prohormone cholecalciferol ($D_3$), the product of solar ultraviolet irradiation of 7-dehydrocholesterol in the skin (2). In 1966, it was first recognized that vitamin D must undergo activation *via* two oxidative metabolic steps (Fig. 35.2). The first oxidation to 25-hydroxycholecalciferol (25(OH)$D_3$: calcifediol; Calderol) occurs in the endoplasmic reticulum of the liver and is catalyzed by vitamin D 25-hydroxylase. This activation step is not

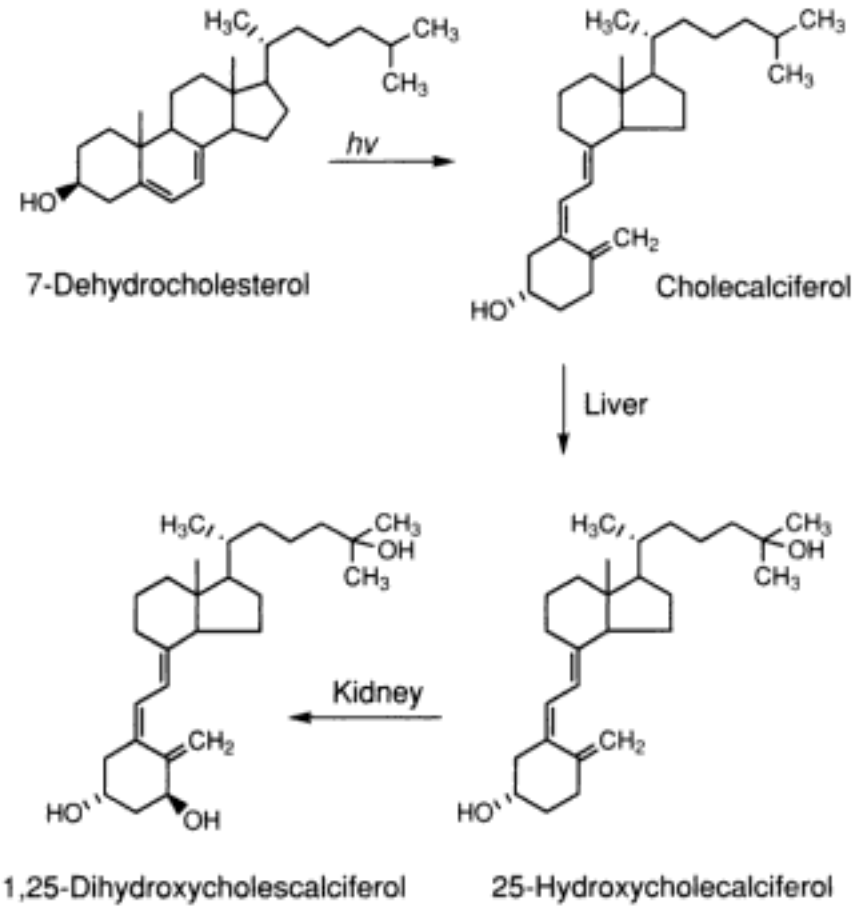

**Fig. 35.2.** Bioactivation of vitamin D.

Copyrighted material

regulated by plasma calcium concentrations. The major circulating form (10–80 μg/mL) is 25(OH)$D_3$, which also is the primary storage form of vitamin D (2). In response to a hypocalcemic state and the secretion of PTH, a second oxidation step is activated in the mitochondria of the kidney, catalyzed by vitamin D 1α-hydroxylase (2,9). The product of this reaction, 1,25-dihydroxycholecalciferol ($1,25(OH)_2D_3$: 1,25-calcitriol; Rocaltrol, Calcijex) is the active form of vitamin D. Its concentration in the blood is 1/500 that of its monohydroxylated precursor. The biosynthesis of vitamin D is tightly regulated based on the serum concentrations of calcium, phosphate, PTH, and active vitamin D (2).

Sterol-specific cytoplasmic receptor proteins (vitamin D receptor) mediate the biological action of vitamin D (9). The active hormone is transported from the cytoplasm to the nucleus via the vitamin D receptor, and as a result of the interaction of the hormone with target genes, a variety of proteins are produced that stimulate the transport of calcium in each of the target tissues. Active vitamin D works in concert with PTH to enhance active intestinal absorption of calcium, to stimulate bone resorption, and to prohibit renal excretion of calcium (2,9). If serum calcium or 1,25-calcitriol concentrations are elevated, then vitamin D 24-hydroxylase (in renal mitochondria) is activated to oxidize 25(OH)$D_3$ to inactive 24,25-dihydroxycholecalciferol and to further oxidize active vitamin D to the inactive 1,24,25-trihydroxylated derivative. Both the 1,24,25-trihydroxylated and the 24,25-dihydroxylated products have been found to suppress PTH secretion as well. Several factors have been identified in the regulation of the biosynthesis of vitamin D, including low phosphate concentrations (stimulatory) as well as pregnancy and lactation (stimulatory).

## NORMAL PHYSIOLOGY

During growth periods in childhood and early adulthood, bone formation characteristically exceeds bone loss. In young adulthood, bone formation and bone resorption are nearly equal. After the age of 40 years, however, bone resorption is slightly greater than bone formation, and this results in a gradual decline in skeletal mass. Osteoblasts, osteoclasts, and osteocytes are the three types of cells that make up the bone remodeling unit (3) or bone metabolizing unit (4) and, therefore, are largely responsible for the bone remodeling process.

Osteoblasts, which are of mesenchymal origin and are formed in the bone marrow, stimulate bone formation (6). In the maturation process, osteoblasts undergo multiple cell divisions and, in so doing, express the gene products that are needed to form the bone matrix or osteoid (3) as well as those products responsible for mineralization of that tissue (6). Multiple endogenous substances are involved in osteoblast maturation, including many cytokines (interleukins and granulocyte-macrophage colony-stimulating-factor) (3) as well as hormones and growth factors (6). It is in the rough endoplasmic reticulum that the biosynthesis of the bone matrix protein occurs (4).

Osteoclasts are the large multinucleated cells of hemopoietic origin (6) that are responsible for carrying out the bone resorption or destroying process. Cytokines, PTH, and the active form of vitamin D activate these cells. Bone lining flat cells, derived from "retired" osteoclasts and osteoblasts, are located on the bone surface (3). The function of these flat cells is thought to serve to identify areas of the bone that have become weakened or misshapen and to send a signal to the bone remodeling unit to prepare the bone. Lining cells then digest the outer layer of the bone matrix in preparation for bone remodeling. The osteoclast membrane then comes into contact with the bone surface and forms an impermeable "sealing zone" of approximately 500 to 1,000 μm in size (2,6). The $H^+$ ATPase-rich osteoclast membrane that is in contact with the bone surface forms a ruffled border, the sealing zone becomes acidified, and ultimately, the bone minerals dissolve (6). Several types of lysosomal enzymes have been proposed to then digest the collagen matrix (3), thereby pitting the bone surface to a depth of 50 μm (4–6). Only calcitonin acts directly on the osteoclast to prevent bone resorption.

Yet another type of cell is found deep within the bone matrix, the osteocyte. The role of this type of cell has yet to be elucidated, but it has been proposed that it may be responsible for maintaining bone integrity (3) and for providing nutrition to the bone.

Parathyroid hormone stimulates bone resorption by several mechanisms: 1) Transformation of osteoprogenitor cells into osteoclasts is stimulated in the presence of PTH, 2) PTH promotes the deep osteocytes to mobilize calcium from perilacunar bone, and 3) surface osteocytes are stimulated by PTH to increase the flow of calcium out of the bone.

Quantification of bone mineral density (BMD) can be measured by noninvasive radiographic tests, such as single-photon (3) or dual-photon absorptiometry (spine, hip, and total body) (10), dual-energy x-ray absorptiometry (3,10,11) (spine, hip, total and body), peripheral dual-energy x-ray absorptiometry (wrist, heel, and finger), single energy x-ray absorptiometry (wrist or heel) (12), quantitative computed tomography (spine) and peripheral quantitative computed tomography (wrist) (10), and quantitative ultrasound (heel, shin bone, and knee cap) (12). Dual-energy x-ray absorptiometry is considered to be the gold standard for measuring bone density and has an accuracy that exceeds 95% (4). These techniques measure the attenuation of x-rays or gamma rays as they cross the spine, hip, or radius before they reach the detector (6). Other methods under development that measure BMD include ultrasound, traditional x-rays, and blood/urine tests (6). Traditional x-rays can identify the site of fracture, but they cannot measure BMD (3). Blood/urine tests can identify if the patient is suffering from a medical condition (3) that is contributing to the loss of BMD and can identify important biochemical markers that can assess the rate of

Table 35.1. Classification of Osteoporosis (14)

| Etiology | Type I (postmenopausal) Increased Osteoclast Activity and Bone Resorption | Type II (senile) Decreased Osteoblast Activity and Bone Formation; Decreased GI Ca Absorption | Type III (secondary) Drug Therapies; Disease States |
|---|---|---|---|
| Typical age at diagnosis | 50–75 | >70 | any age |
| Gender ratio | 6:1 women/men | 2:1 women/men | 1:1 women/men |
| Typical fracture site | vertebrae, distal radius | femoral, neck, hip | vertebrae, hip, extremities |
| Bone morphology | decreased trabecular | decreased trabecular and normal cortical bone | decreased cortical bone |
| Rate of bone loss | 2–3% per year | 0.3–0.5% per year | variable |

bone resorption and bone turnover. The measurement of serum calcium, phosphorous, and vitamin D levels also may provide insight regarding the cause of decreased BMD (3). Often, patients suffer from multiple vertebral compression fractures (3) without seeking treatment other than an over-the-counter analgesic, and the diagnosis of osteoporosis occurs only after the patient has already lost significant (as much as 30%) bone mass.

## DISEASE STATES ASSOCIATED WITH ABNORMAL CALCIUM HOMEOSTASIS

### Osteoporosis

Osteoporosis is a skeletal disease that is characterized by loss of bone mass as well as microarchitectural deterioration of the bone tissue. This disease is associated with increased bone fragility and susceptibility to fracture. It is a condition that is characterized not by inadequate bone formation but, rather, by a deficiency in the production of well-mineralized bone mass. Whereas no medical cause typically is evident in primary osteoporosis (3), secondary osteoporosis classically stems from medical illness or medication use. There are two types of primary adult osteoporosis, type I, or postmenopausal, and type II, or senile (Table 35.1). In type I osteoporosis, there is an accelerated rate of bone loss via enhanced resorption at the onset of menopause. In this form of the disease, the loss of trabecular bone is threefold greater than the loss of cortical bone. This disproportionate loss of bone mass is the primary cause of the vertebral crush fractures and the wrist and ankle fractures experienced by postmenopausal women. In type II osteoporosis, which is associated with aging, the degree of bone loss is similar in both trabecular and cortical bone (5) and is caused by decreased bone formation by the osteoblasts.

Drug- or disease-induced, or type III, osteoporosis (Table 35.2) accounts for up to 30% of the cases of vertebral fractures reported annually. It can be caused by a variety of factors, including long-term suppression of osteoblast function, an inhibition of calcium absorption from the gut, or excessive loss of calcium in the urine, as a result of estrogen deficiency, hyperparathyroidism (6,11), hyperthyroidism (6,11), hypogonadism (11,13), renal disease (6), depression, and treatment with glucocorticoids (13), thyroid hormone, anticonvulsants, methotrexate (13), cyclosporine (13), warfarin, lithium, or immunosuppressive therapy (6). Warfarin impairs the vitamin K–dependent biosynthesis of osteocalcin (13), it prevents the recycling of oxidized vitamin K to its active reduced form via inhibition of vitamin K epoxide reductase and vitamin K reductase. Long-term therapy with glucocorticoids has been shown to directly suppress osteoblast function and reduce calcium absorption from the gut (13). Vitamin D deficiency, as the cause of pseudohyperparathyroidism, is a common cause of osteoporosis in elder persons who are institutionalized and lack adequate sunlight exposure (2).

Osteoporosis is the cause of nearly 1.5 million fractures annually in the United States (3), including 250,000 hip fractures and 550,000 vertebral fractures. As it relates to the percentage of women older than 50 years who are at risk for developing osteoporosis because of low bone mass, the statistics are sobering: 52% of Caucasian and Asian women, 35% of African-American women, and 49% of Hispanic women. It has been predicted that one in every three women who live to the age of 90 years will experience a hip fracture (3,15). It has been estimated that 15 to 35% of hip fracture patients will require long-term nursing home care. A surprising 60% of hip fracture patients do not regain full function, and within 3 to 4

osteoclast activity is inhibited, so bone resorption is slowed. In acute cases of hypercalcemia, calcitonin is administered to reestablish calcium homeostasis. Hypercalcemia also can be treated with sulfate salts, ethylenediaminetetraacetic acid, furosemide, ethacrynic acid, glucocorticoids, and plicamycin.

## Hypoparathyroidism

Hypoparathyroidism is caused by decreased serum PTH concentrations. It is characterized by hypocalcemia, hyperphosphatemia, and reduced levels of circulating vitamin D. The right wings of Arnaud's butterfly model is predominant (Fig. 35.1), and serum calcium concentrations precipitously decrease. Administration of intravenous (IV) calcium gluconate and PTH serves to acutely correct plasma calcium levels. Chronic oral administration of active vitamin D as well as calcium supplements has been effective in maintaining appropriate serum calcium concentrations.

## Pseudohypoparathyroidism

In this disease state, levels of PTH are normal or even elevated; however, serum calcium concentrations are low. End-organ insensitivity to PTH has been proposed to be the cause of the hypocalcemic state. Treatment of this condition with calcium and vitamin D has proven to be successful.

## Hyperparathyroidism

Increased levels of PTH leads to moderately to severely elevated serum calcium concentrations (2) and, as a result, a significant loss of calcium from the bone. Deposits of calcium salts in soft tissue as well as formation of renal calculi also can result from this hormonal imbalance. Treatment of this condition with salmon calcitonin, loop diuretics, or other classical treatments for hypercalcemia has been favorable. The IV vitamin D analogue paricalcitol, which is used for both prevention and treatment of hyperparathyroidism secondary to chronic renal failure, has been shown to reduce parathyroid levels by an average of 30% after 6 weeks of treatment. Whereas paricalcitol is a fully active form of vitamin D, doxercalciferol requires activation by the liver. This analogue also is indicated for the treatment of secondary hyperparathyroidism. Doxercalciferol capsules should be administered three times weekly at the time of dialysis along with close monitoring of calcium and phosphate levels. Treatment of secondary hyperparathyroidism with vitamin D therapy is problematic, however, because it often leads to

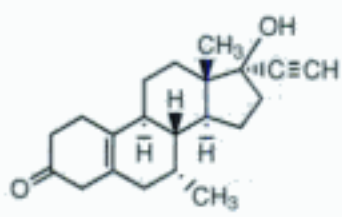
bone remodeling (14). Estrogen improves calcium absorption, promotes calcitonin biosynthesis, and increases the vitamin D receptors on osteoclasts. Although the primary mechanism of action remains unclear and its use is controversial at best, hormone replacement therapy is considered to be second-line therapy for the prevention of osteoporosis (23). Estrogen receptor therapy (ERT; e.g., 17β-estradiol, estrone sodium sulfate, or 17-ethinyl estradiol) (21) is classified as antiresorptive therapy in the prevention of osteoporosis. The pharmacokinetics of the estrogens is covered in detail in Chapter 46.

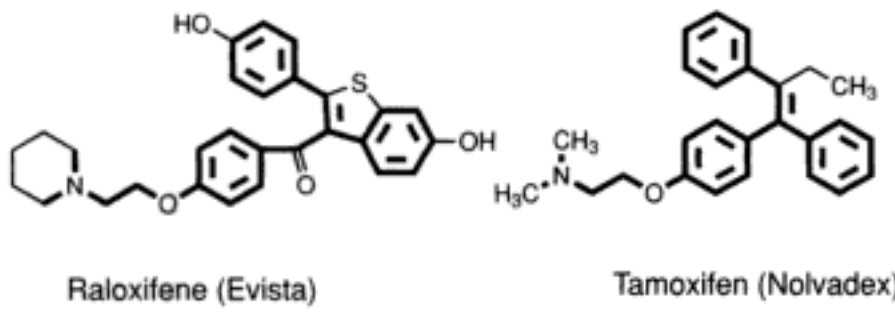
**THERAPEUTIC EFFECTS.** Fractures of the spine, wrist, and hips decrease by 50 to 70%, and spinal bone density increases by 5% (24), in those women treated with estrogen within 3 years of the onset of menopause and for 5 to 10 years thereafter (5,11,25). The minimum dose required and that which is considered to be standard therapy is 0.625 mg/day of conjugated estrogens (Premarin); however, a 0.3 mg/day dose of esterified estrogen (Estratab) has been shown to be adequate for the prevention of osteoporosis (5). Estrogen replacement therapy is available in several types of formulations, including transdermal patches (Climera, Estraderm, Menostar, or Vivelle).

Initiated at the onset of menopause, this therapy also has favorable effects on serum cholesterol levels (reduces low-density lipoprotein and elevates high-density lipoprotein levels). Women taking ERT have found relief from hot flashes, vaginal dryness, and urinary stress incontinence (21). It is recommended that the estrogen be combined with a progestin for those women with an intact uterus so as to decrease the risk of endometrial cancer (14). Hormone replacement therapy is not necessarily the treatment of choice for all women, because some are intolerant to this type of therapy or have a disease state in which ERT is contraindicated (e.g., breast cancer, liver disease, or active thromboembolic disease) (3).

Tamoxifen (Nolvadex)



Raloxifene hydrochloride (Evista)



## Selective Estrogen Receptor Modulators

**RALOXIFENE.** Tamoxifen citrate, which is classified chemically as a triarylethylene, was developed as an antiestrogenic drug and as a selective estrogen receptor modulator (SERM). It is prescribed for the treatment of metastatic breast cancer. Raloxifene hydrochloride, a benzothiophene

Tibolone is a synthetic steroid that has been shown to increase bone mineral density similar to alendronate. The U.S. FDA approval is pending; overseas, this agent is used for the treatment of menopausal symptoms as well as the prevention of osteoporosis. It is considered to be a viable alternative to conjugated equine estrogen plus micronized progesterone. With the 2.5-mg dose and calcium supplementation (800 mg/day), an increase in the lumbar spine and femoral neck bone density has been demonstrated. The ability of tibolone to prevent bone loss is proposed to be mediated through its estrogenic metabolites via the estrogen receptor (26). The most common reason for patient withdrawal from clinical trials was vaginal bleeding (also a common side effect when estrogen therapy is used).

Tibolone

Raloxifene (Evista) Tamoxifen (Nolvadex)

**Fig. 35.3.** Structures of raloxifene and tamoxifen, highlighting the similarity between the two drugs.

derivative (24), also may be considered to be a semirigid analogue of tamoxifen (Fig. 35.3). The two drugs are similar in that they both possess agonist activity in certain tissues (e.g., bone and cardiovascular) and antagonist activity in others (e.g., breast and uterus) (6,21) (see Chapter 46). Raloxifene, the first SERM approved for the prevention of osteoporosis in postmenopausal women, acts as an estrogen agonist on receptors in osteoblasts and osteoclasts but as an antagonist at breast and uterine estrogen receptors. This selective action means that this agent does not increase the risk of endometrial or breast cancer, as is the case with long-term tamoxifen therapy. Because this agent does not have a stimulatory effect at its receptors on most tissues, it does not prevent the hot flashes and other symptoms of menopause as estrogen does (5).

***Therapeutic Action.*** Clinical trials have shown that raloxifene, in combination with oral calcium supplementation, decreases the risk of vertebral fracture and promotes bone formation, albeit to a lesser extent than with estrogen. Raloxifene has been shown to have a beneficial effect on lipid profiles (11). Raloxifene should not be administered in combination with cholestyramine (decreased absorption), coumadin (prothrombin times and international normalized ratios must be monitored more closely), and those drugs that are highly protein bound, such as clofibrate, diazepam, ibuprofen, indomethacin, and naproxen.

***Structure–Activity Relationship.*** From a structural perspective, the only pure antiestrogens are 7α-substituted estrogens (21). In the triarylethylene class of agents, the A ring phenol is critical for binding to the estrogen receptor, because it mimics the essential 3-phenolic group in estrogens (21). The orientation of the three aryl rings in a propeller type of arrangement also is important for tight receptor binding and biological activity (21).

***Pharmacokinetics.*** Raloxifene is rapidly absorbed following oral administration, with an estimated 60% absorption, but it has a very low bioavailability (2%), associated with extensive phase II metabolism. The metabolites are excreted via the bile, with potential enterohepatic recycling that could account for the interaction with cholestyramine. Supportive of the enterohepatic recycling is the half-life of 28 hours. Metabolism of raloxifene occurs to a great extent in the intestine and consists of glucuronide conjugation catalyzed by uridine diphosphate glucuronosyltransferase

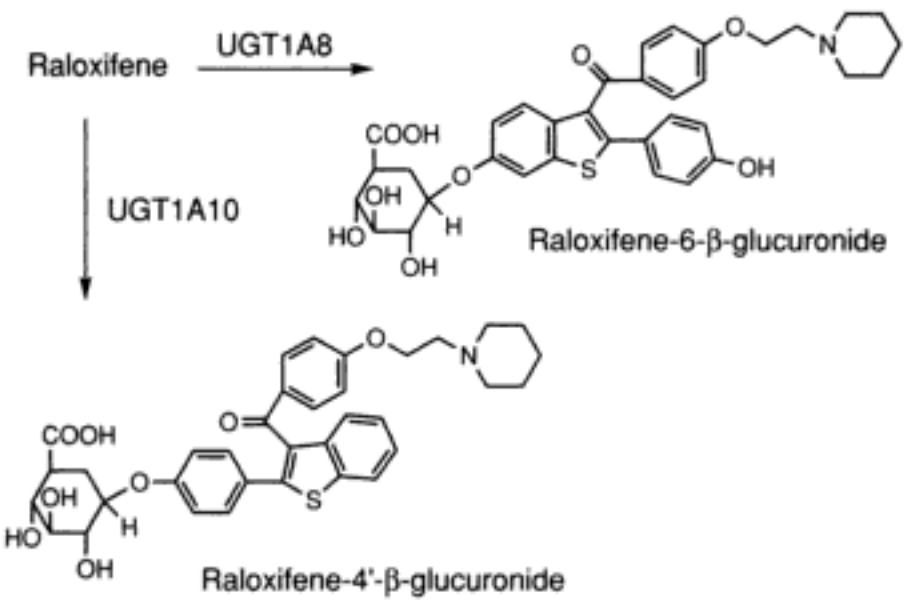


**Fig. 35.4.** Metabolism of raloxifene.

(UGT) (27–29). The UGT1A family is responsible for intestinal human metabolism, as shown in Figure 35.4. Efflux by intestinal cells of the resulting glucuronide occurs via P-glycoprotein and multidrug resistance–related protein. The combination of rapid metabolism and efflux can account for the low bioavailability.

**LASOFOXIFENE.** Lasofoxifene is a very potent second-generation SERM currently in phase III clinical trials for the treatment and prevention of osteoporosis in postmenopausal women (Fig. 35.5). At low doses, this agent has been shown to prevent bone loss and decrease serum cholesterol (dose range, 0.01–20.0 mg/day). In early clinical trials, lasofoxifene improved BMD in the lumbar spine by 3% (after 12 months of therapy), which is twice the improvement observed with similar treatment using raloxifene. Improvement in hip BMD was similar for both agents. Interestingly, a more pronounced reduction

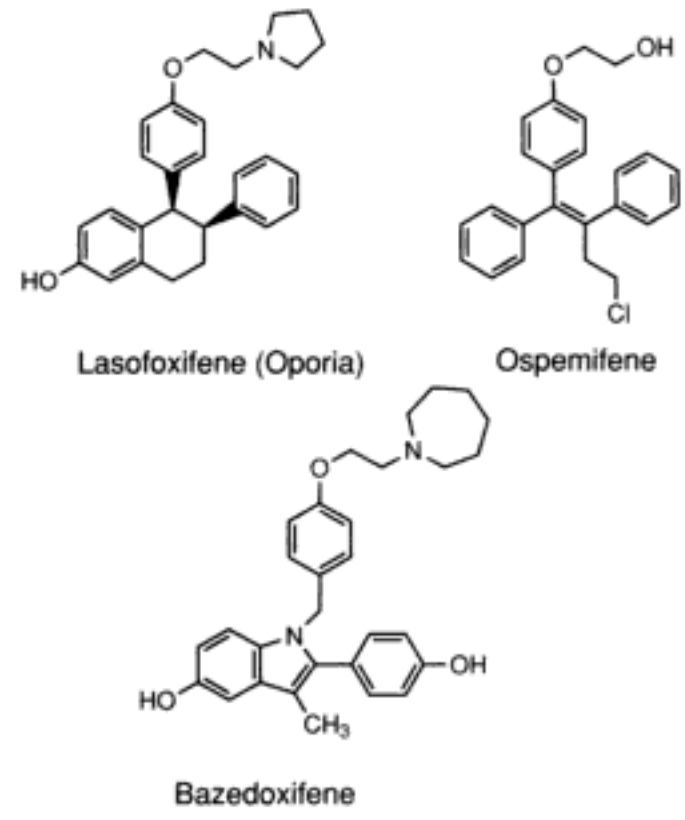

**Fig. 35.5.** Investigational second-generation selective estrogen receptor modulators.

Copyrighted material

as well as improves the antiresorptive character of the agent (21,33). The character of the $R_2$ substituent varies widely and clearly has a significant influence on the potency of this class of compounds (Fig. 35.7). The $R_2$ amino–substituted bisphosphonates (pamidronate, alendronate, and neridronate) are more potent than etidronate and clodronate (not available in the United States). The $R_2$ 4-carbon amino linear chain for alendronate is more potent than the $R_2$ 3-carbon derivative pamidronate and the $R_2$ 6-carbon analogue neridronate (21). Alkylation of the amine functional group improving potency as is demonstrated by compounds with branched amine substituents at $R_2$ (e.g., olpadronate and ibandronate) and those that contain rings at $R_2$ (e.g., risedronate, incandronate, tiludronate, and zoledronate). The third-generation analogues contain a basic heterocyclic side chain at $R_2$ tethered to the central carbon by a variety of linkages (potency: $NH > CH_2 > S > O$) (21,33). Because structural variation of $R_2$ has a significant effect on potency, it can be surmised that $R_2$ interacts at an "active site" and participates in a specific molecular interaction. The bisphosphonate itself as well as the hydroxyl group at $R_1$ also should be included as critical SAR features (21).

**PHARMACOKINETICS.** To date, four generations of bisphosphonates have been developed for the treatment of osteoporosis (Fig. 35.7). Absorption of these agents from the gut is quite poor (1–5%) (11) because of their polar nature, and as a therapeutic class, they have limited cellular penetration. Up to 50% of the actual absorbed dose is taken up specifically by the bone within 4 to 6 hours, and the rest is exclusively excreted by the kidney (6,24). Uptake of these agents in the bone is concentrated in areas of the bone that are actively undergoing remodeling (32). Between the selective uptake and the rapid rate of clearance, the bisphosphonates enjoy a short circulating half-life and very limited drug exposure to nontarget tissues (25). Because the bisphosphonates are only released from the bone when the bone is resorbed, they have a tissue half-life of 1 to 10 years; however, these agents remain pharmacologically active only while they are exposed on bone resorption surfaces (32).

### SPECIFIC DRUGS

***Etidronate Disodium (Didronel).*** Agents in the first generation (e.g., etidronate disodium and tiludronate) that were dosed continuously produced poorly mineralized bone (3), because there was no interval for appropriate bone mineralization to occur. Subsequent studies that used a cyclic dosing schedule (400 mg/day for 2 weeks, followed by 2.5 months of calcium supplementation only) showed improvement in bone mineralization (11,30). Etidronate has been approved for treatment of Paget's disease of the bone but not for treatment of osteoporosis (5). Tiludronate (6) is approximately 10-fold more potent than etidronate and, when given orally for 6 months (200, 400, or 800 mg/day), increases BMD by 2%. No further bone loss was detected in patients 6 months after cessation of therapy.

***Alendronate Sodium (Fosamax).*** The second-generation agent alendronate sodium was the first bisphosphonate agent approved by the U.S. FDA for the prevention and treatment of osteoporosis and Paget's disease of the bone (32,34) and is 1,000-fold more potent than etidronate. This derivative, when dosed continuously (5–10 mg/day for osteoporosis and 40 mg/day for Paget's disease) and given with oral calcium supplements (500 mg/day), produced well-mineralized bone and significantly improved BMD (7% in the spine and 4% in the hip) within 18 months (6). In addition, the vertebral fracture rate was shown to decrease by 47%. A side effect associated with alendronate, chemical esophagitis (2,3,11,24), has been attributed to inadequate intake of water and lying down after taking the medication. Specific patient instructions were developed to limit the incidence of upper gastrointestinal problems and include: 1) taking the medication with 6 to 8 ounces of water on arising in the morning, 2) remaining in an upright position for at least 30 minutes after taking the medication, and 3) delaying drinking other liquids/eating for at least 30 minutes, if not 1 to 2 hours, to allow maximal absorption of the agent (3). To enhance absorption, calcium supplements and any aluminum- or magnesium-containing antacids should be dosed separately from the agents in this class. These agents are not recommended in patients with renal impairment (serum creatinine, <2.5 mg/dL), a history of esophageal disease, gastritis, or peptic ulcer (5).

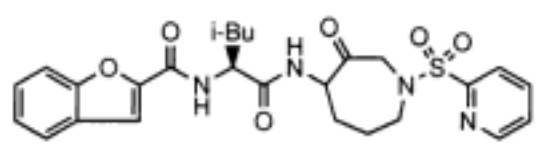
***Risedronate Disodium (Actonel).*** The third-generation agent risedronate disodium has been approved not only for the treatment of osteoporosis but also for the treatment of Paget's disease of the bone and glucocorticoid-induced osteoporosis. Risedronate is 1,000- to 5,000-fold more potent than etidronate. At the end of an 18-month study, 53% of those patients that took risedronate for 2 months remained in remission, as compared to 14% of the patients that took etidronate, an earlier-generation bisphosphonate, for 6 months. Oral administration of this agent suffers from the same problems as that of other bisphosphonate agents. Risedronate should not be given to patients with creatinine clearance of less than 30 mL/min.

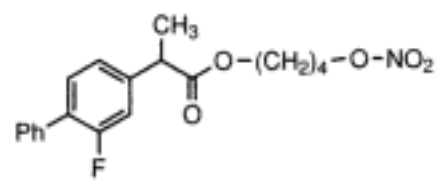
A new formulation of alendronate, FOSAMAX PLUS D, was approved by the U.S. FDA in April 2005. This formulation includes 70 mg of alendronate and 2,800 IU of vitamin $D_3$ (i.e., a 7-day supply of both the bisphosphonate and vitamin D). This formulation should not be used in patients with severe kidney disease or low serum calcium levels and should not be the only therapy used to correct a vitamin D deficiency.

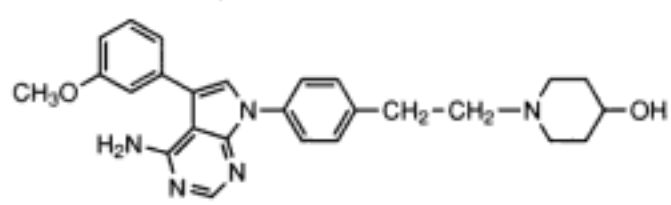
from several large studies conflict, and further study is warranted before the statins can be considered as a viable treatment for osteoporosis (46).

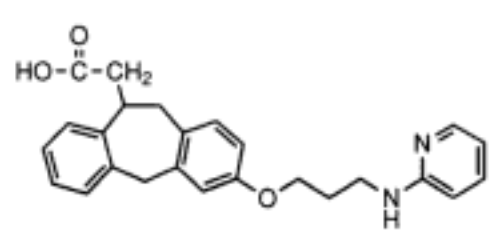
AMG-162 (Amgen) is a fully human monoclonal antibody to the receptor activator of nuclear factor κB ligand (RANKL). Its receptor is located on the surface of osteoclasts and osteoclast precursors. When bound to its receptor, RANKL promotes the formation and activation of osteoclasts. To balance the effects of RANKL, the body produces osteopotegerin, which binds to RANKL and prevents it from binding to and activating its receptor, modulating the production and activation of osteoclasts (47). When an individual develops osteoporosis, this balance is "disrupted," and RANKL overwhelms osteopotegerin activity, causing significant bone loss. AMG-162 was designed to mimic the biochemical effects of osteopotegerin. Studies show that AMG-162 is more effective in improving BMD (4–7%) than weekly administration of alendronate (5%) (47). It is anticipated that this agent will be administered SC biannually. The most commonly reported adverse effect is dyspepsia.

There are a number of agents in the pipeline (Table 35.9), some with very novel mechanisms of action, including inhibitors of cathepsin B and protein tyrosine kinase Src, as well as antagonists at $\alpha_v\beta_3$ integrin receptors (48).





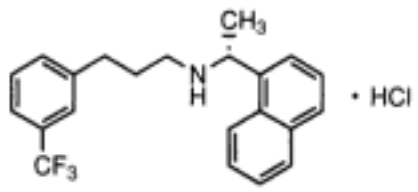




## DRUG THERAPIES USED TO TREAT HYPERPARATHYROIDISM

Increased levels of PTH leads to moderately to severely elevated serum calcium concentrations (2) and alterations in phosphorous metabolism. To modulate the levels of PTH released from the parathyroid gland chief cells, regulation of CaSR sensitivity is required. An agonist at this receptor, a calcimimetic, serves to activate the receptor, whereas an antagonist at this receptor is classified as a calcilytic. There are two types of calcimimetic agents: those that activate the CaSR directly (type I), and those that require the presence of a cation, such as calcium or magnesium (type II) for activation (49). Type I calcimimetics are polycations (e.g., magnesium and neomycin). The first- and second-generation of type II calcimimetics are phenylalkylamine based. They have an indirect/allosteric action on CaSR mediated by a conformational alteration of these receptors.

### Cinacalcet Hydrochloride (Sensipar)



Cinacalcet is the first type II calcimimetic agent approved that improves CaSR sensitivity to calcium (19,50). When calcium is bound to the CaSR, phospholipase C is activated, and the secretion of PTH is inhibited. In the presence of cinacalcet, not only is a drop in

Table 35.9. Experimental Agents for Treatment of Abnormal Calcium Homeostatis

| Drug | Chemical Structure | Mechanism of Action | Stage of Clinical Trial |
|---|---|---|---|
| Precos (recombinant PTH) | 34 amino acids | Treatment of osteoporosis | Phase III |
| SB-357114 |  | Cathepsin K inhibitor | Phase I |
| Osteoprotegerin | — | Inhibitor of osteoclast differentiation and function | Phase II |
| Nitroflurbiprofen (HC–1026) |  | Nitrosylated nonsteroidal anti-inflammatory—decreases bone resorption | Phase II |
| CGP-77675 and AP 23588 |  | Protein tyrosine kinase Src inhibitor—decreases osteoclast mediated bone resorption | Preclinical |
| SB-265123 |  | $\alpha_v\beta_3$ Integrin receptor antagonist | Preclinical |

Copyrighted material

PTH levels observed but also a decrease in serum calcium and phosphorous levels. This represents a significant therapeutic advantage over vitamin D–based treatments for secondary hyperparathyroidism (19). Cinacalcet hydrochloride is a second-generation calcimimetic approved for the treatment of secondary hyperparathyroidism in patients with chronic kidney disease on dialysis and for the treatment of hypercalcemia in patients with parathyroid cancer. It can be used alone, with vitamin D, and/or with a phosphate binder (51).

Cinacalcet hydrochloride (Sensipar)

## DRUG THERAPIES USED TO TREAT HYPERCALCEMIA OF MALIGNANCY

### Zoledronic Acid (Zometa)

Zoledronic acid, a bisphosphonate, was approved by the U.S. FDA in 2001 for the treatment of hypercalcemia of malignancy, a metabolic complication that can be life-threatening (Fig. 35.7). Hypercalcemia of malignancy can occur in up to 50% of patients diagnosed with advanced breast cancer, multiple myeloma, and nonsmall cell lung cancer. This condition arises when chemical moieties produced by the tumor cause overstimulation of osteoclasts. When there is an increase in bone degradation, there is a concomitant release of calcium into the plasma. When serum concentrations of calcium rapidly elevate, the kidneys are unable to handle the overload, and hypercalcemia results. This can lead to dehydration, nausea, vomiting, fatigue, and confusion. Zoledronic acid effectively decreases plasma calcium concentrations via inhibition of bone resorption (inhibition of osteoclastic activity and induction of osteoclast apoptosis). It also prevents the increase in osteoclastic activity caused by tumor-based stimulatory factors. Additionally zoledronic acid has been approved by the U.S. FDA for the treatment of multiple myeloma and bone metastases associated with solid tumor–based cancers (e.g., prostrate and lung). This agent is currently in late-stage clinical trials for the treatment and prevention of osteoporosis and, if approved, will be formulated as a 5-mg, once-yearly IV infusion.

The maximum recommended dose for the treatment of hypercalcemia of malignancy is 4 mg. A clinically significant deterioration in renal function occurs when single doses of this agent exceed 4 mg and the infusion duration is less than 15 minutes (52). It is recommended that patients be well hydrated before infusion. If serum calcium levels do not fall to normal levels, retreatment is appropriate, but retreatment is not recommended until 7 days have elapsed from the initial treatment. For the treatment of multiple myeloma and metastatic bone lesions, a 4-mg initial dose is recommended, followed by additional doses every 3 to 4 weeks for 9 to 15 months (prostate cancer, 15 months; breast cancer, 12 months; other solid tumors, 9 months).

Zoledronic acid is a white, crystalline powder that is available in vials for reconstitution for IV infusion over at least 15 minutes. It does not undergo metabolic transformation and does not inhibit CYP450 enzymes. Clearance of this agent is dependent on the patient's creatinine clearance, not on dose. Serum creatinine levels should be evaluated before every treatment. Zolendronic acid is contraindicated in patients with severe renal impairment.

Zolendronic acid should not be mixed with infusion solutions that contain calcium (e.g., lactated Ringer's) and should be administered via IV infusion in its own line. Because of the possibility of a serious deterioration in renal function, the manufacturer requires strict adherence to the infusion duration being no less than 15 minutes.

### Pamidronate Disodium (Aredia)

Pamidronate, a second-generation bisphosphonate, is 100-fold more potent than etidronate (Fig. 35.7) (6). It has been approved for the treatment of hypercalcemia of malignancy, for Paget's disease, and for osteolytic bone metastases of breast cancer and osteolytic lesions of multiple myeloma. When used to treat bone metastases, pamidronate decreases osteoclast recruitment, decreases osteoclast activity and increases osteoclast apoptosis (53). Erosive esophagitis has been reported with the use of pamidronate sodium.

### Gallium Nitrate (Ganite)

Gallium nitrate (Ganite) has been approved for the treatment of hypercalcemia of malignancy (33) in patients that do not respond to hydration. Its effectiveness stems from its ability to inhibit bone resorption despite the presence of tumor-derived factors that promote calcium loss from the bone. Administered by infusion over 24 hours, the typical dose is 200 $mg/m^2$/day for five consecutive days. A lower dose is recommended if the symptoms of hypercalcemia are mild (100 $mg/m^2$/day for 5 days). Steady state is achieved in 24 to 48 hours. Maintenance of patient hydration is essential during treatment. Gallium nitrate is not significantly metabolized and is largely excreted through the kidneys. It is contraindicated in patients with severe renal impairment. Renal function should be closely monitored in all patients receiving this agent.

SECTION 4 Drugs Affecting the Immune System

# 36. *Nonsteroidal Anti-Inflammatory Drugs*

RONALD BORNE, MARK LEVI AND NORMAN WILSON

## DRUGS COVERED IN THIS CHAPTER:

ANTIPYRETIC ANALGESICS

- Acetaminophen

ANTI-INFLAMATORY ANALGESICS

- Aspirin and other salicylates
- Diflunisal
- Indomethacin
- Diclofenac
- Etodolac
- Nabumetone
- Sulindac
- Tolmetin
- Ibuprofen
- Fenoprofen
- Flurbiprofen
- Ketoprofen
- Ketoraloc
- Naproxen
- Oxaprozin
- Suprofen
- Mefenamic acid
- Meclofenamic acid
- Piroxicam
- Meloxicam

COX-2 INHIBITORS

- Celecoxib
- Rofecoxib
- Valdecoxib
- Etoricoxib
- Lumiracoxib

DRUGS FOR ARTHRITIS

- Gold salts
- Hydroxychloroquine
- Methotrexate
- Leflunomide
- Etanercept
- Infliximab
- Adalimumab
- Rituximab
- Anakinra
- Abatacept

DRUGS FOR THE TREATMENT OF GOUT

- Colchicine
- Probenecid
- Sulfinpyrazone
- Allopurinol

## INTRODUCTION

The classification of drugs covered in this chapter as nonsteroidal anti-inflammatory drugs (NSAIDs) is somewhat misleading, because many of these entities possess antipyretic and analgetic properties in addition to anti-inflammatory properties, which are useful in the treatment of a number of rheumatic disorders. On the other hand, there are drugs that possess analgetic/antipyretic properties but are essentially devoid of anti-inflammatory activity. Additionally, drugs that possess uricosuric properties useful in the treatment of gout will be covered here. The prototype agent of this class is acetylsalicylic acid, aspirin, which has therapeutically useful analgetic, antipyretic, and anti-inflammatory actions; other drugs to be covered may possess only one or two of these properties. Steroids that are useful anti-inflammatory drugs are covered separately in Chapter 33.

Nonsteroidal anti-inflammatory drugs continue to be one of the more widely used groups of therapeutic drugs. The medicinal drugs covered in this chapter represent a major market in both prescription and nonprescription drugs. Other than caffeine or ethyl alcohol, aspirin may be the most widely used drug in the world (1). An estimated 70 to 100 million prescriptions are written annually for NSAIDs, with over-the-counter (OTC) use accounting for an additional use that may be up to sevenfold higher. Rheumatic diseases, which have been classified by the Arthritis Foundation (Table 36.1) (2), are inflammatory disorders affecting more individuals than any chronic illness. The Centers for Disease Control and Prevention estimates that more than 40 million Americans have some form of arthritis or chronic joint disorder. Approximately 7 million Americans suffer from arthritis in its most debilitating forms (3,4). Osteoarthritis is the most common form of arthritis in the United States, affecting about 12% of Americans between the ages of 25 and 74. Rheumatoid arthritis is thought to affect well over 2 million Americans (two to three times more females more than males), whereas juvenile arthritis affects 71,000 children under 16 years of age, 61,000 of whom are females. In addition, nonrheumatoid osteoporosis affects 24 million females (half of all women older than 45 years and 90% of all women older than 75 years) (3,4) and 16 million males. Because more than 80% of the U.S. population older than 55 years have joint abnormalities that are detectable radiographically (5), the use of NSAIDs will increase as Americans experience a greater life expectancy. It is not surprising, therefore, that the development of new NSAIDs continues at a steady pace—a pace slowed down by the recent controversies surrounding selective cyclooxygenase (COX)-2 inhibitors.

The diseases mentioned are considered to be host defense mechanisms. Inflammation is a normal and essential response to any noxious stimulus that threatens the host and may vary from a localized response to a generalized response (6). The resulting inflammation can be summarized as follows: 1) Initial injury causing release

also aids the immigration of phagocytes associated with inflammation. Thus, inhibition of the complement system by controlling its activation or inhibiting those active fragments that are produced should be beneficial in reducing or eliminating tissue damage associated with inflammatory diseases.

Connective tissue diseases include the following states: rheumatoid arthritis, ankylosing spondylitis, systemic lupus erythematosus, polyarteritis nodosa, gout, rheumatic fever, and osteoarthritis, with the most common forms of which are rheumatoid arthritis, osteoporosis, and gout. Rheumatoid arthritis is a chronic, nonsuppurative inflammatory disease of unknown cause affecting primarily peripheral synovial joints. The onset is usually insidious, with immunological reactions playing a major role. The pathogenesis of rheumatoid arthritis has been summarized as follows (10): 1) An unknown initiation factor in the synovial joint causes the production of antigenic immunoglobulin (Ig) G, which stimulates the synthesis of the rheumatoid factors IgM and IgG, forming immune complexes; 2) IgG aggregates activate the complement system, leading to the generation of chemotactic factors (cytokines) that attract polymorphonuclear leukocytes into the articular cavity; 3) the polymorphonuclear leukocytes ingest immune complexes to become rheumatoid arthritis cells, which discharge hydrolases from lysosomal granules that, in turn, degrade extracellular tissue components, polysaccharides, and collagens in cartilage, thus provoking an inflammatory response in rheumatoid joints; and 4) all of which induce expression of cyclooxygenase. Clinical symptoms characteristically include symmetric swelling of at least three joints, accompanied by soft tissue swelling with tenderness, erythema, morning stiffness lasting at least an hour, and pain. The joints primarily involved are those of the extremities, and the patient often suffers a low-grade fever accompanied by malaise, anorexia, and fatigue. Serum protein irregularities and abnormal amounts of rheumatoid factors are common. It often is difficult to distinguish rheumatoid arthritis from other connective tissues disorders because of lack of definitive diagnostic features. Because bone erosions, uniform joint-space narrowing, and osteopenia (decreased bone density) develop within 6 months in about 40% of those with early rheumatoid arthritis, it is more effective to treat early rheumatoid arthritis with disease modifying drug therapy (DMARDs) before structural damage develops than attempting to correct the damage. Corticosteroids are used for controlling the symptoms, not disease modifying.

Osteoarthritis is a degenerative joint disease, and is the most common form of arthritis. It is characterized by degeneration of cartilage and hypertrophy of bone at the articular margin. Secondary inflammation of synovial tissue is common. The most common symptoms involve joint pain associated with movement, joints lose range-of-motion, minimal swelling of the involved joint, and, sometimes, bone enlargement. Weight-bearing joints and joints of the hands and fingers generally are involved. Treatment usually involves exercise and pain medication. Aspirin is considered first-choice therapy, with acetaminophen and NSAIDs being employed in patients who do not tolerate salicylates. Nutritional supplements such as glucosamine and hyaluronic acid have been shown to possibly slow progression of osteoarthritis.

Gout is a metabolic disease characterized by recurrent episodes of acute arthritis, usually monoarticular, and is associated with abnormal levels of uric acid in the body, particularly the presence of monosodium urate crystals in synovial fluid. Primary gout is a hereditary disease in which hyperuricemia is caused by an error in uric acid metabolism—either overproduction or an inability to excrete uric acid. Secondary gout refers to those cases in which hyperuricemia is caused by an acquired disease or disorder, such as chronic renal disease, lead poisoning, or myeloproliferative disorders. Gout generally occurs in

Copyrighted material

mid-life and affects males significantly more than females (9:1). Treatment usually involves the use of uricosuric drugs, colchicine, NSAIDs, or corticosteroids.

The search for new and effective treatment modalities requires the availability of adequate screening tests. Although no model adequately reflects the events that occur in human arthritic conditions, several in vivo and in vitro assays are used. The most common in vivo animal assays measure the ability of anti-inflammatory drugs to inhibit edema induced in the rat paw by carrageenan (a mucopolysaccharide derived from a sea moss of the *Chondrus* species), to inhibit adjuvant arthritis in rats induced by *Mycobacterium butyricum* or *M. tuberculosis*, to inhibit granuloma formation usually induced by the implantation of a cotton pellet beneath the abdominal skin of rats, or to inhibit erythema of guinea pig skin as a result of exposure to ultraviolet radiation. In vitro techniques include the ability of NSAIDs to stabilize erythrocyte membranes or, more commonly, to inhibit the biosynthesis of prostaglandins, particularly in cultured human synoviocytes and chondrocytes, and monocyte culture fluid stimulated bovine synoviocytes and chondrocytes.

## ROLE OF CHEMICAL MEDIATORS IN INFLAMMATION

As indicated previously, a number of chemical mediators have been postulated to play important roles in the inflammatory process. Before 1971, the proposal by Shen (11,12) that the NSAIDs exert their effects by interacting with a hypothetical anti-inflammatory receptor was widely accepted. The topography of the proposed receptor was based on known structure–activity relationships primarily within the series of indole acetic acid derivatives, of which indomethacin was the prototype. Most NSAIDs, whether they be salicylates, arylalkanoic acids, oxicams, or anthranilic acid derivatives, possess the common structural features of an acidic center, an aromatic or heteroaromatic ring, and an additional center of lipophilicity in the form of either an alkyl chain or an additional aromatic ring. The proposed receptor to which indomethacin was postulated to bind consisted of a cationic site to which the carboxylate anion would bind, a flat area to which the indole ring would bind through van der Waals forces, and an out-of-the-plane trough to which the benzene ring of the p-chlorobenzoyl group would bind through hydrophobic or charge-transfer interactions. Additional binding sites for the methoxy and carbonyl groups also were suggested. In 1971, Vane (13) published a classic paper in which he reported that indomethacin, aspirin, and salicylate, in this descending order of potency, inhibited the biosynthesis of prostaglandins from arachidonic acid using cell-free preparations of guinea pig lung, and he further suggested that the clinical actions of these drugs resulted from this inhibition. This theory has become the most widely accepted mechanism of action of NSAIDs. Gund and Shen (14) subsequently modified this hypothesis and proposed that the earlier anti-inflammatory receptor model actually described the active site of the key enzyme in prostaglandin biosynthesis (i.e., prostaglandin cyclooxygenase) (Fig. 36.1).

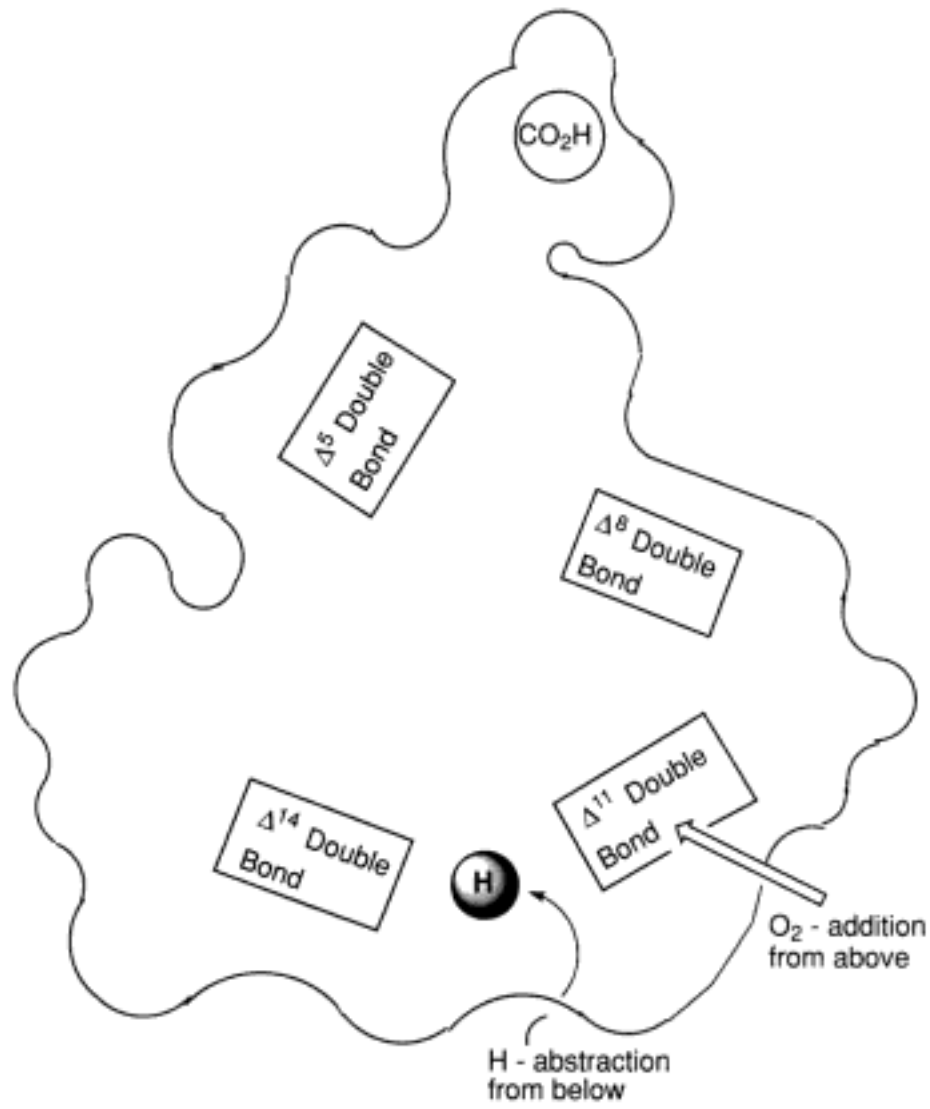

**Fig. 36.1.** Shen's proposed model of the fatty acid substrate binding site of prostaglandin synthetase. (Modified from Gund P, Shen TY. A model for the prostaglandin synthetase cyclooxygenation site and its inhibition by anti-inflammatory arylacetic acids. J Med Chem 1977;20:1146–1152; with permission.)

### Prostaglandins, Thromboxanes, Prostacyclin, and Leukotrienes

Prostaglandins are naturally occurring, 20-carbon, cyclopentano–fatty acid derivatives produced in mammalian tissue from polyunsaturated fatty acids. They belong to the class of eicosanoids, a member of the group of autocoids derived from membrane phospholipids. The eicosanoids are derived from unsaturated fatty acids and include the following groups of compounds: prostaglandins, thromboxanes, prostacyclin, and leukotrienes. They have been found in essentially every compartment of the body. In 1931, Kurzrok and Lieb (15) reported that human seminal fluid possessed potent contractile and relaxant effects on uterine smooth muscle. Shortly thereafter, Goldblatt (16) in England and von Euler (17) in Sweden independently reported vasodepressor and smooth muscle–contracting properties in seminal fluid; von Euler identified the active constituent as a lipophilic acidic substance, which

Copyrighted material

for use as an abortifacient at 12 to 20 weeks of gestation and for evacuation of uterine content in missed abortion or intrauterine fetal death up to 28 weeks of gestation. Additionally, $PGE_2$ is a potent stimulator of smooth muscle of the gastrointestinal (GI) tract and can elevate body temperature in addition to possessing potent vasodilating properties in most vascular tissue while possessing constrictor effects at certain sites. The PGEs in general cause pain when administered via the intradermal route. Many of these properties are shared by $PGF_{2\alpha}$ that also is therapeutically available as an abortifacient at 16 to 20 weeks of gestation and is available as dinoprost tromethamine (Prostin F2α). The synthetic 15-methyl derivative of $PGF_{2\alpha}$, carboprost, also is available as the tromethamine salt (Prostin 15/M) as an abortifacient at 13 to 20 of weeks gestation. However, $PGF_{2\alpha}$ differs from $PGE_2$ in that it does not significantly alter blood pressure in humans. The $PGD_2$ causes both vasodilation and vasoconstriction. The PGEs produce a relaxation of bronchial and tracheal smooth muscle, but the PGFs and $PGD_2$ cause contraction. The $PGE_1$ is available as alprostadil (Prostin VR Pediatric) to maintain patency of the ductus arteriosus in neonates until surgery can be performed to correct congenital heart defects.

The effects of prostaglandins on the GI tract deserve special mention. The PGEs and $PGI_2$ inhibit gastric secretion that may be induced by gastrin or histamine. Prostaglandins appear to play a major cytoprotective role in maintaining the integrity of gastric mucosa. The $PGE_1$ exerts a protective effect on gastroduodenal mucosa by stimulating secretion of an alkaline mucus and bicarbonate ion and by maintaining or increasing mucosal blood flow. Thus, inhibition of prostaglandin formation in joints produces favorable results, as indicated by a reduction in fever, pain, and swelling. Inhibition of prostaglandin biosynthesis in the GI tract is unfavorable, however, because it may cause disruption of mucosal integrity, resulting in peptic ulcer disease that, as will be discussed later, is commonly associated with the use of NSAIDs and aspirin.

Alternatively, nonprostanoids also can be formed from $PGH_2$, as illustrated in Figure 36.4. Thromboxane synthetase acts on $PGH_2$ to produce thromboxane $A_2$ ($TXA_2$), whereas prostacyclin synthetase converts $PGH_2$ to prostacyclin ($PGI_2$), both of which possess short biological half-lives. A potent vasoconstrictor and inducer of platelet aggregation, $TXA_2$ has a biological half-life of approximately 30 seconds, being rapidly nonenzymatically converted to the more stable, but inactive, $TXB_2$. Prostacyclin, a potent hypotensive and inhibitor of platelet aggregation, has a half-life of approximately 3 minutes and is nonenzymatically converted to 6-keto-$PGF_{1\alpha}$. Platelets contain primarily thromboxane synthetase, whereas endothelial cells contain primarily prostacyclin synthetase. Considerable research efforts are being expended in the development of stable prostacyclin analogues and thromboxane antagonists as

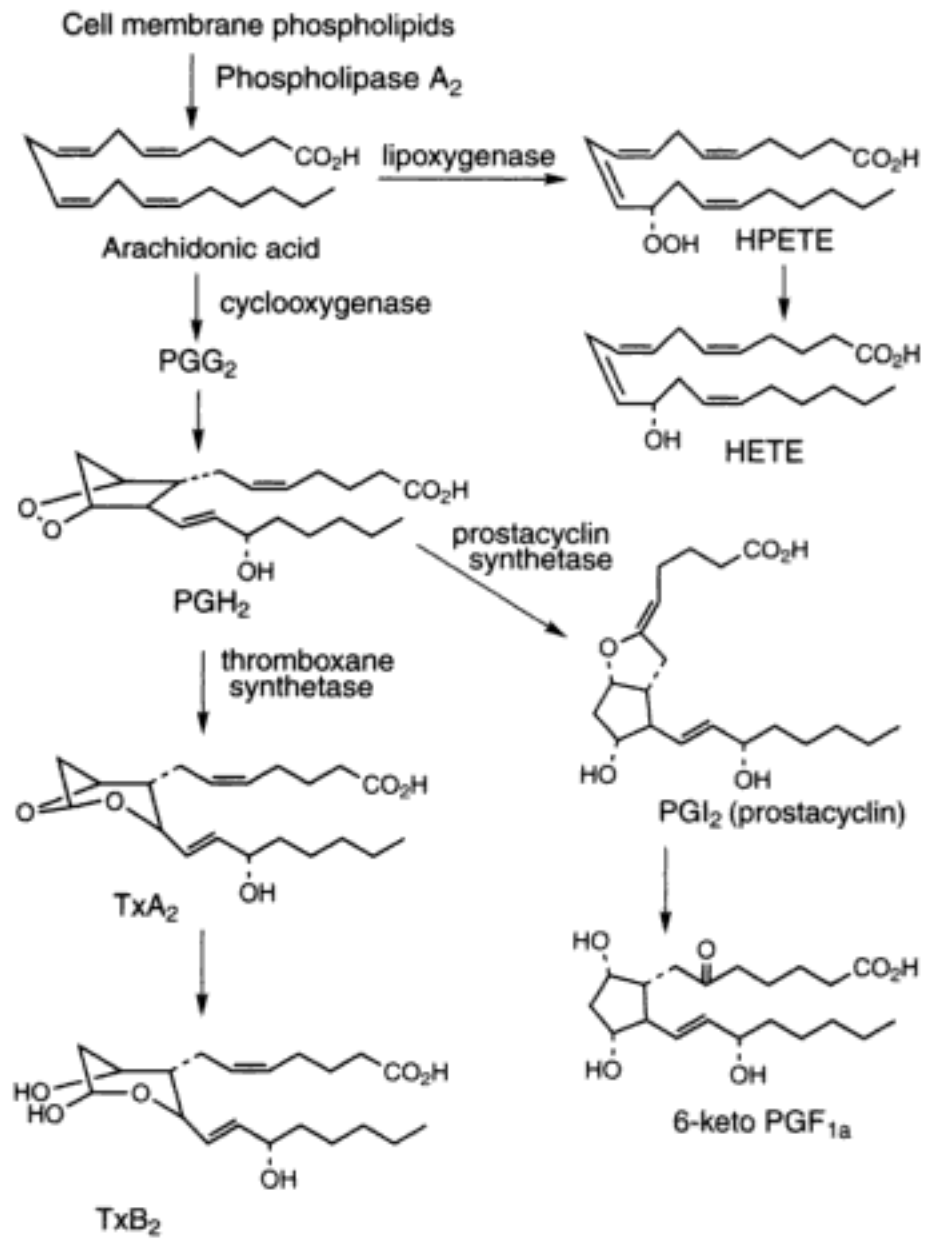

**Fig. 36.4.** Biosynthesis of thromboxanes, prostacyclin and leukotrienes.

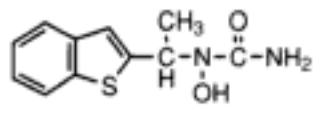

cardiovascular drugs. The pharmacological effects of some prostaglandins, $TXA_2$, and prostacyclin are summarized in Table 36.2.

The existence of distinct prostaglandin receptors may explain the broad spectrum of action displayed by the prostaglandins. The nomenclature of these receptors is based on the affinity displayed by natural prostaglandins, prostacyclin, or thromboxanes at each receptor type. Thus, EP receptors are those receptors for which the PGEs have high affinity, FP receptors are those for PGFs, DP receptors are those for PGDs, IP receptors are those for $PGI_2$, and TP receptors are those for $TXA_2$. These receptors are coupled through G proteins to effector mechanisms that include stimulation of adenylate cyclase and, hence, increased cyclic adenosine monophosphate levels and phospholipase C that results in increased levels of inositol 1,4,5-triphosphate. Three distinct receptors for leukotrienes have been identified as well.

Lipoxygenases are a group of enzymes that oxidize polyunsaturated fatty acids possessing two *cis* double bonds separated by a methylene group to produce lipid hydroperoxides (19). Arachidonic acid is thus metabolized to a number of hydroperoxy-eicosatetraenoic acid

Copyrighted material

antigens, such as grass, cat dander, and ragweed. Zafirlukast reduced the increase in bronchial hyperresponsiveness to inhaled histamine that followed inhaled allergen challenge. It is rapidly absorbed and food reduces bioavailability to approximately 40%. It is extensively metabolized via hydroxylation reactions mediated primarily by CYP2C9, and to a minor extent CYP3A4, to essentially inactive metabolites. Excretion is 90% fecal and 10% via urine. Its elimination half-life is approximately 10 hours. A second leukotriene antagonist, montelukast (Singulair) (Fig. 36.6), was approved shortly thereafter for prophylaxis and chronic treatment of asthma as an antagonist of $LTD_4$ at the $CysLT_1$ receptor. Its oral bioavailability ranges from 60 to 75% depending on the dosage form used. On oral administration, the time to peak concentration ranges from 2 to 4 h. Food can reduce its bioavailability, prolonging time to maximum plasma concentration. Protein binding is more than 99%. Montelukast is also extensively metabolized via hydroxylation reactions mediated by CYP2C9 and CYP3A4 to essentially inactive metabolites. Montelukast is excreted primarily in feces (86%), with an elimination half-life of 3 to 6 hours. The first inhibitor of leukotriene biosynthesis, zileuton (Zyflo), was approved shortly after zafirlukast for prophylaxis and chronic treatment of asthma. Zileuton is a specific inhibitor of 5-lipoxygenase and, thus, inhibits the formation of $LTB_4$, $LTC_4$, $LTD_4$, and $LTE_4$. The *R*- (+)- and *S*-(−)- enantiomers equally inhibit 5-lipoxygenase, and the drug is marketed as the racemic mixture. Zileuton is metabolized primarily to two diasteromeric glucuronide conjugates and the N-dehydroxylated metabolite.

Zileuton

## THERAPEUTIC APPROACH TO ARTHRITIC DISORDERS

The goal of drug treatment in early rheumatoid arthritis is to induce remission or at least eliminate evidence of disease activity. Rheumatoid arthritis was traditionally treated with a stepwise approach starting with NSAIDs and progressing through more potent drugs such as glucocorticoids, DMARDs, and biologic response modifiers. The DMARDs were avoided early in the disease because of their potentially serious side effects and were usually reserved for people who showed signs of joint damage. Over time, however, this strategy was recognized as being faulty, because people treated early with DMARDs have better long-term outcomes, with greater preservation of function and less work disability.

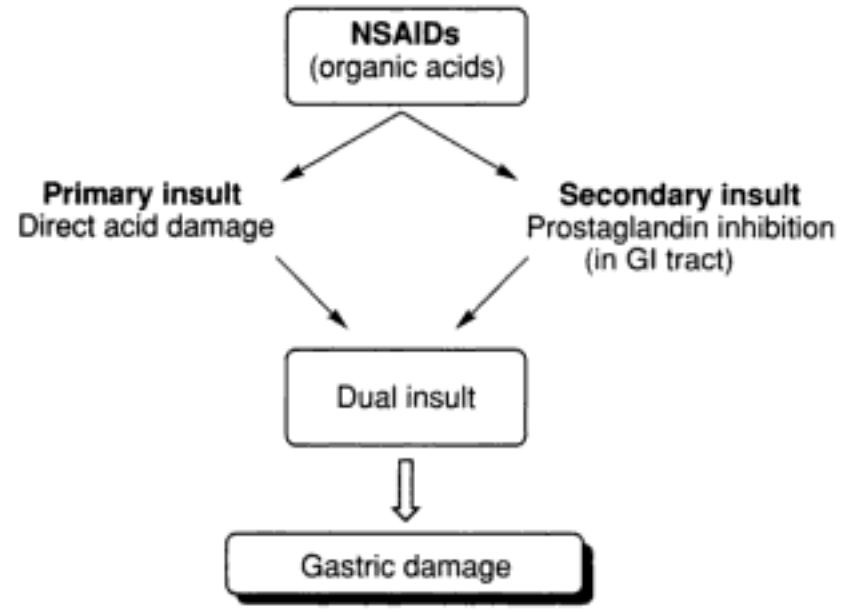

**Fig. 36.7.** NSAID-induced production of gastric damage by a dual-insult mechanism.

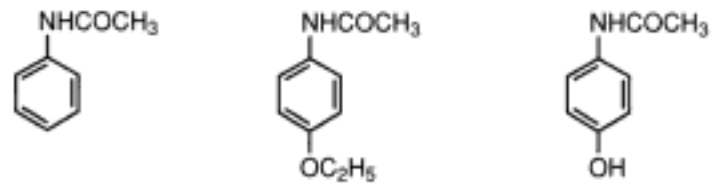

The current approach, therefore, is to treat rheumatoid arthritis aggressively with DMARDs and biologic response modifiers soon after diagnosis. Treating rheumatoid arthritis early with DMARDs, within 3–6 months after symptoms begin, controls inflammation better and is the best way to stop or slow progression of the disease and bring about remission and long term prevention of joint disease. Methotrexate is the cornerstone of DMARD therapy. Long-term treatment with methotrexate and biologic response modifiers may offer the best control of rheumatoid arthritis for the majority of people, which may eliminate the need for other NSAID medications.

A large number of NSAIDs are therapeutically available for the treatment of pain and inflammation associated with arthritic disorders, differing in efficacy but, perhaps more importantly, differing also in overall toxicity. As a group, NSAIDs can cause GI toxicity, such as dyspepsia, abdominal pain, heartburn, gastric erosion leading to wall perforation, peptic ulcer formation, bleeding, diarrhea, renal disorders (e.g., acute renal failure, tubular necrosis, and analgesic nephropathy), and other effects (e.g., tinnitus and headache). Gastric damage produced by NSAIDs generally involves a dual insult mechanism (Fig. 36.7). Most NSAIDs are acidic substances that produce a primary insult because of direct acid damage, an indirect contact effect, and a back diffusion of hydrogen ions. The secondary insult results from inhibition of prostaglandin biosynthesis in the GI tract, where prostaglandins exert a cytoprotective effect. The dual insult leads to gastric damage. A report from the Arthritis, Rheumatism, and Aging Medical Information System Post-Marketing Surveillance Program, before the introduction of COX-2–selective drugs, ranked the overall toxicity of NSAIDs in the following decreasing order: indomethacin > tolmetic > meclofenamate > ketoprofen > fenoprofen > salsalate > aspirin.

## THERAPEUTIC CLASSIFICATIONS

### Antipyretic Analgetics

Acetanilide Phenacetin Acetaminophen

#### Mechanism of Action

Drugs included in this class possess analgetic and antipyretic actions but lack anti-inflammatory effects. Antipyretics interfere with those processes by which pyrogenic factors produce fever, but they do not appear to lower body temperature in afebrile subjects. It had been historically accepted that the antipyretics exert their actions within the central nervous system (CNS), primarily at the hypothalamic thermoregulatory center, but more recent evidence suggests that peripheral actions also may contribute. Endogenous leukocytic pyrogens may be released from cells that have been activated by various stimuli, and antipyretics may act by inhibiting the activation of these cells by an exogenous pyrogen or by inhibiting the release of endogenous leukocytic pyrogens from the cells once they have been activated by the exogenous pyrogen. Substantial evidence exists suggesting a central antipyretic mechanism, an antagonism that may result from either a direct competition of a pyrogen and the antipyretic agent at CNS receptors, or an inhibition of prostaglandins in the CNS (29). Despite the extensive use of acetaminophen, the mechanism of action has not been fully elucidated. Acetaminophen may inhibit pain impulses by exerting a depressant effect on peripheral receptors; an antagonistic effect on the actions of bradykinin may play a role. The antipyretic effects may not result from inhibition of release of endogenous pyrogen from leukocytes but, rather, from inhibiting the action of released endogenous pyrogen on hypothalamic thermoregulatory centers. The fact that acetaminophen is an effective antipyretic/analgetic but an ineffective anti-inflammatory agent may result from its greater inhibition of prostaglandin biosynthesis via inhibition of the COX-3 isoform in the CNS compared with that in the periphery.

Recent research in dogs has revealed a slice variant of COX-1 that was sensitive to inhibition by acetaminophen. This novel variant of the cyclooxygenase system was named COX-3, and it was hypothesized that inhibition of COX-3 could represent a primary CNS mechanism by which acetaminophen and phenacetin exerted their analgesic and antipyretic effects (30). The ability of selected analgesic/antipyretic drugs to inhibit COX-1, COX-2, and COX-3 is shown in Table 36.3 (30).

Further studies revealed that similar cyclooxygenase variants were present in rodents and humans, but these did not appear to be inhibited by acetaminophen (31,32). These cyclooxygenase variants are proposed to be COX-active, however, and to have a role in the biochemistry of these species (33,34). There is substantial nonhomology between the human, canine, and rodent COX-3 proteins.

The mode of action of acetaminophen therefore is still in question. Certainly, the analgetic and antipyretic properties parallel the decrease in $PGE_2$ levels in the CNS caused by acetaminophen. The COX-1–deleted, but not the COX-2–deleted, mice showed a decrease in these actions (35). Those authors suggest that in this species, it is COX-1, or a variant of it, that is affected by acetaminophen. Unlike other NSAIDs, such as ibuprofen or aspirin, acetaminophen does not have significant anti-inflammatory, antiplatelet, or gastric ulcerogenic activity. Other authors claim that the mechanism of action of acetaminophen is thought to involve inhibition of COX-2, and this fits with the therapeutic profile of the recently discovered, powerful, and selective COX-2 inhibitors (36). Acetaminophen is only effective, however, when COX-2 activity is at a low level. This view partially explains the lack of anti-inflammatory action, because COX-2 activity will be high in this situation (37).

Graham and Scott (37) also have put forward the interesting hypothesis that acetaminophen acts by depletion of the stores of glutathione, which is a known cofactor for PGE synthase. This would explain the decrease in PGE production and the concomitant analgetic effect. The depletion of glutathione is the main cause of acetaminophen toxicity. The highly reactive benzoquinoneimine, formed by CYP2E1 isoform, must be conjugated with glutathione before it can react with other crucial cell components. In overdose, failure of this molecular mechanism results in serious liver damage. The depletion of

Table 36.3. Binding Constants ($IC_{50}$ mM) of Selected NSAIDs for the COX enzymes

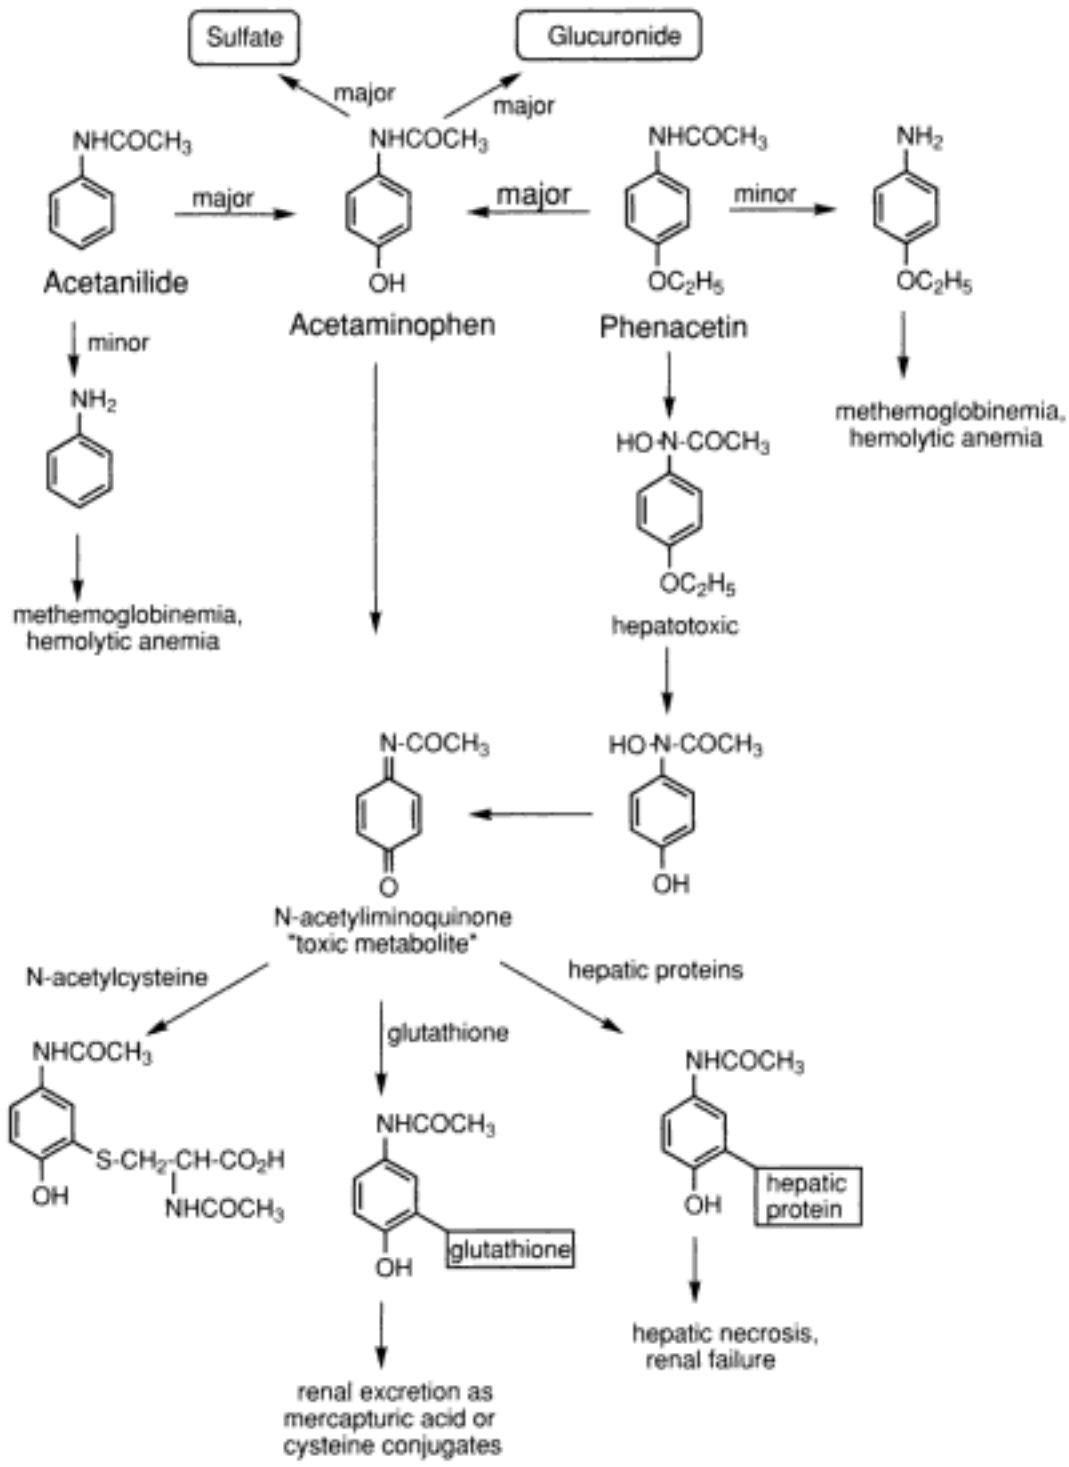

**Fig. 36.8.** Metabolism of acetaminophen.

(Coumadin), dicumarol, anisindione, and diphenadione have been suggested. The mechanism of these interactions has not been fully elucidated but may be associated with competition for plasma protein binding sites, because acetaminophen is a weak acid and is weakly bound, but may also interfere with the enzymes involved in vitamin K-dependent coagulation factor synthesis. The absorption of acetaminophen is enhanced by polysorbate and sorbitol and is reduced by anticholinergics and narcotic analgetics. Chemical incompatibilities also have been reported based on hydrolysis by strong acids or bases or by phenolic oxidation in the presence of oxidizing agents. Acetaminophen forms "sticky" mixtures with diphenhydramine HCl and discolors under humid conditions in the presence of caffeine or codeine phosphate.

## Anti-Inflammatory Drugs

### Salicylates

The use of salicylates dates back to the nineteenth century. Salicylic acid itself was first obtained in 1838 from salicin, a glycoside present in most willow and poplar bark. Interestingly, Hippocrates prescribed chewing willow bark for pain relief in the fifth century AD. In 1860, Kolbe synthesized salicylic acid from sodium phenoxide and carbon dioxide, a method that inexpensively produced large quantities. Derivatives of salicylic acid began to receive medical attention shortly thereafter. Sodium salicylate was employed as an antipyretic/antirheumatic agent in 1875, and the phenyl ester was used in 1886. Acetylsalicylic acid was prepared in 1853 but was not used medicinally until 1899. The term "aspirin" was given to acetylsalicylic acid by Dreser, the director of pharmacology at Frederich Bayer and Company in Germany, as a contraction of the letter "a" from acetyl and "spirin," an older name given to salicylic acid (spiric acid) that was derived from a natural source in spirea plants. Since then, numerous derivatives of salicylic acid have been synthesized and evaluated pharmacologically, yet only a relatively few derivatives have achieved therapeutic utility.

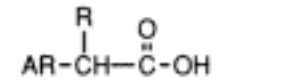
In addition to possessing antipyretic, analgetic, and anti-inflammatory properties, salicylates possess other

Copyrighted material

antipyretic, but it produces less GI irritation and equivalent blood levels and is useful in patients exhibiting hypersensitivity to aspirin. It generates salicylic acid in the GI tract, accounting for some GI irritation, and sodium bicarbonate sometimes is given concomitantly to reduce acidity. Sodium salicylate, unlike aspirin, does not affect platelet function, although prothrombin times are increased. It is available as tablets, enteric-coated tablets, and as a solution for injection.

Choline salicylate has a lower incidence of GI side effects compared with aspirin, and it has been shown to be particularly useful in treating juvenile rheumatoid arthritis, in which aspirin was ineffective. It is absorbed more rapidly than aspirin and produces higher salicylate plasma levels. It is available as a mint-flavored liquid.

Magnesium salicylate has a low incidence of GI side effects. Both sodium salicylate and magnesium salicylate should be used cautiously in individuals in whom excessive amounts of these electrolytes might be detrimental. The possibility of magnesium toxicity in individuals with renal insufficiency exists. It is available as tablets, but its safety in children under 12 years of age has not been fully determined.

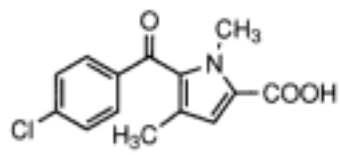


Sodium thiosalicylate (Solate) is administered intramuscularly (IM) for the treatment of rheumatic fever, muscular pain, and acute gout.

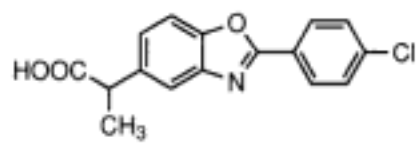
***Salsalate (Disalcid).*** Salsalate, or salicylsalicylic acid, ($pK_a$ 3.5 [COOH], 9.8 [AR-OH]) is a dimer of salicylic acid. It is insoluble in gastric juice but is soluble in the small intestine, where it is partially hydrolyzed to two molecules of salicylic acid and absorbed. On a molar basis, it produces 15% less salicylic acid than aspirin. It does not cause GI blood loss and can be given to aspirin-sensitive patients. Salsalate is available as capsules and tablets.

***Diflunisal (Dolobid).*** Diflunisal ($pK_a$ 3.3) was introduced in the United States in 1982 and has gained considerable acceptance as an analgetic and as a treatment of rheumatoid arthritis and osteoarthritis. Diflunisal is metabolized primarily to ether and ester glucuronide conjugates. No metabolism involving changes in ring substituents has been reported. It is more potent than aspirin but produces fewer side effects and has a biological half-life three to four times greater than that of aspirin. It is rapidly and completely absorbed on oral administration, with peak plasma levels being achieved within 2 to 3 hours of administration. It is highly bound (99%) to plasma proteins after absorption. Its elimination half-life is 8 to 12 hours, and it is excreted into urine primarily as glucuronide conjugates. The most frequently reported side effects include disturbances of the GI system (e.g., nausea, dyspepsia, and diarrhea), dermatological reactions, and CNS effects (e.g., dizziness and headache).

Diflunisal is a moderately potent inhibitor of prostaglandin biosynthesis, but it differs from the manner in which aspirin inhibits the cyclooxygenase system in that the inhibition is competitive and reversible in nature. Diflunisal does not have an appreciable effect on platelet aggregation, however, and does not significantly produce gastric or intestinal bleeding.



### Arylalkanoic Acids



R = H, $CH_3$ or alkyl
AR = aryl or heteroaryl

The largest group of NSAIDs is represented by the class of arylalkanoic acids as typified by the general chemical structure, and several factors have caused this to be one of the most active areas of drug development in recent years. The impact that the introduction of phenylbutazone in the 1950s had on arthritis therapy was more than matched by the interest generated by the introduction of indomethacin in the mid-1960s. As a result of a study designed to investigate the anti-inflammatory activity of 350 indole acetic acid derivatives related structurally to serotonin and metabolites of serotonin, the Merck group led by Shen (49) reported the synthesis and antipyretic and anti-inflammatory activity of the most potent compound in the series, indomethacin. The observation that indomethacin possessed 1,085-fold the anti-inflammatory activity and 20-fold the antipyretic activity of phenylbutazone (and 10-fold the antipyretic activity of aminopyrine) generated considerable interest in the development of other aryl and heteroaryl acetic acid and propionic acid derivatives. The marketplace was ripe for new anti-inflammatory drugs and most pharmaceutical companies joined in the search for new arylalkanoic acids. The introduction of ibuprofen in the 1970s by Upjohn was quickly followed by the appearance of fenoprofen calcium, naproxen, and tolmetin. Sulindac, an analogue of indomethacin, was introduced in the late 1970s. The 1980s produced zomepirac, benoxaprofen, ketoprofen, flurbiprofen, suprofen, and diclofenac sodium. The 1990s produced ketorolac, etodolac, nabumetone, and most significantly, the development of selective COX-2 inhibitors, celecoxib, rofecoxib, and valicoxib, which reached the market during the period from 1997 to 2000. This rapid development has been accompanied by some setbacks, however. Zomepirac, introduced in 1980 as an analgetic, was withdrawn in 1983 because of severe anaphylactoid reactions, particularly in patients sensitive to aspirin. Benoxaprofen was withdrawn within 6 months of its introduction in 1982 because of several deaths caused by cholestatic jaundice in Europe and the United States. In addition, benoxaprofen produced photosensitivity reactions in patients when they were exposed to sunlight and onycholysis (loosening of the fingernails) in some patients. Suprofen, introduced as an analgetic in 1985, was removed from the market two years later because of flank pain and transient renal failure. In 1989, however, it was reintroduced for ophthalmic use. Numerous other arylalkanoic acids currently are being evaluated in various stages of clinical trials.

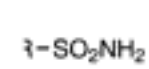
Copyrighted material

Zomepirac

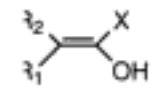
Benoxaprofen

As discussed earlier, most NSAIDs possess a number of biochemical and pharmacological actions. As was the case for the salicylates, the arylalkanoic acids share, to various extents, the property of inhibition of prostaglandin biosynthesis by inhibiting COX-1 and COX-2 with varying degrees of selectivity (Table 36.3).

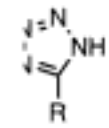
**General structure–activity relationships.** Drugs of this class share a number of common structural features. These general structure–activity relationships will be discussed here as they pertain to the proposed mechanism of action. Specific structure–activity relationships for each drug or drug class will be presented separately, where appropriate.



All nonselective COX inhibitors possess a center of acidity, which can be represented by a carboxylic acid function, an enolic function, a hydroxamic acid function, a sulfonamide, or a tetrazole ring. The relationship of this acid center to the carboxylic acid function of arachidonic acid is obvious. The activity of ester and amide derivatives of carboxylic acids generally is attributed to the metabolic hydrolysis products. One nonacidic drug, nabumetone, has been recently introduced in the United States, but as will be discussed later, its activity is attributed to its bioactivation to an active acid metabolite. The center of acidity generally is located one carbon atom adjacent to a flat surface represented by an aromatic or heteroaromatic ring. The distance between these centers is crucial, because increasing this distance to two or three carbons generally diminishes activity. Derivatives of aryl or heteroaryl acetic or propionic acids are most common. This aromatic system appears to correlate with the double bonds at the 5- and 8-positions of arachidonic acid. Substitution of a methyl group on the carbon atom separating the acid center from the aromatic ring tends to increase anti-inflammatory activity. The resulting α-methyl acetic acid, or 2-substituted propionic acid, analogues have been given the class name "profens" by the U.S. Adopted Name Council. Groups larger than methyl decrease activity, but incorporation of this methyl group as part of an alicyclic ring system does not drastically affect activity. Introduction of a methyl group creates a center of chirality. Anti-inflammatory activity in those cases in which the enantiomers have been separated and evaluated, whether determined in vivo or in vitro by cyclooxygenase assays, is associated with the *S*-(+)-enantiomer. Interestingly, in those cases in which the propionic acid is administered as a racemic mixture, in vivo conversion of the *R*-enantiomer to the biologically active *S*-enantiomer is observed to varying degrees. A second area of lipophilicity that is noncoplanar with the aromatic or heteroaromatic ring generally enhances activity. This second lipophilic area may correspond to the area of the double bond in the 11-position of arachidonic acid. This lipophilic function may consist of an additional aromatic ring or alkyl groups either attached to or fused with the aromatic center.



R–COOH — Carboxylic acid; pKa 4-6



R–CONHOH — Hydroxamic acids; pKa (NH) 8-9

R–$SO_2NH_2$ — Sulfonamide; pKa (NH) 9-10

Enolic (phenol); pKa (OH) 8-10

Tetrazoles; pKa (NH) 4-6

**General metabolism.** Essentially all the arylalkanoic acid derivatives that are therapeutically available are extensively metabolized. Metabolism occurs primarily through hepatic microsomal enzyme systems and may lead to deactivation or bioactivation of the parent molecules. Metabolism of each drug will be treated separately.

**Drug interactions.** All the arylalkanoic acids are highly bound to plasma proteins and, thus, may displace other drugs from protein binding sites, resulting in an enhanced activity and toxicity of the displaced drugs. Interestingly, despite the high degree of plasma protein binding, indomethacin does not display this characteristic drug interaction. The most commonly observed interaction is that between the arylalkanoic acid and oral anticoagulants, particularly warfarin (Coumadin). Coadministration may prolong prothrombin time. Potential interactions with other acidic drugs, such as hydantoins, sulfonamides, and sulfonylureas, should be monitored. Concomitant administration of aspirin decreases plasma levels of arylalkanoic acids by as much as 20%. Probenecid, on the other hand, tends to increase these plasma levels. Interactions with drugs that may induce hepatic microsomal enzyme systems, such as phenobarbital, may enhance or diminish anti-inflammatory activity depending on whether the arylalkanoic acid is metabolically bioactivated or inactivated by this enzyme system. Certain diuretics, such as furosemide, inhibit the metabolism of prostaglandins by 15-hydroxyprostaglandin dehydrogenase, and the resulting increase in $PGE_2$ levels induce plasma renin activity. Because the arylalkanoic acids block the biosynthesis of prostaglandins, the effects of furosemide can be antagonized, in part, offering a potentially significant drug interaction.

**Aryl- and heteroarylacetic acids.** The structures of the aryl- and heteroarylacetic acid derivatives and the aryl- and heteroarylpropionic acids ("profens") available are presented in Figure 36.11.

***Indomethacin.*** Aqueous solutions of indomethacin are not stable because of the ease of hydrolysis of the p-chlorobenzoyl group. The original synthesis of indomethacin by Shen et al. (49) involved the formation of 2-methyl-5-methoxyindole acetic acid and subsequent

Copyrighted material

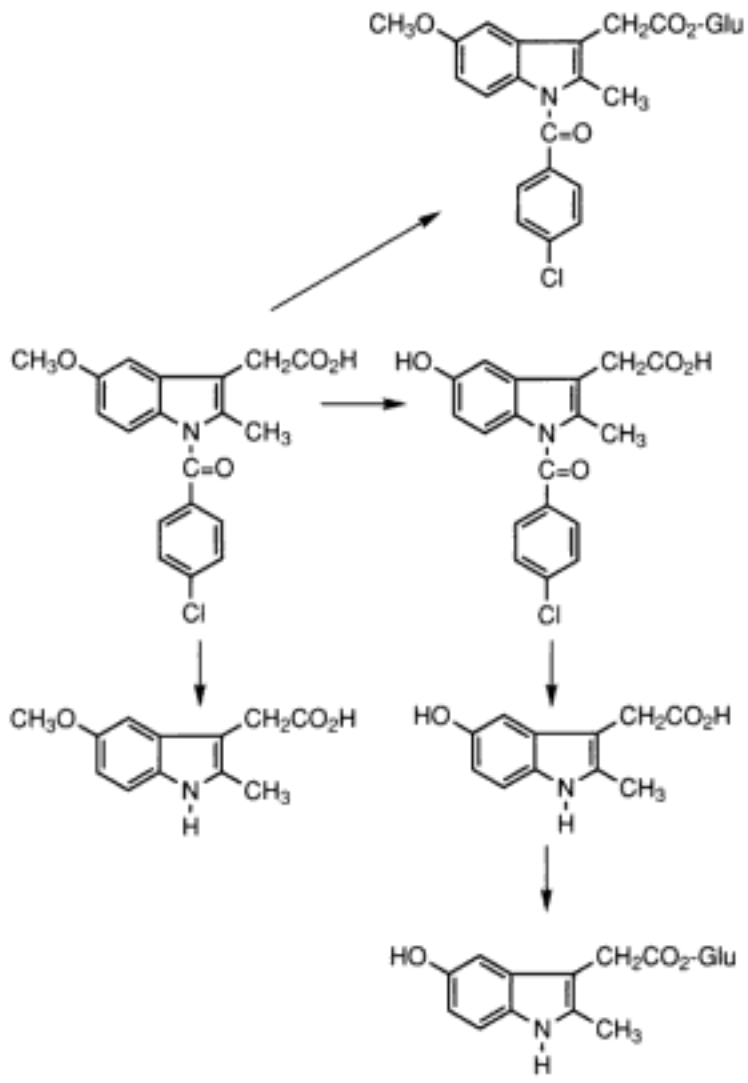


**Fig. 36.12.** Metabolism of indomethacin. Glu, glucuronide.

***Sulindac.*** Sulindac was introduced in the United States in 1978 by Merck as a result of chemical studies designed to produce an analogue without the side effects commonly associated with the use of indomethacin, particularly GI irritation. It achieved wide popularity, and it remains one of the more widely used NSAIDs. Its synthesis also was reported by Shen et al. (50). Sulindac is a prodrug and is converted to a metabolite that appears to inhibit the cyclooxygenase system approximately eightfold as effectively as aspirin. In anti-inflammatory and antipyretic assays, it is only about half as potent as indomethacin but is equipotent in analgetic assays.

***Structure–Activity Relationships.*** The use of classical bioisosteric changes in medicinal chemistry drug design was invoked in the design of sulindac. The isosteric replacement of the indole ring with the indene ring system resulted in a derivative with therapeutically useful anti-inflammatory activity and fewer CNS and GI side effects but with other undesirable effects, particularly poor water solubility and resultant crystalluria. The replacement of the N-p-chlorobenzoyl substituent with a benzylidiene function resulted in active derivatives. However, when the 5-methoxy group of the indene isostere was replaced with a fluorine atom, enhanced analgetic effects were observed. The decreased water solubility of the indene isostere was alleviated by replacing the chlorine atom of the phenyl substituent with a sulfinyl group. The importance of stereochemical features in the action of sulindac, introduced by the benzylidene double bond, is evidenced by the observation that the (Z)-isomer is a much more potent anti-inflammatory agent than the corresponding (E)-isomer (Fig. 36.10). This *cis*-relationship of the phenyl substituent to the aromatic ring bearing the fluoro substituent is similar to the proposed conformation of indomethacin, suggesting that both indomethacin and sulindac assume similar conformations at the active site of arachidonic acid cyclooxygenase.

***Absorption and Metabolism.*** Sulindac is well absorbed on oral administration (90%), reaches peak plasma levels within 2 to 4 hours, and being acidic ($pK_a$ = 4.5), is highly bound to serum proteins (93%). The metabolism of sulindac plays a major role in its actions, because all of the pharmacological activity is associated with its major metabolite. Sulindac is, in fact, a pro-drug, the sulfoxide function being reduced to the active sulfide metabolite. Sulindac is absorbed as the sulfoxide, which is not an inhibitor of prostaglandin biosynthesis in the GI tract. As discussed earlier, prostaglandins exert a protective effect in the GI tract, and inhibition of their synthesis here leads to many of the GI side effects noted for most NSAIDs. Once sulindac enters the circulatory system, it is reduced to the sulfide, which is an inhibitor of prostaglandin biosynthesis in the joints. Thus, sulindac produces less GI side effects, such as bleeding, ulcerations, and so on, than indomethacin and many other NSAIDs. In addition, the active metabolite has a plasma half-life approximately twice that of the parent compound (~16 hours versus 8 hours), which favorably affects the dosing schedule. In addition to the sulfide metabolite, sulindac is oxidized to the corresponding sulfone, which is inactive. A minor product results from hydroxylation of the benzylidene function and the methyl group at the 2-position. Glucuronides of several metabolites also are found. Sulindac as well as the sulfide and the sulfone metabolites are all highly protein-bound. Despite the fact that the sulfide metabolite is a major activation product and is found in high concentration in human plasma, it is not found in human urine, perhaps because of its high degree of protein binding. The major excretion product is the sulfone metabolite and its glucuronide conjugate. The complete metabolism of sulindac is illustrated in Figure 36.13.

Whereas the toxicity of sulindac is lower than that observed for indomethacin and other NSAIDs, the spectrum of adverse reactions is very similar. The most frequent side effects reported are associated with irritation of the GI tract (e.g., nausea, dyspepsia, and diarrhea), although these effects generally are mild. Effects on the CNS (e.g., dizziness and headache) are less common. Dermatological effects are less frequently encountered.

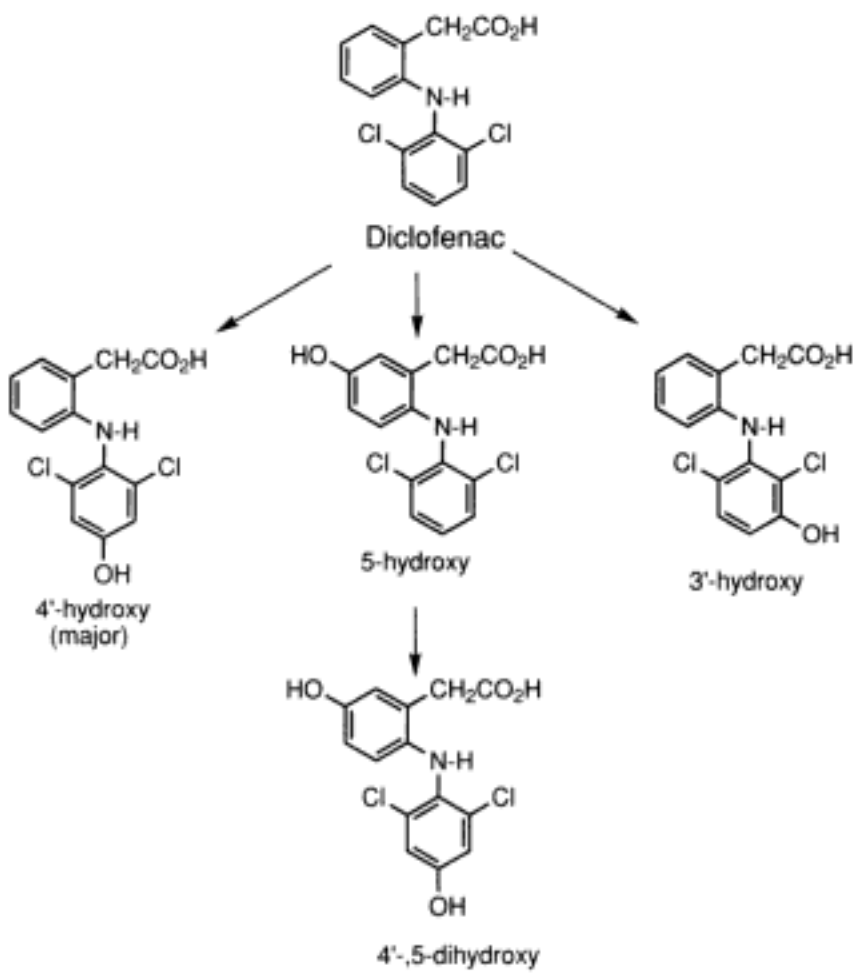
Sulindac is indicated for long-term use in the treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, and acute gouty arthritis. The usual maximum dosage is 400 mg/day, with starting doses recommended at 150 mg twice a day. It is recommended that sulindac be administered with food.

Copyrighted material

2) inhibition of the lipoxygenase pathway, resulting in decreased production of leukotrienes, particularly the pro-inflammatory $LKB_4$; and 3) inhibition of arachidonic acid release and stimulation of its reuptake, resulting in a reduction of arachidonic acid availability.

***Structure–Activity Relationships.*** Structure–activity relationships in this series have not been extensively studied. It does appear that the function of the two *o*-chloro groups is to force the anilino-phenyl ring out of the plane of the phenylacetic acid portion, this twisting effect being important in the binding of NSAIDs to the active site of the COX, as previously discussed.

***Absorption and Metabolism.*** Diclofenac is rapidly and completely (~100%) absorbed on oral administration, with peak plasma levels being reached within 1.5 to 2.5 hours. The free acid ($pK_a$ = 4.0) is highly bound to serum proteins (99.5%), primarily albumin. Only 50 to 60% of an oral dose is bioavailable because of extensive hepatic metabolism. Four major metabolites resulting from aromatic hydroxylation have been identified. The major metabolite via CYP3A4 is the 4′-hydroxy derivative and accounts for 20 to 30% of the dose excreted, whereas the 5-hydroxy, 3′-hydroxy, and 4′,5-dihydroxy metabolites via CYP2C9 account for 10 to 20% of the excreted dose. The remaining drug is excreted in the form of sulfate conjugates. Although the major metabolite is much less active than the parent compound, it may exhibit significant biological activity, because it accounts for 30 to 40% of all of the metabolic products. The metabolism of diclofenac is illustrated in Figure 36.14.



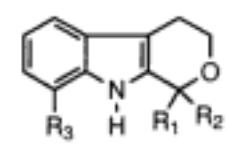


**Fig. 36.14.** Metabolism of diclofenac.

Diclofenac sodium is indicated for the treatment of rheumatoid arthritis, osteoarthritis, and ankylosing spondylitis.

***Etodolac.*** Etodolac is promoted as the first of a new chemical class of anti-inflammatory drugs, the pyranocarboxylic acids. Although not strictly an arylacetic acid derivative (because there is a two-carbon atom separation between the carboxylic acid function and the heteroaromatic ring) (Fig. 36.10), it still possesses structural characteristics similar to those of the heteroarylacetic acids and is classified here. It was introduced in the United States in 1991 for acute and long-term use in the management of osteoarthritis and as an analgetic. It also possesses antipyretic activity. Etodolac is marketed as a racemic mixture, although only the *S*-(+)-enantiomer possesses anti-inflammatory activity in animal models. Etodolac also displays a high degree of enantioselectivity in its inhibitory effects on the arachidonic acid cyclooxygenase system. With regard to its anti-inflammatory actions, etodolac was approximately 50 times more active than aspirin, three times more potent than sulindac, and one-third as active as indomethacin. The ratio of the anti-inflammatory activity to the median effective dose (ED50) for gastric ulceration or erosion was more favorable for etodolac (median inhibitory dose [ID50]/ED50 = 10) than for aspirin, naproxen, sulindac, or indomethacin (ID50/ED50 = 4). At 2.5 to 3.5 times the effective anti-inflammatory dose, etodolac was reported to produce less GI bleeding than indomethacin, ibuprofen, or naproxen. The primary mechanism of action appears to be inhibition of the biosynthesis of prostaglandins at the cyclooxygenase step, with no inhibition of the lipoxygenase system. Etodolac, however, possesses a more favorable ratio of inhibition of prostaglandin biosynthesis in human rheumatoid synoviocytes and chondrocytes than by cultured human gastric mucosal cells compared to ibuprofen, indomethacin, naproxen, diclofenac, and piroxicam. Thus, although etodolac is no more potent an NSAID than many others, the lower incidence of GI side effects represents a potential therapeutic advantage.

***Structure–Activity Relationships.*** During a search for newer, more effective antiarthritic drugs in the 1970s, the Ayerst group led by Humber investigated a series of pyranocarboxylic acids of the general structure shown below (53,54).

Structure–activity relationship studies indicated that alkyl groups at $R_1$ and an acetic acid function at $R_2$ enhanced anti-inflammatory activity. Lengthening the acid chain, or ester or amide derivatives, gave inactive compounds. The corresponding α-methylacetic acid derivatives also were inactive. Increasing the chain length of the $R_1$ sub-

Copyrighted material

stituent to ethyl or n-propyl gave derivatives that were 20 times more potent than methyl. A number of aromatic substituents in the aromatic ring were evaluated, and substituents at the 8-position were most beneficial. Among the most active were the 8-ethyl, 8-n-propyl, and 7-fluoro-8-methyl derivatives. Etodolac was found to possess the most favorable anti-inflammatory to gastric distress properties among these analogues.

***Absorption and Metabolism.*** Etodolac is rapidly absorbed following oral administration, with maximum serum levels being achieved within 1 to 2 hours, and it is highly bound to plasma proteins (99%) with $pK_a$ 4.7. The penetration of etodolac into synovial fluid is greater than or equal to that of tolmetin, piroxicam, or ibuprofen. Only diclofenac appears to provide greater penetration. Etodolac is metabolized to three hydroxylated metabolites and to glucuronide conjugates, none of which possesses important pharmacological activity. Metabolism appears to be the same in the elderly as in the general population, so no dosage adjustment appears necessary.

Etodolac is indicated for the management of the signs and symptoms of osteoarthritis and for the management of pain.

***Nabumetone.*** Nabumetone is unique among the NSAIDs in that it represents a new class of nonacidic prodrugs, being rapidly metabolized after absorption to form a major active metabolite, 6-methoxynaphthaleneacetic acid. It was introduced in the United States in 1992 and is synthesized from 2-acetyl-6-methoxynaphthalene (55). Nabumetone, being nonacidic, does not produce a significant primary insult and is an ineffectual inhibitor of prostaglandin cyclooxygenase in gastric mucosa, thus producing minimum secondary insult. The result is that gastric side effects of nabumetone appear to be minimized. Once the parent drug enters the circulatory system, however, it is metabolized to an active metabolite, 6-methoxynaphthalene-2-acetic acid (6MNA), which is an effective inhibitor of cyclooxygenase in joints. Nabumetone thus represents a classic example of the prodrug approach in drug design.

In the carrageenan-induced rat paw assay, nabumetone is approximately 13 times more potent than aspirin, one-third as active as indomethacin, and half as active as diclofenac. It is only half as active as aspirin as an analgetic, as measured by the phenylquinone-induced writhing assay in mice. Despite its lower potency, the advantages of nabumetone may reside in its favorable gastric irritancy profile. The ratio of gastric irritancy dose in rats to anti-inflammatory activity in rats (ED50) for nabumetone is 21.25, whereas this ratio is 0.41 for aspirin, 0.55 for indomethacin, 0.72 for diclofenac, 3.00 for tolmetin, and 7.85 for zomepirac.

***Structure–Activity Relationships.*** Introduction of methyl or ethyl groups on the butanone side chain greatly reduced anti-inflammatory activity. The ketone function can be converted to a dioxolane with retention of activity, whereas converting the ketone to an oxime reduced activity. Removal of the methoxy group at the 6-position reduced activity, but replacement of the methoxy with a methyl or chloro group gave active compounds. Replacement of the methoxy with hydroxyl, acetoxy, or N-methylcarbamoyl groups, or positional isomers of the methoxy group at the 2- or 4-positions, greatly reduced activity. The active metabolite, 6-MNA, is closely related structurally to naproxen, differing only by the lack of an α-methyl group. The ketone precursor, [4-(6-methoxy-2-naphthyl)pentan-2-one], that would be expected to produce naproxen as a metabolite was inactive in chronic models of inflammation.

***Absorption and Metabolism.*** Nabumetone is absorbed primarily from the duodenum. Milk and food increase the rate of absorption and the bioavailability of the active metabolite. Plasma concentrations of unchanged drug are too low to be detected in most subjects after oral administration, so most pharmacokinetic studies have involved the disposition of the active metabolite. Pharmacokinetic properties are altered in elderly patients, with higher plasma levels of the active metabolite being noted. Nabumetone undergoes rapid and extensive metabolism in the liver, with a mean absolute bioavailability of the active metabolite of 38%. The metabolism of nabumetone is illustrated in Figure 36.15. The major,

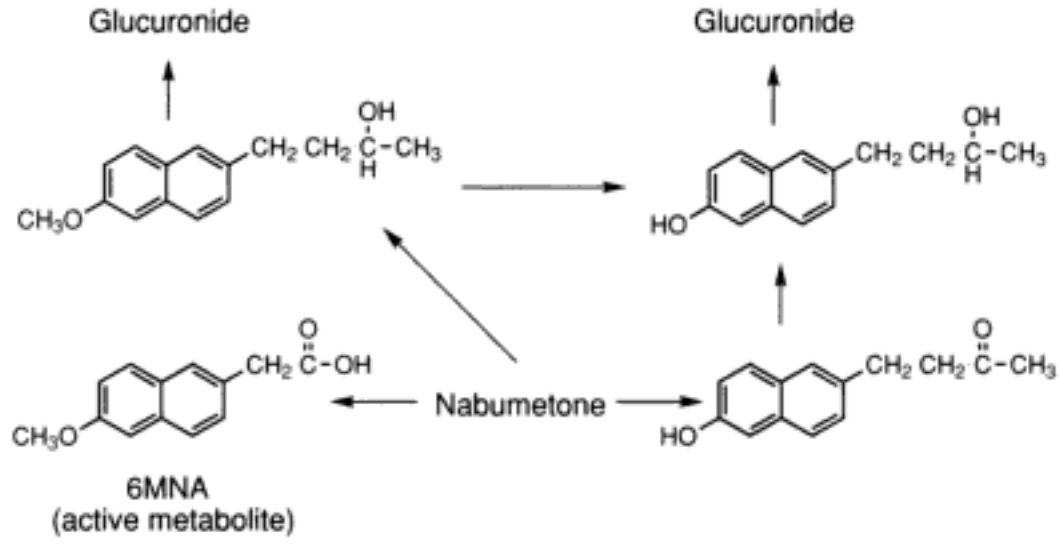

**Fig. 36.15.** Metabolism of nabumetone.

Copyrighted material

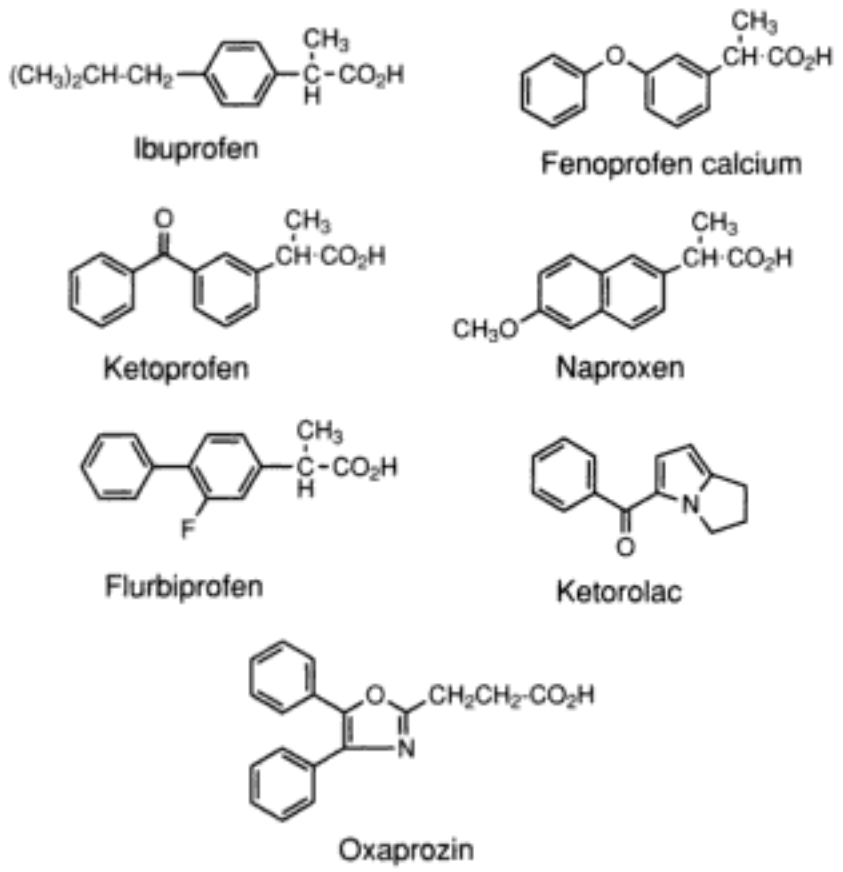

**Fig. 36.16.** Structures of aryl- and heteroarylpropionic acid derivatives.

most active metabolite is 6MNA, but the initial alcohol metabolite, a minor product, and its esters also possess significant anti-inflammatory properties.

Nabumetone is indicated for the acute and chronic treatment of the signs and symptoms of osteoarthritis and rheumatoid arthritis. The recommended starting dosage is 1,000 mg as a single dose with or without food. More symptomatic relief of severe or persistent symptoms may be obtained at doses of 1,500 or 2,000 mg/day.

**ARYL- AND HETEROARYLPROPIONIC ACIDS.** Structures of aryl- and heteroarylpropionic acid derivatives are shown in Figure 36.16.

***±-Ibuprofen.*** The synthesis of ibuprofen was originally reported in 1964 from p-isobutylacetophenone (56), but the drug was not marketed in the United States until 1974, despite the fact that it had been available for several years in Europe. It was the first NSAID approved since indomethacin, and was immediately accepted into therapy. Its success precipitated the introduction of many new drugs in the 1970s. This chemical class currently comprises the largest group of NSAIDs. Ibuprofen became the first prescription NSAID to become available as an OTC analgetic in almost 30 years and is available under a number of brand names. It is marketed as the racemic mixture, although biological activity resides almost exclusively in the *S*-(+)-isomer. Ibuprofen is more potent than aspirin but less potent than indomethacin in anti-inflammatory and prostaglandin biosynthesis inhibition assays, and it produces moderate degrees of gastric irritation.

***Structure–Activity Relationships.*** The substitution of an α-methyl group on the alkanoic acid portion of acetic acid derivatives enhances anti-inflammatory actions and reduces many side effects. For example, the acetic acid analogue of ibuprofen, ibufenac (*p*-isobutylphenylacetic acid), is less potent and more hepatotoxic than ibuprofen. The stereochemistry associated with the chiral center in the arylpropionic acids, but lacking in the acetic acid derivatives, plays an important role in both the in vivo and in vitro activities of these drugs. As indicated earlier, although marketed as a racemic mixture, the (+)-enantiomer of ibuprofen possess greater activity in vitro than the (−)-isomer. The eudismic (*S*/*R*) ratio for the inhibition of bovine prostaglandin synthesis is approximately 160, but in vivo, the two enantiomers are equiactive (see next section on absorption and metabolism). The (+)-enantiomer of ibuprofen—and of most of the arylpropionic acids under investigation—has been shown to possess the (*S*)-absolute configuration.

***Absorption and Metabolism.*** Ibuprofen is rapidly absorbed on oral administration, with peak plasma levels being generally attained within 2 hours and a duration of action of less than 6 hours. As with most of these acidic NSAIDs, ibuprofen ($pK_a$ = 4.4) is extensively bound to plasma proteins (99%) and will interact with other acidic drugs that are protein bound. Metabolism occurs rapidly, and the drug is nearly completely excreted in the urine as unchanged drug and oxidative metabolites within 24 hours following administration (Fig. 36.17). Metabolism by CYP2C9 (90%) and CYP2C19 (10%) involves primarily ω-, and $\omega_1$-, and $\omega_2$-oxidation of the p-isobutyl side chain, followed by alcohol oxidation of the primary alcohol resulting from ω–oxidation to the corresponding carboxylic acid. All metabolites are inactive. When

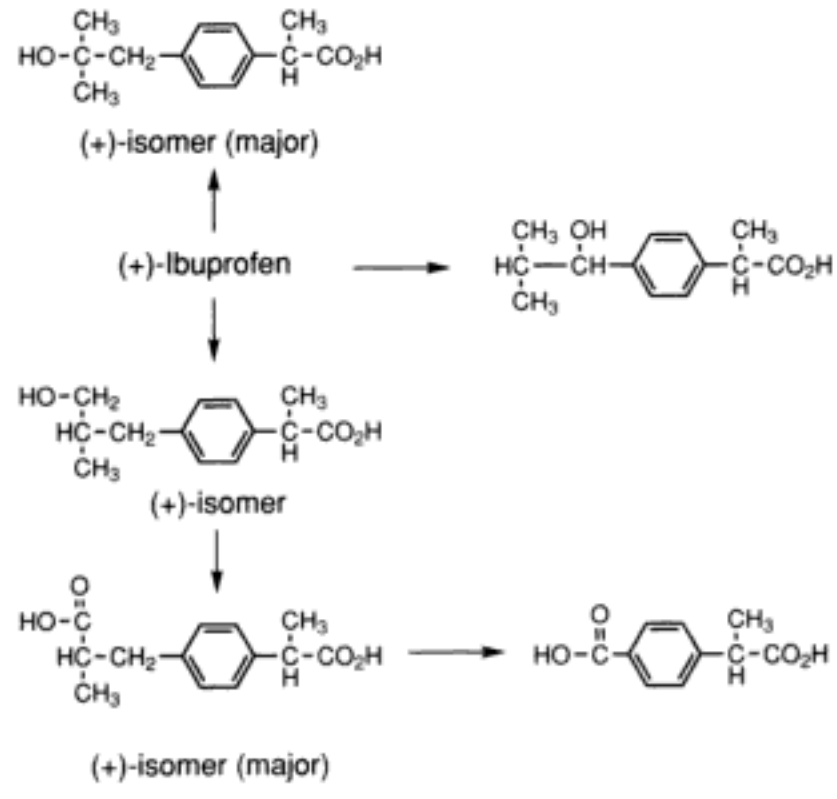

**Fig. 36.17.** Metabolism of ibuprofen.

Copyrighted material

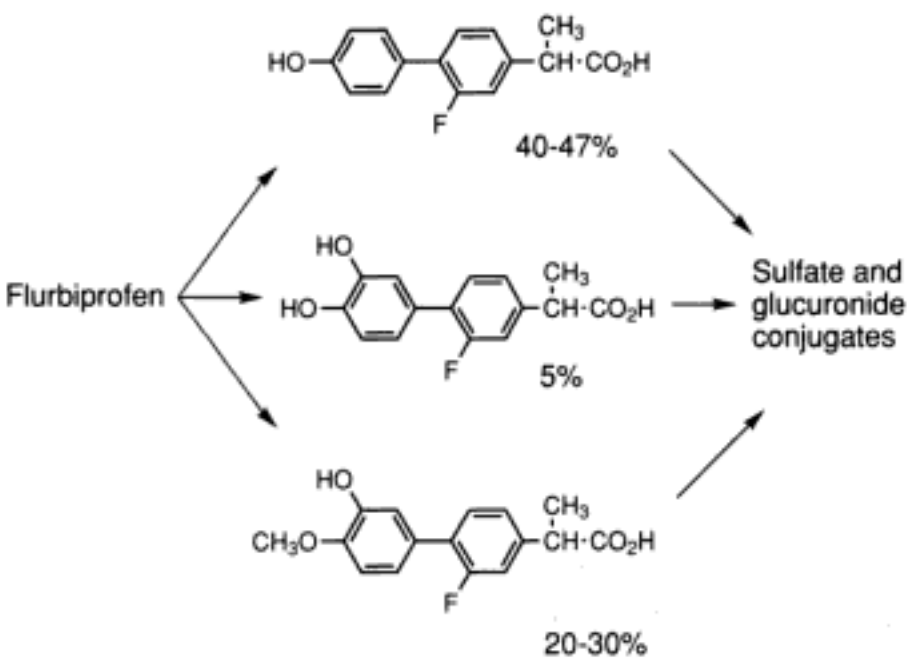

**Fig. 36.18.** Metabolism of flurbiprofen.

short-term use and for the relief of ocular itching caused by seasonal allergic conjunctivitis, although it exhibits anti-inflammatory and antipyretic activity as well. It was initially introduced only in an injectable form, but recently, an oral formulation has been made available. Its analgetic activity resembles that of the centrally acting analgetics, with 15 to 30 mg of ketorolac producing analgesia equivalent to a 12-mg dose of morphine, and it has become a widely accepted alternative to narcotic analgesia. Ketorolac inhibits prostaglandin synthesis. Although the analgetic effect is achieved within 10 minutes of injection, peak analgesia lags behind peak plasma levels by 45 to 90 minutes. The free acid has a $pK_a$ of 3.5, and it is not surprising that it is highly plasma protein bound (>99%). Ketorolac is metabolized by CYP2C9 to its *p*-hydroxy derivative and to conjugates that are excreted primarily in the urine.

***Oxaprozin.*** Oxaprozin (Fig. 36.10) was marketed in 1993 for acute and long-term use in the management of signs and symptoms of osteoarthritis and rheumatoid arthritis. Oxaprozin is synthesized by condensing benzoin with succinic anhydride and cyclizing the resulting benzoin hemisuccinate with ammonium acetate. Although not formally a propionic acid of the α-methylacetic acid type, it appears to be similar to the other propionic acid derivatives considered here. Oxaprozin is well absorbed (100%) following oral administration, but maximum plasma concentrations are not reached until 3 to 5 hours following ingestion. Oxaprozin is an anti-inflammatory agent possessing a rapid onset of action and a prolonged duration of action. In both the carrageenan raw paw edema assay and analgetic tests, it was equipotent with aspirin. Oxaprozin has been associated with the appearance of rash and/or mild photosensitivity. Some patients experience an increased incidence of rash on sun-exposed skin during clinical testing. Oxaprozin, aspirin, ibuprofen, indomethacin, naproxen, and sulindac have comparable efficacy in the treatment of rheumatoid arthritis, whereas oxaprozin, aspirin, naproxen, and piroxicam have comparable efficacy in osteoarthritis. It is highly bound to plasma proteins (99%), is highly lipophilic, and undergoes little first-pass metabolism. Metabolism is via hepatic microsomal oxidation and glucuronidation. Active phenolic metabolites are produced (<5%) but do not appear to contribute significantly to the overall pharmacological activity of oxaprozin.

Oxaprozin possesses a relatively long elimination half-life of 59 hours (range, 26–92 hours), enabling once-daily dosing. Administration with food appears to delay absorption but not bioavailability.

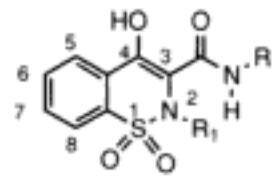
Several properties of the NSAIDs are summarized in Table 36.4.

### N-Arylanthranilic Acids (Fenamic Acids)

The anthranilic acid class of NSAIDs is the result of the application of classical medicinal chemistry bio-isosteric drug design concepts, because these derivatives are nitrogen isosteres of salicylic acid. In the early 1960s, the Parke-Davis research group reported the development of a series of N-substituted anthranilic acids that have since been given the chemical class name of fenamic acids. The fact that this class of compounds possesses little advantage over the salicylates with respect to their anti-inflammatory and analgetic properties has diminished interest in their large-scale development relative to the arylalkanoic acids. Mefenamic acid was introduced in the United States in 1967 as an analgetic, and this remains the primary indication despite the fact that it possesses modest anti-inflammatory activity. Flufenamic acid has been available in Europe as an antirheumatic agent, but there are no apparent plans to introduce this drug in the United States. With regard to anti-inflammatory activity, mefenamic acid is approximately 1.5 times as potent as phenylbutazone and half as potent as flufenamic acid. Meclofenamic acid was introduced in the United States as its sodium salt in 1980, primarily as an antirheumatic agent and analgetic. The structures of these fenamic acids are shown in Figure 36.19.

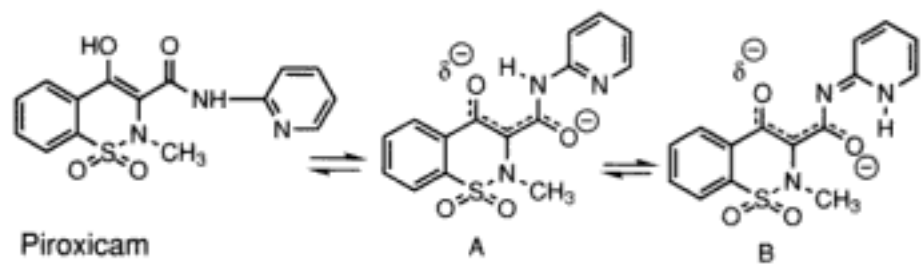
The fenamic acids share a number of pharmacological properties with the other NSAIDs. Because these drugs are potent inhibitors of prostaglandin biosynthesis, it is tempting to speculate that this represents their primary mechanism of action. Scherrer, like Shen, had proposed a hypothetical receptor for NSAIDs and later modified (64) the receptor to represent the active site of arachidonic acid cyclooxygenase. Structurally, the fenamic acids fit the proposed active site of arachidonic acid cyclooxygenase proposed by Shen (12) (Fig. 36.1), because they possess an acidic function connected to an aromatic ring along with an additional lipophilic binding site—in this case, the N-aryl substituent. The greater anti-inflammatory activity of meclofenamic acid compared to that of mefenamic acid correlates well with its ability to inhibit prostaglandin synthesis. Scherrer (65) compared the in vivo anti-inflammatory activities, clinical

Copyrighted material



series of 4-hydroxy-1,2-benzothiazine carboxamides that possess anti-inflammatory and analgetic properties. These structurally distinct substances resulted from extensive studies by the Pfizer group in an effort to produce non-carboxylic acid, potent, and well-tolerated anti-inflammatory drugs. Several series were prepared, including 2-aryl-1,3-indanediones, 2-arylbenzothiophen-3-(2H)-one 1,1-dioxides, dioxoquinoline-4-carboxamides, and 3-oxa-2H-1,2-benzothiazine-4-carboxamide 1,1-dioxides, and evaluated. These results, combined with the previously known activity of 1,3-dicarbonyl derivatives, such as phenylbutazone, led to the development of the oxicams. The first member of this class, piroxicam, was introduced in the United States in 1982 as Feldene and gained immediate acceptance.

Piroxicam is potent in standard in vivo assays, being 200 times more potent than aspirin and at least 10 times as potent as any other standard agent in the ultraviolet erythema assay, as potent as indomethacin and more potent than phenylbutazone or naproxen in the carrageenan-induced rat paw edema assay, and equipotent with indomethacin and 15 times more potent than phenylbutazone in the rat adjuvant arthritis assay. It is less potent than indomethacin, equipotent with aspirin, and more potent than fenoprofen, ibuprofen, naproxen, and phenylbutazone as an analgetic in the phenylquinone writhing assay. Piroxicam inhibits the migration of polymorphonuclear cells into inflammatory sites and inhibits the release of lysosomal enzymes from these cells. It also inhibits collagen-induced platelet aggregation. It is an effective inhibitor of arachidonic acid cyclooxygenase, being almost equipotent with indomethacin and more potent than ibuprofen, tolmetin, naproxen, fenoprofen, phenylbutazone, and aspirin in the inhibition of prostaglandin biosynthesis by methylcholanthrene-transformed mouse fibroblasts (MC-5) assay. A template for designing anti-inflammatory compounds based on CPK space-filling models of the peroxy radical precursor of PGG and inhibitors of cyclooxygenase was proposed (67), and the ability of oxicams, particularly piroxicam, to inhibit this enzyme was subsequently rationalized on the ability of oxicams to assume a conformation resembling that of the peroxy radical precursor (68).



Approximately 20% of individuals on piroxicam report adverse reactions. Not unexpectedly, the greatest incidence of side effects result from GI disturbances. The reported incidence of peptic ulcers, however, is less than 1%.

As will be discussed later, a new oxicam derivative, meloxicam, has been approved as a selective COX-2 inhibitor for the treatment of osteoarthritis.

**General structure–activity relationships.** Within the series of 4-hydroxy-1,2-benzothiazine carboxamides represented by the general structure shown below, optimum

activity was observed when $R_1$ was a methyl substituent. The carboxamide substituent, R, generally is an aryl or heteroaryl substituent, because alkyl substituents are less active. Oxicams are acidic compounds, with $pK_a$ values in the range of four to six. N-heterocyclic carboxamides generally are more acidic than the corresponding N-aryl carboxamides, and this enhanced acidity was attributed (69) to stabilization of the enolate anion by the pyridine nitrogen atom, as illustrated in tautomer A and additional stabilization by tautomer B:

This explains the observation that primary carboxamides are more potent than the corresponding secondary derivatives, because no N-H bond would be available to enhance the stabilization of the enolate anion. When the aryl group is *o*-substituted, variable results were obtained, whereas *m*-substituted derivatives generally are more potent than the corresponding *p*-isomers. In the aryl series, maximum activity is observed with a *m*-Cl substituent. No direct correlations were observed between acidity and activity, partition coefficient, and electronic or spatial properties in this series. Two major differences, however, are observed when R = heteroaryl rather than aryl: The $pK_a$ values generally are two to four units lower, and anti-inflammatory activity increased as much as sevenfold. The greatest activity is associated with the 2-pyridyl (as in piroxicam), 2-thiazolyl, or 3-(5-methyl) isoxazolyl ring systems, with the latter derivative (isoxicam) having been withdrawn from the European market in 1985 following several reports of severe skin reactions. In addition to possessing activity equal to or greater than indomethacin in the carrageenan-induced rat paw edema assay, the heteroaryl carboxamides also possess longer plasma half-lives, providing an improvement in dosing scheduling regimens.

**General metabolism.** Although the metabolism of piroxicam varies quantitatively from species to species, qualitative similarities are found in the metabolic pathways of humans, rats, dogs, and rhesus monkeys. It is extensively metabolized in humans, with less than 5% of an administered dose being excreted unchanged. The major metabolites in humans result from CYP2C9 hydroxylation of the pyridine ring and subsequent glucuronidation; other metabolites are of lesser importance

Copyrighted material

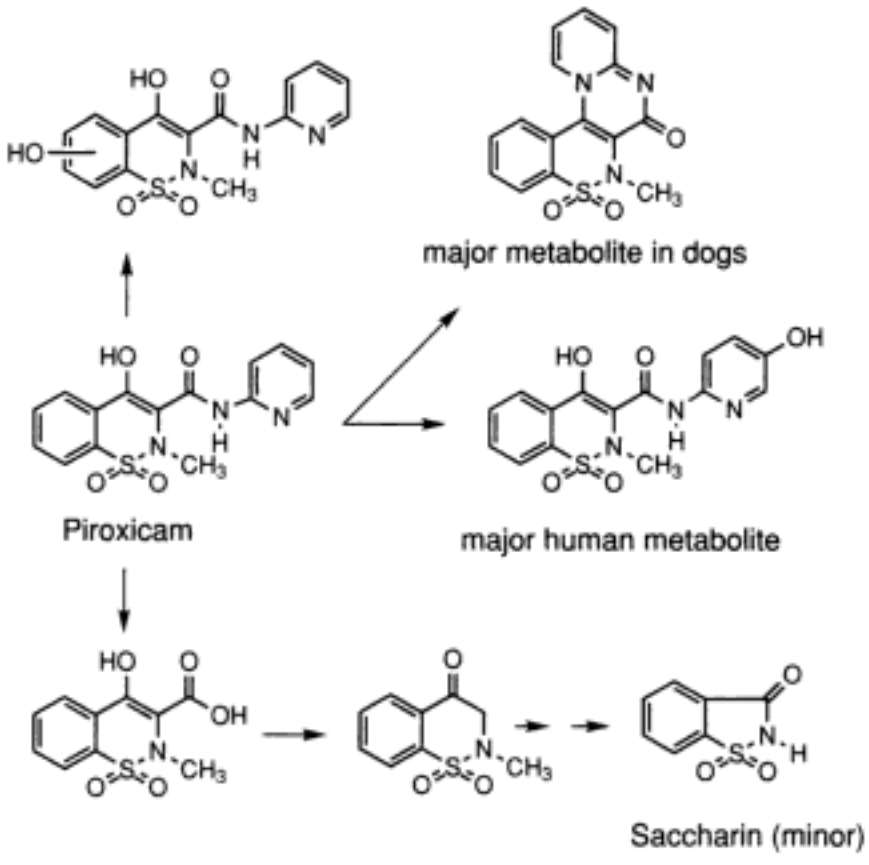


**Fig. 36.22.** Metabolism of piroxicam.

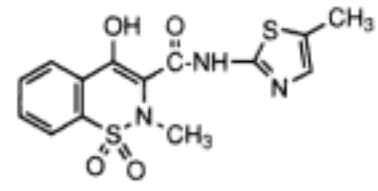


(Fig. 36.22). Aromatic hydroxylation at several positions of the aromatic benzothiazine ring also occurs; two hydroxylated metabolites have been extracted from rat urine. On the basis of NMR deuterium-exchange studies, hydroxylation at the 8-position was ruled out, indicating that hydroxylation occurs at two of the remaining positions. Other novel metabolic reactions occur. Cyclodehydration gave a tetracyclic metabolite (the major metabolite in dogs), whereas ring contraction following amide hydrolysis and decarboxylation eventually yields saccharin. All the known metabolites of piroxicam lack anti-inflammatory activity. For example, the major human metabolite is 1,000-fold less effective as an inhibitor of prostaglandin biosynthesis than piroxicam itself. Related oxicams undergo different routes of metabolism. For example, sudoxicam (the N-2-thiazolyl analogue) undergoes primarily hydroxylation of the thiazole ring, followed by ring-opening, whereas isoxicam undergoes primarily cleavage reactions of the benzothiazine ring.

**Drug interactions.** Few reports of therapeutically significant interactions of oxicams with other drugs have appeared. Concurrent administration of aspirin has been shown to reduce piroxicam plasma levels by approximately 20%, whereas the anticoagulant effect of acenocoumarin is potentiated, presumably as a result of plasma protein displacement.

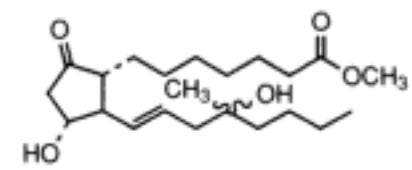
### *Specific Drugs*

***Piroxicam.*** Prixoicam is synthesized by ring-expansion reactions of saccharin derivatives (70). Piroxicam is readily absorbed on oral administration, reaching peak plasma levels in approximately 2 hours. Peak plasma levels appear to be lower when given with food at low doses (30 mg), with no differences appearing with a 60-mg dose, but in general, food does not markedly affect bioavailability. Being acidic ($pK_a$ = 6.3), it is highly bound to plasma proteins (99%). Piroxicam possesses an extended plasma half-life (38 hours), making single daily dosing possible. Piroxicam is indicated for long-term use in rheumatoid arthritis and osteoarthritis.

***Meloxicam.*** In April 2000, the U.S. FDA approved meloxicam for the treatment of osteoarthritis. When meloxicam was initially introduced in the United Kingdom, it was promoted as a selective COX-2 inhibitor. Meloxicam, however, is less selective than celecoxib and much less selective than rofecoxib in in vitro studies (see *Selective COX-2 Inhibitors*). Meloxicam is readily absorbed when administered orally and is highly bound to plasma proteins. Meloxicam is extensively metabolized in the liver, primarily by CYP2C9 and, to a lesser extent, by CYP3A4. The advantages of meloxicam over celecoxib and rofecoxib in the treatment of osteoarthritis (or rheumatoid arthritis) are not readily apparent.

Meloxicam

### Gastroenteropathy Induced By Nonselective COX NSAIDs

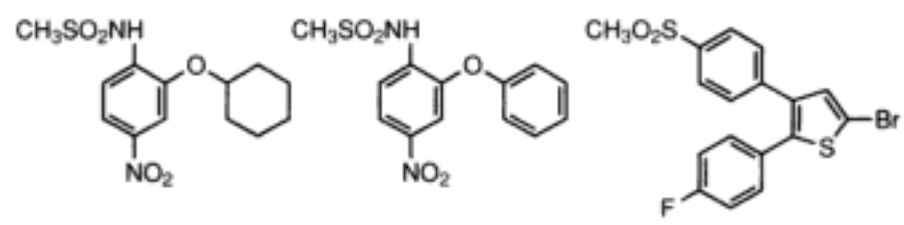


The effectiveness and popularity of the NSAIDs in the United States and Europe make this class one of the most commonly used classes of therapeutic entities. More than 75 million prescriptions are written annually for the NSAIDs, including aspirin. Unfortunately, until the introduction of the selective COX-2 inhibitors, almost all of the current drugs, which are nonselective COX-1 and COX-2 inhibitors, share the undesirable property of producing damaging effects to gastric and intestinal mucosa, resulting in erosion, ulcers, and GI bleeding, and these represent the major adverse reactions to the use of NSAIDs. As many as 20,000 deaths and 100,000 hospitalizations per year have been associated with GI complications resulting from the use of NSAIDs. Approximately 30 to 40% of patients taking NSAIDs report some type of gastric injury, and approximately 10% discontinue therapy because of these effects. These acute and chronic injuries to gastric mucosa result in a variety of lesions referred to as NSAID gastropathy, which differs from peptic ulcer disease by their localization more frequently in the stomach rather than in the duodenum. Additionally, NSAID-induced lesions occur more frequently in the elderly than typical peptic ulcers do. Normally, the stomach protects itself from the harmful effects of hydrochloric acid and pepsin by a number of protective mechanisms referred to as the gastric mucosal barrier, which consists of epithelial cells, the

Copyrighted material

mucous and bicarbonate layer, and mucosal blood flow. Gastric mucosa actually is a gel consisting of polymers of glycoprotein, which limit the diffusion of hydrogen ions. These polymers reduce the rate at which hydrogen ions (produced in the lumen) and bicarbonate ion (secreted by the mucosa) mix; thus, a pH gradient is created across the mucus layer. Normally, gastric mucosal cells are rapidly repaired when they are damaged by factors such as food, ethanol, or acute ingestion of NSAIDs. Among the cytoprotective mechanisms is the ability of prostaglandins of the PGE series, particularly $PGE_1$, to increase the secretion of bicarbonate ion and mucus and to maintain mucosal blood flow. The prostaglandins also decrease acid secretion, permitting the gastric mucosal barrier to remain intact.

As mentioned earlier, Figure 36.7 illustrates the ability of aspirin and NSAIDs to induce gastric damage by a dual-insult mechanism. Aspirin and the NSAIDs are acidic substances that can damage the GI tract, even in the absence of hydrochloric acid, by changing the permeability of cell membranes, allowing a back diffusion of hydrogen ions. These weak acids remain un-ionized in the stomach, but the resulting lipophilic nature of these substances allows accumulation or concentration in gastric mucosal cells. Once inside these cells, however, the higher pH of the intracellular environment causes the acids to dissociate and become "trapped" within the cells. The permeability of the mucosal cell membrane is thus altered, and the accumulation of hydrogen ions causes mucosal cell damage. This gastric damage is a result, therefore, of the primary insult of acidic substances. As detailed earlier in this chapter, the primary mechanism of action of the NSAIDs is to inhibit the biosynthesis of prostaglandins at the cyclooxygenase step. The resulting nonselective inhibition of prostaglandin biosynthesis in the GI tract prevents the prostaglandins from exerting their protective mechanism on gastric mucosa; thus, the NSAIDs induce gastric damage through this secondary insult mechanism.



The use of $PGE_1$ to reduce NSAID-induced gastric damage is limited by the fact that it is ineffective orally and degrades rapidly on parenteral administration, primarily by oxidation of the 15-hydroxy group. To overcome these limitations, misoprostol was synthesized as a prostaglandin pro-drug analogue in which oral activity was achieved by administering the drug as the methyl ester, allowing the bioactive acid to be liberated after absorption. Oxidation of the 15-hydroxy group was overcome by moving the hydroxy group to the 16-position, thus "fooling" the enzyme prostaglandin 15-OH dehydrogenase. Oxidation was further limited by the introduction of a methyl group at the 16-position, producing a tertiary alcohol that is more difficult to oxidize than the secondary alcohol group of the prostaglandins. Misoprostol was introduced in 1989 as a mixture of stereoisomers at the 16-position as Cytotec for the prevention of NSAID-induced gastric ulcers (but not duodenal ulcers) in patients at high risk of complications from a gastric ulcer, particularly the elderly and patients with concomitant debilitating disease and in individuals with a history of gastric ulcers.

Misoprostol

### Selective COX-2 Inhibitors

As previously discussed, the most notable achievement in the development of NSAIDs has been in the area of selective COX-2 inhibitors (coxibs). Classical NSAIDs share similar side effect profiles, particularly on the GI tract, many of which have been attributed to the inhibition of cyclooxygenase, the rate-limiting step in prostaglandin biosynthesis. With the discovery of two isoforms of cyclooxygenase, COX-1 and COX-2, and the realization that COX-1 is beneficial in maintaining normal processes in the GI tract by producing cytoprotective prostaglandins, stimulating bicarbonate secretion and mucus and producing an overall reduction in acid secretion, the search for drugs that selectively inhibit the COX-2 isoform has received much attention. The traditional NSAIDs inhibit COX-1, COX-2, and thromboxane synthetase to varying degrees of selectivity. Decreased gastric mucosal protection (resulting in an enhanced risk of ulceration) and stress-induced decreased renal perfusion result from nonselective inhibition of COX, whereas inhibition of thromboxane synthesis results in increased prostaglandin synthesis and a reduction in platelet aggregation and, thus, an increased bleeding tendency. Those NSAIDs with a greater selectivity for COX-1 generally cause greater GI bleeding and renal toxicity than those with greater selectivity for COX-2.

NS-398 Nimesulide DuP 697

These early studies led to extensive efforts by many laboratories to develop selective inhibitors of the COX-2 isoform with the goal of developing an "ideal" NSAID—that is, one that selectively inhibits COX-2, thus reducing the inflammatory response but not interfering with the GI-protective functions of COX-1. Two early lead compounds were developed, NS-398 and DuP 697, which have served as the basis of the development of two widely explored chemical classes. NS-398 and nimesulide are the prototypes of compounds known as "sulides,"

Copyrighted material

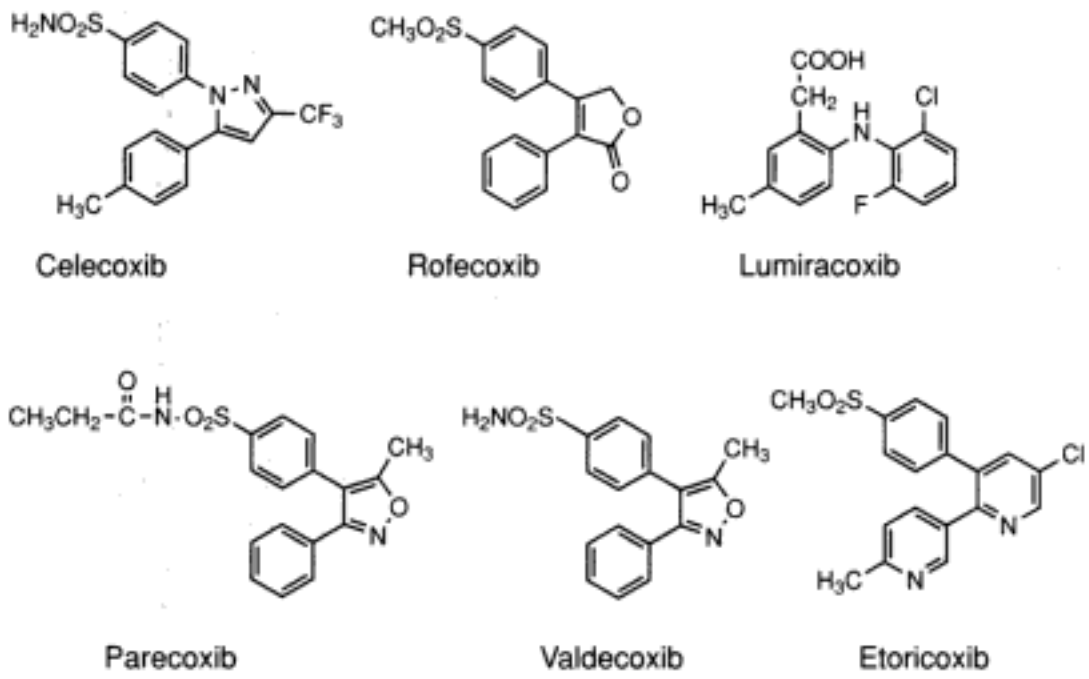


**Fig. 36.23.** Structures of selective COX-2 inhibitors.

whereas DuP 697 is the prototype of a class of COX-2 inhibitors termed "coxibs." These efforts led to the introduction of three selective COX-2 inhibitors in the U.S. market (celecoxib, rofecoxib, and valdecoxib), whereas other selective inhibitors under investigation may have been halted (Fig. 36.23). An excellent review of the various chemical classes of selective COX-2 inhibitors has been published (71). Selective COX-2 inhibitors were designed to take advantage of the much larger NSAID binding site on COX-2 compared to the NSAID binding site on COX-1, resulting from the substitution of the smaller amino acid valine in COX-2 for isoleucine at position 523 in COX-2 (see earlier discussion). In COX-1, the larger isoleucine residue near the active site restricts access by larger, relatively rigid side-chain substituents, such as sulfamoyl or sulfonyl side chains usually seen in the selective COX-2 inhibitors.

A comparison of the selectivity of several NSAIDs and selective COX-2 inhibitors was recently presented (Fig. 36.24) (72). In another study regarding the pharmacological and biochemical profile of a new investigational selective COX-2 inhibitor, etoricoxib, the following comparison of COX-1/COX-2 selectivity for several selective and nonselective inhibitors in human whole blood assays was reported (Table 36.5) (73).

The U.S. FDA classifies only celecoxib, rofecoxib, and valdecoxib as selective COX-2 inhibitors. It classifies all other NSAIDs as nonselective.

Perhaps as interesting as the role that COX-2 selective inhibitors play in reducing the incidence of GI side effects among NSAIDs are the reports of other potential therapeutic uses for this new class of drugs, including potential use in the treatment of Alzheimer's disease and carcinomas of various types. The COX-2 appears to be induced in inflammatory plaques that are evident in the CNS in Alzheimer's disease. Several reports have appeared indicating that patients taking NSAIDs have a lower incidence and a decreased rate of progression of Alzheimer's disease. Epidemiological studies suggest a significant reduction in the risk for colon cancer in patients regularly taking aspirin. Additionally, NSAIDs have been reported to reduce the growth rate of polyps in the colon in humans as well as the incidence of tumors of the colon in animals. The expression of COX-2 appears to be significantly up-regulated in carcinoma of the colon. The effectiveness of NSAIDs in the prevention and treatment of other cancers, such as prostate cancer and mammary carcinoma, has been reported as well.

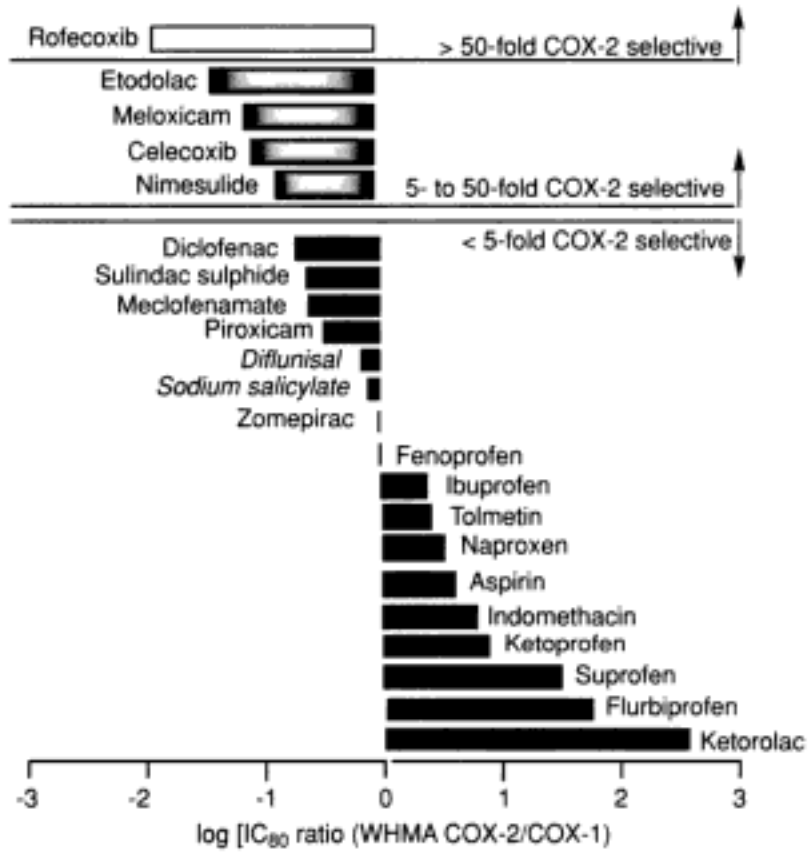

**Fig. 36.24.** Selectivity of COX-2 inhibitors and NSAIDs given as log inhibitory concentration (IC80) ratio. The "0" line indicates equipotency. (Adapted from Warner TD, Giuliano F, Vojnovic I, et al. Nonsteroid drug selectivities for cyclooxygenase-1 rather than cyclooxygenase-2 are associated with human gastrointestinal toxicity: a full in vitro analysis. Proc Natl Acad Sci U S A 1999; 96:7563–7568; with permission.)

Copyrighted material

dysmenorrhea. Rofecoxib, diclofenac, and ibuprofen possess comparable efficacy in the treatment of osteoarthritis, but serious adverse effects on the GI tract are not observed with rofecoxib. In the treatment of pain, a single 50-mg dose of rofecoxib, a single 550-mg dose of naproxen sodium, and a single 400-mg dose of ibuprofen possess similar onsets of action. Rofecoxib, naproxen sodium, and ibuprofen displayed similar effectiveness in the treatment of postoperative dental pain. A 50-mg dose of rofecoxib was as effective as a 550-mg dose of naproxen sodium in the relief of primary dysmenorrhea in adults. Like celecoxib, rofecoxib does not affect platelet aggregation or bleeding and should not be used as a substitute for aspirin in the prevention of cardiovascular events. A more detailed discussion of the chemical, pharmacological, pharmacokinetic, and clinical aspects of rofecoxib is available (83).

Rofecoxib is approved for the relief of the signs and symptoms of osteoarthritis and the treatment of primary dysmenorrheal.

***Valdecoxib (Bextra).*** Valdecoxib is freely soluble in alkaline aqueous solutions. At recommended doses, the mean oral bioavailability for valdecoxib is 83%, and the time to peak concentration is approximately 3 hours. Time to peak plasma concentration was delayed by 1 to 2 hours when administered with a high-fat meal. Protein binding is very high at 98%. Valdecoxib exhibits linear pharmacokinetics over the usual clinical dose range. Valdecoxib is extensively metabolized in humans. The primary metabolite for valdecoxib involved CYP2C9 hydroxylation of the 5-Me group, which was further metabolized to the inactive carboxylate, and N-hydroxylation at the sulfonamide moiety. Oxidative breakdown of the N-hydroxy sulfonamide function group led to the formation of the corresponding sulfinic acid and sulfonic acid metabolites. The O-and N-glucuronides were the major urinary metabolites. Only 3% of the administered dose was recovered in urine as unchanged valdecoxib. Its elimination half-life is 8 to 11 hours. Approximately 70% of a valdecoxib dose is eliminated in the urine as metabolites, and less than 5% is excreted in the feces and urine unchanged.

Valdecoxib is approved for the relief of the signs and symptoms of osteoarthritis and adult rheumatoid arthritis and for the treatment of primary dysmenorrhea. Valdecoxib is contraindicated for the treatment of postoperative pain immediately following coronary artery bypass graft surgery.

> Valdecoxib (Bextra) was voluntarily withdrawn from the U.S. market on April 7, 2005, because of safety concerns regarding increased risk of cardiovascular events and reports of serious and potentially life-threatening skin reactions, including deaths, in patients taking valdecoxib.

Precautions to consider for valdecoxib are that it may cause bronchoconstriction or anaphylaxis in aspirin-sensitive patients with asthma, who have experienced severe bronchospasm after taking aspirin or other NSAIDs.

***Parecoxib (Parecoxib Sodium, Dynstat).*** As shown in Figure 36.23, parecoxib is a pro-drug of valdecoxib administered IM or IV for perioperative analgesic and anti-inflammatory use. As a pro-drug, it undergoes rapid in vivo hydrolysis to valdecoxib. It is the only parenterally administered coxib. Parecoxib at greater than 20 mg has analgesic activity superior to that of placebo and similar to that of parenteral 30 or 60 mg of ketorolac in patients with postoperative dental pain. A significant adverse effect is drug hypersensitivity. Parecoxib is currently marketed worldwide but has not been approved for use in the United States.

***Etoricoxib (Arcoxia).*** Etoricoxib (Fig. 36.23) is a selective COX-2 inhibitor being developed for postsurgical treatment of dental pain (120 mg) and osteoarthritis. It has a methylsulfonyl group common to the other coxib inhibitors. Etoricoxib is rapidly absorbed, with an oral bioavailability of 80 to 100%, and reaches maximum plasma concentrations in 1 to 2 hours after dosing. Food decreases the rate of absorption but has no effect on the extent of absorption. It exhibits a long elimination half-life of approximately 22 hours, demonstrating linear plasma pharmacokinetics with no accumulation during multiple dosing. Etoricoxib is metabolized involving oxidation of its 6′-methyl group primarily by CYP3A4 but is not an inhibitor of CYP3A4. Other metabolites include 1′-N-oxide and glucuronides. Etoricoxib is primarily excreted as metabolites into the urine.

***Lumiracoxib (Prexige).*** Lumiracoxib (Fig. 36.23) is a selective COX-2 inhibitor developed for the treatment of osteoarthritis, rheumatoid arthritis, and acute pain. It structurally differs from the other selective COX-2 inhibitors in being a phenylacetic acid with a carboxylic acid group ($pK_a = 4.7$). Lumiracoxib is rapidly absorbed, with an oral bioavailability of 74%, and reaches a maximum plasma concentration 2 hour after dosing. It is highly plasma protein bound and has a short elimination half-life of approximately 4 hours, demonstrating linear plasma pharmacokinetics with no accumulation during multiple dosing. Lumiracoxib is extensively metabolized involving oxidation of its 5-Me group and 4′-hydroxylation of the dihalogenated aromatic ring. The major in vitro oxidative pathways is catalyzed primarily by CYP2C9. Lumiracoxib and its metabolites are excreted via renal and fecal routes in approximately equal amounts. The COX-2 selectivity was confirmed by a lack of inhibition of arachidonic acid and collagen-induced platelet aggregation. As with other selective coxibs, lumiracoxib exhibits a reduced incidence of gastroduodenal erosions compared with that of naproxen. It was approved for use in the United Kingdom and the United States in 2007.

Copyrighted material

aggregation of macroglobulins and, in turn, inhibit the formation of immune complexes may account for their ability to slow connective tissue degradation. Interaction with collagen fibrils and, thus, reduction of collagen reactivity that alters the course of the arthritic process also have been postulated. Perhaps the most widely accepted mechanism of action is related to the ability of gold compounds to inhibit lysosomal enzymes, the release of which promotes the inflammatory response. The lysosomal enzymes glucuronidase, acid phosphatase, collagenase, and acid hydrolases are inhibited, presumably through a reversible interaction of gold with sulfhydryl groups on the enzymes. Gold thiomalate inhibits glucosamine-6-phosphate synthetase, a rate-limiting step in mucopolysaccharide biosynthesis and a property shared, to a lesser extent, by several NSAIDs. Gold sodium thiosulfate is a potent uncoupler of oxidative phosphorylation. Gold sodium thiomalate also is a fairly effective inhibitor of prostaglandin biosynthesis in vitro, but the relationship of this effect to the antiarthritic actions of gold compounds has not been clarified.

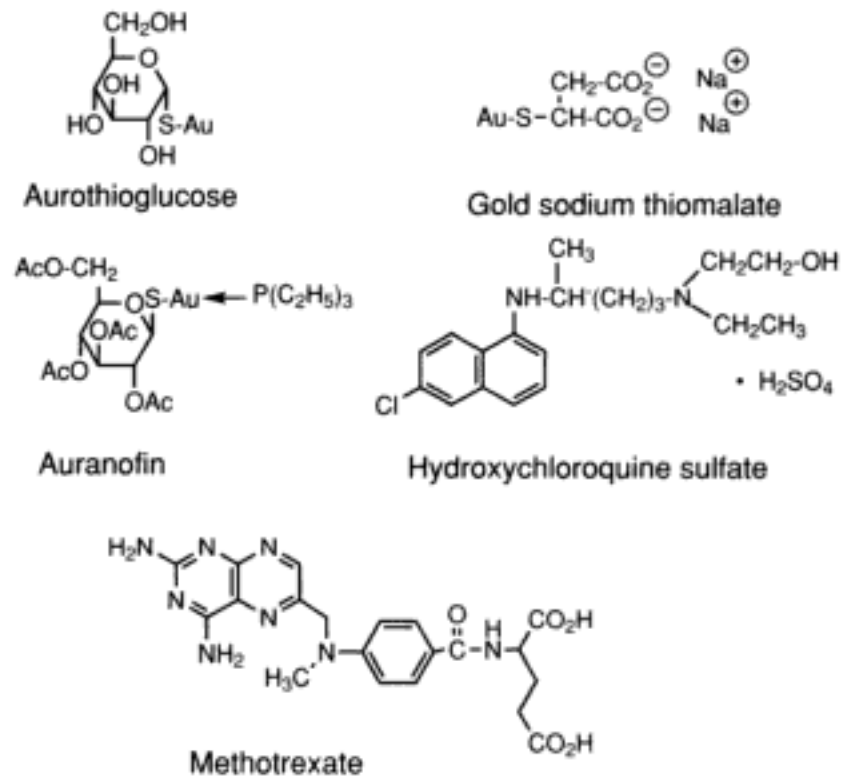

**Fig. 36.27.** Structures of disease-modifying antirheumatic drugs (DMARDs).

***Side Effects.*** Toxic side effects have been associated with the use of gold compounds, with the incidence of reported adverse reactions in patients on chrysotherapy being as high as 55%. Serious toxicity occurs in 5 to 10% of reported cases. The most common adverse reactions include dermatitis (e.g., erythema, papular, vesicular, and exfoliative dermatitis), mouth lesions (e.g., stomatitis preceded by a metallic taste and gingivitis), pulmonary disorders (e.g., interstitial pneumonitis), nephritis (e.g., albuminuria and glomerulitis), and hematologic disorders (e.g., thrombocytopenic purpura, hypoplastic and/or aplastic anemia, and eosinophilia; blood dyscrasias are rare in incidence but can be severe). Less commonly reported reactions are GI disturbances (e.g., nausea, anorexia, and diarrhea), ocular toxicity (e.g., keratitis with inflammation and ulceration of the cornea and subepithelial deposition of gold in the cornea), and hepatitis. In those cases in which severe toxicity occurs, excretion of gold can be markedly enhanced by the administration of chelating agents, the two most common of which are dimercaprol (British Anti-Lewisite [BAL]) and penicillamine. Corticoids also suppress the symptoms of gold toxicity and the concomitant administration of dimercaprol, and corticosteroids have been recommended in cases of severe gold intoxication.

***General Structure–Activity Relationships.*** Structure–activity relationships of gold compounds have not received a great amount of attention. Two important relationships, however, have been established: 1) Monovalent gold (aurous ion [$Au^+$]) is more effective than trivalent gold (auric ion [$Au^{3+}$]) or colloidal gold, and 2) only those compounds in which aurous ion is attached to a sulfur-containing ligand are active (Fig. 36.27). The nature of the ligands affects tissue distribution and excretion properties and, usually, are highly polar, water-soluble functions. Aurous ion has only a brief existence in solution and is rapidly converted to metallic gold or auric ion. Aqueous solutions decompose on standing at room temperature, posing a stability problem for the two injectable gold compounds therapeutically available (aurothioglucose and gold sodium thiomalate). Complexation of $Au^+$ with phosphine ligands stabilizes the reduced valence state and results in both nonionic complexes that are soluble in organic solvents and an enhancement of oral bioavailability. Other changes also occur. In the phosphine-Au-S compounds, gold has a coordination number of 2, and the molecules are nonconducting monomers in solution. The injectable gold compounds are monocoordinated. Whereas nongold phosphine compounds are ineffective in arthritic assays, the nature of the phosphine ligand in the gold coordination complexes appears to play a greater role in antiarthritic activity than the other groups bound to gold. Within a homologous series, the triethylphosphine gold derivatives provide greatest activity.

The structures of the three therapeutically available gold compounds in the United States are shown in Figure 36.27.

***Absorption and Metabolism.*** Gold compounds generally are rapidly absorbed following IM injection, and the gold is widely distributed in body tissues, with the highest concentrations found in the reticuloendothelial system and in adrenal and renal cortices. Binding of gold from orally administered gold to red blood cells is higher than that of injectable gold. Gold accumulates in inflamed joints, where high levels persist for at least 20 days following injection. Although gold is excreted primarily in the urine, the bulk of injected gold is retained. Gold can be found in the urine months later.

***Drug Interactions.*** The only significant drug interactions reported are the concurrent administration of drugs that

Copyrighted material

also produce blood dyscrasias (most notably phenylbutazone and the antimalarial and immunosuppressive drugs).

### *Specific Drugs*

***Gold Sodium Thiomalate.*** Gold sodium thiomalate (actually a mixture of mono- and disodium salts of gold thiomalic acid) is very water soluble. It is available as a light-sensitive, aqueous solution of pH 5.8 to 6.5. The gold content is approximately 50%. It is administered IM, because it is not absorbed on oral administration and is highly bound (95%) to plasma proteins.

Gold sodium thiomalate is indicated in the treatment of active adult and juvenile rheumatoid arthritis as one part of a complete therapy program. It is recommended that injections be given to patients only when they are in a supine position. They must remain so for 10 minutes following injection.

***Aurothioglucose.*** Aurothioglucose is highly water soluble, and its aqueous solutions decompose on long standing. It therefore is available as a suspension in sesame oil. Gold content is approximately 50%. Following IM injection, it is highly protein bound (95%), and peak plasma levels are achieved within 2 to 6 hours. Following a single 50-mg dose, the biological half-life ranges from 3 to 27 days, but following successive weekly doses, the half-life increases to 14 to 40 days after the third dose. The therapeutic effect does not correlate with serum plasma gold levels but appears to depend on total accumulated gold. Aurothioglucose is indicated for the adjunctive treatment of adult and juvenile rheumatoid arthritis.

***Auranofin.*** Auranofin contains approximately 29% gold. The carbohydrate portion assumes a chair conformation, with all substituents occupying the equatorial position. It is the first orally effective gold compound used to treat rheumatoid arthritis. On a mg gold/kg basis, it is reported to be as effective in the rat adjuvant arthritis assay as the parenterally effective drugs. Daily oral doses produce a rapid increase in kidney and blood gold levels for the first 3 days of treatment, with a more gradual increase on subsequent administration. Plasma gold levels are lower than those attained with parenteral gold compounds. The major route of excretion is via the urine. Auranofin may produce fewer adverse reactions than parenteral gold compounds, but its therapeutic efficacy also may be less.

Auranofin is indicated in adults with active rheumatoid arthritis who have not responded sufficiently to one or more NSAIDs.

### Aminoquinolines

**BACKGROUND.** The 4-aminoquinoline class of antimalarial drugs has been known to possess pharmacological actions that are beneficial in the treatment of rheumatoid arthritis. Two of these drugs, chloroquine and hydroxychloroquine (Fig. 36.27), have been used as antirheumatics since the early 1950s. The corneal and renal toxicity of chloroquine, however, has resulted in its discontinuance for this purpose, although it is still indicated as an antimalarial agent and an amebicide. Whereas hydroxychloroquine is less toxic, it also is less effective than chloroquine as an antirheumatic. The mechanism of action of these drugs as an antirheumatic remains unresolved. Interestingly, most of the data available relates to chloroquine rather than hydroxychloroquine but is assumed to be applicable to the latter. The spectrum of action of the 4-aminoquinolines differs from the NSAIDs in that chloroquine appears to be an antagonist of certain preformed prostaglandins. This effect, however, would indicate an acute, rather than a chronic, antirheumatic effect, whereas chloroquine has been shown to be similar to gold compounds in that it possesses a slow onset of action. Beneficial effects are noted only after 1 to 2 months of administration. Chloroquine inhibits chemotaxis of polymorphonuclear leukocytes in vitro but not in vivo. Its effects on collagen metabolism in connective tissue also are unclear. The most widely accepted mechanism of action of chloroquine and, presumably, of hydroxychloroquine is related to its ability to accumulate in lysosomes. Although evidence indicating stabilization of lysosomal membranes is not convincing, it may inhibit the activity of certain lysosomal enzymes, such as cartilage chondromucoprotease and cartilage cathepsin B. There does not appear to be a correlation of the antirheumatic effects of the 4-aminoquinolines with their antimalarial activity.

**HYDROXYCHLOROQUINE SULFATE.** Hydroxychloroquine sulfate is highly water soluble and exists in two different forms of different melting points. It is readily absorbed on oral administration, reaching peak plasma levels within 1 to 3 hours. It concentrates in organs such as the liver, spleen, kidneys, heart, lung, and brain, thereby prolonging elimination. Hydroxychloroquine is metabolized by N-dealkylation of the tertiary amines, followed by oxidative deamination of the resulting primary amine to the carboxylic acid derivative. In addition to possessing corneal and renal toxicity, hydroxychloroquine also may cause CNS, neuromuscular, GI, and hematological side effects. Hydroxychloroquine sulfate is indicated for the treatment of rheumatoid arthritis, lupus erythematosus, and malaria.

**IMMUNOSUPPRESSANTS.** The discovery of drugs that modify the immune response, whether as immunoregulatory, immunostimulatory, or immunosuppressive agents, has been the focus of much recent research activity. Several substances that suppress the immune system have been explored as antirheumatic drugs, because the etiology of rheumatoid arthritis may involve a destructive immune response (3,4). Thus, unlike drugs previously discussed, immunosuppressive drugs may act at the steps involved in the pathogenesis of the inflammatory disorders. As a group, however, these drugs are cytotoxic, as evidenced

Copyrighted material

by the initial development of these drugs as anticancer agents. Among the more widely employed immunosuppressants are azathioprine, methotrexate, leflunomide, and cyclophosphamide. All of these drugs are quite toxic and, generally, are indicated for rheumatoid arthritis only in those patients with severe, active disease who have not responded to full-dose NSAID therapy and at least one DMARD and a corticosteroid. Interestingly, although aspirin and NSAIDs are effective in only one-third of children with juvenile arthritis, methotrexate, when given only once a week at low doses (<20 mg) to minimize side effects, is effective. Cyclosporine (Sandimmune) has been investigated in rheumatoid arthritis and appears to offer short-term benefits, although its toxic effects also limit its long-term use. Cyclosporine appears to inhibit the proliferation of T-helper/inducer lymphocytes, blocking the signaling pathway involved in the etiology of rheumatoid arthritis. The immunosupressants can have potentially serious side effects, such as increased susceptibility to infection.

### *Specific Drugs*

***Leflunomide.*** Leflunomide is a DMARD with anti-inflammatory and immunosuppressive activity used for the management of rheumatoid arthritis. It retards structural damage associated with arthritis in adults who have moderate to severe active rheumatoid arthritis. Leflunomide also is being investigated for use in patients with solid tumors and organ transplant recipients.

Leflunomide is a pro-drug that is rapidly and almost completely metabolized (half-life, <60 minutes) following oral administration to teriflunomide, the pharmacologically active α-cyanoenol metabolite (Fig. 36.28). The $C_5$-H of the isoxazole ring is essential for the ring opening to its active metabolite. The reaction is similar to CYP1A2-catalyzed dehydration of aldoximes. The exact mechanism of action of leflunomide in the management of rheumatoid arthritis has not been fully elucidated but appears to principally involve inhibition of B-lymphocyte (B-cell) proliferation, reducing antibody formation. Activated lymphocytes must proliferate and synthesize large quantities of cytokines, requiring increased de novo synthesis of uridine monophosphate (UMP) and other pyrimidine nucleotides for its cell life cycle. Therefore, any substance that reduces the intracellular concentration of pyrimidine nucleotides will affect the growth of these activated cells.

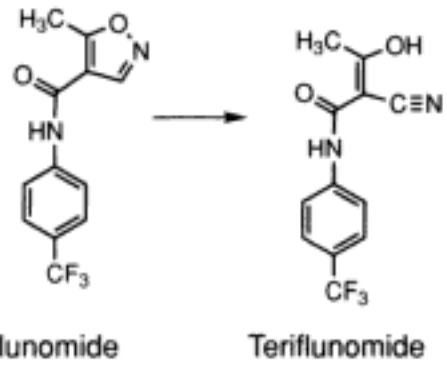

**Fig. 36.28.** Metabolism of leflunomide.

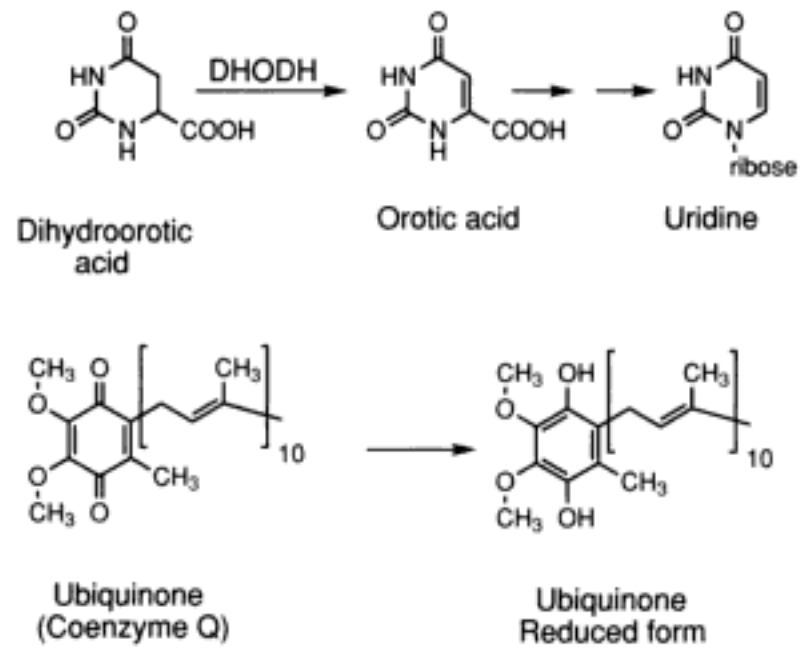

**Fig. 36.29.** Dihydroorotate dehydrogenase (DHOH) pathway with cofactor, coenzyme Q.

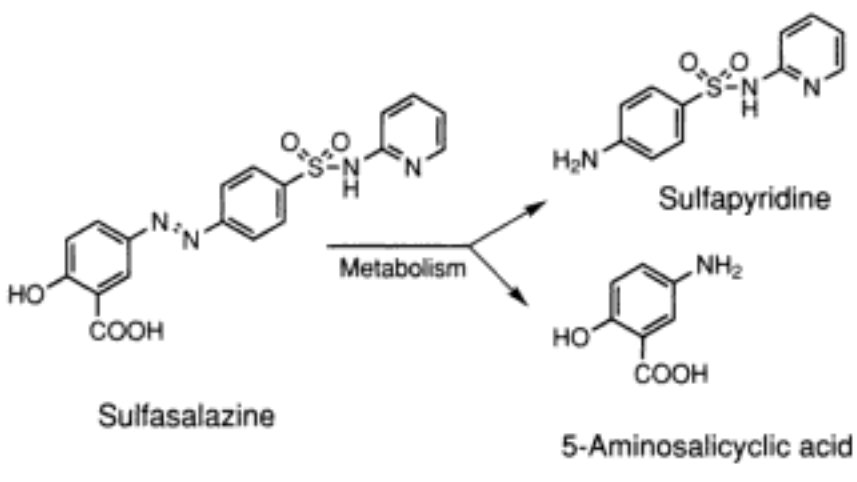
Leflunomide is inactive, but teriflunomide inhibits pyrimidine de novo synthesis at low therapeutic doses by inhibiting dihydroorotate dehydrogenase (the rate-determining enzyme for the synthesis of UMP), decreasing DNA and RNA synthesis, and arresting the cell proliferation cycle and production of antibodies. The reduction of dihydroorotate to orotate occurs concurrently with the reduction of its cofactor, ubiquinone (coenzyme Q) (Fig. 36.29). The inhibition of dihydroorotate dehydrogenase by teriflunomide demonstrates noncompetitive and uncompetitive kinetics. Administration of leflunomide in patients with rheumatoid arthritis results in progressive removal of B cells and down-regulation of the immune process. Teriflunomide not only inhibits B-cell proliferation but also T-cell proliferation, blocking the synthesis of immunosuppressive cytokines. At high therapeutic doses, leflunomide inhibits protein tyrosine kinases.

Leflunomide is administered orally as a single daily dose without regard to meals. Therapy may be initiated with a loading dosage given for 3 days, followed by the usual maintenance dose. It undergoes primarily enterohepatic circulation, extending its duration of action. Cholestyramine can be used to enhance its elimination in cases of toxicity.

***Methotrexate.*** Methotrexate (Fig. 36.27) is an antifolate drug approved for the treatment of severe active rheumatoid arthritis in adults who are intolerant to or have had an insufficient response to first-line therapy. Although the mechanism of action of methotrexate in rheumatoid arthritis is unknown, recent studies have shown that methotrexate reversibly inhibits dihydrofolate reductase, blocking the proliferation of B cells by interfering with DNA synthesis, repair, and replication. Oral absorption is dose-dependent, being well-absorbed at doses of 7.5–25 mg once a week. At this dose, oral bioavailability is approximately 60%, and food can delay absorption and reduce peak concentration. The volume of distribution is 0.4 to 0.8 L/kg. Protein binding is approximately 50%. It is metabolized to active metabolites, methotrexate



Copyrighted material

polyglutamates and 7-hydroxymethotrexate. Some metabolism occurs by intestinal flora after oral administration. Methotrexate is actively transported into the urine (80–90% unchanged in the urine within 24 hours) via the folate transporter, an organic anion transporter. Its elimination half-life is 3 to 10 hours.

Life-threatening drug interactions are known to occur between methotrexate and NSAIDs, probenecid, and penicillin G. The NSAIDs (salicylate, ibuprofen, ketoprofen, piroxicam, and indomethacin), probenecid, and penicillin G dose dependently inhibited methotrexate elimination into urine by human organic anion transporters (hOAT1, hOAT3, and hOAT4). The inhibitory effects of these drugs on hOAT3 were comparable, with therapeutically relevant plasma concentrations of unbound drugs. Thus, patients with rheumatoid arthritis should not take NSAIDs while taking methotrexate.

Methotrexate therapy requires monitoring of liver enzymes and is contraindicated in those with hepatic disease and in women considering pregnancy.

***Sulfasalazine (Azulfidine).*** Sulfasalazine is a pro-drug that is not active in its ingested form. It is broken down by colonic bacteria into 5-aminosalicylic acid (5-ASA; mesalamine) and sulfapyridine. Some controversy exists regarding which of these two products are responsible for the activity of azulfidine. 5-Aminosalicylic acid, however, is known to have a therapeutic benefit, although it is not clear whether sulfapyridine adds any further benefit. In the colon, the products created by the breakdown of sulfasalazine work as anti-inflammatory agents for treating colon inflammation. The beneficial effect of sulfasalazine is believed to result from a local effect on the bowel, although there also may be a beneficial systemic immune-suppressant effect. Sulfasalazine was approved in 1950.

Following oral administration, sulfasalazine is poorly absorbed, with approximately 20% of the ingested sulfasalazine reaching the systemic circulation. The remainder of the ingested dose is metabolized by colonic bacteria into its components, sulfapyridine and mesalamine (5-ASA). Most of the sulfapyridine metabolized from sulfasalazine (60–80%) is absorbed in the colon following oral administration, and approximately 25% of the 5-ASA metabolized from sulfasalazine is absorbed in the colon. The apparent volume of distribution of sulfasalazine in eight healthy volunteers was 64 L/kg, and that of sulfapyridine was 0.4 to 1.2 L/kg. Protein binding is approximately 99% for sulfasalazine, approximately 50% for sulfapyridine, and approximately 43% for 5-ASA. The absorbed sulfapyridine is acetylated and hydroxylated in the liver, followed by conjugation with glucuronic acid and, for 5-ASA, acetylation in the intestinal mucosal wall and the liver. The elimination half-life is 5 to 10 hours for sulfasalazine and 6 to 14 hours for sulfapyridine, depending on acetylator status of the patient, and 0.6 to 1.4 hours for 5-ASA. Time to peak serum concentration is 1.5 to 6 hours for oral sulfasalazine and 9 to 24 hours for oral sulfapyridine; for enteric-coated tablets, time to peak serum concentration is 3 to 12 hours for sulfasalazine and 12 to 24 hours for sulfapyridine. Approximately 5% of sulfapyridine and approximately 67% of mesalamine are eliminated in the feces, and 75 to 91% of sulfasalazine and sulfapyridine metabolites are excreted in urine within 3 days, depending on the dosage form used. 5-Aminosalicyclic acid is excreted in urine mostly in acetylated form.

Sulfasalazine is used for the treatment of mild to moderate ulcerative colitis; as adjunct therapy in the treatment of severe ulcerative colitis, for the treatment of Crohn's disease, and for the treatment of rheumatoid arthritis or ankylosing spondylitis. Contraindications include hypersensitivity to sulfa drugs, salicylates, intestinal or urinary obstruction, and porphyria.

## Biological Disease-Modifying Antirheumatic Drugs

### CYTOKINE INHIBITORS

***Tumor Necrosis Factor Blockers.*** T lymphocytes (T cells), a type of white blood cell, are important cells of the immune system. Patients with rheumatoid arthritis have increased numbers of T cells within the inflamed joints. These T cells are "activated"—that is, they multiply and release chemicals (cytokines) that promote the destruction of tissues surrounding the joints and cause the signs and symptoms of rheumatoid arthritis (84).

As discussed earlier in this chapter (see also Chapter 6 for a detailed discussion of cytokines), there is considerable expression of the cytokines, interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF) α by the rheumatoid synovium. TNFα is a proinflammatory cytokine (cell protein) that plays a major role in the pathological inflammatory process of rheumatoid arthritis. TNF is an important mediator of local inflammation, and the release of TNFα from T-cells produces increased vascular permeability, release of nitric oxide with vasodilation, local activation of vascular endothelium, increased expression of adhesion molecules on endothelial blood vessels, and increased platelet activation and adhesion. As TNFα builds up in the joints, it leads to joint inflammation, which ultimately results in joint destruction. Because of its role in the progression of rheumatoid arthritis, methods for rendering TNFα inactive has

Copyrighted material

become a key focus of therapies for rheumatoid arthritis (84). Patients with rheumatoid arthritis display elevated levels of the cytokines, TNFα, IL-1, and IL-6 in synovial fluid and tissue, and there appears to be a correlation between the amount of these products present and the severity of the disease. A significant advance in the treatment of arthritic diseases was the observation that therapy directed toward diminishing the effects of TNFα appeared to also improve the symptoms of ankylosing spondylitis and psoriatic arthritis.

Two different approaches have been developed to decrease TNF activity that has resulted in marketable drugs: administration of soluble TNF receptors (TNFRs; etanercept), and treatment with anti-TNFα antibodies (e.g., infliximab, adsalimumab). These compounds are designed to target and neutralize the effects of TNF, helping to reduce pain, morning stiffness, and tender or swollen joints, usually within 1 or 2 weeks after treatment begins. Evidence suggests that TNF blockers also may halt the progression of the disease. These medications work synergistically with methotrexate and therefore are often taken with methotrexate. The TNF blockers approved for treatment of rheumatoid arthritis are etanercept, infliximab, adalimumab, and rituximab. Potential side effects include injection site irritation (adalimumab and etanercept), worsening congestive heart failure (infliximab), blood disorders, lymphoma, demyelinating diseases, and increased risk of infection. These drugs should not be taken if an active infection is present. Effectiveness is lost if the drugs are discontinued.

Because TNF also is important for host defense against infections, the effects of long-term use on toxicity require further study. Substantial improvements in the course of the disease have been noted with both therapeutic approaches.

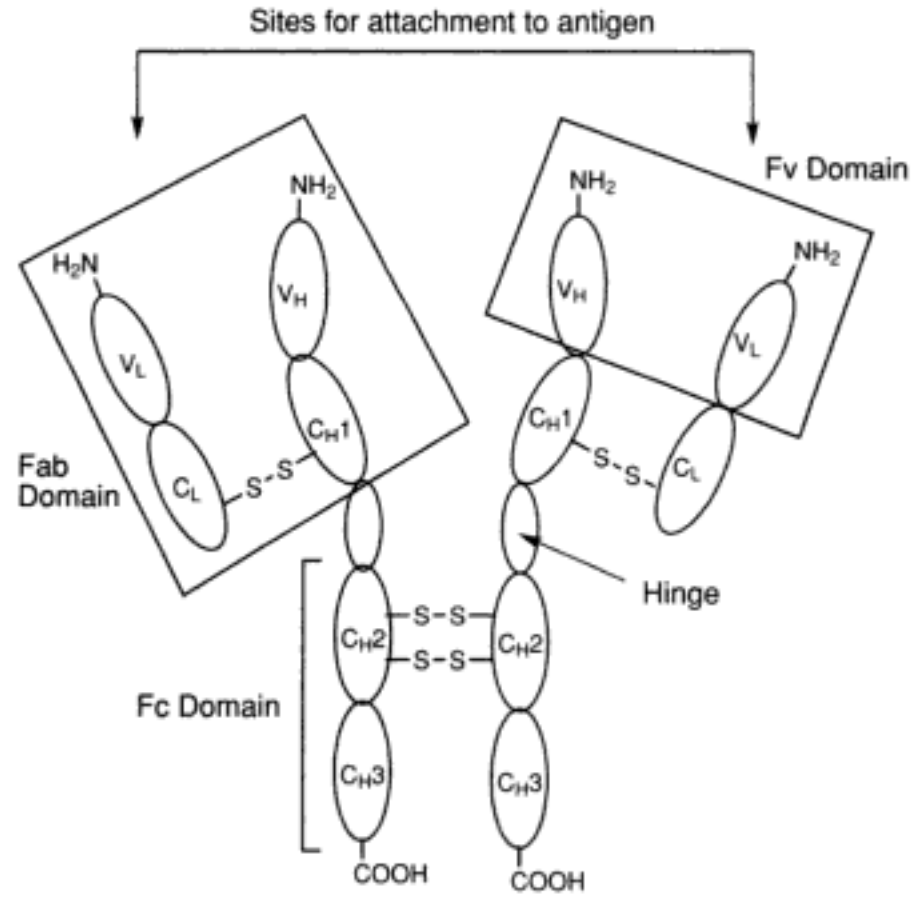


**Fig. 36.30.** Anti-tumor necrosis factor (TNF) agents. Etanercept is the extracellular portion of the human TNFR fused to the Fc domain of human immunoglobulin Ig G1. Infliximab is a partially humanized monoclonal antibody against TNFα. The Fv domains are derived from mouse antihuman sequences, whereas the Fc domain is composed of human IgG1 sequences. Adalimumab is fully humanized antibody to human TNFα (Fv and Fc derived from human sequences). Rituxan is a partially humanized monoclonal antibody against CD40. The Fv domains are derived from mouse antihuman sequences, and the Fc domain is composed of human IgG1 sequences.

***Etanercept (Enbrel).*** Etanercept (Fig. 36.30) is produced by recombinant DNA technology in a Chinese hamster ovary mammalian cell line and is the first biotechnology-derived drug to be introduced for the reduction of the signs and symptoms of moderately to severely active rheumatoid arthritis in patients who have not adequately responded to one or more of the synthetic DMARDs. It is a dimeric soluble form of the p75 TNFR capable of binding to two TNF molecules in the circulation. It consists of the extracellular ligand binding portion of the 75-kDa human TNFR fused to the Fc portion of human IgG1 (Fig. 36.30). The Fc component of etanercept contains the $C_H2$ domain, the $C_H3$ domain, and the hinge region, but not the $C_H1$ domain of IgG1. It consists of 934 amino acids and has an apparent molecular weight of approximately 150 kDa. Two TNFRs have been identified, a 75-kDa protein and a 55-kDa protein, that occur as monomeric molecules on cell surfaces and soluble forms in the blood. The biological activity of TNF requires its binding to either of the two cell surface TNFRs. Etanercept can bind specifically to two molecules of TNFα in the circulation, preventing its interaction with cell surface TNFRs. It can be used as monotherapy or in combination with methotrexate. Some concern exists because of reports that etanercept may, in some cases, cause serious infections and may have contributed to the deaths of several patients using the drug. An excellent review of the properties and use of etanercept has recently appeared (6,85). Etanercept also binds TNFβ.

Etanercept is available as a powder for injection in single-use vials containing 25 mg of the drug. The reconstituted solution that is administered as a twice weekly subcutaneous injection should be clear and colorless.

Etanercept has been approved for reducing signs and symptoms, inhibiting the progression of structural damage, and improving physical function in patients with moderately to severely active rheumatoid arthritis; for reducing signs and symptoms in patients with active arthritis in patients with psoriatic arthritis; and for reducing signs and symptoms in patients with active ankylosing spondylitis.

***Infliximab (Remicade).*** Infliximab is a chimeric ("humanized") IgG1κ monoclonal antibody to human TNFα (see Chapter 6 for detailed discussions for monoclonal antibodies). By combining the Fv domain of the

Copyrighted material

mouse antibody responsible for recognizing TNFα with parts of the human Fc domain of IgG1 (IgG1κ), the fused protein looks more like normal human IgG1 molecule ("humanized"), so there is a better chance the fused protein will not be destroyed by the patient's own immune system. Infliximab has an approximate molecular weight of 149,100 daltons and binds specifically, with high affinity, to both the transmembrane and soluble forms of TNFα in the blood, thus neutralizing its biological activity (Fig. 36.30). It does not bind to TNFβ (lymphotoxin A), a related cytokine that uses the same receptors as TNFα. Infliximab is produced by a recombinant cell line cultured by continuous perfusion and is purified by a series of steps that includes measures to inactivate and remove viruses. Cells expressing transmembrane TNFα bound by infliximab can be lysed. The TNFα antibodies decrease synovitis and joint erosions in a murine model of collagen-induced arthritis and, when administered after disease onset, allows eroded joints to heal.

After treatment with infliximab, patients with rheumatoid arthritis or Crohn's disease exhibited reduced infiltration of inflammatory cells and TNFα production in inflamed tissues and decreased levels of serum IL-6 and C-reactive protein compared to baseline. In psoriatic arthritis, treatment with infliximab resulted in a reduction in the number of T cells and blood vessels in the synovium and psoriatic skin as well as a reduction of macrophages in the synovium. Single IV infusions showed a linear relationship between the dose administered and the maximum serum concentration. The volume of distribution at steady state was independent of dose and indicated that infliximab was distributed primarily within the vascular compartment. The terminal half-life of infliximab is 8.0 to 9.5 days. No systemic accumulation of infliximab occurred on continued repeated treatment at 4- or 8-week intervals.

Infliximab is supplied as a sterile, white, lyophilized powder formulated for IV infusion. Following reconstitution with Sterile Water for Injection, the solution should be used immediately after reconstitution, because the vials do not contain antibacterial preservatives. The reconstituted solution should be colorless to light yellow and opalescent.

Infliximab is indicated for the treatment of rheumatoid arthritis in combination with methotrexate and for Crohn's disease. Long-term use may be associated with the development of anti-infliximab antibodies, an effect that does not appear when it is used with methotrexate. Warnings associated with the use of infliximab include risks of autoimmunity, infections, and hypersensitivity reactions. An excellent review of the properties and use of infliximab has recently appeared (84). Infliximab is more specific than etanercept, because etanercept binds to both TNFα and TNFβ whereas infliximab is an antibody that binds only to TNFα. Infliximab possesses a longer half-life giving a dosing schedule of approximately every 6 to 8 weeks.

Infliximab, in combination with methotrexate, is indicated for reducing signs and symptoms, inhibiting the progression of structural damage, and improving physical function in patients with moderately to severely active rheumatoid arthritis; for reducing signs and symptoms and maintaining clinical remission in patients with moderately to severely active Crohn's disease who have had an inadequate response to conventional therapy; for reducing signs and symptoms in patients with active arthritis and in patients with psoriatic arthritis; and for reducing signs and symptoms in patients with active ankylosing spondylitis.

***Adalimumab (Humira).*** Adalimumab is a recombinant human IgG1 monoclonal antibody targeted for human TNFα. Adalimumab is produced by recombinant DNA technology in a mammalian cell expression system using a protein-engineering strategy for creating a TNFα antibody with human-derived, heavy- and light-chain variable regions (Fab) and human IgG1κ constant regions. It consists of 1,330 amino acids and has a molecular weight of approximately 148 kDa (Fig. 36.30). Adalimumab, as an antibody, works by targeting and binding TNFα, thus neutralizing the effect of TNFα and, thereby, reducing the symptoms of rheumatoid arthritis and slowing the progression of structural joint damage caused by the disease. Adalimumab does not bind or inactivate TNFβ.

Adalimumab is supplied in single-use, prefilled, glass syringes as a sterile, preservative-free, colorless solution for subcutaneous administration. The pharmacokinetics of adalimumab were linear over the dose range of 0.5 to 10.0 mg/kg following a single IV dose. The mean elimination half-life was approximately 2 weeks.

***Rituximab (Rituxan).*** Rituximab is a genetically engineered, fused mouse/human anti-CD40 monoclonal antibody that targets B lymphocytes by binding specifically to CD20 antigen, a protein found on the surface of B cells at certain stages in their life cycle. Rituximab is composed of two heavy chains of 451 amino acids and two light chains of 213 amino acids with an approximate molecular weight of 145 kDa (Fig. 36.30). Its binding affinity for the CD20 antigen is approximately 8.0 nM.. The mouse light- and heavy-chain Fab domains of rituximab, which binds to the CD20 antigen on B cells, is linked to the human Fc domains of IgG1κ. Once the rituximab molecule attaches to the B cells, it initiates B-cell lysis, inducing rapid and profound depletion of peripheral B cells, with patients showing near complete B-cell depletion within 2 weeks after receiving the first dose of rituximab. Because rituximab does not target B cells at the earliest stages of their development, however, these B-cell depletions usually are temporary. In clinical trials, the majority of patients showed peripheral B-cell depletion for at least 6 months, followed by subsequent gradual recovery. A small proportion of patients (4%) had prolonged peripheral B-cell depletion lasting more than 3 years after a single course of treatment.

Copyrighted material

Meadowsweet (*Filipendula ulmaria*) is a common wild plant in Britain, Europe, and North America that also contains salicin, but it is not as potent as willow bark which has a higher salicin content. Its primary medicinal actions are antirheumatic, anti-inflammatory, carminative, antacid, antiemetic, astringent, and diuretic. The flower buds of meadowsweet are the source for salicin and methyl salicylate. Ingestion of the flower buds in a tea results in the breakdown of salicin to salicylic acid. Nicholas Culpeper, a seventeenth-century English pharmacist, mentioned the use of meadowsweet flower buds to help break fevers and promote sweating during a cold or flu.

## DRUGS USED TO TREAT GOUT

### Pathophysiology

Gout is an inflammatory disease characterized by elevated levels of uric acid (as urate ion) in the plasma and urine and may take two forms, acute and chronic. Acute gouty arthritis results from the accumulation of needle-like crystals of monosodium urate monohydrate within the joints, synovial fluid, and periarticular tissue and usually appears without warning. Initiating factors may be minor trauma, fatigue, emotional stress, infection, overindulgence in alcohol or food, or drugs, such as penicillin or insulin. Chronic gout symptoms develop as permanent erosive joint deformity appears. The increase in extracellular urate may result from increased uric acid biosynthesis, decreased urinary excretion of uric acid, or perhaps, a combination of both. The formation of uric acid from adenine and guanine is illustrated in Figure 36.32. Uric acid is formed by the oxidation of xanthine by the enzyme xanthine oxidase. Xanthine is a metabolic product of adenine (via hypoxanthine) and guanine formed by the enzymes adenine deaminase and guanine deaminase, respectively. Thus, uric acid is the excretory product of purine metabolism in humans as well as the scavenging of potential harmful oxygen free radicals in the body. In other mammals, uric acid is hydrolyzed to allantoin by the enzyme uricase, which is then subsequently hydrolyzed by allantoinase to allantoic acid. Hydrolysis of allantoic acid by allantoicase yields the final products, urea and glyoxylic acid.

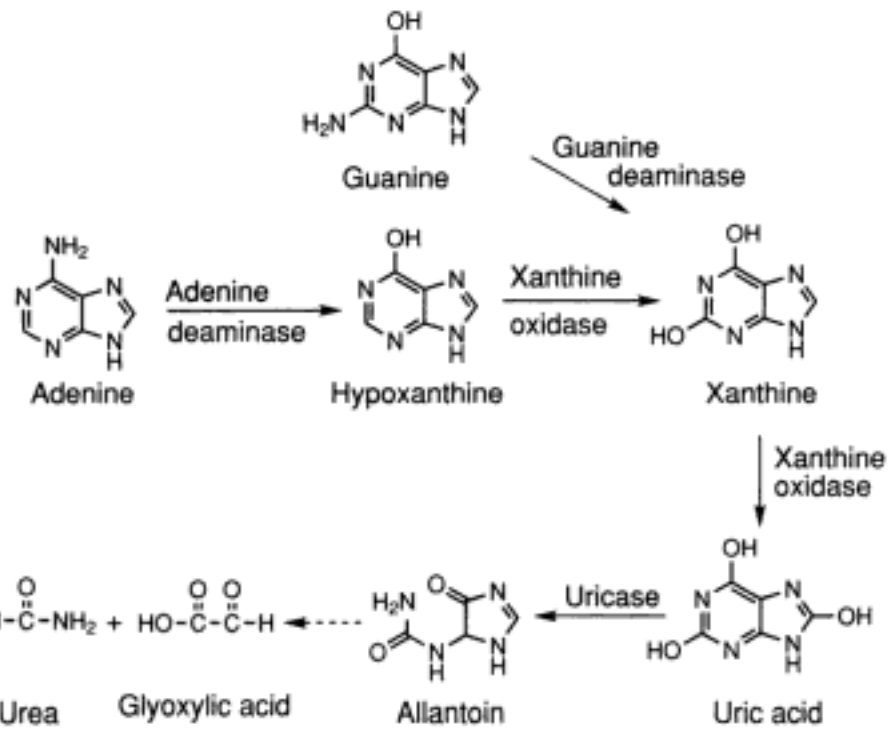

**Fig. 36.32.** Formation of uric acid, urea, and glyoxylic acid from purines.

Normal pool levels of uric acid are approximately 1,000 to 1,200 mg in males and half that in females. In patients suffering from gout, these levels may be as high as two- or three times the normal levels. Uric acid is a weak acid with two $pK_a$ values 5.7 and 10.3, with very low water solubility (~6 mg/100 mL). At physiological pH, it exists primarily as the monosodium salt, which is approximately 50 times more soluble in aqueous media than the free acid. Blood levels of urate are maintained by a careful balance between its formation and excretion. The kidney plays a dominant role in urate elimination, excreting about 70% of the daily urate production. The excretion of urate has been implicated in the development of hyperuricemia that leads to gout. In humans, the excretion of urate requires the urate anion transporter (URAT1) located in renal proximal tubule cells, which plays a central role in urate homeostasis. The URAT1 is targeted by uricosuric and antiuricosuric agents that affect urate excretion.

When levels of uric acid in the body increase, either as a result of decreased excretion or increased formation, the solubility limits of sodium urate are exceeded, and precipitation of the salt from the resulting supersaturated solution causes deposits of urate crystals to form. It is the formation of these urate crystals in joints and connective tissue that initiate attacks of gouty arthritis. The control of gout has been approached from the following therapeutic strategies: 1) control of acute attacks by drugs that reduce inflammation caused by the deposition of urate crystals (these drugs may possess only an anti-inflammatory component, such as colchicine, or both anti-inflammatory and analgetic actions, such as indomethacin, phenylbutazone and naproxen), 2) increasing the rate of uric acid excretion (by definition, these drugs are termed "uricosuric drugs" and include probenecid and sulfinpyrazone), and 3) inhibiting the biosynthesis of uric acid by inhibiting the enzyme xanthine oxidase by drugs such as allopurinol.

### Treatment of Acute Gout

The management of gout has been approached with the following therapeutic strategies: 1) control of acute attacks with drugs that reduce inflammation caused by the deposition of urate crystals, and 2) control of chronic gout by increasing the rate of uric acid excretion ("uricosuric drugs") and inhibiting the biosynthesis of uric acid by inhibiting the enzyme xanthine oxidase. Treatment of acute gout includes NSAIDs, such as indomethacin, colchicines, and glucocorticoids. The choice of an NSAID generally is based on the side effect profile.

#### Colchicine

Colchicine is a pale-yellow powder that is obtained from various species of *Colchicum*, primarily *Colchicum autum-*

Copyrighted material

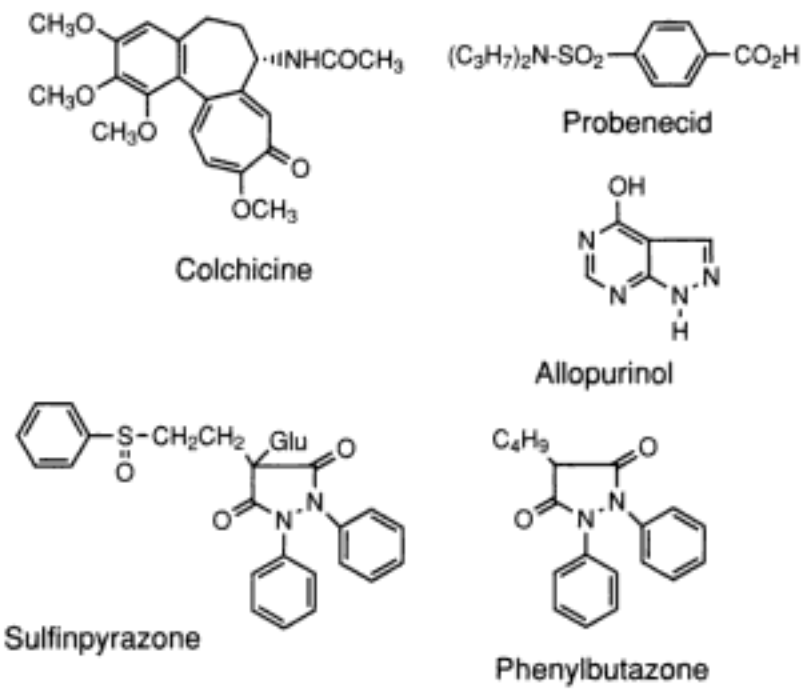

**Fig. 36.33.** Structures of agents used to control gout.

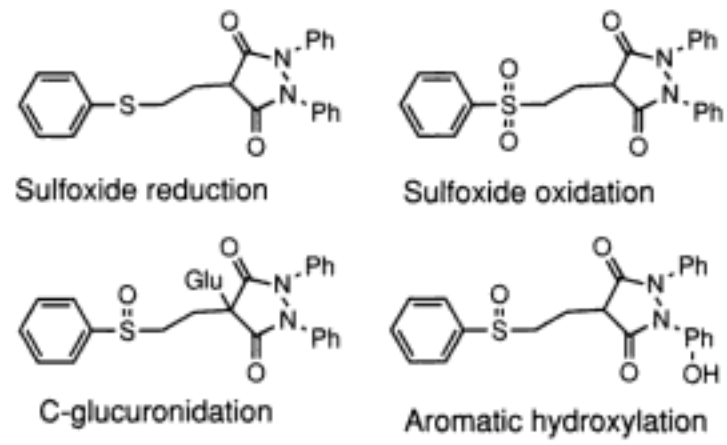


the high degree of plasma protein binding, displacement interactions with other drugs bound to plasma proteins does not appear to occur to any significant extent. Salicylates counteract the uricosuric effects of probenecid. Because probenecid inhibits their renal excretion, increased plasma levels of the following drugs may be observed: aminosalicylic acid, methotrexate, sulfonamides, dapsone, sulfonylureas, naproxen, indomethacin, rifampin, and sulfinpyrazone. (The effects on penicillin plasma levels were discussed previously.)

Probenecid is indicated for the treatment of hyperuricemia associated with gout and gouty arthritis and for the elevation and prolongation of plasma levels of penicillins and cephalosporins. In gout, treatment should not begin until an acute attack has subsided. It is not recommended in individuals with known uric acid kidney stones or blood dyscrasias or for children under 2 years of age.

**SULFINPYRAZONE.** Sulfinpyrazone (Fig. 36.33) is soluble in alkaline solutions. Its synthesis is similar to that of phenylbutazone (87) (Fig. 36.33). It produces its uricosuric effect in a manner similar to that of probenecid. A dose of 35 mg produces a uricosuric effect equivalent to that produced by 100 mg of probenecid, whereas 400 mg/day of sulfinpyrazone produces an effect comparable to that obtained with doses of 1.5 to 2 g of probenecid. It also possesses, not surprisingly, some of the properties of phenylbutazone. It is an inhibitor of human platelet prostaglandin synthesis at the cyclooxygenase step, resulting in a decrease in platelet release and a reduction in platelet aggregation. This antiplatelet effect suggests a role for sulfinpyrazone in reducing the incidence of sudden death, which can occur in the first year following a myocardial infarction; however, it lacks the analgetic and anti-inflammatory effects of phenylbutazone.

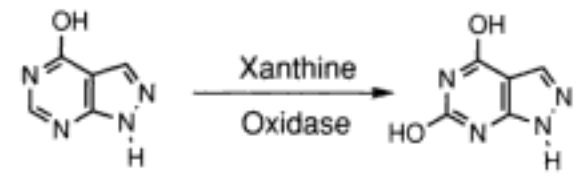
Sulfinpyrazone is a strong acid (enolic OH $pK_a = 2.8$), a factor that is important in the production of the uricosuric effect, because within a series of pyrazolidinedione derivatives, the stronger the acid, the more potent the uricosuric effect. Polar substitution on the side chain also influences uricosuric activity, as discussed previously with regard to the pyrazolidinediones.

Oral administration results in rapid and essentially complete absorption, with peak plasma levels being attained within 1 to 2 hours of administration. It is highly bound (98–99%) to plasma proteins, and it is excreted in the urine primarily (50%) as unchanged drug.

The metabolites produced result from sulfoxide reduction, sulfur and aromatic oxidation, and C-glucuronidation of the heterocyclic ring in a manner similar to that for phenylbutazone. The metabolite resulting from *p*-hydroxylation of the aromatic ring possesses uricosuric effects in humans. The sulfide metabolite, a major metabolic product, may contribute to the antiplatelet effects of sulfinpyrazone but not to the uricosuric effects. The most frequent adverse reactions are GI disturbances; however, the incidence is relatively low. It has been suggested that sulfinpyrazone is a much weaker inhibitor of prostaglandin synthesis in bovine stomach microsomes than either aspirin or indomethacin, a factor that may account for its gastric tolerance. Much rarer have been reports of blood dyscrasias and rash. Overdosage produces symptoms that are primarily GI in nature (e.g., nausea, diarrhea, and vomiting) but also may involve impaired respiration and convulsions. Treatment consists of emesis or gastric lavage and supportive care. Like probenecid, its uricosuric effects are antagonized by salicylates, and probenecid markedly inhibits the renal tubular secretion of sulfinpyrazone. It potentiates the actions of other drugs that are highly plasma protein bound, such as coumarin-type oral anticoagulants, antibacterial sulfonamides, and hypoglycemic sulfonylureas.

Sulfinpyrazone is indicated for the treatment of chronic and intermittent gouty arthritis.

## Drugs That Decrease Uric Acid Formation



### ALLOPURINOL

***Mechanism of Action.*** The biosynthesis of uric acid from the immediate purine precursor xanthine that results from adenine, via the intermediate hypoxanthine, or from guanine is illustrated in Figure 36.32. The enzyme xanthine oxidase (a molybdenum hydroxylase enzyme) is involved in two steps, the conversion of hypoxanthine to xanthine, and the final step, the conversion of xanthine to uric acid. Allopurinol originally was designed

Copyrighted material

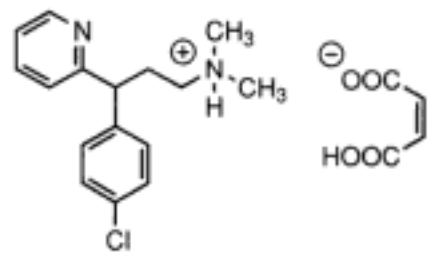
as an antineoplastic antimetabolite to antagonize the actions of key purines inasmuch as it differs from normal purines only by the inversion of the nitrogen and carbon atoms at the 7- and 8-positions of the purine ring system but was found to have little or no effect on experimental tissues. It was subsequently found that allopurinol serves as a substrate for xanthine oxidase (15 to 20 times the affinity of xanthine) and reversibly inhibits that enzyme. Normally, uric acid is a major metabolic end product in humans. When allopurinol is administered, however, xanthine and hypoxanthine are elevated in the urine, and uric acid levels decrease. When the synthesis of uric acid is inhibited, plasma urate levels decrease, supersaturated solutions of urate are no longer present, and urate crystal deposits dissolve, eliminating the primary cause of gout. The increased plasma levels of hypoxanthine and xanthine pose no real problem, because they are more soluble than uric acid and are readily excreted.

***Absorption and Metabolism.*** Allopurinol was synthesized in 1956 as part of a study of purine antagonists (88). It is well absorbed on oral administration, with peak plasma concentrations appearing within 1 hour. Decreases of uric acid can be observed within 24 to 48 hours. Excretion of allopurinol and its metabolite occurs primarily in the urine, with approximately 20% of a dose being excreted in the feces. Allopurinol is rapidly metabolized via oxidation and the formation of numerous ribonucleoside derivatives. The major oxidation metabolite, alloxanthine or oxypurinol, has a much longer half-life (18–30 hours versus 2–3 hours) than the parent drug and is an effective, although less potent, inhibitor of xanthine oxidase. The longer plasma half-life of alloxanthine results in an accumulation in the body during chronic administration, thus contributing significantly to the overall therapeutic effects of allopurinol. The major adverse effects are primarily dermatological in nature (e.g., skin rash and exfoliative lesions). Other effects, such as GI distress (e.g., nausea, vomiting, and diarrhea), hematopoietic effects (e.g., aplastic anemia, bone marrow depression, and transient leukopenia), neurological disorders (e.g., headache, neuritis, and dizziness), and ophthalmological effects (e.g., cataracts) are less commonly encountered. Allopurinol also may initiate attacks of acute gouty arthritis during the early stages of therapy and may require the concomitant administration of colchicine. Drug interactions include those drugs that normally also are metabolized by xanthine oxidase. For example, the oxidation of 6-mercaptopurine, a useful antineoplastic agent, is inhibiting, permitting a reduction in the therapeutic dose. Allopurinol also has an inhibitory effect on liver microsomal enzymes, thus prolonging the half-lives of drugs, such as oral anticoagulants, that normally are metabolized and inactivated by these enzymes, although this effect is quite variable. The incidence of ampicillin-related skin rashes increases with the concurrent administration of allopurinol.

Allopurinol Alloxanthine (oxypurinol)

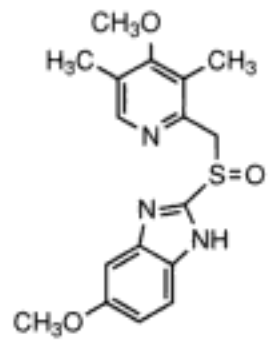
Allopurinol is indicated for the treatment of primary and secondary gout, for malignancies such as leukemia and lymphoma, and for the treatment of patients with recurrent calcium oxalate calculi.

## CASE STUDY



***Victoria F. Roche and S. William Zito***

PR is a 15-year-old female gymnast who has just been named to the U.S. Olympic Team after months of grueling and highly competitive trials. Her specialty events are the uneven parallel bars and the "horse," but she has performed well enough on all events to earn this coveted spot on the team. She is ecstatic but understandably nervous, because she is, by nature, a private person and the media spotlight has been intense since the announcement.



PR has consulted the team physician about dysmenorrhea that has become increasingly worse over the past 6 months. The cramping is now almost incapacitating for 2 to 3 days out of each period, and it has been interfering with her training. She knows just when the "big pain" will start, because PMS symptoms routinely begin 36 hours before the onset of bleeding. She has looked ahead, and if her cycles remain regular, she is due to have her period during the week of the summer Olympic games. From her medication history, the MD can see that PR takes OTC chlorpheniramine maleate (Chlortrimeton) fairly frequently for seasonal and pet-related allergies. Despite her young age, she has complained of a "nervous stomach," which has prompted her to try Prilosec OTC (omeprazole), especially before competitions when her emotions and GI distress are heightened. PR speaks of her very jam-packed schedule of school and training, and she asks for once-daily therapy to treat her menstruation-related pain if possible. As the pharmacist for the team, consider the following NSAID therapeutic choices, and prepare to make a recommendation.

1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the SAR findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

# 37. *Antihistamines and Related Antiallergic and Antiulcer Agents*

WENDEL L. NELSON

**DRUGS COVERED IN THIS CHAPTER:**

ANTIHISTAMINES

- Acrivastine
- Azelastine
- Carebastine
- Cetirizine
- Cromolyn
- Desloratadine
- Ebastine
- Emedastine
- Epinastine
- Fexofenadine
- Ketotifen
- Levocetirizine
- Levocobastine
- Lodoxamide
- Loratadine
- Mizolastine
- Nedocromil
- Olopatadine
- Pemirolast
- Terfenadine

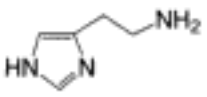
ANTIULCER AGENTS

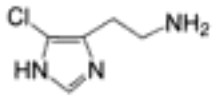
- Cimetidine
- Esomeprazole
- Famotidine
- Lansoprazole
- Metoclopromide
- Misoprostol
- Nizatidine
- Omeprazole
- Pantoprazole
- Rabeprazole
- Ranitidine
- Sucralfate

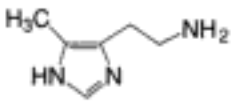
## INTRODUCTION

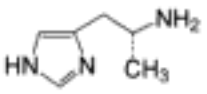
Histamine [2-(imidazol-4-yl)ethylamine] was synthesized and its effects in model biological systems were studied before it was found physiologically. Its synthesis occurs in many tissues, including mast cells, parietal cells of the gastric mucosa, and neurons of the central nervous system (CNS) and the periphery. Early hypotheses about its physiological function were based on the observed, dramatic effects of histamine in guinea pigs. These effects include massive bronchial spasm and effects on smooth muscle and the vasculature that resemble anaphylactic shock. Marked species differences in the observed effects occur, however, and these dramatic effects are not observed in humans.

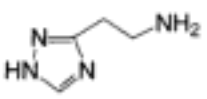
Histamine is located in many tissues, and on release, its effects are principally local ones, because it functions as an autocoid or paracrine (1). Its physiological function is complex and not completely understood. Histamine is one of the many mediators involved in allergic inflammatory responses, and it has an important role in regulating the secretion of gastric acid. These observations have led to development of many important drugs that antagonize its effects and are useful in treatment of allergic inflammatory disorders ($H_1$ antihistamines) and in the treatment of gastric hypersecretory disorders ($H_2$ antihistamines).

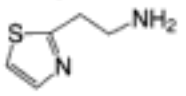


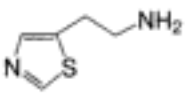


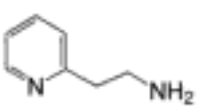


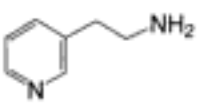


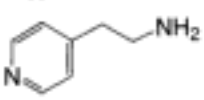












Besides its role in allergic inflammatory processes and gastric acid secretion, a physiological role at axons in several regions of the CNS has established its role in the regulation of sleeping and waking, in energy and endocrine homeostasis, and in cognition and memory. Histamine modulates the release of neurotransmitters via $H_3$ auto- and heteroreceptors located at histaminergic and nonhistaminergic neurons both centrally and peripherally. A novel $H_4$ receptor also been described where histamine facilitates the synthesis and release of other proinflammatory mediators and modulates the chemotactic responses, principally at mast cells and eosinophils.

## CHEMISTRY

Histamine has $pK_a$ values of 5.80 (imidazole) and 9.40 (aliphatic primary amine) (2). At physiological pH, it exists as an equilibrium mixture of tautomeric cations, with the monocation making up more than 96% of the total and the dication approximately 3%, with only a very small amount of the nonprotonated species. At lower pH values (e.g. the pH of acidic lipids), a much larger proportion of the dication exists. The two protonated species (mono- and dication) often are considered to be the biologically active forms. Penetration of membranes by histamine would be expected to occur via the nonprotonated species, and the unprotonated imidazole group would be expected to participate readily in proton-transfer processes physiologically. Several aromatic ring congeners of histamine with weakly and very weakly basic heteroaromatic rings (e.g., 4-chloroimidazole, 1,2,4-triazole, thiazole, and pyridine) exhibit histamine agonist activity (Table 37.1) (3), although they are less potent than histamine. These data suggest that the monocation (protonated aliphatic amine) is sufficient for agonist activity and that protonation of the heterocyclic ring is not an absolute requirement.

In aqueous solutions, the tautomeric equilibrium of the imidazole ring apparently favors the $N^{\tau}$-H tautomer by approximately 4:1. The free base also prefers the $N^{\tau}$-H tautomer. In the crystalline form of the monohydrochloride salt of histamine, however, where intermolecular crystal

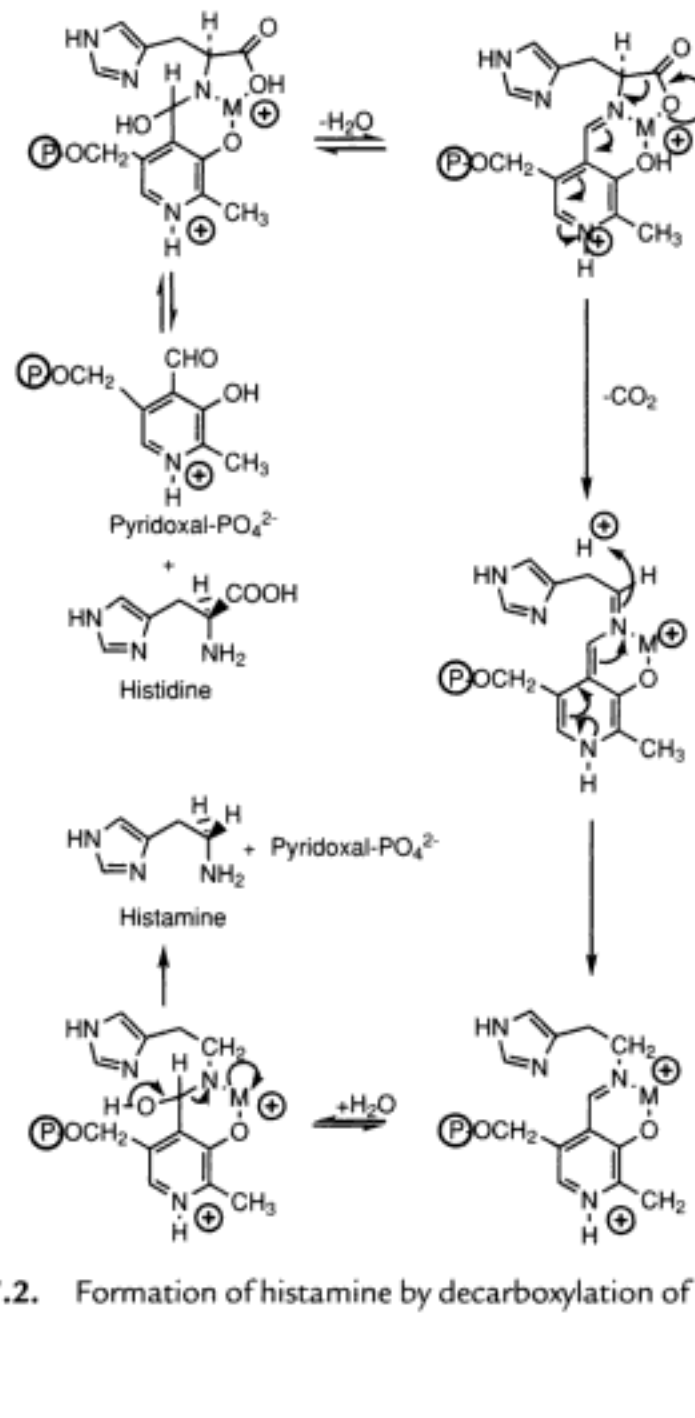

**Fig. 37.2.** Formation of histamine by decarboxylation of histidine.

This conversion is catalyzed by L-histidine decarboxylase, with pyridoxal phosphate serving as a cofactor for this process. The reaction mechanism for this decarboxylation probably involves the formation of an imine intermediate, followed by the loss of carbon dioxide, a mechanism demonstrated to occur for decarboxylation of many α-amino acids (Fig. 37.2). Pyridoxal phosphate provides an important catalytic function, and in the final step, the product is released by hydrolysis of the enzyme-bound Schiff base of histamine. Mechanism-based inhibitors of this process, such as α-fluoromethylhistidine, decrease the rate of synthesis of histamine and, thus, deplete cells of histamine. As such, α-fluoromethylhistidine is an important pharmacological tool (4). This approach, however, has not been successfully developed into agents for the treatment allergic inflammatory disorders, peptic ulcer, or motion sickness.

Once released, histamine is rapidly metabolized in vivo (based on products from radiolabeled histamine administered intradermally) to nearly inactive metabolites by two major pathways: N-methylation, and oxidation (Fig. 37.3). Methylation (S-adenosylmethionine), which is catalyzed by the intracellular enzyme N-methyltransferase, yields an inactive metabolite. A portion of the N-methylated metabolite is oxidized sequentially via monoamine oxidase and then via aldehyde oxidase to the corresponding N-methylimidazole acetic acid. Histamine also is oxidized to imidazole acetic acid by diamine oxidase (histaminase). A small amount of this acid intermediate is converted to the corresponding ribotide, an unusual metabolite (5).

## Storage and Release of Histamine

In mast cells, histamine is stored in secretory granules as a complex with acidic residues of the proteoglycan heparin and in basophils in the blood as a complex with chondroitin sulfate (6,7). Mast cells are distributed in areas of skin and mucous membranes of the respiratory, gastrointestinal, and genitourinary tracts and in tissue adjacent to blood and lymph vessels. Although histamine is secreted at low levels from these mast cells and basophils, the primary mechanism of release is associated with cell activation by immunoglobulin (IgE)–mediated hypersensitivity processes (Fig. 37.4). Immediate hypersensitivity is initiated when allergen molecules cross-link to Fab components of adjacent IgE antibody molecules bound to high-affinity FcεRI receptors on the surface of these cells ($Fc\varepsilon RI^+$ cells). Dimerization of occupied IgE-Fc receptors results in several membrane and cytosolic events. These include release of preformed mediators

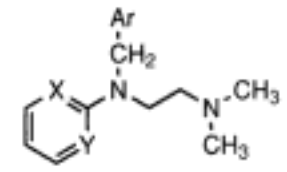
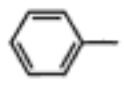
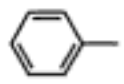
an ether oxygen atom in the ethanolamine ether series, or only a carbon atom in the alkyl amines. The spacer usually is two or three carbons in length, and it may be in a ring, may be branched, and may be saturated or unsaturated. The R groups attached to the aliphatic amine usually are simple alkyl groups, generally methyl or, occasionally, aralkyl groups. One of the early thiophene-containing analogues was carcinogenic in rats. After thiophene versus benzene replacement in other series of compounds demonstrated some toxic effects, thiophene was relegated to one of the low-priority choices for isosteric replacement of a phenyl group.

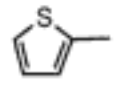
Most $H_1$ antihistamines are inverse agonists rather than neutral antagonists. Like other histamine receptors, $H_1$ receptors have constitutive G protein–coupled activity in the absence of the agonist histamine that results in activation of second-messenger signaling pathways, such as phospholipase C activity and NFκB-mediated gene transcription (19). A model of active and inactive conformations of histamine receptors has been advanced to accommodate these biochemical findings. Inverse agonists bind to the inactive conformation of the receptor, shifting the equilibrium toward the inactive state. Neutral antagonists interact with both conformations of the receptor.

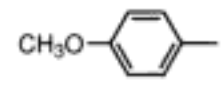


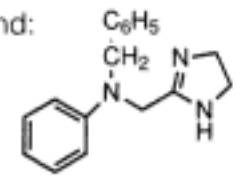
## First-Generation $H_1$ Antihistamines











### Ethylenediamines

The earliest series of $H_1$ antihistamines is the ethylenediamines. Two 2-carbon spacers may appear between the two nitrogen atoms in the piperazine series (vide infra). Examples of agents in the ethylenediamine class, of which phenbenzamine was the first of these agents, appear in Table 37.2. Compounds with several different but closely related aromatic rings are useful, such as phenyl, 2-pyridyl, halogen- and methoxy-substituted phenyl, or pyrimidyl. Thiazole-, furanyl-, and thiophene-ring congeners also were available in the past. The small alkyl substituents on basic nitrogen usually are methyl groups. A number of these agents are still used. With the exception of antazoline, all have the ethylenediamine spacer. In antazoline, the alkyl tertiary amine in phenbenzamine is replaced with an imidazoline group. Central nervous system effects, usually sedation, are very common among agents in this class.

Information regarding pharmacokinetic and metabolic disposition is limited, because this early group of compounds was not studied in depth. Only later, with second-generation $H_1$ antihistamines, and/or when issues of potential toxicity have arisen concerning some of the early compounds, has the metabolic disposition been examined more completely. Thus, the available information concerning the metabolism on these early antihistamines is sparse. From some of the ethylenediamines, expected products of N-demethylation and subsequent deamination have been reported. In addition, some produce quaternary N-glucuronides as urinary metabolites, a process that occurs, to some extent, in many relatively unhindered tertiary aliphatic amines among the antihistamines and also in other lipophilic aliphatic tertiary amine drug classes.

### Ethanolamine Ethers

**STRUCTURE ACTIVITY RELATIONSHIPS.** The prototype of the aminoalkyl ethers is diphenhydramine, a benzhydryl ether which more than a half-century after its introduction remains still widely used for allergic conditions. Structural analogues with various ring substituents (Me, OMe, Cl, and Br) in one of the aromatic rings also have been developed, as have compounds with a 2-pyridyl group replacing one of the phenyl groups (Table 37.3).

Significant anticholinergic side effects are observed among members of the group (e.g., dry mouth, blurred vision, tachycardia, urinary retention, and constipation). It should be noted that diphenydramine is used in the treatment of parkinsonism because of its central anticholinergic properties. Other anticholinergic agents that are structurally related to the benzydryl ether antihistamines also are used in the treatment of parkinsonism (see Chapter 25). Sedative properties are very common as well. Sedation, accompanied by a short half-life and a wide margin of safety, allows some of these compounds to be used as OTC sleep aids. The 8-chlorotheophyllinate salt of diphenhydramine is marketed as dimenhydrinate for use in the treatment of motion sickness. The compound with the aryl groups *p*-Cl-Ph and 2-pyridyl is carbinoxamine, a potent antihistamine. Substitution of a methyl group at the carbon α to the ether function affords the related compound doxylamine, in which the aryl groups are phenyl and 2-pyridyl. Clemastine, a

homologue with an additional carbon atom between the oxygen and the basic nitrogen, which is incorporated into a ring, is a recent addition to the group, with less sedative properties. Other analogues are used elsewhere. For example, setastine, a compound with the alkyl amine substituent being incorporated into a 7-membered hexahydroazepine ring, is available in Europe.

**ANTIHISTAMINIC VERSUS ANTICHOLINERGIC ACTIVITY.** Besides the structural analogues in Table 37.3 that possess increased selectivity for histamine $H_1$ receptors over muscarinic receptors, introduction of alkyl substituents at C-2' or C-4' of one aromatic ring results in significant changes in selectivity in tissue-based assays for antihistaminic versus anticholinergic activity. With increasing alkyl group size (Me, Et, iPr, and tBu) at C-2', large decreases in antihistaminic activity and increases in anticholinergic activity are observed (20). With larger alkyl groups, the possible spatial orientations of the two aromatic rings with regard to each other are limited because of increasing rotameric restrictions. Introduction of these alkyl substituents at C-4' decreases anticholinergic activity and yields small increases in antihistaminic activity. A chiral center is introduced with these changes, and differences in pharmacological properties of the enantiomers of each compound are observed. Two examples are shown in Table 37.4.

**STEREOCHEMICAL AND STRUCTURAL EFFECTS.** The observed differences in potency of enantiomers in tissue-based assays suggest significant stereoselective interactions of antagonists at the receptor level. Differences in affinity of 60- to 200-fold are noted between enantiomers in several

analogues where the chiral center results because of differences in the two aromatic rings, such as Ph and 2-pyridyl, or Ph and *p*-Br-Ph (21). Enantiomers with the *S*-absolute configuration usually are more potent. Clemastine, a more complex homologue, is marketed as the *R,R*-enantiomer, which is the more potent of the *R,R*- and *S,S*-enantiomeric pair and more potent than either the *R,S*- and *S,R*-enantiomers of the other diastereomer (22). Consistent with results from related compounds, the chiral center at the benzhydryl carbon has a significant influence on potency, whereas the one in the pyrrolidine ring is of lesser importance (Table 37.5).

Very small changes in the arrangement of aromatic groups in the members of the ethanolamine ether series significantly alter the scope of their pharmacological properties. Previous work has shown that the two aromatic rings in diphenhydramine can be located slightly differently with respect to each other, as in phenyltoloxamine, a potent antihistamine. A retro arrangement of carbon and oxygen atoms, however, prepared in an

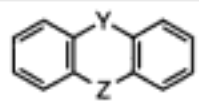
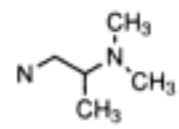
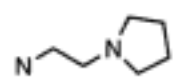
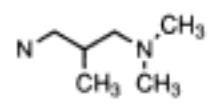
carbons long, unbranched, and usually, without substituents in the aromatic ring. Besides useful antihistaminic effects, most have pronounced sedative effects and long durations of action. Other uses include the treatment of nausea and vomiting associated with anesthesia and for the treatment of motion sickness.

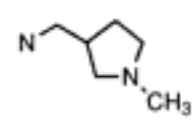


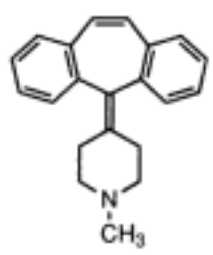
**CONFORMATIONAL AND STEREOCHEMICAL EFFECTS.** In the active agents, the steric restrictions and decreased degrees of conformational freedom resulting from the connection of the two aromatic rings together suggests that certain spatial relationships between these two rings are acceptable in the drug–receptor interaction of $H_1$ antihistamines. These ring systems are not flat but, rather, are somewhat puckered, with the two aromatic rings not in the same plane. Usually, however, the conformations undergo rapid intraconversion. In some closely related systems, in which this intraconversion is very slow, conformational enantiomers (atropisomers) have been obtained and studied, including cyproheptadine, doxepine, and hydroxylated metabolites of loratadine (27,28). The enantiomers of 3-methoxycyproheptadine have significantly different pharmacological potency as antihistamines, antiserotonin, and anticholinergic agents (Fig. 37.12) (29). The (−)-isomer retained antihistaminic, antiserotonin, and appetite-stimulating effects similar to cyproheptadine, whereas the (+)-enantiomer had greater anticholinerigic potency. Differences of 9- to 60-fold have been observed in the reported assays.

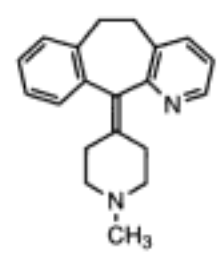












Promethazine, an early agent in the series, has many useful pharmacological affects other than being an antihistamine. It has significant antiemetic and anticholinergic properties. It also has sedative-hypnotic properties and has been used to potentiate the effects of analgesic drugs. Subsequent analogues, such as trimeprazine and methdilazine, are used as antipruritic agents in the treatment of urticaria.

Compounds in which the sulfur atom is replaced with another bridge (e.g., two methylene groups) also are available. Some have a pyridine ring replacing one of the benzenoid systems. Cyproheptadine, with a 2-carbon spacer between the aromatic rings, also has anticholinergic, antiserotonergic, and appetite-stimulating properties, which are useful in treatment of anorexic nervosa and in cachexia. The pyridine analogue apparently lacks most of these qualities. Doxepine, an oxygen-containing congener of cyproheptadine, also has significant affinity for other receptors, and it has CNS-depressant qualities. It exists as a mixture of *Z*- and *E*-isomers (15:85) in its olefinic, nonpiperidine side chain. In tissue-based assays, the *Z*-isomer is more potent than the *E*-isomer by more than threefold (27). The most widely used among the group is loratadine, which is considered to be in the category of nonsedating, second-generation antihistamines (vide infra).

**METABOLISM.** Information regarding the metabolic disposition and pharmacokinetic properties of agents in this group is limited, including incomplete identification of primary metabolic pathways, results of liver microsomal metabolic experiments, and only occasionally, pharmacokinetic information. In humans, products from the

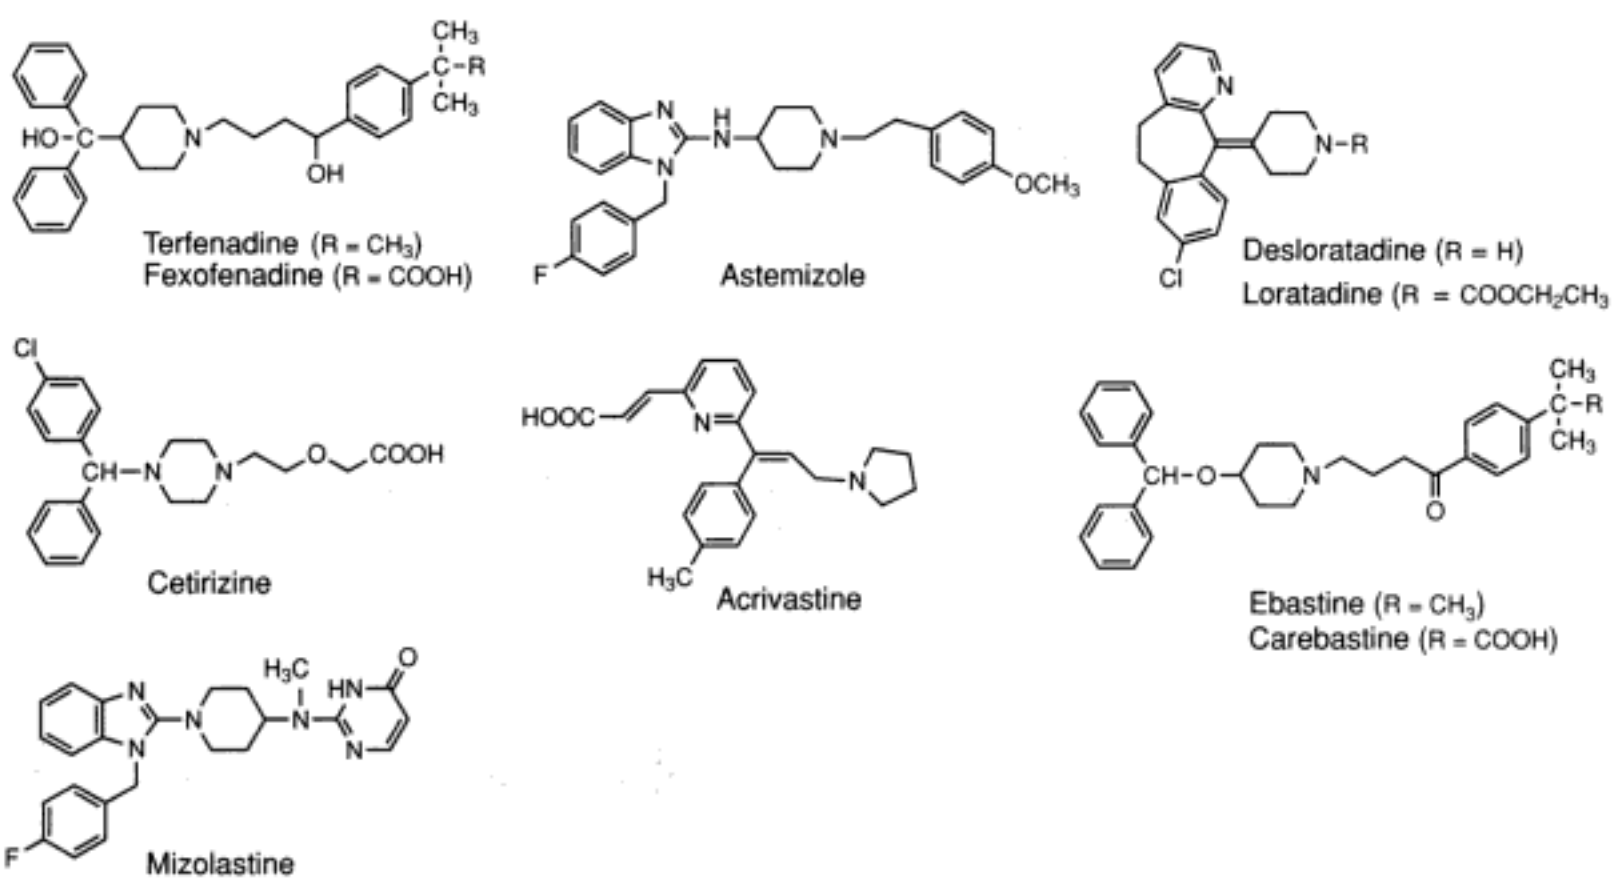
phenothiazines include products of N-demethylation, aromatic hydroxylation, and occasionally, sulfoxidation. From tricyclic analogues, metabolites resulting from N-demethylation, aromatic hydroxylation, and formation of N-quaternary glucuronides have been reported (30).

## Second-Generation Nonsedating $H_1$ Antihistamines

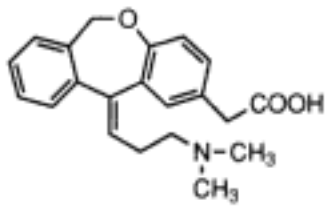
### Background



The second-generation antihistamines marketed over the last 20 to 25 years have improved $H_1$ selectivity, have little or no sedative qualities, and they may have antiallergic effects apart from antihistaminic activity (31). They vary widely in structure (Table 37.8) but less so in pharmacological properties, having effects principally in the periphery. Structural resemblance to the first-generation $H_1$ antagonists is not always obvious. because some of these agents were discovered while investigating new molecular structures for other pharmacological targets. These agents possess selective peripheral $H_1$ antihistaminic effects, and they usually have less anticholinergic activity. Furthermore, they also have decreased affinity for adrenergic and/or serotonergic receptors and limited CNS effects. The active agents apparently do not penetrate the blood-brain barrier significantly, perhaps because of their amphoteric nature (most are zwitterionic at physiological pH) and partitioning characteristics and/or because they are substrates for the drug efflux P-glycoprotein transporter or organic anion transporter proteins. A slow rate of dissociation from $H_1$ receptors also is reported for some of the agents. Several have antiallergic properties that are separate from their antihistaminic properties, which are not thoroughly understood. In most cases, the parent drug or its important metabolites have half-lives that are sufficiently long to account for the extended duration of action (32). Most are administered once daily.

### Specific Drugs

#### FEXOFENADINE (ALLEGRA) AND TERFENADINE



***Pharmacological Effects.*** This group of nonsedating antihistamines usually is thought to include fexofenadine and its parent terfenadine, astemizole, cetirizine, and loratadine and its metabolite desloratadine. Terfenadine was synthesized as an analogue of azacyclanol in a search for antipsychotic agents. The initial reports of its antihistaminic properties included the observation of similar effects of it acid metabolite fexofenadine (33). Whereas terfenadine is no longer available, it was once a very widely used nonsedating antihistamine. Extensive clinical experience resulted in the reports of dangerous cardiac arrhythmias occurring occasionally when certain other drugs were taken concomitantly. These cardiac arrhythmias included prolongation of the QT interval and torsades de pointes, a life-threatening ventricular arrhythmia. These cardiac effects are now known to be associated with blockade of the hERG (human ether-a-go-go) gene product, the α-subunit of an inward rectifying cardiac $K^+$ channel (34,35). These effects are associated only with the parent molecule. The side effects occur primarily at high concentrations of this lipophilic amine and, usually, in the presence of other CYP3A4 substrates, such as ketoconazole or macrolide antibiotics (e.g., triacetyloleandomycin). In the presence of competing CYP3A4 substrates and inhibitors,

Epinastine

histamine receptor affinity and a slow rate of receptor dissociation. The presence of the carboxylic acid side chain apparently is responsible for the observed lack of muscarinic receptor affinity. This feature also may be responsible for limited penetration. Olapatadine also a mast cell stabilizer as well. The mechanism for this activity has not been delineated, but it has been shown to stabilize model cell membranes by interaction with phospholipid monolayers.

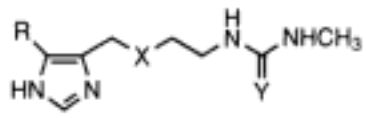
**Levocobastine (Livostin).** Levocobastine is a potent, selective $H_1$ receptor antagonist used topically in eye drops for seasonal allergic conjunctivitis. A small amount of systemic absorption of the compound is reported. The agent also prevents release of transmitters from mast cells. A nasal spray used for allergic rhinitis is available outside the United States.

**Emedastine (Emadine).** Emedastine also is a newer antihistamine used topically in the eye for conjunctivitis. It has very high $H_1$ receptor selectivity characteristics, and it is structurally related to the benzimidazoles, such as astemizole. Inhibition of mast cell release of inflammatory mediators has been noted.

**Azelastine (Astelin).** Azelastine, although not a close structural analogue to the benzimidazoles, has some structural similarities to them. It is used as a nasal spray for allergic rhinitis and as eye drops for allergic conjunctivitis. Like olopatadine, azelastine also stabilizes mast cells, preventing degranulation and subsequent release of histamine, leukotrienes, and $PGD_2$. It is available in Europe for systemic use in the treatment of asthma and seasonal allergies. Besides antihistaminic effects, it also may block release of histamine and other inflammatory mediators from mast cells. When administered orally, the N-dealkylated metabolite appears to contribute significantly to its pharmacological effects.

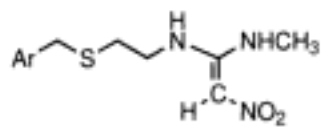
**Ketotifen (Zaditor).** Ketotifen is a potent, selective $H_1$ antihistamine that also prevents release of transmitters from mast cells. It is approved in the United States for topical use to prevent itching of the eye because of allergic conjunctivitis, It is used as a systemic antiallergy agent in several countries outside the United States for the treatment of seasonal allergic rhinitis, hay fever, and asthma. Being structurally analogous to the cyproheptadine-like antihistamines, differences in activity of the two enantiomers (atropisomers) has been noted, being approximately six- to seven-fold in ligand displacement and rodent-based assays (44). Ketotifen has been shown to stabilize mast cells and to inhibit degranulation of eosinophils. Like olopatadine, it has been shown to interact with model membranes, stabilizing them by interaction with phospholipids monolayers.

**Epinastine (Elestat).** Epinastine is a potent, long-acting $H_1$ antihistamine and an inhibitor of the release of histamine and other transmitters from mast cells. It has some affinity for $H_2$ receptors as well. It is used as an eye drop for allergic conjunctivitis. It does not penetrate into the CNS and is classified as a nonsedating antihistamine.



## Antiulcer Agents

### Background



The secretion of gastric acid occurs at the level of parietal cells of the oxyntic gland in the gastric mucosa (Fig. 37.17), producing 2 to 3 L of gastric juice per day, pH 1 in hydrochloric acid. Ultimately, this secretory process occurs via an $H^+,K^+$-ATPase that exchanges hydronium ion ($H_3O^+$) with uptake of a potassium ion. Several mediators regulate this secretion by way of receptor systems on the basolateral membrane. The $H_2$ histaminergic pathway is cAMP dependent. Gastrin and muscarinic receptors also regulate the secretion of gastric acid through calcium ion dependent pathways. In parietal cells, E-series prostaglandins work in opposition to the histaminergic pathway, inhibiting histamine-stimulated adenylyl cyclase activity. Other epithelial cells in the mucosal lining under the influence of prostaglandin-mediated pathways secrete bicarbonate and mucus, both of which are important in protecting the gastric lining from the effects of acid secretion. In many cases, hypersecretion of gastric acid appears to be associated with *Helicobacter pylori* infection, which may contribute to defects in mucosal protective defenses. Evidence suggests that some $H_2$ antihistamines, particularly cimetidine and ranitidine, have regulatory effects on T-cell lymphocyte proliferation by augmenting cytokine production and Ig

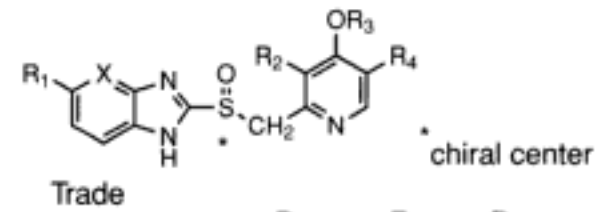
| Ranitidine | Zantac |  |
| Nizatidine | Axid |  |

Famotidine (Pepcid)

**METABOLISM.** Cimetidine, ranitidine, and famotidine are subject to first-pass metabolism, and each has oral bioavailability of approximately 50%. The oral bioavailability of nizatidine is approximately 90%. All have half-lives of 1.5 to 4.0 hours, with that of nizatidine being the shortest. Significant amounts of each of these $H_2$ antihistamines are excreted unchanged, with small amounts of urinary products of sulfoxidation being a common metabolic feature. As expected, hydroxylation of the imidazole C-4 methyl group of cimetidine occurs. Ranitidine is excreted largely unchanged, but minor metabolic pathways include N-demethylation as well as N- and S-oxidation. The metabolites are not thought to contribute to the therapeutic properties of the parent drugs, with the exception of nizatidine, from which the N-desmethyl metabolite retains $H_2$ antihistamine activity (47).



**SIDE EFFECTS AND DRUG INTERACTIONS.** Cimetidine, the earliest of these agents, shows the greatest number of drug interactions (48). Among them are somnolence and confusion in elderly patients with decreased renal function. Gynecomastia, presumably related to increased prolactin secretion, has been reported. Cimetidine inhibits CYP450-dependent metabolic processes, affording increased concentration of several agents, the most important being those having narrow therapeutic concentration windows (e.g., phenytoin, theophylline, some benzodiazepines, warfarin, and quinidine). Inhibition of several CYP450 oxidative processes is associated with the presence of imidazole ring of cimetidine, which apparently replaces the histidine that serves as a ligand to the porphyrin iron in CYP450 enzymes. Other agents in this group contain heterocyclic rings other than imidazole and do not show this effect. Cimetidine is an inhibitor of renal tubular secretion of some drugs (e.g., procainamide). These tubular secretion effects also are less prevalent or even absent with other agents in this class. The other agents in the group are more potent than cimetidine, and significant differences are noted among them. Of these, ranitidine is the most widely used. The agents have OTC status and are widely available for gastric hyperacidity.

### Proton Pump Inhibitors

Proton pump inhibitors are widely used in the treatment of duodenal and gastric ulcer, erosive esophagitis, GERD, GERD-related laryngitis, and hypersecretory conditions (e.g., Zollinger-Ellison syndrome) (49,50). The final step in acid secretion in parietal cells of the gastric mucosa is a process mediated by $H^+,K^+$-ATPase, the gastric proton pump, an enzyme with significant homology to $Na^+,K^+$-ATPase. This $H^+,K^+$-ATPase has some similarities to the $H^+,K^+$-ATPase in osteoclasts, which is involved in bone resorption. Gastric acid secretion can be inhibited in many ways. These include by antagonists at muscarinic, gastrin, or histamine $H_2$ receptors; by agonists at inhibitory receptors for prostaglandins and somatostatin; by proton pump inhibitors; or by carbonic anhydrase inhibitors.

**MECHANISM OF ACTION.** Omeprazole, lansoprazole, and related analogues (Table 37.11), produce inhibition of stimulated gastric acid secretion irrespective of the receptor stimulation process. Nearly all the compounds are close structural relatives, being weakly basic 2-pyridylmethylsulfinylbenzimidazoles. An analogue, tenatoprazole, which is an imidazopyridine isostere, is currently in clinical trials.

**COMBINATION THERAPY IN *HELICOBACTER PYLORI* INFECTIONS.** The majority of peptic ulcers are related to *H. pylori* infections and nonsteroidal anti-inflammatory drug (NSAID) therapy. *Helicobacter pylori* apparently penetrates the layer of gastric mucus by producing ammonia and carbon dioxide (urease-catalyzed hydrolysis of urea) to withstand the acidic environment of the stomach. More than 90% of patients with duodenal ulcer, excluding those with gastrinoma or taking NSAIDs, show the presence of *H. pylori*. Determination of *H. pylori* infection is routinely performed by measuring production of carbon dioxide (breath) or bicarbonate (blood) after oral administration of $^{13}C$- or $^{14}C$-labeled urea. Endoscopic examination and antigen-based serological tests may be used as confirmation (58). Eradication of *H. pylori* markedly decreases the incidence of ulcer recurrence. Several regimens of antibiotic therapy, widely used with proton pump inhibitors or less commonly with $H_2$-antagonists, are effective. Double- and triple-drug combinations, such as proton pump inhibitors with amoxicillin and clarithromycin or metronidazole, are used.

### Competitive $K^+$ Inhibitors

Newer agents that block gastric acid secretion at the $H^+,K^+$-ATPase by binding as competitive inhibitors at the $K^+$ binding site are under development (Fig. 37.20) (45,49). An initial compound, SCH 28080, was hepatotoxic. Newer agents have included soraprazan and revaprazan. Each of them binds ionically to the proton pump at or near the $K^+$ binding site. Revaprazan has reached clinical trials. Studies to determine whether these or other related compounds can become useful drugs are ongoing.

### Prokinetic Agents

Prokinetic drugs like metoclopramide, cisapride, and levosulpiride increase esophageal sphincter pressure and enhance peristalsis and gastric emptying, thus counteracting factors that lead to esophagitis (Fig. 37.21) (59). These agents appear to be 5-$HT_4$ partial agonists in the enteric nervous system, leading to release of acetylcholine. In addition, metoclopramide and levosulpiride are dopamine $D_2$ antagonists. Metoclopromide is used in

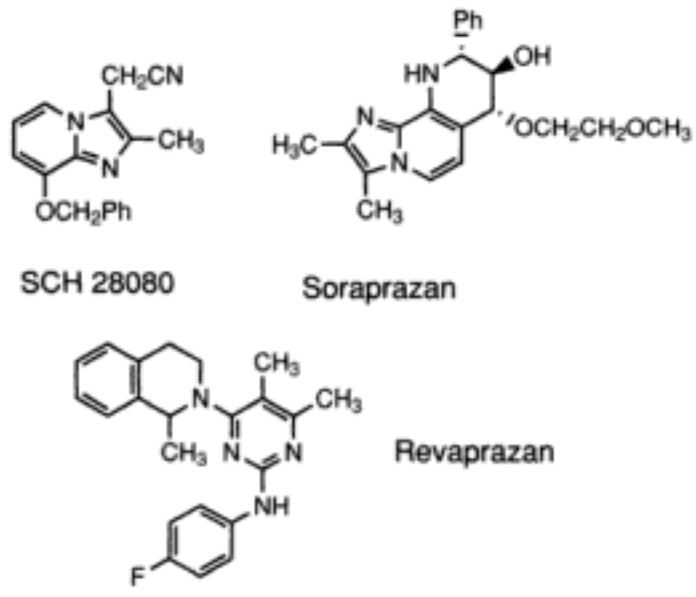

**Fig. 37.20.** Examples of proton pump competitive $K^+$ inhibitors.

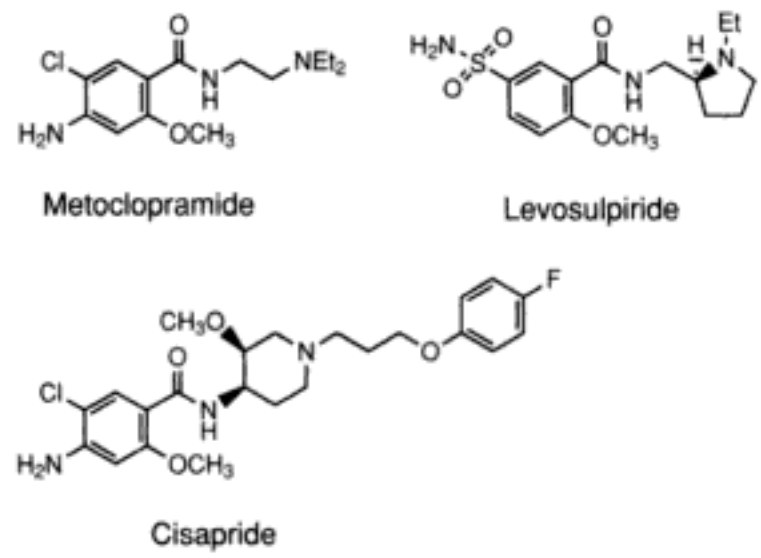

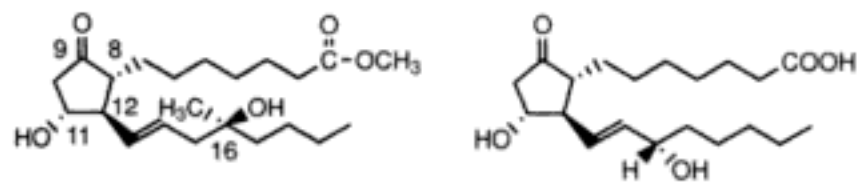

**Fig. 37.21.** Examples of prokinetic agents.

GERD, in diabetic gastroparesis, and in nausea and vomiting of emetogenic cancer chemotherapy. Cisapride was removed from the U.S. prescription market because of metabolism-based interactions. In the presence of competing CYP3A4 substrates, high concentrations of the parent molecule lead to life-threatening cardiac arrhythmias via interaction with the hERG $K^+$ channel, similar to $H_1$ antihistamines terfenadine and astemizole. It is available only through an investigational limited-access program. Levosulpiride is available in Europe. Tegaserod (Zelnorm), also a selective 5-$HT_4$ partial agonist used in irritable bowel syndrome in women, has been used successfully in critically ill patients with gastroparesis.

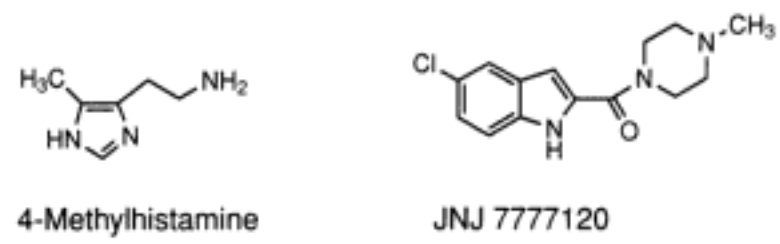
### Prostaglandins

Prostaglandins have antisecretory effects on gastric acid (Fig. 37.17). Besides inhibiting adenylyl cyclase activity in parietal cells, which results in secretion of gastric acid, prostaglandins stimulate secretion of mucus and bicarbonate in adjacent superficial cells. Cytoprotective effects of endogenous E-series prostaglandins and of other, more stable synthetic congeners are observed. The only available oral prostaglandin in the United States is misoprostol. The orally administered carboxylic acid ester is hydrolyzed to the pharmacologically active carboxylic acid. It is a synthetic analogue of prostaglandin $E_1$, in which structural changes at C-13,14,15,16 are made to prevent rapid metabolic conversion to inactive products. The presence of the tertiary alcohol 1-carbon removed to C-16 obviates the usual conversion of the allylic secondary alcohol ($\Delta^{13,14}$-15-alcohol) of prostaglandins to the corresponding saturated ketones. A mixture of diastereomers of misoprostol is used; most of the activity arises from the 11*R*,16*S*-isomer (60). Misoprostol reduces basal levels of gastric acid secretion, but it has considerable smooth muscle contraction effects.

Copyrighted material

changes on $H_1$ and $H_2$ agonist activity. Other selective agonists are the isothiourea imetit, immepip and its N-methyl analogue (methimepip), both substituted piperidines, immethridine, a pyridine congener of immepip, and SCH 50971. All retain the imidazole ring of histamine.

Early $H_3$ antagonists, like thioperamide and clobenpropit analogues of immepip and imetit, respectively, are primarily pharmacological tools. Like the $H_3$ agonists, these agents retain the imidazole group but possess widely varying N-substituents. Some of the imidazole-containing agonist and antagonist analogues have affinity for other receptors (e.g., some α-adrenergic receptor subtypes), and they have the potential to interact with CYP450 enzymes as an iron–porphyrin ligand. Thus, nonimidazole-containing ligands have been sought.



Allergic rhinitis is one condition in which $H_3$ antihistamines may be useful. Thioperamide and clobenpropit are effective in animal models alone and in combination with $H_1$ antihistamines. Dual $H_1/H_3$ antihistamines are being studied, including a chlorpheniramine analogue that incorporates the imidazole alkylamine group of many $H_3$ antagonists (Table 37.12).

Centrally acting $H_3$ antagonists are under study by several drug companies. Agents are sought for a variety of disorders. These include treatment of depression, mild cognitive impairment, Alzheimer's disease, schizophrenia, narcolepsy, obesity, and attention-deficient hyperactivity disorder. Two examples are JNJ 5207852 (63), a compound that increases wakefulness, and ABT-239, a compound that is being evaluated for treatment of cognition related disorders (64).

## $H_4$ RECEPTOR AGONISTS AND ANTAGONISTS

### Physiological Role of $H_4$ Receptors

The $H_4$ receptor is expressed in mast cells, eosinophils, and other cells of hematopoietic lineage, including basophils and T cells. It is a relatively recent discovery; thus, much is not yet understood about its physiological role. It is thought to play a role in inflammatory responses, especially in the mediation of chemotactic responses. Its sequence homology is greatest with the $H_3$ receptor (35–40%) and is very low versus $H_1$ and $H_2$ receptors (65).

4-Methylhistamine JNJ 7777120

**Fig. 37.22.** Other ligands at the $H_4$ receptor.

### $H_4$ Agonists and Antagonists

Classical leukocyte chemoattractant effects that occur are blocked by thioperamide, an $H_3/H_4$ antihistamine. Other $H_3$ receptor ligands, such as *R*-α-methylhistamine and imetit, also are agonists at $H_4$ receptors, but they have lower affinity than at $H_3$ receptors (Table 37.12). Clobenpropit is a partial agonist at $H_4$ receptors, but it is an $H_3$ antihistamine (inverse agonist). Thioperamide is an inverse agonist at $H_4$ and $H_3$ receptors. 4-Methylhistamine (Fig. 37.22) has greater affinity (>100-fold) for $H_4$ receptors than other histamine receptor subtypes (66).

A selective $H_4$ antihistamine has recently been reported, JNJ 7777120 (Fig. 37.22). It blocks many mediated functions, including histamine-induced chemotaxis in mast cells and eosinophils (67). Conditions in which $H_4$ antagonists might be useful include autoimmune inflammatory and allergic disorders, including rheumatoid arthritis, asthma, and allergic rhinitis. Nasal stuffiness and blockage in allergic rhinitis, conditions that are poorly treated with $H_1$ and $H_2$ antihistamines, suggest the possible use of $H_4$ antihistamines in these conditions as well.

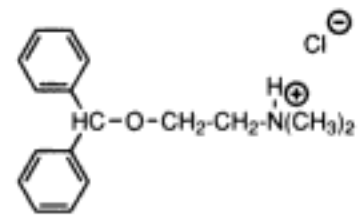
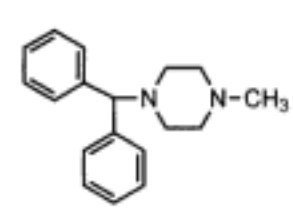
## CASE STUDY

***Victoria F. Roche and S. William Zito***



BL is a 71-year-old financial advisor on vacation at the Gulf Coast with his wife of 47 years. It has been a therapeutic getaway, especially for Mrs. BL, who lost her central vision to exudative macular degeneration 18 months ago. While they hate to see their week of surf, sun, and relaxation come to an end, they are really looking forward to the drive to Albuquerque they will begin tomorrow for the wedding of their only granddaughter. On their last Gulf Shore night, they made reservations for a gala evening aboard the cruise ship *Chichibabin*, complete with dancing to the area's best Dixieland jazz band and a sumptuous buffet of Cajun foods. They had a ball, but unfortunately, BL experienced a severe allergic reaction to the crayfish he consumed (he ate two dozen) and had to be taken off the ship to the emergency room, where he received an injection of hydrocortisone. Although he can now breathe easier, he still has a red, itchy, and unsightly rash on the upper half of his body, including his arms, hands, and face. In addition to being uncomfortable, he is worried about how he will look for his granddaughter's big day.

Before heading out on their drive to Albuquerque, BL and his wife stop at a local pharmacy for some calamine lotion and an antihistamine to keep BL comfortable on the trip. He will be behind the wheel the whole way, because his wife can no longer see well enough to drive. As the pharmacist on duty that day, consider the antihistaminic structures below, and provide this couple with some much-needed pharmaceutical care.



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

SECTION 5 Chemotherapeutic Agents

# 38. *Antibiotics and Antimicrobial Agents*

LESTER A. MITSCHER, THOMAS L. LEMKE, AND ELMER J. GENTRY

## DRUGS COVERED IN THIS CHAPTER:

ANTIBACTERIALS

- Methenamine
- Phosphomycin
- Quinolone class
- Sulfonamide class
- Trimethoprim

ANTIBIOTICS

- Penicillin class
  - Ampicillin
  - Amoxacillin
  - Bacampicillin
  - Benzylpenicillin
  - Carbenicillin and indanyl carbenicillin
  - Clavulanic acid
  - Methicillin
  - Mezlocillin and piperacillin
  - Nafcillin
  - Oxacillin, cloxacillin, and dicloxacillin
  - Phenoxymethyl penicillin
  - Piperacillin and tazobactam
  - Sulbactam
  - Ticarcillin
- Cephalosporin class
  - Cefaclor
  - Cefadroxil
  - Cefamandole nafate
  - Cefazolin
  - Cefdinir
  - Cefditoren pivoxil
  - Cefepime
  - Cefixime
  - Cefmetazole
  - Cefonicid
  - Cefoperazone
  - Cefotaxime
  - Cefotetan
  - Cefoxitin
  - Cefpodoxime proxetil
  - Cefprozil
  - Ceftazidime
  - Ceftibuten
  - Ceftizoxime
  - Ceftriaxone
  - Cefuroxime
  - Cephalexin
  - Cephapirin
  - Cephradine
  - Loracarbef
- Carbapenems
  - Ertapenem
  - Imipenem
  - Meropenem
- Monobactams
  - Aztreonam
- Aminoglycosides
  - Amikacin
  - Gentamicin
  - Kanamycin
  - Neomycin
  - Spectinomycin
  - Tobramycin
- Macrolides and ketolides
  - Azithromycin
  - Clarithromycin
  - Erythromycin estolate
  - Erythromycin ethylsuccinate
  - Erythromycin stearate
  - Telithromycin
  - Lincosamides
    - Clindamycin
    - Lincomycin
- Tetracyclines and glycylcyclines
  - Demeclocycline
  - Doxycycline
  - Oxytetracycline
  - Minocycline
  - Tetracycline
  - Tigecycline
- Bacitracin
- Chloramphenicol
- Daptomycin
- Linezolid
- Mupirocin
- Polymyxin B
- Quinupristin/dalfopristin
- Vancomycin

## INTRODUCTION

Antibiotics are microbial metabolites or synthetic analogues inspired by them that, in small doses, inhibit the growth and survival of microorganisms without serious toxicity to the host. Selective toxicity is the key concept. Antibiotics are among the most frequently prescribed medications today, although microbial resistance resulting from evolutionary pressures and misuse threatens their continued efficacy. In many cases, the clinical utility of natural antibiotics has been enhanced through medicinal chemical manipulation of the original structure, leading to broader antimicrobial spectrum, greater potency, lesser toxicity, more convenient administration, and additional pharmacokinetic advantages. Through customary usage, the many synthetic substances that are unrelated to natural products but still inhibit or kill microorganisms are referred to as antimicrobial agents instead.

Because of a significant decrease in the pace of novel anti-infective discovery, increased regulatory constraints, and greater profits to be made by the use of medications for chronic conditions, there is presently a decreased research emphasis on antimicrobial agents. This coincides with a dramatic increase in microbial resistance to chemotherapy, that portends a bleak future in which humankind may once again face infectious diseases with few available countermeasures.

Our environment, body surfaces, and cavities support a rich and characteristic microbial flora. These cause us no significant illness or inconvenience as long as our neighbors or we do not indulge in behavior that exposes us to exceptional quantities or unusual strains of microbes or introduces bacteria into parts of the body where they are not normally resident. Protection against this happening is obtained primarily through public

## CLINICAL SIGNIFICANCE

The treatment of bacterial infections is one of the few disease states that all clinicians are guaranteed to be challenged with at some time in their career. Because bacteria are constantly changing, the selection of appropriate antimicrobial therapy is crucial in providing efficacious treatment of infections. It is of the utmost importance that clinicians understand the medicinal chemistry of antimicrobial agents to choose the most effective therapy for their patients. Antimicrobial resistance trends are constantly changing and vary from institution to institution, so a complete understanding of the structural relationship differences between antibiotics, even in the same class, is helpful in selecting the most appropriate therapy for an individual patient. In addition, side chains and subtle structural differences within antimicrobial classes can change the side-effect profiles of these agents. The informed clinician therefore can optimize their treatment choices from patient to patient while avoiding severe adverse effects.

The development of newer and more effective antimicrobial agents is essential in the fight against infectious diseases. Understanding the medicinal chemistry of the older and newer antimicrobial agents helps the clinician to comprehend their differences in antimicrobial spectrum and side-effect profile. Newer antibiotics are continuously being developed; however, many of them are from antimicrobial classes already established, with only small changes on the functional groups and/or side chains leading to dramatic differences in their antimicrobial spectrum. As stated previously, bacteria are constantly changing, as are antimicrobial susceptibility patterns. To optimize patient care, a clinician needs to stay informed about the effects of the medicinal chemistry differences as newer drugs come to market and antimicrobial resistance trends change.

*University of Houston College of Pharmacy*

health measures, healthful habits, intact skin and mucosal barriers, and a properly functioning immune system. All parts of our bodies that are in contact with the environment support microbial life. It is estimated that 1 g of feces contains approximately $10^{13}$ microorganisms! All our internal fluids, organs, and body structures, however, are sterile under normal circumstances, and the presence of bacteria, fungi, viruses, or other organisms in these places is diagnostic evidence of infection. When mild microbial disease occurs, the otherwise healthy patient often will recover without requiring treatment. Here, an intact, functioning immune system is called on to kill invasive microorganisms. When this is insufficient to protect us, appropriate therapeutic intervention is indicated.

The chronicle of civilization before the discovery of bacteria and their role in infectious disease and, subsequently, the discovery of antibiotics and antimicrobial agents is punctuated by the outbreak of recurrent, devastating pandemics. An example is the successive waves of bubonic plague that dramatically decreased the population of Europe during the Middle Ages. Humankind was mystified as to the cause of infectious disease and what one might constructively do for prevention and cure. In warfare, infections often disabled or killed more individuals than the action of generals did. Our own family histories record the premature loss of loved ones, particularly small children, to one infection or another, and in the Third World, this pattern remains all too common today. This depressing picture was altered dramatically in the 20th century by the discovery and application of the powerful therapeutic agents described in this chapter. Fortunately, it no longer is common for persons to live short lives, and it now is rare for parents to bury their children. Public health measures, such as purification of water supplies, proper sewage disposal, routine preventive vaccination, pasteurization of milk, improved personal hygiene, and avoidance of unhealthy behavior (e.g., spitting in public places) also have greatly diminished our exposure to infection.

Considering that the first truly effective antimicrobial agents date from the mid-1930s (the sulfonamides) and the first antibiotics came into use in the 1940s (the penicillins), it is amazing that we have already grown complacent. Diseases that very recently seemed to be on their way to extinction, such as tuberculosis and gonorrhea, are once again becoming serious public health problems because of societal changes, persistent poverty, lack of education, ease of international travel, and the emergence of resistance by pathogens. It is disturbing to consider that previously unknown infectious diseases, such as acquired immunodeficiency syndrome (AIDS), Ebola virus infections, and Legionnaires' disease, are an increasing feature of modern life. Unfortunately, we can no longer confidently depend on the discovery of increasing numbers of novel antibiotics and antimicrobial agents to keep infectious diseases under control, but we must increasingly pay attention to neglected public health measures and concentrate on using antibiotics only when those measures fail.

## HISTORY

Humankind has been subject to infection by microorganisms since before the dawn of recorded history. One presumes that humankind has been searching for suitable

Copyrighted material

therapy for nearly as long. This was a desperately difficult enterprise given the acute nature of most infections and the nearly total lack of understanding about their origins that was prevalent until the last century. One can find indications in old medical writings of folkloric use of plant and animal preparations, soybean curd, moldy bread and cheese, counterinfection with other microbes, the slow development of public health measures, and an understanding of the desirability of personal cleanliness, but these factors were erratically and inefficiently applied and, when they were applied, often failed. Until the discovery of bacteria 300 years ago and the subsequent understanding of their role in infection about 150 years ago, there was no hope for rational therapy.

In Germany during the 19th century, Robert Koch showed that specific microorganisms could always be isolated from the excreta and tissues of people with particular infectious diseases and that these same microorganisms usually were absent in healthy individuals. They could then be grown on culture media and be administered to healthy individuals to reproduce in those healthy individuals all the classic symptoms of the same disease. Finally, the identical microorganism could then be isolated from this deliberately infected person. Following these rules, at long last, a chain of evidence connecting cause and effect was forged between certain microorganisms and specific infectious diseases. This work laid the foundation for rational prevention of and therapy for infectious diseases.

In 1877, Louis Pasteur reported that when what he termed "common bacteria" were introduced into a pure culture of anthrax bacilli, the bacilli died, and that an injection of deadly anthrax bacilli into a laboratory animal was harmless if "common bacteria" were injected along with it. This did not always work, but it did lead to the appreciation of antibiosis, wherein two or more microorganisms competed with one another for survival. Not until more than a half century later, however, did the underlying mechanisms begin to be appreciated and applied to achieve successful therapy.

The modern anti-infective era opened with the discovery of the sulfonamides in France and Germany in 1936 as an offshoot of Paul Ehrlich's earlier achievements in treating infections with organometallics and his theories of vital staining. The discovery of the utility of sulfanilamide was acknowledged by the awarding of a Nobel Prize in 1938. The well-known observation of a clear zone of inhibition (lysis) in a bacterial colony surrounding a colony of contaminating airborne *Penicillium* mold by Alexander Fleming in England in 1929, and the subsequent purification of penicillin from it in the late 1930s and early 1940s by Florey, Chain, Abraham, and Heatley, provided important additional impetus. With the first successful clinical trial of crude penicillin on February 12, 1941, and the requirements of wartime, an explosion of successful activity ensued that continues some 65 years later. In rapid succession, deliberate searches of the metabolic products of a wide variety of soil microbes led to the discovery of tyrothricin (1939), streptomycin (1943), chloramphenicol (1947), chlortetracycline (1948), neomycin (1949), and erythromycin (1952). These discoveries ushered in the age of the so-called "miracle drugs."

Microbes of soil origin remain to this day the most fruitful sources of antibiotics, although the specific means employed for their discovery are infinitely more sophisticated today than those employed 50 years ago. Initially, extracts of fermentations were screened simply for their ability to kill pathogenic microorganisms in vitro. Those that did were pushed along through ever more complex pharmacological and toxicological tests in attempts to discover clinically useful agents. Today, many thousands of such extracts of increasingly exotic microbes are tested each week, and the tests now include sophisticated assays for agents operating through particular biochemical mechanisms or possessing particular desirable properties.

Today, combinatorial chemical synthesis coupled with high-throughput screening make it possible to screen, in a short time, hundreds of thousands of compounds for antimicrobial activity. This is coupled with dramatic advances in all the relevant sciences. One would logically suppose that this would lead to the emergence of a large number of new antimicrobial agents. That this is yet to happen, however, is a measure of the complexity of the task. The impact of genomics and proteomics is predicted to have a favorable impact on this effort. The genome of *Haemophilus influenzae* was determined in 1995, and a decade later, more than 200 microbial genomes have been deciphered and are publicly available (http://www.ncbi.nlm.nih.gov/genomes/Complete.html). Of the 1,709 genes of *H. influenzae*, it is thought that 256 are potentially essential and, thus, are targets for antimicrobial drug development. These exciting new possibilities have yet to yield practical results, however, because of to the inherent complexity of the task.

In the year 2005, annual worldwide commerce in antibiotics was measured in multiple tons and was valued in excess of $10 billion. About half of this was associated with β-lactam antibiotics alone. Approximately 20% of the most frequently prescribed outpatient medications in the United States are anti-infective agents. Approximately 100 antibiotics have seen substantial clinical use, representing the most attractive of more than 20,000 known natural antibiotics and an order of magnitude more semisynthetic and totally synthetic antimicrobial agents. These agents have had a major impact on the practice of medicine and pharmacy and on the lives of persons still living, who remember well the perils and uncertainties of life before antibiotics became available.

This salubrious picture has an increasing dark side, however, because of the growing impact of bacterial resistance. Intrinsic resistance to antimicrobial agents (resistance present before exposure to antibiotics) was recognized from the beginning. Some bacteria are immune to treatment from the outset, because they do not take up the antibiotic or lack a susceptible target. Starting in the 1940s, however, and encountered with

Copyrighted material

increasing frequency to this day, bacteria that previously were expected to respond were found to be resistant. Alarmingly, many became resistant during the course of chemotherapy, and others were simultaneously resistant to several different antibiotics. The latter were found to be capable of passing on this trait to other bacteria—even to those belonging to different genera. Similar findings are now encountered with fungi, viruses, and even tumors, indicating that this is a general biological phenomenon. The spread of this phenomenon is abetted by their short generation time (measured in fractions of an hour) and genetic versatility as well as by poor antibiotic prescription and utilization practices. Some authorities predict an impending return to the defenseless days of the preantibiotic era. For example, in the United Kingdom, resistance of the important Gram-positive pathogen *Staphylococcus aureus* has risen from approximately 2% in the 1990s to nearly 42% by the year 2000. Resistance to vancomycin in the United States among patients infected with *Enterococcus faecium* amounts to approximately 20 to 30%; such resistance was almost unknown a decade ago. Many other microbes and medicaments could be cited as well. An understanding of these phenomena and the devising of appropriate practical response measures are important contemporary priorities.

## GENERAL THERAPEUTIC APPROACH

### Drug Nomenclature

The names given to antimicrobials and antibiotics are as varied as their inventor's taste; however, some helpful unifying conventions are followed. For example, the penicillins are derived from fungi and have names ending in the suffix -cillin, as in ampicillin. The cephalosporins likewise are fungal products, although their names mostly begin with the prefix cef- (or, sometimes, following the English practice, ceph-). The synthetic fluoroquinolones mostly end in the suffix -floxacin. Although helpful in many respects, this nomenclature does result in many related substances possessing quite similar names. This can make remembering them a burden. Most of the remaining antibiotics are produced by fermentation of soil microorganisms belonging to various *Streptomyces* species. By convention, these have names ending in the suffix -mycin, as in streptomycin. Some prominent antibiotics are produced by fermentation of various soil microbes known as *Micromonospora* sp.; these antibiotics have names ending in -micin, as in gentamicin. The student has to take considerable care to avoid confusing them.

In earlier times, the terms "broad spectrum" and "narrow spectrum" had specific clinical meaning. The widespread emergence of microbes resistant to single agents and to multiple agents, however, has made these terms much less meaningful. Nonetheless, it still is valuable to remember that some antimicrobial families have the potential of inhibiting a wide range of bacterial genera belonging to both Gram-positive and Gram-negative cultures and so are called broad spectrum (e.g., the tetracyclines). Others inhibit only a few bacterial genera and are called narrow spectrum (e.g., the glycopeptides, typified by vancomycin, which are used almost exclusively for a few Gram-positive and anaerobic microorganisms).

### The Importance of Pathogen Identification

#### Empiric-Based Therapy

Fundamental to appropriate antimicrobial therapy is an appreciation that individual species of bacteria are associated with particular infective diseases and that specific antibiotics are more likely to be useful than others for killing them. Sometimes, this can be used as the basis for successful empiric therapy. For example, first-course, community-acquired urinary tract infections in otherwise healthy individuals are most commonly caused by Gram-negative *Escherichia coli* of fecal origin. Even just knowing this much can give the physician several convenient choices for useful therapy. Likewise, skin infections, such as boils, are commonly the result of infection with Gram-positive *Staphylococcus aureus*. In most other cases, however, the cause of the disease is less obvious, and so, likewise, is the agent that might be useful against it. It is important to determine the specific disease that one is dealing with in these cases and what susceptibility patterns are exhibited by the causative microorganism. Knowing these factors

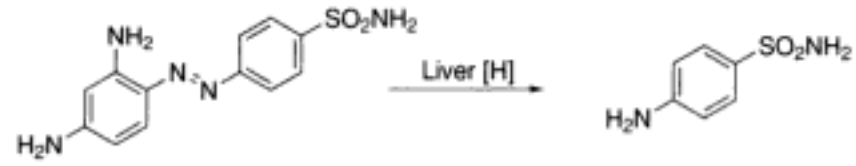
#### Gram Stain

Hans C.J. Gram, a Danish microbiologist, developed the Gram method for staining bacteria so that they were more readily visible under the microscope. The term has proven to be particularly useful in describing antibiotics as well, because antibiotics are conveniently classified by their activity against microorganisms depending on their reaction to this method. Gram-positive microorganisms are stained blue by contact with a methyl violet–iodine process. This is largely a consequence of their lack of an outer membrane and the nature of the thick cell wall surrounding them. Gram-negative microorganisms do not retain the methyl violet–iodine stain when washed with alcohol but, rather, are colored pink when subsequently treated with the red dye safranin. The lipopolysaccharides on their outer membrane apparently are responsible for the staining behavior of Gram-negative cells.

Because the Gram stain is dependent on the outer layers of bacterial cells and this also strongly influences the ability of antimicrobial agents to reach their cellular targets, knowing the Gram-staining behavior of infectious bacteria helps one to decide which antimicrobial might be effective in therapy.

Not all bacteria can be stained by the Gram procedure, however, and these often require special staining processes for visualization. Among the more prominent of these for our purposes are the mycobacteria (the causative agents of tuberculosis, for example). These very waxy cells are called acid-fast and are stained by carbol fuchsin instead.

such as penicillin allergy or subsequent infection higher up the food chain by drug-resistant microbes can occur. Several instances of death in humans have been recorded in the 1990s from such incidents. Animals grow demonstrably more rapidly to marketable size when antibiotics are added to their feed, even though the animals have no apparent infection. This is believed to result, in large part, from suppression of subclinical infections that, consequently, would divert protein biosynthesis from muscle and tissue growth into proteins needed to combat the infection. Under appropriate conditions, antibiotic feed supplementation is responsible, in part, for the comparative wholesomeness and cheapness of our food supplies. This practice has the potential, however, to contaminate the food that we consume or to provide reservoirs of drug-resistant enteric microorganisms. Occasionally, infections are traced to this cause, and resistance genes can originate in this manner and pass from strain to strain—and even to other species.



## THERAPEUTIC CLASSES

### Synthetic Antimicrobial Agents

Synthetic antimicrobial agents have not been modeled after any natural product, so they may not properly be termed "antibiotics." Some synthetics are extremely effective for treatment of infections and are widely used. Very few antibiotics are known to work in precisely the same way as these agents in killing bacteria. Also curious is the fact that those agents, for which the molecular mode of action is known, are at present nearly all effective against key enzymes needed for the biosynthesis or functioning of nucleic acids. Because they interrupt the biosynthesis or functions of nucleic acids rather than attack the finished products or substitute for them in nucleic acids, they are not genotoxic but are comparatively safe to use.

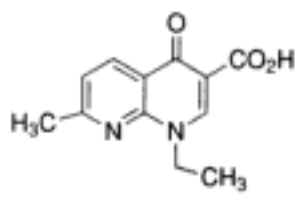
#### Sulfonamides

**INTRODUCTION.** The antibacterial properties of the sulfonamides were discovered in the mid-1930s following an incorrect hypothesis but after observing the results carefully and drawing correct conclusions. Prontosil rubrum, a red dye, was one of a series of dyes examined by Gerhard Domagk of Bayer of Germany in the belief that it might be taken up selectively by certain pathogenic bacteria and not by human cells, in a manner analogous to the way in which the Gram stain works, and, therefore, serve as a selective poison to kill these cells. The dye, indeed, proved to be active in vivo against streptococcal infections in mice. Curiously, it was not active in vitro. Trefouel and Bovet in France soon showed that the urine of prontosil rubrum–treated animals was bioactive in vitro. Fractionation led to identification of the active substance as *p*-aminobenzenesulfonic acid amide (sulfanilamide), a colorless cleavage product formed by reductive liver metabolism of the administered dye. Today, we would call prontosil rubrum a pro-drug. The discovery of the in vivo antibacterial properties of sulfanilamide ushered in the modern anti-infective era, and these investigators shared a Nobel Prize for medicine in 1938. For the first time in the long and weary chronicle of human struggle against infectious disease, physicians now had a comparatively safe and responsive oral drug to use. Considered along with the use of penicillin only 5 years later, the era of the so-called "wonder drugs" had dawned.

Prontosil Rubrum Sulfanilamide

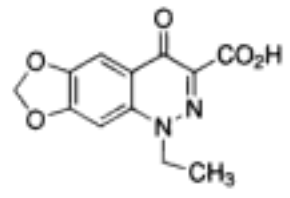
Once mainstays of antimicrobial chemotherapy, the sulfonamides have decreased enormously in popularity and now are comparatively minor drugs. The relative cheapness of the sulfonamides is one of their most attractive features and accounts for much of their persistence in the market.

**MECHANISM OF ACTION.** The sulfonamides are bacteriostatic when administered to humans in achievable doses. They inhibit the enzyme dihydropteroate synthase, an important enzyme needed for the biosynthesis of folic acid derivatives and, ultimately, the thymidine required for DNA. They do this by competing at the active site with *p*-aminobenzoic acid (PABA), a normal structural component of folic acid derivatives. PABA is otherwise incorporated into the developing tetrahydrofolic acid molecule by enzyme-catalyzed condensation with 6-hydroxymethyl-7,8-dihydropterin-pyrophosphate to form 7,8-dihydropteroate and pyrophosphate. Thus, sulfonamides also may be classified as antimetabolites (Fig. 38.3). Indeed, the antimicrobial efficacy of sulfonamides can be reversed by adding significant quantities of PABA into the diet (in some multivitamin preparations and as metabolites of certain local anesthetics) or into the culture medium. Most susceptible bacteria are unable to take up preformed folic acid from their environment and convert it to a tetrahydrofolic acid but, instead, synthesize their own folates de novo. Folates are essential intermediates for the biosynthesis of thymidine, without which bacteria cannot multiply. This inhibition is strongly bacteriostatic and, ultimately, bactericidal. Humans are unable to synthesize folates from component parts, because we lack the necessary enzymes, including dihydropteroate synthase, and folic acid is supplied to us in our diet. Consequently, sulfonamides have no similarly lethal effect on human cell growth. The basis for the selective toxicity of sulfonamides thus is clear.



In a few strains of bacteria, however, the picture is somewhat more complex. Here, sulfonamides are attached to the dihydropteroate diphosphate in the place of the normal PABA. The resulting unnatural product, however, is not capable of undergoing the next necessary reaction (condensation with glutamic acid). This false metabolite

Copyrighted material

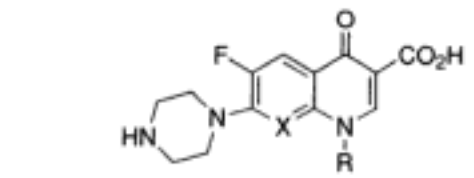


**RESISTANCE.** Bacterial resistance to trimethoprim is increasingly common. In pneumococcal infections, it can result from a single amino acid mutation (Ile-100 to Leu) in the dihydrofolate reductase enzyme. Overexpression of dihydrofolate reductase by *Staphylococcus aureus* has been reported in resistant strains as well.

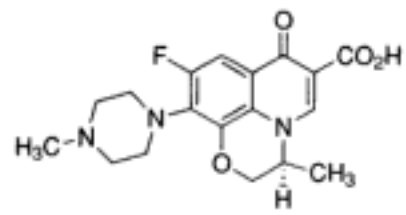
## Quinolones

### INTRODUCTION

Nalidixic Acid

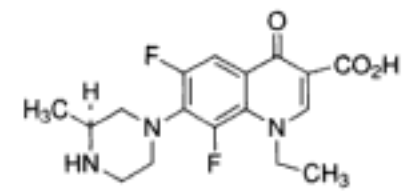


Cinoxacin



The quinolone antimicrobials comprise a group of synthetic substances possessing in common an N-1-alkylated 3-carboxypyrid-4-one ring fused to another aromatic ring, which itself carries other substituents. The first quinolone to be marketed (in 1965) was nalidixic acid. Nalidixic acid and cinoxacin are classified as first-generation quinolones based on their spectrum of activity and pharmacokinetic properties. While still available, they are considered to be minor urinary tract disinfectants that are effective primarily against certain susceptible Gram-negative bacteria. Thus, the quinolones were of little clinical significance until the discovery that the addition of a fluoro group to the 6-position of the basic nucleus greatly increased the biological activity. Brought to the market in 1986, norfloxacin, the first of the second-generation quinolones, has a broad spectrum and equivalent in potency to many of the fermentation derived antibiotics. Following its introduction, intense competition ensued, more than a thousand second-, third-, and fourth-generation analogues have now been made. Alatrofloxacin, ciprofloxacin, enoxacin, gatifloxacin, gemifloxacin, lomefloxacin, norfloxacin, ofloxacin, levofloxacin, moxifloxacin, sparfloxacin, and trovafloxacin are currently marketed in the United States (Fig. 38.6). Ciprofloxacin and levofloxacin dominate the worldwide fluoroquinolone market, accounting between them for over $3 billion in 2002.

It should be noted that the more recent quinolones also are referred to as the fluoroquinolones and that these agents are now an important class of antimicrobial agents.



**MECHANISM OF ACTION.** The quinolones are rapidly bactericidal, largely as a consequence of inhibition of DNA gyrase and topoisomerase IV, key bacterial enzymes that dictate the conformation of DNA. The *Escherichia coli* chromosome is a single, circular molecule of approximately 1 mm in length, whereas the cell is only 1 to 3 μm long. Thus, the DNA molecule must be dramatically compacted in a conformationally stable way so that it can fit. Using the energy generated by adenosine triphosphate (ATP) hydrolysis, the molecule is progressively wound about itself in a positive super coil. In the absence

Copyrighted material

Finally, a chemical incompatibility common to all the quinolones involves the ability of these drugs to chelate polyvalent metal ions ($Ca^{2+}$, $Mg^{2+}$, $Zn^{2+}$, $Fe^{2+}$, and $Al^{3+}$), resulting in decreased solubility and reduced drug absorption. Chelation occurs between the metal and the 3-carboxylic acid and 4-keto groups. Agents containing polyvalent metals should be administered at least 4 hours before or 2 hours after the quinolones.

**PHARMACOKINETICS.** The fluoroquinolones are well absorbed following oral administration, with excellent bioavailability. The maximum plasma concentration usually is reached within a few hours, and the drugs are moderately bound to plasma protein, leading to comparatively long half-lives (Table 38.2). Earlier quinolones were rapidly excreted into the urine, which limited their therapeutic application to urinary tract infections, whereas the newer drugs are distributed to alveolar macrophages, bronchial mucosa, epithelial lining fluid, and saliva, improving the use in various systemic infections. Several studies have suggested that the ratio of mean peak plasma concentration to MIC and the 24-hour area under the curve to MIC may correlate with therapeutic outcomes. If this proves to be true, it could greatly help the clinician in choosing the appropriate drug and dosing schedule.

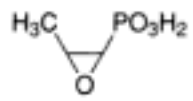
**THERAPEUTIC APPLICATIONS.** The quinolones therapeutically fall into one of four classifications (Table 38.3). The specific drugs within each classification include nalidixic acid and cinoxin as first-generation agents, with utility limited to uncomplicated urinary tract infections. The second-generation quinolones include norfloxacin, lomefloxacin, enoxacin, ofloxacin, and ciprofloxacin. Whereas norfloxacin is used mainly for urinary tract infections (*Enterobacter* sp., *Enterococcus* sp., or *Pseudomonas aeruginosa*), ciprofloxacin also is used for prostatitis, upper respiratory tract infections, bone infections, septicemia, staphylococcal and pseudomonal endocarditis, meningitis, sexually transmitted diseases (gonorrhea and chlamydia), chronic ear infections, and purulent osteoarthritis. The third-generation quinolones, which include levofloxacin, sparfloxacin, gatifloxacin, and gemifloxacin, are used to treat infections caused by *Legionella* sp., *Chlamydia* sp., and *Mycoplasma* sp., as well as *Streptococcus pneumoniae*. These agents may find use in the treatment of acute bacterial exacerbation of chronic bronchitis and community-acquired pneumonia. Gemifloxacin has been approved for use against multidrug-resistant *S. pneumoniae*. Additional indications may include skin and skin structure infections and acute sinusitis caused by *S. pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. The fourth-generation quinolines include trovafloxacin and moxifloxacin, which have a spectrum of activity that includes anaerobes, such as *Bacteroides fragilis*.

Table 38.2. Pharmacokinetic Properties for Selective Quinolones

| Drug | Bioavailability (%) | Protein Binding (%) | Half-life (hours) |
|---|---|---|---|
| Ciprofloxacin | 70 | 30 | 3.5 |
| Enoxacin | 90 | 40 | 3–6 |
| Gatifloxacin | 96 | 20 | 8.0 |
| Gemifloxacin | 71 | 60–70 | 8.0 |
| Levofloxacin | 99 | 31 | 6.9 |
| Lomefloxacin | 95 | 10 | 8 |
| Moxifloxacin | 86 | 47 | 12.1 |
| Norfloxacin | 30–40 | 10–15 | 3–4 |
| Ofloxacin | 98 | 32 | 9 |
| Sparfloxacin | 90 | 56 | 18.7 |
| Trovafloxacin | 88 | 73 | 11.0 |

Table 38.3. Therapeutic Classification of Quinolones

| Generation | Characteristics |
|---|---|
| First generation | Poor serum and tissue concentration<br>Not valuable for systemic infections<br>Lack activity against *Pseudomonas aeruginosa*, Gram-positive organisms, and anaerobes |
| Second generation | Adequate serum and tissue concentration<br>Good for systemic infections<br>Active against Gram-negative organisms, including *P. aeruginosa*; weak activity against *Streptococcus pneumoniae*; no activity against anaerobes |
| Third generation | Once-daily dosing<br>Active against *S. pneumoniae* and atypical bacteria; less active against *P. aeruginosa* |
| Fourth generation | Active against anaerobes and aerobic Gram-positive and Gram-negative organisms |



**RESISTANCE.** Resistance to the quinolones is becoming more frequent and is associated with spontaneous mutations in two genes (*gyrA* and *gyrB*) that encode for the quinolone target protein, DNA gyrase. A single step mutation can lead to low-level resistance, whereas mutations in both genes lead to high-level resistance. This mechanism of resistance would be expected to produce cross-resistance within the class of quinolones. In addition, there are suggestions that resistance may be associated with an increase in drug efflux or a decrease in outer membrane permeability affecting drug influx. Such a mechanism of resistance would be expected to be more common in Gram-negative organisms with a more complex cell wall than in Gram-positive organisms with its cell envelope.

**ADVERSE EFFECTS.** The quinolone class is associated with more side effects than the β-lactam and macrolide classes but, nonetheless, see very widespread medicinal use.

Copyrighted material

A venerable drug used for the disinfection of acidic urine, methenamine is a low-molecular-weight polymer of ammonia and formaldehyde that reverts to its components under mildly acidic conditions. Formaldehyde is the active antimicrobial component. Methenamine is used for recurrent urinary tract infections. The drug is available in various dosage forms as well as various salts, including the hippurate and mandelate.

### PHOSPHOMYCIN

Phosphomycin (Monurol)

Phosphomycin, introduced in 1972, inhibits enolpyruvial transferase, an enzyme catalyzing an early step in bacterial cell wall biosynthesis. Inhibition results in reduced synthesis of peptidoglycan, an important component in the bacterial cell wall. Phosphomycin is bactericidal against *Escherichia coli* and *Enterobacter faecalis* infections.

## Antibiotics: Inhibitors of Bacterial Cell Wall Biosynthesis

**BACTERIAL CELL WALL.** Bacterial cells are enclosed within a complex and largely rigid cell wall. This differs dramatically from mammalian cells, which are surrounded by a flexible membrane, the chemical composition of which is dramatically different. This provides a number of potentially attractive targets for selective chemotherapy of bacterial infections. For one thing, enzymes that have no direct counterpart in mammalian cells construct the bacterial cell wall. Three of the main functions of the bacterial cell wall are 1) to provide a semipermeable barrier interfacing with the environment through which only desirable substances may pass, 2) to provide a sufficiently strong barrier so that the bacterial cell is protected from changes in the osmotic pressure of its environment, and 3) to prevent digestion by host enzymes. The initial units of the cell wall are constructed within the cell, but soon, the growing and increasingly complex structure must be extruded; final assembly takes place outside of the inner membrane. This circumstance makes the enzymes involved in the late steps more vulnerable to inhibition, because they are at or near the cell surface. Whereas individual bacterial species differ in specific details, the following generalized picture of the process is sufficiently accurate to illustrate the process.

***Gram-Positive Bacteria.*** The cell wall of Gram-positive bacteria, although complex enough, is simpler than that of Gram-negative organisms. A schematic representation is shown in Figure 38.9. On the very outside of the cell is a set of characteristic carbohydrates and proteins that, together, make up the antigenic determinants that differ from species to species and that also cause adherence to particular target cells. There also may be a lipid-rich capsule surrounding the cell (not shown in Fig. 38.9). The next barrier that the wall presents is the peptidoglycan layer.

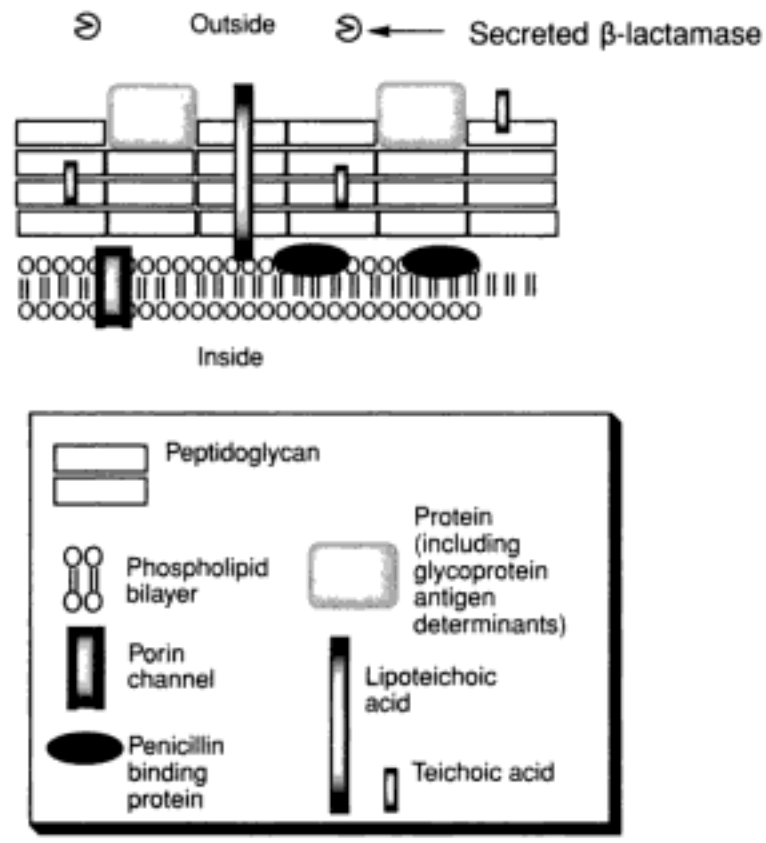


**Fig. 38.9.** Schematic of some features of the Gram-positive bacterial cell wall.

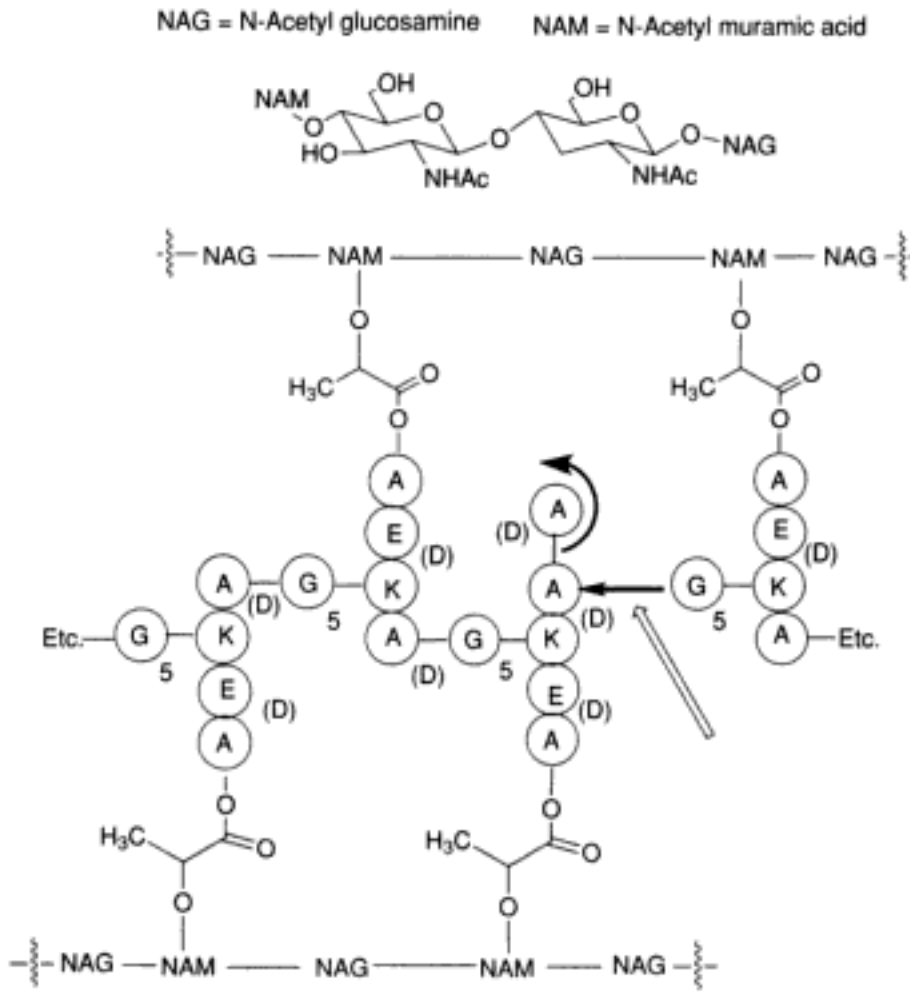
This is a spongy, gel-forming layer consisting of a series of alternating sugars (N-acetylglucosamine and N-acetylmuramic acid) linked (1,4)-β in a long chain (Fig. 38.10). To the lactic acid carboxyl moieties of the N-acetylmuramic acid units is attached, through an amide linkage, a series of amino acids, of which L-alanyl-D-glutamyl-L-lysyl-D-alanine is



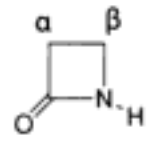


**Fig. 38.10.** Schematic of cell wall cross-linking. Pentaglycyl group replaces terminal D-alanine.

Copyrighted material

up of two or three monomeric proteins. The center of this array is a transmembranal pore of various dimensions. Some allow many kinds of small molecules to pass, and others contain specific receptors that allow only certain molecules to come in. The size, shape, and lipophilicity of drugs are important considerations controlling porin passage. Antibiotics have greater difficulty in penetrating into Gram-negative bacterial cells as a consequence. Next comes a periplasmic space containing a somewhat less impressive and thinner, as compared to the Gram-positive organisms, layer of peptidoglycan. Also present is a phospholipid-rich cytoplasmic membrane in which floats a series of characteristic proteins with various functions. The β-lactam targets (i.e., the PBPs) are found here.

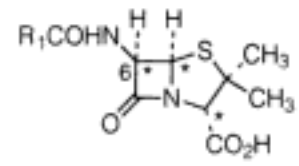
Other inner membrane proteins are involved in transport, energy, and biosynthesis. In many such cells are proteins that actively pump out antibiotics and other substances at the expense of energy and that may require the simultaneous entrance of oppositely charged materials to maintain an electrostatic balance.

## β-Lactam antibiotics

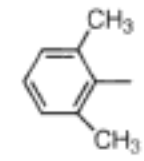
β -lactam
azetidinone

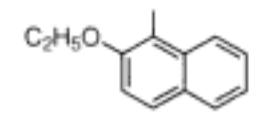
The name "lactam" is given to cyclic amides and is analogous to the name "lactone," which is given to cyclic esters. In an older nomenclature, the second carbon in an aliphatic carboxylic acid was designated α, the third β, and so on. Thus, a β-lactam is a cyclic amide with four atoms in its ring. The contemporary name for this ring system is azetidinone. This structural feature was very rare when it was found to be a feature of the structure of the penicillins, so the name "β-lactam" came to be a generic descriptor for the whole family. It is fortunate that this ring ultimately proved to be the main component of the pharmacophore, so the term possesses medicinal as well as chemical significance. The penicillin subclass of β-lactam antibiotics is characterized by the presence of a substituted 5-membered thiazoldine ring fused to the β-lactam ring. This fusion and the chirality of the β-lactam ring results in the molecule roughly possessing a "V"-shape. This drastically interferes with the planarity of the lactam bond and inhibits resonance of the lactam nitrogen with its carbonyl group. Consequently, the β-lactam ring is much more reactive and, therefore, more sensitive to nucleophilic attack when compared with normal planar amides.

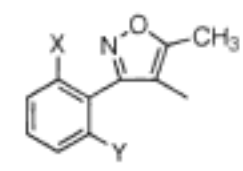
***History.*** The story of the discovery of the penicillins are widely known. In 1929, Alexander Fleming, a physician and a clinical microbiologist, was preserving a culture of a pathogen, and the plate became contaminated with an airborne fungus, *Penicillium notatum* (now named *Penicillium chrysogenum*), which not only grew on the plate but also produced a clear zone of inhibition around its colony. On returning from a vacation and finding this, he recognized the potential significance of this antibiotic effect, so he preserved the fungus and tried to identify its active constituent. The state of development of the art as well as his background and training were insufficient for the task at that time. It was not until a decade later that a group of English chemists, including Abraham, Chain, Florey, and Heatley, succeeded in purifying the unstable antibiotic. Finally, on February 12, 1941, following heroic efforts necessitated by wartime conditions, enough material was available for clinical examination and the demonstration that penicillin actually worked in humans. Much new technology had to be developed before large-scale use of penicillin could take place. The efforts of an international team solved, for example, the problems of large-scale sterile aerobic submerged fermentation, directed fermentation, strain improvement, and many other vexing problems. By 1943, penicillin was being produced in very large quantities for use by the armed forces. When peace came in 1945, production was in tons, and the drug was available very cheaply.

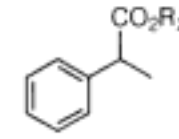


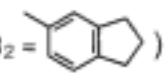
The earliest penicillins were produced by fungi from media constituents. The bicyclic heterocyclic nucleus of 6-aminopenicillanic acid (6-APA) was constructed by an involved process catalyzed by enzymes. The side chain was added essentially intact from media constituents. It was discovered that certain arylacetic acids, when added to the medium, were used to form the side chain amide moiety and that this was very important for stability and breadth of spectrum. It was later discovered that exclusion of such materials from the medium allowed the production of 6-APA without a side chain. Chemists could then add a much wider variety of side chains without being limited by the specific requirements of the enzymes. With this breakthrough, the penicillin field expanded to include orally active, broad-spectrum, and enzymatically stable penicillins. The cephalosporins were discovered as secondary metabolites of a different fungal species. Because it was stable to many activity-destroying β-lactamases, its core nucleus, 7-aminocephalosporanic acid, was substituted with a wide variety of unnatural side chains, and three generations of clinically useful analogues resulted. Later work produced the monobactams, carbapenems, and β-lactamase inhibitors. In the year 2005, about half of the money spent worldwide on antibiotics was for β-lactams. More than 100,000 of these compounds have been prepared by partial or total chemical synthesis, and a significant number of these remain on the market more than 60 years after their discovery.

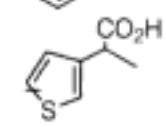


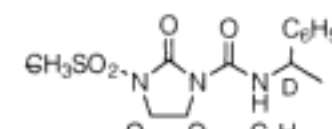


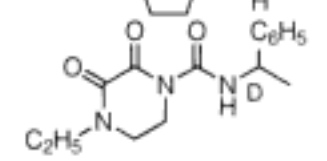


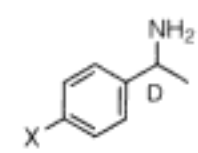












***Penicillins.*** The medicinal classifications, chemical structures, and generic names of the penicillins currently available are presented in Table 38.5.

***Preparation of Penicillins.*** The original fermentation derived penicillins were produced by growth of the fungus

## Table 38.5. Commercially Significant Pencillins and Related Molecules

| Generic name | Trade name | $R_1$ |
|---|---|---|
| **Fermentation-Derived Penicillins** | | |
| 6-Aminopenicillanic acid | | H |
| Benzylpenicillin (Penicillin G) | Generic | $C_6H_5$-$CH_2$- |
| Phenoxymethylpenicillin (Penicillin V) | Generic | $C_6H_5$-$OCH_2$- |
| **Semi-Synthetic Penicillinase-Resistant Parenteral Penicillins** | | |
| Methicillin | |  |
| Nafcillin | Nallpen, Unipen |  |
| **Semi-Synthetic Penicillinase-Resistant Oral Penicillins** | | |
| Oxacillin (X = Y = H) | Bactocill |  |
| Cloxacillin (X = Cl, Y = H) | Cloxapen | |
| Dicloxacillin (X = Y = Cl) | Dycill, Pathocil | |
| **Semi-Synthetic Penicillinase-Sensitive, Broad Spectrum, Parenteral Penicillins** | | |
| Carbenicillin ($R_2$ = H) | Geocillin |  |
| Carbenicillin indanyl ($R_2$ =  ) | | |
| Ticarcillin | Ticar |  |
| Mezlocillin | Mezlin |  |
| Piperacillin | Pipracil |  |
| **Semi-Synthetic Penicillinase-Sensitive, Broad-Spectrum, Oral Penicillins** | | |
| Ampicillin (X = H) | Principen, Omnipen |  |
| Amoxicillin (X = OH) | Amoxil, Trimox, Wymox | |

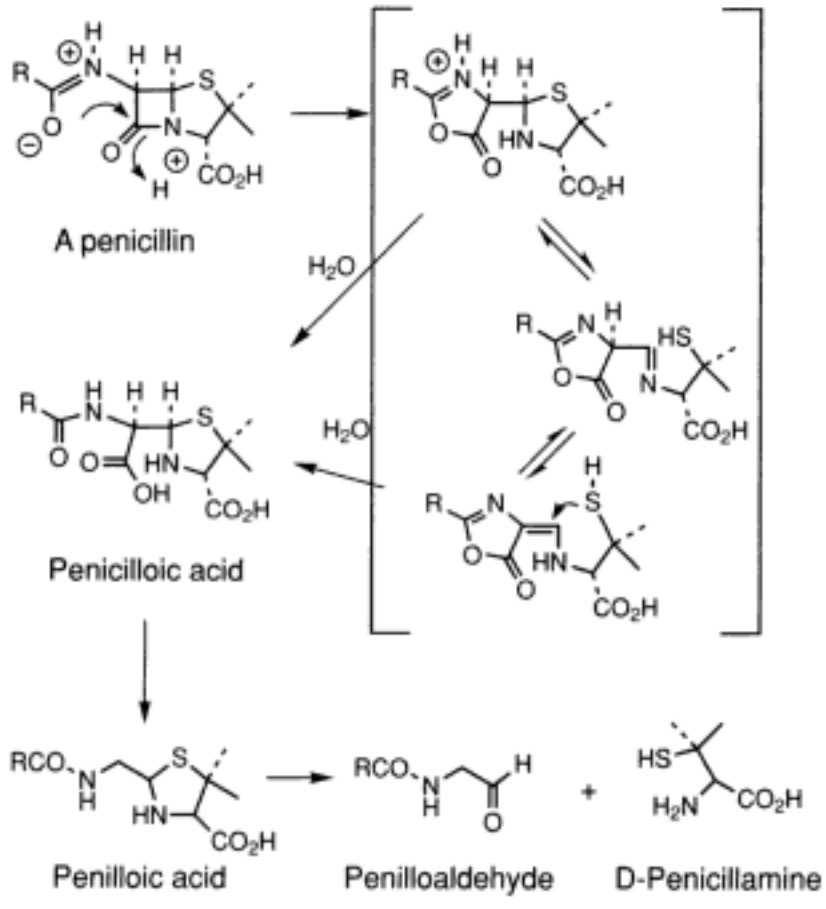
*Penicillium chrysogenum* on complex solid media, with the result that they were mixtures differing from one another in the identity of the side-chain moiety. When a sufficient supply of phenylacetic acid is present in liquid media, this is preferentially incorporated into the molecule to produce mainly benzylpenicillin (penicillin G in the old nomenclature). Use of phenoxyacetic acid instead leads to phenoxymethyl penicillin (penicillin V). More than two dozen different penicillins have been made in this way, but these two are the only ones that remain in clinical use. The bicyclic penicillin nucleus itself is prepared biosynthetically via a complex process from an acylated cysteinyl valyl peptide. The complete exclusion of side chain precursor acids from the medium produces the fundamental penicillin nucleus, 6-APA, but in poor yield. By itself, 6-APA has only very weak antibiotic activity, but when substituted on its primary amino group with a suitable amide side chain, its potency and antibacterial spectrum are profoundly enhanced. With this key precursor isolated, limitations caused by enzyme specificities in biosynthesis could be overcome by use of partial chemical synthesis. A more practical modern process for making 6-APA employs naturally occurring fungal enzymes that selectively hydrolyze away the side chain of natural penicillins without cleaving the β-lactam bond. These enzymes are found in certain Gram-negative bacteria but

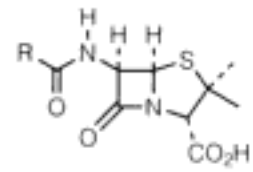
Copyrighted material

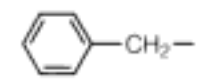
available penicillin salts may be contaminated with small amounts of these antigenic penicilloyl proteins derived from reaction with proteins encountered in their fermentative production or by high-molecular-weight, self-condensation–derived polymers resulting when penicillins are concentrated and react with themselves. Both of these classes of impurities are antigenic and may sensitize some patients.

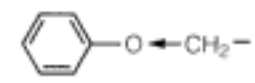
Solutions of penicillins for parenteral use should be refrigerated, used promptly, and not stored. In acidic solutions, the hydrolysis of penicillins is complex. Hydrolysis of the β-lactam bond can be shown through kinetic analysis to involve participation of the side-chain amide oxygen, because the rate of this reaction differs widely depending on the nature of the R group. The main end products of the acidic degradation are penicillamine, penilloic acid, and penilloaldehyde (Fig. 38.14). The intermediate penicillenic acid is highly unstable and undergoes subsequent hydrolysis to the corresponding penicilloic acid. An alternate pathway involves sulfur ejection to a product that, in turn, fragments to liberate penicilloic acid as well. Penicilloic acid readily decarboxylates to penilloic acid. The latter hydrolyzes to produce penilloaldehyde and penicillamine (itself used clinically as a chelating agent). Several related fragmentations to a variety of other products take place. None of these products has antibacterial activity. At gastric pH (~2.0) and temperature of 37°C, benzylpenicillin has a half-life measured in minutes. The less water-soluble amine salts are more stable.

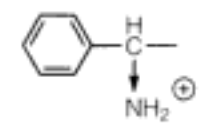
***Structure–Activity Relationship.*** The chemical substituents attached to the penicillin nucleus can greatly influence











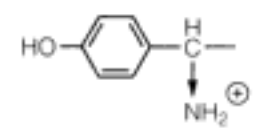


**Fig. 38.14.** Instability of penicillins in acid. Hydrolysis involves the C-6 side chain.

Table 38.6. Improved Acid Stability and Absorption of Substituted Penicillins

| Drug | R | % Absorption intact drug |
|---|---|---|
| Benzylpenicillin |  | 15–30 |
| Pen V |  | 60–73 |
| Ampicillin |  | 30–50 |
| Amoxicillin |  | 75–90 |

the stability of the penicillins as well as the spectrum of activity. It is important to recognize whether the structural changes affect drug stability on the shelf or in the GI tract (in vivo), improve stability toward bacterial metabolism, or enlarge the spectrum of activity.

The substitution of a side-chain R group on the primary amine with an electron-withdrawing group decreases the electron density on the side-chain carbonyl and protects these penicillins, in part, from acid degradation. This property has clinical implications, because these compounds survive passage through the stomach better and many can be given orally for systemic purposes. The survival of passage and degree of absorption under fasting conditions is shown in Table 38.6.

In addition, in vitro degradation reactions of penicillins can be retarded by keeping the pH of solutions between 6.0 and 6.8 and by refrigerating them. Metal ions, such as mercury, zinc, and copper, catalyze the degradation of penicillins, so they should be kept from contact with penicillin solutions. The lids of containers used today are routinely made of inert plastics, in part, to minimize such problems.

The more lipophilic the side chain of a penicillin, the more serum protein bound is the antibiotic (Table 38.7).

Table 38.7. Protein Binding of Penicillins

| Penicillin | % Protein binding |
|---|---|
| Benzyl penicillin | 45 - 68% |
| Phenoxymethyl penicillin | 75 - 89% |
| Methicillin | 35 - 80% |
| Ampicillin | 25 - 30% |
| Amoxicillin | 25 - 30% |
| Carbenicillin | ~50% |
| Oxacillin | >90% |
| Cloxacillin | >90% |

Table 38.8. β-lactamase Classifications According to Sykes and Matthew

| Type | Substrate preferences | Gene location | Inducibility |
|---|---|---|---|
| Gram +/– | Penicillins mainly | r-Plasmid | Mostly |
| I | Cephalosponins mainly | Chromosome | Mainly |
| II | Penicillins mainly | Chromosome | Constituitive |
| III | Broad spectrum | r-Plasmid | Constituitive |
| IV | Broad spectrum | Chromosome | Constituitive |
| V | Methicillin, oxacillin, cloxacillin | r-Plasmid | Constituitive |

Sykes RB, Matthew M. The beta-lactamases of gram-negative bacteria and their role in resistance to beta-lactam antibiotics. J Antimicrob Chemother 1976; 2: 115–117.

β-lactamase and that this will be less prevalent, but not uncommon, among *Haemophilus influenzae, Moraxella catarrhalis, Escherichia coli, and Klebsiella, Enterobacter, Serratia, Pseudomonas,* and *Bacteroides sp.* strains.

***Allergenicity.*** Approximately 6 to 8% of the U.S. population is allergic to β-lactam antibiotics. Most commonly, this is expressed as a mild drug rash or itching and is of delayed onset. Occasionally, the reaction is immediate and profound. It may include cardiovascular collapse and shock and can even result in death. Sometimes, penicillin allergy can be anticipated by taking a medication history, and often, the patients who are likely to be allergic are those with a history of hypersensitivity to a wide variety of allergens (e.g., foods and pollens). A previous history of allergy to penicillins is a contraindicating factor to their use. Topical wheal-and-flare tests are available when there is doubt. When an allergic reaction develops, the drug must be discontinued, and, because cross-sensitivity is common, other β-lactam drugs should generally be avoided. Considering all therapeutic categories, penicillins, especially the ones most commonly employed (benzylpenicillin and ampicillin/amoxicillin), are probably the drugs most associated with allergy. Erythromycin and clindamycin are useful alternate choices for therapy in many cases of penicillin allergy.

In some cases, the patient may have become sensitized without knowing it because of previous passive exposure through contaminated foodstuffs or cross-contaminated medications. Penicillins are manufactured in facilities separate from those used to prepare other drugs to prevent cross-contamination and possible sensitization. Animals treated with penicillins are required to be drug-free for a significant time before products prepared from them can be consumed. The number of pharmacists who unknowingly override these protective measures by failing to cleanse their pill counters properly between prescriptions is unknown.

Because the origin of the allergy is a haptenic reaction with host proteins and the responsible bond in the drug is the β-lactam moiety, this side effect is caused by the pharmacophore of the drug and is unlikely to be overcome by molecular manipulation.

Table 38.9. β-Lactamase Classification According to Ambler[a] and Bush-Jacoby-Medeiros[b]

| Class[a] | Characteristics |
|---|---|
| A | Penicillinases and TEM-type, broad-spectrum enzymes |
| B | Increased activity against cephalosporins |
| C | Chromosomal cephalosporinases of Gram-negative bacteria |
| D | Oxacillin-hydrolyzing enzymes |
| **Group[b]** | **Characteristics** |
| 1 | Cephalosporinases that are not inhibited by clavulanic acid |
| 2 | β-Lactamases inhibited by β-lactamase inhibitors |
| 3 | Metallo-β-lactamases that are poorly inhibited by all classical β-lactamase inhibitors |
| 4 | Penicillinases that are not inhibited by clavulanic acid |

[b]Bush K, Jacoby GA, Medeiros AA. A functional classification scheme for beta-lactamase and its correlation with molecular structure. Antimicrob Agents Chemother 1995;39:1211–1233.

***Individual Penicillins.*** The penicillins usually are discussed under various groups based on spectrum of activity and sensitivity or resistance toward β-lactamase. One of the earliest and still most commonly used penicillin is benzylpenicillin.

*Benzylpenicillin Group*

BENZYLPENICILLIN (PENICILLIN G, TABLE 38.5). With the exception of *Neisseria gonorrhoeae* and *Haemophilus influenza* and a few bacteria encountered less frequently, the useful antimicrobial spectrum of benzylpenicillin is primarily against Gram-positive cocci. Because of its cheapness, efficacy, and lack of toxicity (except for acutely allergic patients), benzylpenicillin remains a remarkably useful agent for the treatment of diseases caused by susceptible microorganisms. As with most antibiotics, susceptibility tests must be performed, because many formerly highly sensitive microorganisms are now comparatively resistant. Infections of the upper and lower respiratory tract and of the genitourinary tract are the particular province of benzylpenicillin. Infections

Copyrighted material

caused by group A β-hemolytic streptococci (pharyngitis, scarlet fever, cellulitis, pelvic infections, and septicemia) are commonly responsive. Group B hemolytic streptococci infections; especially of neonates (acute respiratory distress, pneumonia, meningitis, septic shock, and septicemia) usually respond. *Pneumococcal* pneumonia, *Haemophilus influenza* pneumonia of children, *Streptococcus pneumoniae*– and *Streptococcus pyogenes*–caused otitis media and sinusitis, meningococcal meningitis and brain abscess, meningococcal and pneumococcal septicemia, streptococcal endocarditis (often by *Streptococcus viridans*), pelvic inflammatory disease (often by *Neisseria gonorrhoeae* and *S. pyogenes*), uncomplicated gonorrhea (*N. gonorrhoeae*), meningitis (*Neisseria meningitidis*), syphilis (*Treponema pallidum*), Lyme disease (*Borrelia burgdorferi*), gas gangrene (*Clostridium perfringens*), and tetanus (*Clostridium tetani*) are among the diseases that commonly respond to benzylpenicillin therapy, either alone or sometimes with other drugs used in combination. Non-penicillinase-producing *Staphylococcus aureus* and *Staphylococcus epidermidis* are quite sensitive but are all too rare today. Other, less common bacterial diseases also respond, such as those caused by *Bacillus anthracis* (anthrax) and *Corynebacterium diphtheriae* (diptheria).

Because of its cheapness, mild infections with susceptible microorganisms can be treated with comparatively large oral doses, although the most effective route of administration is parenteral, because fivefold the blood level can be regularly achieved in this manner. As previously indicated (see *Clinically relevant chemical instabilities* above), penicillin G is unstable under the acidic conditions of the stomach.

Very water-insoluble penicillin salts form with procaine and with N, N′-benzathine. These find therapeutic application for deep intramuscular (IM) injections. This produces lower but prolonged levels of penicillin as the drug slowly diffuses from the injection site.

The need to improve defects in benzylpenicillin stimulated an intense research effort that persists to this day. Overcoming such negative features as comparative instability (particularly to acid), comparatively poor oral absorption, allergenicity, sensitivity to β-lactamases, and relatively narrow antimicrobial spectrum have been objectives of this work. Only antigenicity has failed to respond significantly to this effort.

PHENOXYMETHYL PENICILLIN (PENICILLIN V, TABLE 38.5). Penicillin V is produced by fermentation in which the medium is enriched in phenoxyacetic acid. It also can be prepared by semisynthesis, and it is considerably more acid stable than benzylpenicillin, as indicated by oral absorption (Table 38.6). This is rationalized as being caused by the electronegative oxygen atom in the C-7 amide side chain inhibiting participation in β-lactam bond hydrolysis. In any case, penicillin V was the first of the so-called oral penicillins, giving higher and more prolonged blood levels than penicillin G itself. Its antimicrobial and clinical spectrum is roughly the same as that of benzylpenicillin, although it is somewhat less potent and is not, as a rule, used for acutely serious infections. Penicillin V has approximately the same sensitivity to β-lactamases and allergenicity as penicillin G.

*Penicillinase-Resistant Parenteral Penicillins*

METHICILLIN (TABLE 38.5). Although archaic today, methicillin was the first of the penicillinase-resistant agents to reach the clinic. It is unstable to gastric acid, having a half-life of 5 minutes at pH 2, so it must be administered via injection. As shown in Figure 38.15, increased bulk resulting from the addition of the dimethoxybenzoyl group to 6-APA leads to methicillin and a β-lactamase–resistant drug. Methicillin has a significantly narrower antimicrobial spectrum and less potency, so it was restricted to clinical use primarily for parenteral use in infections caused by β-lactamase–producing *Staphylococcus aureus* and a few other infections. Lately, an increasing number of infections have been found that are caused by MRSA. The mode of resistance in these cultures appears to be a reduced uptake and alteration in the PBPs. In particular, an altered PBP-2 is formed that has a very low affinity for β-lactams, including methicillin. Furthermore, methicillin is an efficient inducer of penicillinases, further counting against it. Consequently, this drug fell out of favor, and methicillin has now been supplanted by a number of agents.

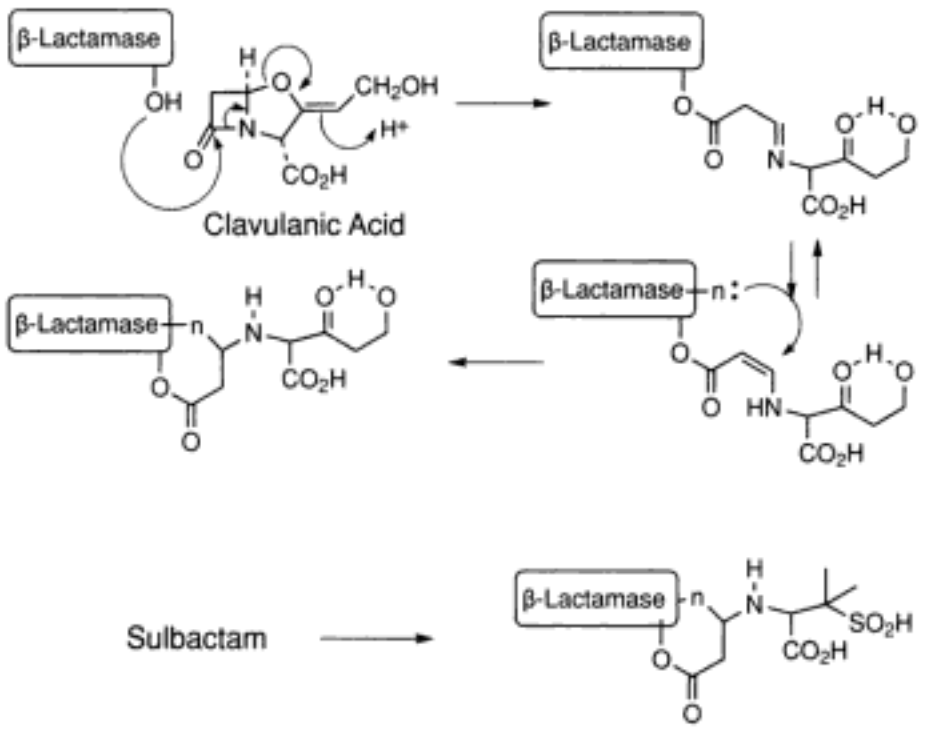
NAFCILLIN (TABLE 38.3). Nafcillin has a fused benzene ring on one flank and an ethoxy moiety on the other of the side-chain amide linkage. Although slightly more acid stable than methicillin, it is virtually identical to it clinically.

OXACILLIN, CLOXACILLIN, AND DICLOXACILLIN. Using an isoxazolyl ring as a bio-isosteric replacement for the benzene ring and a methyl on one flank and a substituted benzene ring on the other in place of the methoxyls of methicillin produces the isoxazolyl penicillins. These are oxacillin, cloxacillin, and dicloxacillin (Table 38.5). Chemically, they differ from one another in the number of chlorine substituents on the benzene ring. Like methicillin, these generally are less potent than benzylpenicillin against Gram-positive microorganisms (generally staphylococci and streptococci) that do not produce a β-lactamase but retain their potency against those that do. An added bonus exists in that they are somewhat more acid stable. Thus, they may be taken orally, and they are more potent as well. Because they are highly serum protein bound (Table 38.7), they are not good choices for treatment of septicemia. Microorganisms resistant against methicillin generally also are resistant to the isoxazolyl group of penicillins.

Like nafcillin, the isoxazoyl group of penicillins is primarily used against *Staphylococcus aureus* in osteomyelitis, septicemia, endocarditis, and CNS infections.

Vancomycin (discussed later) is the current favorite for treatment of infections by MRSA with cotrimoxazole and rifampin often of value as well.

Copyrighted material



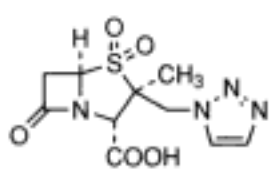


**Fig. 38.18.** Speculative mechanism for irreversible inactivation of β-lactamase by clavulanic acid and sulbactam.

If instead of a β-lactamase, ampicillin resistance is caused by a penetration barrier, clavulanic acid and sulbactam are not able to overcome this, because the underlying mechanism is different. Not all β-lactamases, however, are sensitive to the presence of clavulanic acid or to sulbactam.

*Penicillinase-Sensitive, Broad-Spectrum, Parenteral Penicillins*

MEZLOCILLIN AND PIPERACILLIN. Mezlocillin and piperacillin are ampicillin derivatives in which the D–side chain amino group has been converted by chemical processes to a variety of substituted urea analogues (Table 38.5). They are known as acylureidopenicillins. They preserve the useful anti-Gram-positive activity of ampicillin but have higher anti-Gram-negative potency. Even some strains of *Pseudomonas aeruginosa* are sensitive to these agents. It is speculated that the added side-chain moiety mimics a longer segment of the peptidoglycan chain than ampicillin does. It is recalled that this cell wall fragment usually is a tetrapeptide, so there certainly is room for an extension in this direction. This would give more possible attachment points to the penicillin biding proteins, and perhaps these features are responsible for their enhanced antibacterial properties. These agents are used parenterally with particular emphasis on Gram-negative bacteria, especially *Klebsiella pneumoniae* and the anaerobe *Bacteroides fragilis*. Resistance caused by β-lactamases is a prominent feature of their use, so disk testing and incorporation of additional agents (e.g., an aminoglycoside) for the treatment of severe infections is advisable.

PIPERACILLIN AND TAZOBACTAM COMBINATION (ZOSYN)

Tazobactam

Tazobactam often is coadministered with piperacillin because of tazobactam's ability to inhibit β-lactamases. Tazobactam, like other β-lactamase inhibitors, has little or no antibacterial activity. This effect is analogous to that of clavulanic acid and sulbactam (discussed above).

CARBENICILLIN AND INDANYL CARBENICILLIN. Carbenicillin is a benzylpenicillin analogue in which one of the methylene hydrogens of the side chain has been substituted with a carboxylic acid moiety (Table 38.5). The specific stereochemistry of this change is not very important, because both diastereoisomers are configurationally unstable and mutarotate with time to produce the same mixture of epimers. The introduction of the side-chain carboxyl produces enhanced anti-Gram-negative activity. In fact, carbenicillin is intrinsically one of the broadest spectrum penicillins. Carbenicillin is an order of magnitude less potent than the acylureidopenicillins. The drug is susceptible to β-lactamases and is acid unstable, so it must be given by injection.

Because it is a malonic acid hemiamide with a carbonyl (amide) moiety β to the carboxyl group, carbenicillin can decarboxylate readily to produce benzylpenicillin (Fig. 38.19). Although still an antibiotic, this degradation product has no activity against the organisms for which carbenicillin would be indicated, so this is still considered to be a degradation. In addition, the large doses of carbenicillin sodium that had to be employed (multigrams per day) resulted in ingestion of a significant amount of sodium ion, which could be a consideration with heart patients. Many of these problems were avoided by switching to the oral prodrug ester indanyl carbenicillin. This pro-drug is primarily used for oral treatment of urinary tract infections.

TICARCILLIN. Ticarcillin is a sulfur-based bio-isostere of carbenicillin that cannot decarboxylate as the carboxyl group of carbenicillin does (Table 38.5). This agent is somewhat more potent against pseudomonads compared with indanyl carbenicillin.

When potassium clavulanate is added to ticarcillin (Timentin), the combination has enhanced antipse–domonad activity because of its enhanced stability to lactamases.

***Summary Statement.*** The penicillins ushered in the era of powerful antibiotics, and their use transformed the practice of antimicrobial chemotherapy. A significant percentage of the population alive today owe their

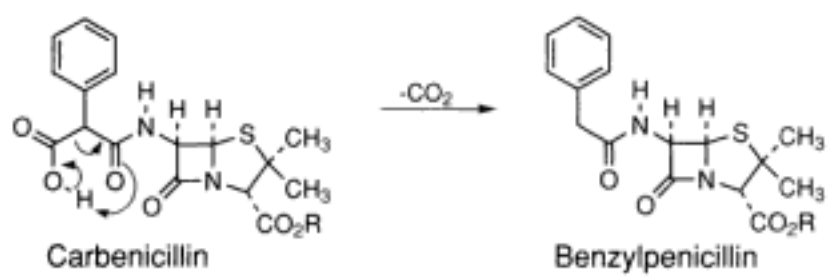

**Fig. 38.19.** Decarboxylation of carbenicillin to benzylpenicillin.

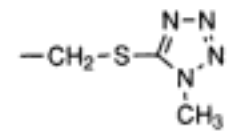
Copyrighted material

staphylococcal β-lactamase, although it is sensitive to many other β-lactamases. Cephapirin also is sensitive to host deacetylation in the liver, kidneys, and plasma, which reduces potency by about half. Nonetheless, it finds significant use in the parenteral treatment of infections because of susceptible bacteria. It is a substitute for the nafcillin subgroup of penicillins. It is not orally active. It is comparatively painful on IM injection, and its doses must be reduced in the presence of renal impairment. Following injection, it is excreted primarily in the urine, partly by glomerular filtration and partly by tubular secretion.

*Cefazolin.* Cefazolin has the natural acetyl side chain at C-3 replaced by a thio-linked thiadiazole ring. Although this group is an activating leaving group, the moiety is not subject to the inactivating host hydrolysis reaction that characterizes cephapirin. At C-7, it possesses a tetrazoylmethylene unit. Cefazolin is less irritating on injection than its cohort in this generation of drugs and has a longer half-life than cephapirin. Its dosing should be reduced in the presence of renal impairment. It is comparatively unstable and should be protected from heat and light.



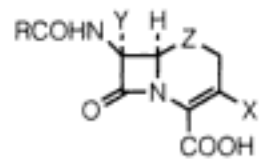
*Cephalexin.* Use of the ampicillin-type side chain conveys oral activity to cephalexin. Whereas it no longer has an activating side chain at C-3 and, as a consequence, is somewhat less potent, it does not undergo metabolic deactivation and, thus, maintains potency. It is rapidly and completely absorbed from the GI tract and has become quite popular. Somewhat puzzling is the fact that the use of the ampicillin side chain in the cephalosporins does not result in a comparable shift in antimicrobial spectrum. Cephalexin, like the other first-generation cephalosporins is active against many Gram-positive aerobic cocci but is limited against Gram-negative bacteria. It is a widely used drug, particularly against Gram-negative bacteria causing urinary tract infections, Gram-positive infections (*Staphylococcus aureus*, *Streptococcus pneumoniae* and *Streptococcus pyogenes*) of soft tissues, pharyngitis, and minor wounds.

*Cefadroxil.* Cefadroxil has an amoxicillin-like side chain at C-7 and is orally active. There are some indications that cefadroxil has some immunostimulant properties mediated through T-cell activation and that this is of material assistance to patients in fighting infections. The prolonged biological half-life of cefadroxil allows once-a-day dosage.

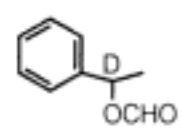
*Cephradine.* In cephradine, an interesting drug design device has been used. The aromatic ring in the ampicillin side chain has been partially hydrogenated by a Birch reduction such that the resulting molecule is still planar and π-electron excessive but has no conjugated olefinic linkages. It is comparatively acid stable and, therefore, is rapidly and nearly completely absorbed from the GI tract. Cephradine has the useful characteristic that it can be used both orally and IM so that parenteral therapy can be started in an institutional setting and then the patient can be sent home with the oral form, thus avoiding the risk of having to establish a different antibiotic. This is consistent with the present economics requiring sending patients home earlier than some physicians prefer. Unfortunately, however, for other reasons the IM and intravenous (IV) versions of cephradine are no longer available in the United States.

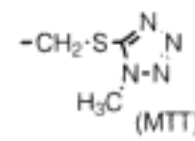
### *Second-Generation Cephalosporins (Table 38.11)*

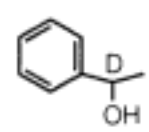
*Cefamandole nafate.* Cefamandole nafate has a formylated D-mandelic amide moiety at C-7. The formate ester is cleaved rapidly in the host to release the more active cefamandole. The esterification also apparently overcomes the instability of cefamandole when it is stored in dry form. This agent has increased activity against *Haemophilus influenzae* and some Gram-negative bacilli as compared with the first-generation cephalosporins. Loss of the 5-thio-l-methyl-l-H-tetrazole moiety (referred to sometimes by the acronym MTT) from C-3 is associated with prothrombin deficiency and bleeding problems as well as with an Antabuse-like acute alcohol intolerance. On the other hand, this grouping enhances potency and prevents metabolism by deacetylation. Like the other second-generation cephalosporins, cefamandole is more active against Gram-negative bacteria. The principle clinical use is for lower respiratory tract, skin and skin structures, and bone and joint infections as well as septicemia and urinary tract infections when the organisms are sensitive.

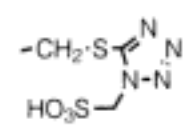


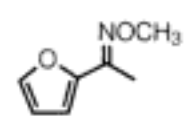
MTT

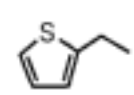


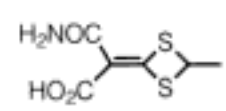


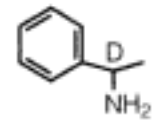


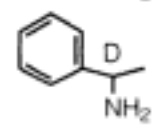


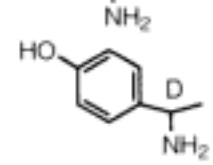












*Cefonicid.* Cefonicid has an unesterified D-mandelic acid moiety at C-7 and a methylsulfothiotetrazole group at C-3. The latter is related to the MTT moiety mentioned above under cefamandole nafate; however, the clotting problems and Antabuse-like side effects associated with MTT have not been reported with cefonicid. The extra acid group in the C-3 side chain leads to this molecule being sold as an injectable disodium salt. Pain and discomfort at IM sites is experienced by some patients, as is a burning sensation and phlebitis. Cefonicid has a longer half-life than the other members of its group but achieves this at the price of somewhat lower potency against Gram-positive bacteria and aerobes. The drug is somewhat unstable, needs to be protected from light and heat, and may yellow or darken. If modest, however, this does not necessarily mean that the potency has decreased significantly, but overt precipitation does. Kirby-Bauer disk testing may overestimate the sensitivity of β-lactamase–producing bacteria to this agent, so some extra caution in interpretation of laboratory results is required.

*Cefuroxime.* Cefuroxime has a *Z*-oriented methoxyimino moiety as part of its C-7 side chain (Fig. 38.22). This conveys

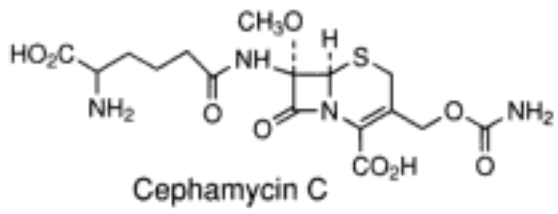
| Cefprozil | Cefzil |  |  | H | S | - |

considerable resistance to attack by many β-lactamases, but not by all. This is believed to result from the steric demands of this group. This hypothesis is supported by the finding that the *E*-analogue is attacked by β-lactamases. Resistance by *Pseudomonas aeruginosa*, on the other hand, is attributed to lack of penetration of the drug rather than to enzymatic hydrolysis. The carbamoyl moiety at C-3 is intermediate in metabolic stability between the classic acetyl moieties and the thiotetrazoles. Cefuroxime penetrates comparatively well into cerebral spinal fluid and is used in cases of *Haemophilus influenzae* meningitis.

In the form of its axetil ester (1-[acetyloxy]ethyl ester) pro-drug, cefuroxime axetil, a more lipophilic drug is produced that gives satisfactory blood levels on oral administration. The ester bond is cleaved metabolically, and the resulting intermediate form loses acetaldehyde spontaneously to produce cefuroxime itself. Conveniently for the patient, cefuroxime axetil is stable for approximately 24 hours when it is dissolved in apple juice. The axetil is the only antibiotic officially labeled for treatment of Lyme disease (although doxycycline often is the first choice even without a label indication for that purpose).



Cefuroxime axetil

*Cefoxitin.* Cefoxitin contains the same C-7 side chain as cephalothin and the same C-3 side chain as cefuroxime. The most novel chemical feature of cefoxitin is the possession of an α-oriented methoxyl group in place of the normal H-atom at C-7. This increased steric bulk conveys very significant stability against β-lactamases. The inspiration for these functional groups was provided by the discovery of the naturally occurring antibiotic cephamycin C

Copyrighted material

derived from fermentation of *Streptomyces lactamdurans*. Cephamycin C itself has not seen clinical use but, rather, has provided the structural clue that led to useful agents such as cefoxitin. Agents that contain this 7α methoxy group are commonly referred to as cephamycins. Ingenious chemical transformations now enable synthetic introduction of such a methoxy group into cephalosporins lacking this feature.

Cephamycin C

Cefoxitin has useful activity against gonorrhea and some anaerobic infections as compared with its second-generation relatives. On the negative side, cefoxitin has the capacity to induce certain broad-spectrum β-lactamases.

*Cefotetan.* Clearly, cefotetan also is inspired by cephamycin C but has a rather unusual sulfur-containing C-7 side-chain amide. Possession of two carboxyl groups leads to marketing it as a disodium salt. The C-3 MTT side chain suggests caution in monitoring prothrombin levels and bleeding times as well as in ingesting alcohol when using this agent. Like cefoxitin, cefotetan has better activity than the rest of this group against anaerobes. Cefotetan is comparatively stable, lasting for approximately 24 hours at room temperature when reconstituted. Slight yellowing and slight darkening produce materials that are still acceptable for therapy. Cefotetan is chemically incompatible with tetracycline, aminoglycosides, and with heparin, often forming precipitates with them. With respect to its molecular mode of action, it has a special affinity for PBP-3 of Gram-negative bacteria, consequently producing filamentous forms. It also binds well with PBP-1A and -1B, therefore leading to cell lysis and death. Whereas it is stable to a wide range of β-lactamases, it also is a potent inducer in some bacteria.

*Cefaclor.* Cefaclor differs from cephalexin primarily in the bio-isosteric replacement of methyl by chlorine at C-3 and is quite acid stable, allowing oral administration. It also is quite stable to metabolism. It is less active against Gram-negative bacteria compared with the other second-generation cephalosporins but is more active against Gram-negative bacteria compared with the first-generation drugs.

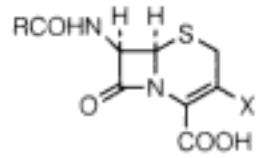
*Loracarbef.* Loracarbef is a synthetic C-5 "carba" analogue of cefaclor. The smaller methylene moiety (as compared to sulfur) would be expected to make loracarbef more reactive/potent, and this seems to be the case. It is more stable chemically, however, and this adds to its virtues. Diarrhea is the most common adverse effect with loracarbef and, along with certain other adverse effects, is seen more frequently with children, so this lessens enthusiasm for the drug in patients younger than 12 years.

*Cefprozil.* Cefprozil has an amoxicillin-like side chain at C-7, but at C-3, there is now a l-propenyl group conjugated with the double bond in the 6-membered ring. The double bond is present in its two geometric isomeric forms, both of which are antibacterially active. Fortunately, the predominant trans form (Table 38.11) is much more active against Gram-negative organisms. Cefprozil most closely resembles cefaclor in its properties but is a little more potent. It is approximately 90% bioavailable following oral administration, and peak levels are not significantly smaller when taken with food. The oral suspension of cefprozil is sweetened with aspartame, so phenylketonuric patients should be wary of this formulation.

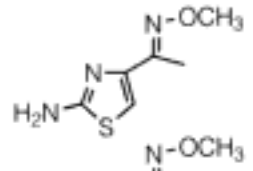
*Cefmetazole.* Cefmetazole is a cephamycin with a nonaromatic side chain at C-7. In addition to a fairly characteristic second-generation cephalosporin antimicrobial spectrum, it possess fairly significant anti-antiaerobic activity. The ejection of its C-3 side chain leads to alcohol intolerance of the disulfuram type and prolonged clotting times.

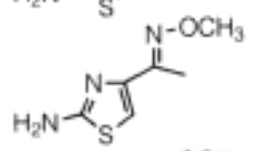
### *Third-Generation Cephalosporins (Table 38.12)*

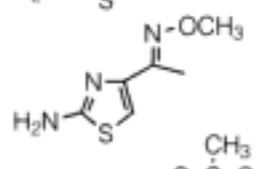
*Cefotaxime.* Cefotaxime, like cefuroxime, has a *Z*-methoxyimino moiety at C-7 that conveys significant β-lactamase resistance. Microorganisms that produce chromosomally mediated β-lactamases usually are resistant following mutation to derepression of these enzymes. Cefoxitin, cefotetan, and imipenems are quite effective inducers of these enzymes. The enzymes that result either hydrolyze the drug in the usual way or bind tightly to them, preventing them from attaching to the PBPs. The clinical importance of this phenomenon is unclear.

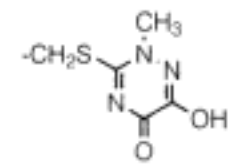


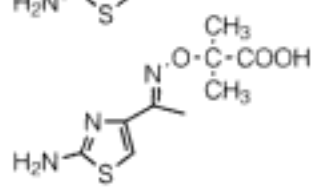
The oxime moiety of cefotaxime is connected to an aminothiazole ring. Like other third-generation cephalosporins, it has excellent anti-Gram-negative activity and is useful institutionally. It has a metabolically vulnerable acetoxy group attached to C-3 and loses approximately 90% of its activity when this is hydrolyzed. This metabolic feature also complicates the pharmacokinetic data, because both active forms are present and have different properties. Cefotaxime should be protected from heat and light and may color slightly without significant loss of potency. Like other third-generation cephalosporins, cefotaxime has less activity against staphylococci but has greater activity against Gram-negative organisms.

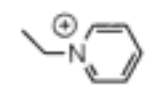


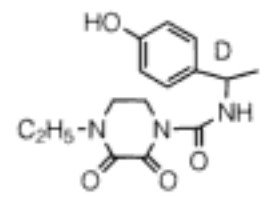


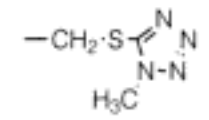


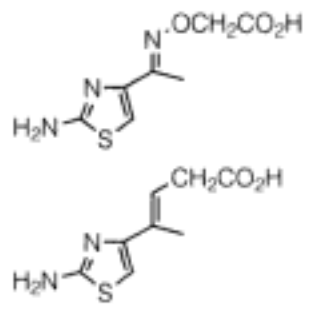


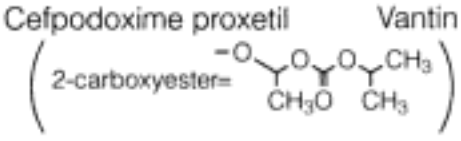


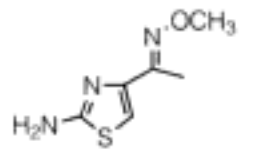


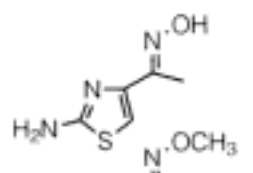


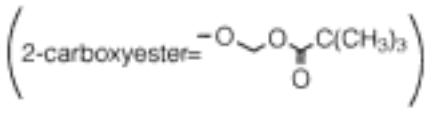


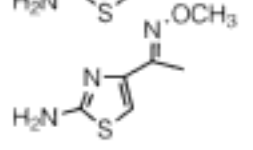


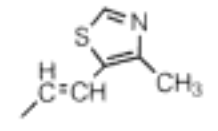












*Ceftizoxime.* In ceftizoxime, the whole C-3 side chain has been omitted to prevent deactivation by hydrolysis. It rather resembles cefotaxime in its properties; however, not being subject to metabolism, its pharmacokinetic properties are much less complex.

*Ceftriaxone.* Ceftriaxone has the same C-7 side-chain moiety as cefotaxime and ceftizoxime, but the C-3 side chain consists of a metabolically stable and activating thiotriazinedione in place of the normal acetyl group. The C-3 side chain is sufficiently acidic that at normal pH, it forms an enolic sodium salt; thus, the commercial

product is a disodium salt. It is useful for many severe infections and, notably, in the treatment of some meningitis infections caused by Gram-negative bacteria. It is quite stable to many β-lactamases but is sensitive to some inducible chromosomal β-lactamases.

*Ceftazidime.* In ceftazidime the oxime moiety is more complex, containing two methyl groups and a carboxylic acid. This assemblage conveys even more pronounced β-lactamase stability, greater anti–*Pseudomonas aeruginosa*, and increased activity against Gram-positive organisms. The C-3 side chain has been replaced by a charged pyridinium moiety. The latter considerably enhances water solubility and also highly activates the β-lactam bond toward cleavage. The drug must be protected against heat and light and may darken without significant loss of potency. It is not stable under some conditions. such as the presence of aminoglycosides and vancomycin. It also is attacked readily in sodium bicarbonate solutions. Resistance is mediated by chromosomally mediated β-lactamases and by lack of penetration into target bacteria. Otherwise, it has a very broad antibacterial spectrum.

Copyrighted material

***Monobactams***
***Aztreonam***

Aztreonam disodium (Azactam)

Fermentation of unusual microorganisms led to the discovery of a class of monocyclic β-lactam antibiotics, named monobactams. None of these natural molecules have proven to be important, but the group served as the inspiration for the synthesis of aztreonam. Aztreonam is a totally synthetic parenteral antibiotic, the antimicrobial spectrum of which is devoted almost exclusively to Gram-negative microorganisms, and it is capable of inactivating some β-lactamases. Its molecular mode of action is closely similar to that of the penicillins, cephalosporins, and carbapenems, the action being characterized by strong affinity for PBP-3, producing filamentous cells as a consequence. Whereas the principal side chain closely resembles that of ceftazidime, the sulfamic acid moiety attached to the β-lactam ring was unprecedented. Remembering the comparatively large size of sulfur atoms, this assembly may sufficiently spatially resemble the corresponding C-2 carboxyl group of the precedent β-lactam antibiotics to confuse the penicillin binding protons. The strongly electron-withdrawing character of the sulfamic acid group probably also makes the β-lactam bond more vulnerable to hydrolysis. In any case, the monobactams demonstrate that a fused ring is not essential for antibiotic activity. The α-oriented methyl group at C-2 is associated with the stability of aztreonam towards β-lactamases.

The protein binding is moderate (~50%), and the drug is nearly unchanged by metabolism. Aztreonam is given by injection and is primarily excreted in the urine. The primary clinical use of aztreonam is against severe infections caused by Gram-negative microorganisms, especially those acquired in the hospital. These are mainly urinary tract, upper respiratory tract, bone, cartilage, abdominal, obstetric and gynecologic infections, and septicemias. The drug is well tolerated, and adverse effects are infrequent. Interestingly, allergy would not be unexpected, but cross-allergenicity with penicillins and cephalosporins has not often been reported.

## Antibiotics: Inhibitors of Protein Biosynthesis

**BASIS FOR SELECTIVITY.** Once the bacterial cell wall is traversed, complex cellular machinery deeper within the cell becomes available to antibiotics. Some of the most successful antibiotic families exert their lethal effects on bacteria by inhibiting ribosomally mediated protein biosynthesis. At first glimpse, this may seem to be anomalous, because eukaryotic organisms also construct their essential proteins on ribosomal organelles and the sequence of biochemical steps is closely analogous to that in prokaryotic microorganisms. At a molecular level, however, the apparent anomaly resolves itself, because the detailed architecture of prokaryotic ribosomes is rather different. In *Escherichia coli*, for example, the 70S ribosomal particle is composed not only of three RNA molecules but also of 55 different structural and functional proteins arranged in a nonsymmetrical manner. The small (30S) subunit has a 16S rRNA molecule and approximately 20 different proteins. The large subunit has a 23S and a 5S rRNA and more than 30 proteins. Quite recently, the x-ray crystal structure of the components of the bacterial ribosome has been determined. This is a landmark achievement given the size and complexity of this organelle. The available picture is still fuzzy but allows one to unravel the molecular details not only of how proteins are biosynthesized but also where important antibiotics bind when they interrupt this process. The functioning parts of the ribosome are the RNA molecules, and the proteins organize the whole and catalyze some portions of the biosynthetic cycle. The tRNA molecules bind roughly at the interface where the 50S and 30S subparticles come together. The codon–anticodon interaction with mRNA takes place in the 30S subunit, and the incoming amino acid and the growing peptide chain being made lies in the 50S subunit. Upsetting the view held for decades that the antibiotics bound to ribosomal proteins, it is now known that they bind to the rRNA instead. Aside from this important fact, most of the other key beliefs are still valid. Of key importance, the vital repeated movement of the tRNA bases mostly take place near interfaces between individual rRNA molecules, where this would be easiest. In agreement, it has been found that this region is comparatively disordered consistent with that movement (Fig. 38.24).

At normal doses, antibiotics do not bind to or interfere with the function of eukaryotic 80S ribosomal particles. The basis for the selective toxicity of these antibiotics is then apparent. Interference with bacterial protein biosynthesis prevents repair, cellular growth, and reproduction and can be clinically bacteriostatic or bactericidal.

### AMINOGLYCOSIDES AND AMINOCYCLITOLS

***Introduction.*** The aminoglycoside/aminocyclitol class of antibiotics contains a pharmacophoric 1,3-diaminoinositol moiety consisting of either streptamine, 2-deoxystreptamine, or spectinamine (Fig. 38.25). Several of the alcoholic functions of the 1,3-diaminoinositol are substituted through glycosidic bonds with characteristic amino sugars to form pseudo-oligosaccharides. The chemistry, spectrum, potency, toxicity, and pharmacokinetics of these agents are a function of the specific identity of the diaminoinositol unit and the arrangement and identity of the attachments. The various aminoglycoside antibiotics

Copyrighted material

cases, chemical deletion of the functional groups transformed by these enzymes leaves a molecule that is still antibiotic but is no longer a substrate; thus, agents with an intrinsically broader spectrum can be made semisynthetically in this way. In some other cases, novel functional groups can be attached to remote functionality that converts these antibiotics to poorer substrates for these R factor–mediated enzymes, and this expands their spectra (discussed later). Resistance also can involve point mutations of the ribosomal A site. These involve single-nucleotide residues at specific positions. The substituent at position 6′ of the aminoglycoside, the number of protonated amino groups, and the linkage between the sugar rings and the central deoxystreptamine moiety are particularly important in the interactions with the rRNA. Resistance caused by decreased aminoglycoside/aminocyclitol uptake into bacterial cells also is encountered.

***Therapeutic Application.*** Intrinsically, aminoglycosides have broad antibiotic spectra against aerobic Gram-positive and Gram-negative bacteria but are reserved for use in serious infections caused by Gram-negative organisms because of serious toxicities that often are delayed in onset. They are active against Gram-negative aerobes, such as *Acinetobacter* sp., *Citrobacter* sp., *Enterobacter* sp., *Escherichia coli, Klebsiella* sp., *Proteus vulgaris, Providencia* sp., *Pseudomonas aeruginosa, Salmonella* sp., *Serratia marscesans, Shigella* sp., and Gram-positive aerobes (e.g., *Staphylococcus epidermidis).*

Streptomycin and spectinomycin differ from the others in their useful antimicrobial spectra. Streptomycin is most commonly used for the treatment of tuberculosis and spectinomycin for treatment of gonorrhea. The other antibiotics of this class are inferior for these purposes.

These antibiotics have similar clinical spectra to those of the quinolones and are decreasing in popularity as quinolone use increases. Some aminoglycoside antibiotics in present clinical use are illustrated in Figure 38.26 along with some of their sites of enzymatic inactivation. There has not been a new aminoglycoside antibiotic introduced since the 1970s.

***Adverse Effects.*** The toxicities associated with the aminoglycosides involve ototoxicity to functions mediated by the eighth cranial nerve, such as hearing loss and vertigo. Their use also can lead to kidney tubular necrosis, producing decreases in glomerular function. These toxic effects are related to blood levels and, apparently, are mediated by the special affinity of these aminoglycosides to kidney cells and to the sensory cells of the inner ear. The effects may have a delayed onset, making them all the more treacherous, because the patient can be injured significantly before symptoms appear. Less common is a curare-like neuromuscular blockade believed to be caused by competitive inhibition of calcium ion–dependent acetylcholine release at the neuromuscular junction. This effect can exaggerate the muscle weakness of patients with myasthenia gravis or Parkinson's disease. In current practice, all these toxic phenomena are well known; therefore, creatinine clearance should be determined and the dose adjusted downward accordingly so that these adverse effects are less common and less severe.

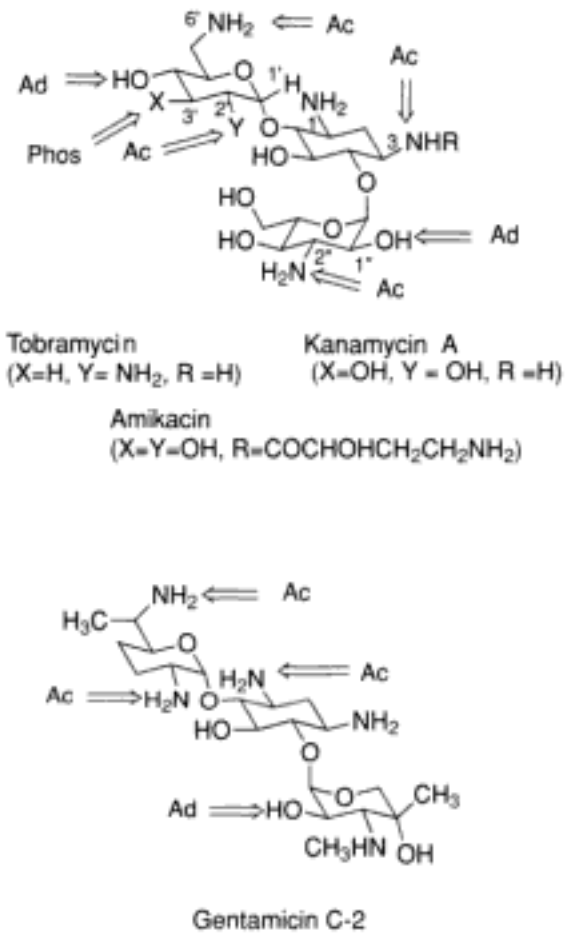

**Fig. 38.26.** Commercially important 2-desylstreptamine–containing aminoglycosides. Some points of inactivating attack by specific R factor–medicated enzymes are indicated by the following symbols. Ad ⇒ adenylation; Ac ⇒ acetylation; Phos ⇒ phosphorylation. APH(3′)-1, for example, is an acronym for an enzyme that phosphorylates aminoglycosides at the 3′-OH position.

### *Specific Agents*

***Kanamycin (Kantrex).*** Kanamycin is a mixture of at least three components (A, B, and C, with A predominating) isolated from *Streptomyces kanamyceticus.* In addition to typical aminoglycoside antibiotic properties, kanamycin, along with gentamicin, neomycin, and paromomycin, is among the most chemically stable of the common antibiotics. Kanamycin can be heated without loss of activity for astonishing periods in acid or alkaline solutions and can even withstand autoclaving temperatures. Kanamycin, however, is unstable to R-factor enzymes, being O-phosphorylated on the C-3′hydroxyl by enzymes APH(3′)-I and APH(3′)-II and also is N-acetylated on the C-6′amino group, among others (Fig. 38.26). These transformation products are antibiotically inactive. Kanamycin is used parenterally against some Gram-negative bacteria, but *Pseudomonas aeruginosa* and anaerobes usually are resistant. Although it also can be used in combination with other agents against certain mycobacteria (*Mycobacterium kansasii, Mycobacterium marinum,* and *Mycobacterium intracellulare*), its popularity for this use is fading. Injections of kanamycin are painful enough to require use of a local

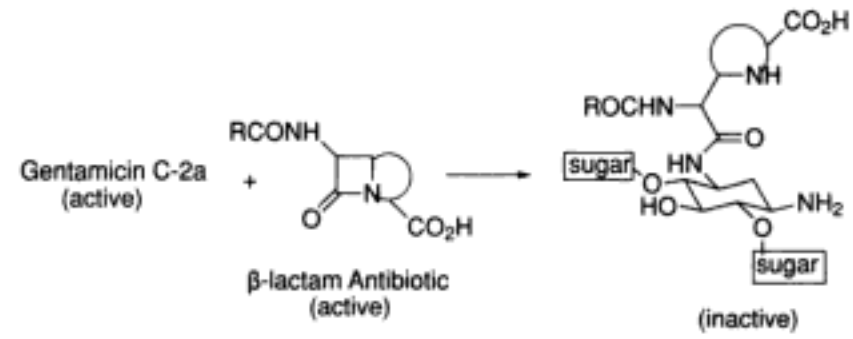
Copyrighted material

anesthetic. Kanamycin occasionally is used in antitubercular admixtures.

***Amikacin (Amikin).*** Amikacin is made semisynthetically from kanamycin A. Interestingly, the L-hydroxyaminobutyryl amide (HABA) moiety attached to N-3 inhibits adenylation and phosphorylation in the distant amino sugar ring (at C-2′ and C-3′), even though the HABA substituent is not where the enzymatic reaction takes place. This effect is attributed to decreased binding to the R factor–mediated enzymes. With this change, both potency and spectrum are strongly enhanced, and amikacin is used for the treatment of sensitive strains of *Mycobacterium tuberculosis, Yersinia tularensis,* and severe *Pseudomonas aeruginosa* infections resistant to other agents.

***Tobramycin (Nebcin).*** Tobramycin is one component (factor 6) of a mixture produced by fermentation of *Streptomyces tenebrarius.* Lacking the C-3′ hydroxyl group, it is not a substrate for APH(3′)-1 and APH(3′)-II and so has an intrinsically broader spectrum than kanamycin. It is a substrate, however, for adenylation at C-2′ by ANT(2′) and acetylation at C-3 by AAC(3)-I and AAC(3)-II and at C-2′ by AAC(2′) (Fig. 38.26). It is widely used parenterally for difficult infections, especially those by gentamicin-resistant *Pseudomonas aeruginosa.* It is believed by some clinicians to be less toxic than gentamicin.

***Gentamicin (Garamycin).*** Gentamicin is a mixture of several antibiotic components produced by fermentation of *Micromonospora purpurea* and other related soil microorganisms (hence its name is spelled with an "i" instead of a "y"). Gentamicins C-1, C-2, and C-1a are most prominent. Gentamicin is the most important of the aminoglycoside antibiotics still in use. Gentamicin was, for example, one of the first antibiotics to have significant activity against *Pseudomonas aeruginosa* infections. This water-loving, opportunistic pathogen frequently is encountered in burns, pneumonias, and urinary tract infections. It is highly virulent. As noted above, some of the functional groups that serve as targets for R factor–mediated enzymes are missing in the structure of gentamicins, so their antibacterial spectrum is enhanced. They are, however, inactivated through C-2′ adenylation by the enzyme ANT(2′) and acetylation at C-6′ by AAC(6′), at C-1 by AAC(1)-I and AAC(1)-II, and at C-2′ by AAC(2′). It often is combined with other anti-infective agents, and an interesting incompatibility has been uncovered. With certain β-lactam antibiotics, the two drugs react with each other so that N-acylation on C-1 of gentamicin by the β-lactam antibiotic takes place, thus inactivating both antibiotics (Fig. 38.27). The two agents should not, therefore, be mixed in the same solution and should be administered into different tissue compartments (usually one in each arm) to prevent this. This incompatibility is likely to be associated with other aminoglycoside antibiotics as well.



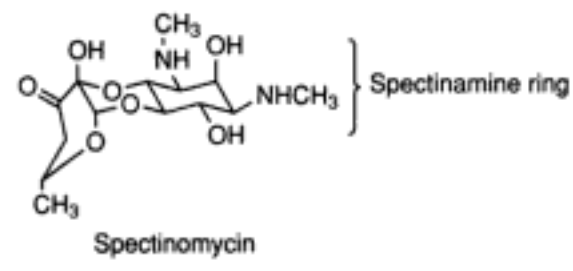


**Fig. 38.27.** A chemical drug–drug incompatibility between gentamicin C-2a and β-lactams.

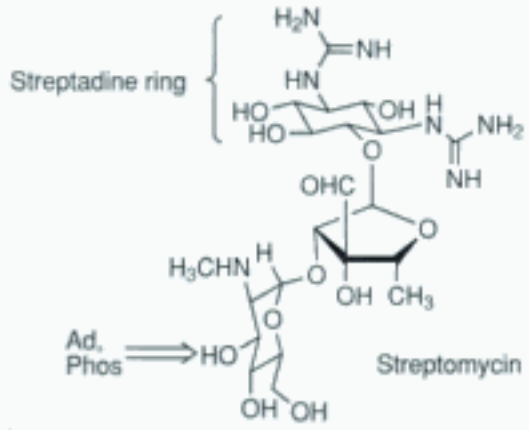
Gentamicin is used for urinary tract infections, burns, some pneumonias, and bone and joint infections caused by susceptible Gram-negative bacteria. It often is used to prevent fouling of soft contact lenses. It also is used in polymer matrices in orthopaedic surgery to prevent sealed-in sepsis. It is given topically, sometimes in special dressings, to burn patients.

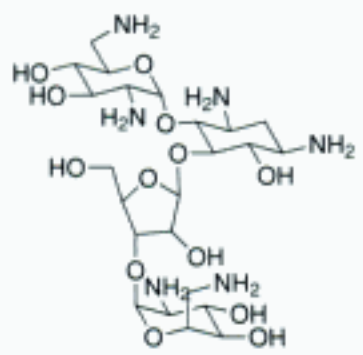


***Spectinomycin (Trobicin)***

An unusual aminoglycoside antibiotic, spectinomycin is produced by fermentation of *Streptomyces spectabilis* and differs substantially in its clinical properties from the others. The diaminoinositol unit (spectinamine) contains two mono-N-methyl groups, and the hydroxyl between them has a stereochemistry opposite to that in streptomycin. The glycosidically attached sugar also is unusual in that it contains three consecutive carbonyl groups, either overt or masked, and is fused by two adjacent linkages to spectinamine to produce an unusual, fused, three-ring structure. Spectinomycin is bacteriostatic as normally employed. It is used almost exclusively in a single bolus injection IM against *Neisseria gonorrhea,* especially penicillinase-producing strains, in cases of urogenital or oral gonorrhea and does not apparently produce any serious oto- or nephrotoxicity when used in this way. It is particularly useful for the treatment of patients allergic to penicillin and patients not likely to comply well with a medication scheme. It would likely be more widely used except that syphilis and chlamydia do not respond to it. It causes significant mistranslation following ribosomal binding but does not cause much inhibition of overall programmed protein biosynthesis. Resistance to spectinomycin by a kinase phosphorylating a hydroxyl group has been reported.

Copyrighted material

**Streptomycin**



Streptomycin is produced by fermentation of *Streptomyces griseus* and several related soil microorganisms. It was introduced in 1943 primarily for the treatment of tuberculosis (see Chapter 41). Control of this ancient scourge was greeted with such enthusiasm that Selmon Waksman, the discoverer of streptomycin, received a Nobel Prize in 1952. Streptomycin differs from the typical aminoglycosides with a modified pharmacophore in that the diaminoinositol unit is streptamine. Streptomycin also has an axial hydroxyl group at C-2 and two highly basic guanido groups at C-l and C-3 in place of the primary amine moieties of 2-deoxystreptamine. It is possible that the unusual pharmacophore of streptomycin accounts in large measure for its unusual antibacterial spectrum. Another molecular feature, the α-hydroxyaldehyde moiety, is a center of instability such that streptomycin cannot be sterilized by autoclaving, so streptomycin sulfate solutions that need sterilization are made by ultrafiltration. Streptomycin is rarely used today as a single agent.

Resistance to streptomycin takes the familiar course of N-acetylation, O-phosphorylation, and O-adenylation of specific functional groups.

***Orally Used Aminoglycosides.*** Kanamycin and another archaic member of the aminoglycoside antibiotic group, paromomycin (Humatin) finds some oral use for the suppression of gut flora. Paromomycin is also used for the oral treatment of amoebic dysentery. Amoebas are persistent pathogens causing chronic diarrhea and are acquired most frequently by travelers who consume food supplies contaminated with human waste.

***Neomycin***

Neomycin B

Neomycin is a mixture of three compounds produced by fermentation of *Streptomyces fradiae,* with neomycin B predominating. It is most commonly used in preoperative bowel sanitation and the treatment of enteropathogenic *Escherichia coli* infections. It also is found in nonprescription ointments and is used topically for treatment of bacterial skin infections. When applied to intact skin, the drug is not absorbed, but when applied to large, denuded areas, systemic absorption occurs with the potential for toxic side effects. It also has seen some use in lowering serum cholesterol.

## MACROLIDE ANTIBIOTICS

***Introduction.*** The term "macrolide" is derived from the characteristic large lactone (cyclic ester) ring found in these antibiotics. The clinically important members of this antibiotic family (Fig. 38.28) have two or more characteristic sugars (usually cladinose and desosamine) attached to the 14-membered ring. One of these sugars usually carries a substituted amino group, so their overall chemical character is weakly basic ($pK_a \sim 8$). They are not very water-soluble as free bases. Salt formation with certain acids (glucoheptonic and lactobiononic acids in Fig. 38.28), however, increases water solubility, whereas other salts decrease solubility (laurylsulfate and stearic). Macrolide antibiotics with 16-membered rings are popular outside the United States, but one example, tylosin, finds extensive agricultural use in the United States. The 14-membered ring macrolides are biosynthesized from propionic acid units so that every second carbon of erythromycin, for example, bears a methyl group and the rest of the ring carbons, with one exception, are oxygen bearing. Two carbons bear so-called "extra" oxygen atoms introduced later in the biosynthesis (not present in a propionic acid unit), and two hydroxyls are glycosylated (Fig. 38.29).

***Chemical Properties.*** The early macrolides of the erythromycin class are chemically unstable because of rapid acid-catalyzed internal cyclic ketal formation, leading to inactivity (Fig. 38.30). This reaction that occurs in the GI tract is clinically important. Most acid-susceptible macrolides are administered in coated tablets to minimize this effect. Semisynthetic analogues have been prepared that are structurally incapable of undergoing this reaction (clarithromycin, dirithromycin, and azithromycin) (Fig. 38.28) and have become very popular of late in the clinic.

Many macrolides have an unpleasant taste, which is partially overcome with water-insoluble dosage forms that also reduce acid instability and gut cramps. Enteric coatings are beneficial in reducing these adverse effects as well.

***Mechanism of Action.*** The macrolides inhibit bacteria by interfering with programmed ribosomal protein biosynthesis by binding to the 23S rRNA in the polypeptide exit tunnel adjacent to the peptidyl transferase center in the 50S subparticle (Fig. 38.24). Binding appears to occur at two specific regions within the rRNA, which are referred to as domain V at adenine 2058 and 2059 and domain II

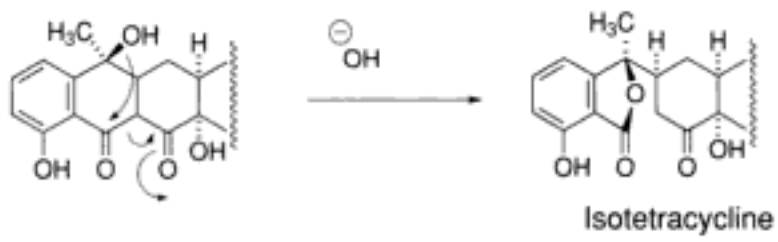


**Fig. 38.34.** Base-catalyzed instability of tetracyclines.

***Phototoxicity.*** Certain tetracyclines, most notably those with a C-7-chlorine, absorb light in the visible region, leading to free radical generation and, potentially, cause severe erythema to sensitive patients on exposure to strong sunlight. Patients should be advised to be cautious about such exposure for at least their first few doses to avoid potentially severe sunburn. This effect is comparatively rare with most currently popular tetracyclines.

***Mechanism of Action.*** The tetracyclines of clinical importance interfere with protein biosynthesis at the ribosomal level, leading to bacteriostasis. Tetracyclines bind to rRNA in the 30S subparticle with the possible cooperation of a 50S site by a process that remains imprecisely understood despite intensive study (Fig. 38.24). There is more than one binding site, but only one is believed to be critical for its action. The points of contact with the rRNA are those associated with antibiosis with the puzzling exception of the dimethylamino function. Studies have suggested that the tetracyclines bind to the 16S rRNA via the functional groups located at the 1- and 10- to 12a-positions (referred to as the southern face of the tetracycline) and at the 2- and 3-positions (referred to as the eastern face of the tetracycline) (Fig. 38.35). The dimethylamino function is known to be essential for activity but does not appear to bind in the x-ray pictures that are presently available. Once the tetracycline binds, it inhibits subsequent binding of aminoacyltransfer-RNA to the ribosomes, resulting in termination of peptide chain growth. Newer analogues of the tetracyclines suggest that substitution on the western and northern faces of the tetracycline are allowed as indicated by the newest glycylcyclines (see *Tigecycline* below).

The more lipophilic tetracyclines, typified by minocycline, also are capable of disrupting cytoplasmic membrane function, causing leakage of nucleotides and other essential cellular components from the cell, and have bactericidal properties. The more lipophilic tetracyclines enter bacterial cells partly by passive diffusion and the more water-soluble members partly through water-lined protein porin routes, perhaps assisted by the formation of highly lipophilic calcium and magnesium ion chelates. Deeper passage, however, through the inner cytoplasmic membrane is an energy-requiring active process, suggesting that the tetracyclines are mistaken by bacteria as food.

***Resistance.*** Resistance to tetracyclines results in part from an unusual ribosomal protection process involving elaboration of bacterial proteins. These proteins associate with the ribosome, thus allowing protein

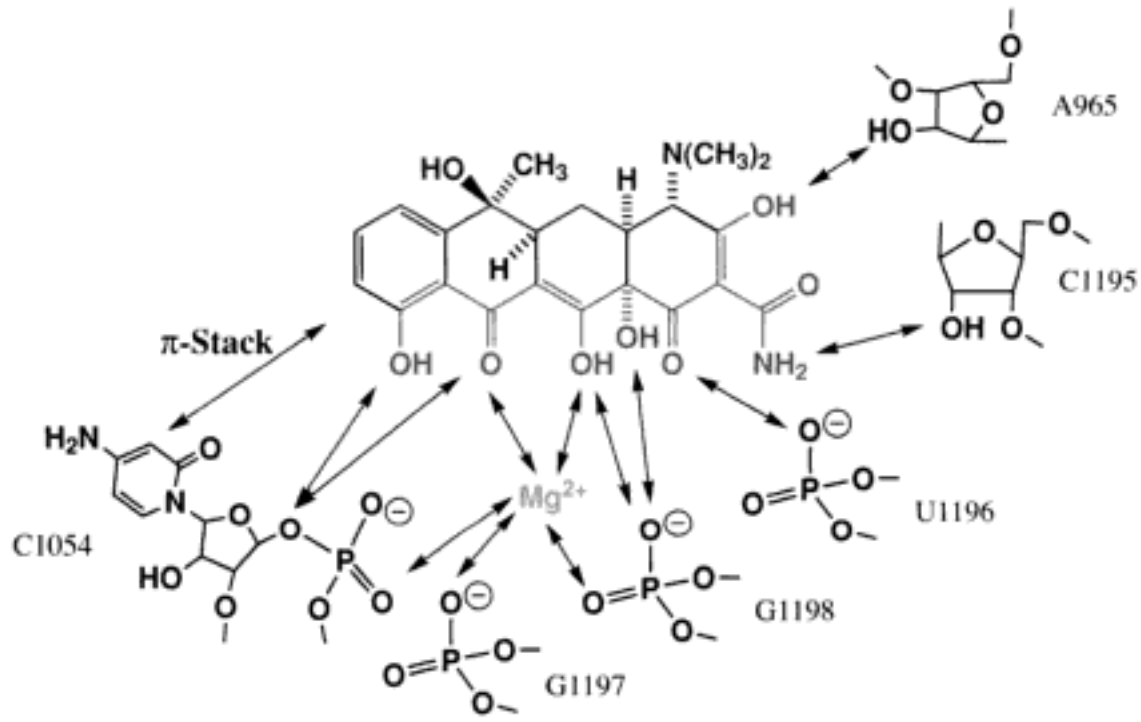

**Fig. 38.35.** Schematic representation of the primary binding site for a tetracycline and the sugar phosphate groups of 16S rRNA, which also involves a magnesium ion and the critical functional groups on the "southern" and "eastern" face of the tetracycline. (Adapted from Brodersen et al. The structural basis for the action of the antibiotics tetracycline, pactamycin, and hygromycin B on the 30S ribosomal subunit. Cell 2000;103:1143–1154, with permission from Elsevier.)

Copyrighted material

biosynthesis to proceed even in the presence of bound tetracycline, although exactly how this works is not well understood. Another important resistance mechanism involves R factor–mediated, energy-requiring, active efflux of tetracyclines from the bacterial cells. Some of the efflux proteins have activity that is limited to older tetracyclines, whereas others confer resistance to the entire family with the exception of glycylcyclines. Efflux resistance to glycylcylines, however, has been demonstrated in the laboratory, which suggests that it may occur clinically with extended use. Certain other microbes, such as *Mycoplasma* and *Neisseria* sp., seem to have modified membranes that either accumulate fewer tetracyclines or have porins through which tetracyclines have difficulty in passing. Because resistance is now widespread, these once extremely popular antibiotics are falling into comparative disuse.

***Therapeutic Application.*** The tetracyclines possess very wide bacteriostatic antibacterial activity. Because of the resistance phenomenon and the comparative frequency of troublesome side effects, they are rarely the drugs of first choice today. Nonetheless, they are still popular for office use against susceptible microbes. The differences between the antimicrobial spectra of various tetracyclines are not large, although greater resistance to older agents may limit their use. They are used for low-dose oral and topical therapy for acne, first-course community-acquired urinary tract infections (largely caused by *Escherichia coli*), brucellosis, borreliosis, sexually transmitted diseases (especially chlamydia), rickettsial infections, mycoplasmal pneumonia, prophylaxis of malaria, prevention of traveler's diarrhea, cholera, *Enterobacter* infections, as part of *Helicobacter* cocktails, Lyme disease, Rocky Mountain spotted fever, anthrax, and for many other less common problems. The tetracyclines also are widely used for agricultural purposes.

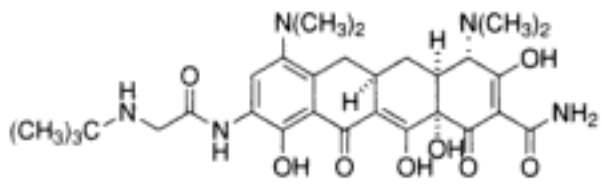
***Adverse Effects.*** In addition to the adverse effects mentioned earlier (tooth staining, phototoxicity, and potential kidney damage with outdated drug), the tetracyclines are associated with nausea, vomiting, diarrhea, and some CNS effects (dizziness and vertigo). Rapid administration or prolonged IV use can lead to thrombophlebitis. Therefore, tetracyclines generally are administered orally, because they are well absorbed. They also distinguish imperfectly between the bacterial 70S ribosomes and the mammalian 80S ribosomes, so in high doses or special situations (i.e., IV use during pregnancy), these drugs demonstrate a significant antianabolic effect. This may lead to severe liver and kidney damage; therefore, tetracyclines generally are not recommended in these situations. In cases of significant renal impairment, higher serum levels of tetracyclines can lead to azotemia. Additionally, inducers of cytochrome P450 metabolism (i.e., rifampin, barbiturates, and carbamazepine) increase metabolism of tetracyclines (especially doxycycline), so the dose of the tetracycline may require adjustment.

### *Specific Agents (Table 38.11)*

***Tetracycline.*** Tetracycline is produced by fermentation of *Streptomyces aureofaciens* and related species or by catalytic reduction of chlortetracycline. The blood levels achieved on oral administration often are irregular. Food and milk lower absorption by approximately 50%.

***Demeclocycline.*** Demeclocycline lacks the C-6-methyl of tetracycline and is produced by a genetically altered strain of *Streptomyces aureofaciens*. Because it is a secondary alcohol, it is more chemically stable than tetracycline against dehydration. Food and milk co-consumption decrease absorption by half, although it is 60 to 80% absorbed by fasting adults. It is the tetracycline most highly associated with phototoxicity and has been shown to produce dose-dependent, reversible diabetes insipidus with extended use.

***Oxytetracycline.*** It also is one of the classic tetracyclines. It is produced by fermentation of *Streptomyces rimosis* and other soil microorganisms. The most hydrophilic tetracycline on the market, it has largely now been replaced by its semisynthetic descendants. It is primarily used today for IM injections.



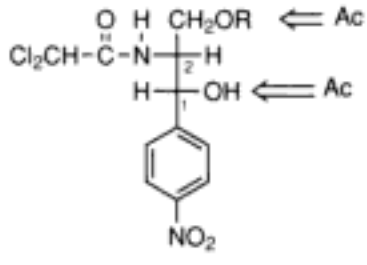
***Minocycline.*** An important antibiotic produced by semisynthesis from demeclocycline is minocycline. It is much more lipophilic than its precursors, gives excellent blood levels following oral administration (90–100% available), and can be given once a day. Its absorption is lowered by approximately 20% when taken with food or milk. It is less dependent on active uptake mechanisms and has a somewhat broader antimicrobial spectrum. It also, apparently, is less painful on IM or IV injection, but it has vestibular toxicities (e.g., vertigo, ataxia, and nausea) not generally shared by other tetracyclines.

***Doxycycline.*** It is produced by semisynthesis from other tetracycline molecules and is the most widely used of the tetracycline family. Doxycycline is well absorbed on oral administration (90–100% when fasting; reduced by 20% by co-consumption with food or milk), has a half-life permitting once-a-day dosing for mild infections, and is excreted partly in the feces and partly in the urine.

Once very widely used, tetracyclines have faded considerably in popularity because of widespread resistance and the introduction of newer broad-spectrum agents, such as amoxicillin with clavulanate. Research, however, continues, and novel analogues can be expected as indicated by the recent U.S. FDA approval of tigecycline, the first of a new class of tetracyclines referred to as the glycylcyclines.

Copyrighted material

***Tigecycline***



Tigecycline
(Tygacil)

The increased incidence of resistance to the tetracyclines led to a renewed research effort to find novel agents within this class. This effort led to the discovery of a new class of antibiotics, the glycylcyclines, that are closely related structurally to the tetracyclines but lack many of the clinical resistance issues. They are characterized by having an additional glycylamido substitution at the 9-position. As indicated earlier, substitution on the western face does not appear to interfere with binding of the drug to the rRNA. Tigecycline is the first of these agents to be marketed. Although it has limited indications (treatment of complicated skin/skin structure and complicated intra-abdominal infections), this agent is a broad-spectrum antibiotic based on the in vitro data. It is administered IV and, like the tetracyclines, can cause injection site pain and thrombophlebitis. It is expected to have other adverse effects similar to the tetracyclines.

**SPECIAL PURPOSE ANTIBIOTICS.** This group of antibiotics consists of a miscellaneous collection of structural types for which the toxicities or narrow ranges of applicability give them a more specialized place in antimicrobial chemotherapy than those covered to this point. They generally are reserved for special purposes.

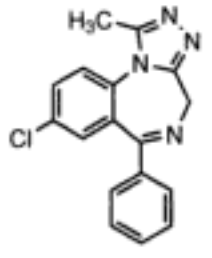
***Chloramphenicol (Chloromycetin)***

| | |
|---|---|
| R = H | Chloramphenicol (Chloromycetin) |
| R = $COCH_2CH_2CO_2H$ | Chloramphenicol hemisuccinate |
| R = $CO(CH_2)_{12}CH_3$ | Chloramphenicol palmitate |

***Introduction.*** Chloramphenicol was originally produced by fermentation of *Streptomyces venezuelae*, but its comparatively simple chemical structure soon resulted in several efficient total chemical syntheses. With two asymmetric centers, it is one of four diastereomers, only one of which (1*R*,2*R*) is significantly active. Because total synthesis produces a mixture of all four, the unwanted isomers must be removed before use. Chloramphenicol is a neutral substance that is only moderately soluble in water, because both nitrogen atoms are nonbasic under physiologic conditions (one is an amide and the other a nitro moiety). It was the first broad-spectrum oral antibiotic used in the United States (1947) and was once very popular. Severe potential blood dyscrasia has greatly decreased its use in North America. Although its cheapness and efficiency makes it still very popular in much of the rest of the world where it can often be purchased over-the-counter without a prescription.

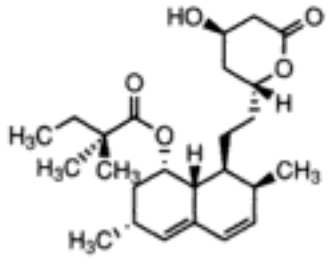
***Mechanism of action.*** Chloramphenicol is bacteriostatic by virtue of inhibition of protein biosynthesis in both bacterial and, to a lesser extent, host ribosomes. Chloramphenicol binds to the 50S subparticle in a region near where the macrolides and lincosamides bind (Fig. 38.24).

Resistance is mediated by several R-factor enzymes that catalyze acetylation of the secondary and, to some extent, the primary hydroxyl groups in the aliphatic side chain. These products no longer bind to the ribosomes and so are inactivated. *Escherichia coli* frequently is resistant because of chloramphenicol's lack of intercellular accumulation.



***Metabolism.*** When given orally, it is rapidly and completely absorbed but has a fairly short half-life. It is mainly excreted in the urine in the form of its metabolites, which are a C-3 glucuronide, and, to a lesser extent, its deamidation product and the product of dehalogenation and reduction. These metabolites are all inactive. The aromatic nitro group also is reduced metabolically, and this product can undergo amide hydrolysis. The reduction of the nitro group, however, does not take place efficiently in humans but, rather, primarily occurs in the gut by the action of the normal flora. Chloramphenicol potentiates the activity of some other drugs by inducing liver metabolism. Such agents include anticoagulant coumarins, sulfonamides, oral hypoglycemics, and phenytoin.

***Pro-Drug Forms.*** Two pro-drug forms of chloramphenicol are available (only the injectable form is available in the United States). The drug is intensively bitter, but this can be masked for use as a pediatric oral suspension by the C-3 palmitate, which is cleaved in the duodenum to liberate the drug. Chloramphenicol's poor water solubility is largely overcome by conversion to the C-3 hemisuccinoyl ester, which forms a water-soluble sodium salt. This is cleaved in the body by lung, liver, kidney, and blood esterases to produce active chloramphenicol. Because cleavage in muscles is slow, this pro-drug is used IV rather than IM.



***Therapeutic Applications.*** Despite potentially serious limitations, chloramphenicol is an effective drug when used carefully. Its special value is in typhoid fever, *Haemophilus* infections (especially epiglottitis and meningitis, when given along with ampicillin), rickettsial infections, and in cases in which susceptible organisms have proven to be

## DRUGS COVERED IN THIS CHAPTER:

DRUG TREATMENT OF AMEBIASIS, GIARDIASIS, TRICHOMONIASIS
- Diloxanide furoate
- Metronidazole
- Nitazoxanide
- Tinidazole

TREATMENT OF PNEUMOCYSTIS
- Atovaquone
- Penamidine isethionate
- Sulfamethoxazole–trimethoprim
- Trimetrexate glucuronate

TREATMENT OF TRYPANOSOMIASIS
- Benznidazole
- Eflornithine
- Melarsoprol
- Niturtimox
- Pentamidine isethionate
- Suramin sodium

TREATMENT OF LEISHMANIASIS
- Sodium stibogluconate

ANTIMALARIALS
- Atovaquone–proguanil
- Chloroquine
- Halofantrine
- Mefloquine
- Pyrimethamine
- Quinine

ANTHELMINTICS
- Albendazole
- Diethylcarbamazine
- Ivermectin
- Mebendazole
- Oxamniquine
- Praziquantel
- Pyrantel pamoate
- Thiabendazole

SCABICIDES AND PEDICULOCIDES
- Crotamiton
- Lindane
- Permethrin
- Pyrethrin

## GENERAL CONSIDERATIONS

An introduction to the topic of parasitic diseases usually emphasizes two points. First, parasitic infections affect huge numbers of individuals. It is estimated that well over 1 billion people are infected worldwide. Second, the majority of these parasitic infections are found in developing nations, in which the cost of health care is the dominant factor that determines whether the patient is (or is not) treated. The incidence of some parasitic diseases may exceed 80% of the population. The high cost of drug discovery and the low incidence of many of the parasitic infections in affluent Western countries have combined to reduce the incentive for both the study of the diseases and the development of effective therapy. This may be changing, however, because of global travel, improved communications, and growth of the developing countries, leading to an increased demand for more effective treatments.

The diseases associated with parasitic infections represent a large and diverse number of conditions, some common and some relatively unheard of by the general population. Included under the title of parasitic infections are the numerous types of protozoal infections: amebiasis, giardiasis, babesiosis, Chagas' disease, leishmaniasis, malaria, sleeping sickness, toxoplasmosis, trichomoniasis, and pneumocystosis (also considered to be a fungal infection). Helminth infections (worms) also are considered to be parasitic infections and may be caused by any of three classes of helminths: nematodes, cestodes, and trematodes. Insect infections, such as scabies, lice (pediculosis), and chiggers, also are considered to be parasitic infections.

## PROTOZOAL DISEASES

### Amebiasis

Amebiasis is a disease of the large intestine caused by *Entamoeba histolytica*. The disease occurs mainly in the tropics, but it also is seen in temperate climates. Amebiasis may be carried without significant symptoms or may lead to severe, life-threatening dysentery. The organism exists in one of two forms, the motile trophozoite form or the dormant cyst form. The trophozoite form is found in the intestine or wall of the colon and may be expelled from the body with the stools. The cyst form is encased by a chitinous wall that protects the organism from the environment, including chlorine used in water purification; thus, the organism may be transmitted through contaminated water and foods. It is the cyst form that is responsible for transmission of the disease. The cyst is spread by direct person-to-person contact and is commonly associated with living conditions in which poor personal hygiene, poor sanitation, poverty, and ignorance exist. The hosts may be rendered susceptible to infection by preexisting conditions, such as protein malnutrition, pregnancy, HIV infection, or high carbohydrate intake. Under these conditions, the organism is capable of invading body tissue. The protozoal invasion is not well understood. but it does appear to involve the processes indicated in Table 39.1. Symptoms may range from intermittent

## CLINICAL SIGNIFICANCE

Parasitic infections affect more than half the world's population and are responsible for significant health complications, especially in underdeveloped areas. Drug therapy for parasitic infections is quite challenging to practitioners for multiple reasons. Many practitioners lack experience with these agents and are unfamiliar with the toxicities and monitoring parameters associated with these drugs. Certain agents are available in only a limited number of countries, and opinions regarding safety and efficacy vary greatly among practitioners. Understanding the medicinal chemistry, pharmacodynamics, and pharmacokinetics of these agents is of utmost importance.

Despite efforts of vaccine development, drug therapy remains the most effective means to control parasitic infections. Limited introduction of new antiparasitic agents and drug shortages make the treatment of parasitic infestations challenging. Understanding which drugs work at different parts of the life cycle of the parasite also must be taken into consideration. Furthermore, the use of many antiparasitic agents are associated with toxicities, including precipitating severe inflammatory reactions, which may then be treated with anti-inflammatory agents and other supportive measures.

*Department of Clinical Science & Administration*
*University of Houston College of Pharmacy.*

diarrhea (foul-smelling loose/watery stools) to tenderness and enlargement of the liver (with the extraintestinal form) to acute amoebic dysentery. Many patients may experience no symptoms, and the organism remains in the bowels as a commensal organism.

### Giardiasis

Giardiasis is a disease that shows considerable similarity to amebiasis. It is caused by *Giardia lamblia*, an organism that may be found in the duodenum and jejunum. The organism exists in a motile trophozoite form and an infectious cyst form. The cyst form can be deposited in water (lives up to 2 months), and the contaminated water may then be ingested by the human. The trophozoite, if expelled from the gastrointestinal (GI) tract, normally will not survive. *Giardia lamblia* is the single most common cause of waterborne diarrhea in the United States. Giardiasis is a common disease among campers who drink water from contaminated streams. It also may be spread between family members, children in day care centers, and dogs and their masters. The organism can attach to the mucosal wall via a ventral sucking disk, and similar to amebiasis, the patient may be asymptomatic or develop watery diarrhea, abdominal cramps, distention and flatulence, anorexia, nausea, and vomiting. Usually, the condition is self limiting in 1 to 4 weeks.

### Trichomoniasis

Trichomoniasis is a protozoal infection caused by *Trichomonas vaginalis*, which exists only in a trophozoite form. The organs most commonly involved in the infection include the vagina, urethra, and prostate; thus, the disease is considered to be a venereal infection. The condition is transmitted by sexual contact, and it is estimated that trichomoniasis affects 180 million individuals worldwide. Infections in the male may be asymptomatic, whereas in the female, the symptoms may consist of vaginitis, profuse and foul-smelling discharge, burning and soreness on urination; and vulvar itching. Diagnosis is based on microscopic identification of the organism in fluids from the vagina, prostate, or urethra.

### Pneumocystis

The organism responsible for pneumocystis (pneumocystosis) in humans is *Pneumocystis carinii*. It has the morphologic

**Organisms that Commonly Cause Vaginitis**

Vaginitis also may be caused by *Haemophilus vaginalis* (bacteria) or *Candida albicans* (fungus), which are treated differently from the protozoal infection.

Table 39.1. *Entamoeba Histolytidavasion* of Host

characteristics of a protozoan (i.e., lack of ergosterol in its cell membrane), but its rRNA and mitochondrial DNA pattern resembles that of fungi. Acute pneumocystis rarely strikes healthy individuals, although the organism is harbored in a wide variety of animals and most humans without any apparent adverse effect. *Pneumocystis carinii* becomes active only in those individuals who have a serious impairment of their immune systems. Thus, the organism is considered to be an opportunistic pathogen. More recently, this disease has appeared in patients with AIDS, 80% of whom ultimately contract *P. carinii* pneumonia (PCP), as one of the main causes of death. The disease also occurs in those receiving immunosuppressive drugs to prevent rejection following organ transplantation or for the treatment of malignant disease. Additionally, pneumocystis is seen in malnourished infants whose immunologic systems are impaired. The disease is thought to be transmitted via an airborne route. The disease is characterized by a severe pneumonia caused by rapid multiplication of the organisms, almost exclusively in lung tissue, with the organism lining the walls of the alveoli and gradually filling the alveolar spaces. Untreated, the acute form of the disease generally is fatal. Even patients who recover from pneumocystosis are at risk of recurrent episodes. Patients with AIDS experience a recurrence rate of approximately 50%.

Extrapulmonary pneumocystosis—that is, pneumocystosis outside of the lungs—also is known to exist and may be more common than presently recognized. This infection may be complicated by the presence of coinfectious organisms. Fortunately, drug therapy utilized for treatment of the pulmonary infection is beneficial for the extrapulmonary condition, although intravenous (IV) administration of the drugs may be necessary.

## Tritryps

Three protozoan pathogens that belong to the family Trypanosomatidae, the order Kinetoplastida, and the genus *Trypanosoma* are *Leishmania major*, which is responsible for leishmaniasis; *Trypanosoma brucei*, which is responsible for African trypanosomiasis (African sleeping sickness); and *Trypanosoma cruzi*, which is responsible organism for Chagas' disease. Referred to as the "tritryps," these eukaryotic organisms share characteristic subcellular structures of a kinetoplast and glycosomes, are unicellular motile protozoa, are transmitted by various insect vectors, and infect mammalian hosts. The genomes of tritryps have recently been reported (1–3). Together, they infect hundreds of millions of people annually.

### Trypanosomiasis (4)

There are two distinct forms of trypanosomiasis: Chagas' disease, and African sleeping sickness.

**CHAGAS' DISEASE.** Chagas' disease, also known as American trypanosomiasis, is caused by the parasitic protozoa *Trypanosoma cruzi* and is found only in the Americas, primarily in Brazil but also in the southern United States. The protozoa lives in mammals and is spread by the bloodsucking insect known as the reduviid bug, assassin bug, or kissing bug. The insect becomes infected by drawing blood from an infected mammal and releasing the protozoa with discharged feces. The pathogen then enters the new host through breaks in the skin. Inflammatory lesions are seen at the site of entry. The disease also may be spread through transfusion with contaminated blood. Signs of initial infection may include malaise, fever, anorexia, and skin edema at the site where the protozoa entered the host. The disease ultimately may invade the heart, where after decades of infection with chronic Chagas' disease, the patient may experience an infection-associated heart attack. It is estimated that 5% of the Salvadorian and Nicaraguan immigrants to the United States may have chronic Chagas' disease.

**AFRICAN TRYPANOSOMIASIS.** African trypanosomiasis, or sleeping sickness, is caused by several subspecies of *Trypanosoma brucei* (*T. brucei rhodesiense* [east African sleeping sickness] and *T. brucei gambiense* [west African sleeping sickness]). In this case, the infected animal is bitten by the bloodsucking tsetse fly, which in turn transmits the protozoa via inoculation during a subsequent bite of a human. The protozoa, initially present in the gut of the vector. appears in the salivary gland for inoculation during the subsequent biting of a human. It is estimated that some 50 million people are at risk of African sleeping sickness, with 300,000 to 500,000 cases occurring in sub-Saharan Africa each year. The infection progresses through two stages. Stage I may present as fever and high temperatures lasting several days; hematologic and immunologic changes occur during this stage. Stage II occurs after the organism enters the central nervous system (CNS) and may involve symptoms suggesting the disease name—daytime somnolence, loss of spontaneity, halting speech, listless gaze, and extrapyramidal signs (e.g., tremors and choreiform movements). A breakdown of neurological function leading to coma and death may occur. Death may occur within weeks if untreated (*T. brucei rhodesiense*) or only after several years (*T. brucei gambiense*).

It should be noted that the sole source of energy for the trypanosomal organism is glycolysis, which in turn may account for the hypoglycemia seen in the host. In addition, the migration of the organism into the CNS may be associated with the organism's search for a rich source of available glucose.

### Leishmaniasis

Leishmaniasis is a disease caused by a number of protozoa in the genus *Leishmania*. The protozoa may be harbored in diseased rodents, canines, and various other mammals and transmitted from the infected mammal to man by bites from female sandflies of the genus *Phlehotomus* and then appears in one of four major clinical syndromes: visceral leishmaniasis, cutaneous leishmaniasis, mucocutaneous leishmaniasis, or diffuse cutaneous leishmaniasis.

Copyrighted material

The sandfly, the vector involved in spreading the disease, breeds in warm, humid climates; thus, the disease is more common in the tropics. As many as 12 million individuals, worldwide are infected by this organism.

The visceral leishmaniasis, also known as kala azar (black fever), is caused by *Leishmania donovani.* This form of the disease is systemic and is characterized in patients by fever, typically nocturnal, diarrhea, cough, and enlarged liver and spleen. The skin of the patient may become darkened. Without treatment, death may occur in 20 months and is commonly associated with diarrhea, superinfections, or GI hemorrhage. Visceral leishmaniasis is most commonly found in India and Sudan.

Both cutaneous and monocutaneous leishmaniasis are characterized by single or multiple localized lesions. These slow-healing and, possibly, painful ulcers can lead to secondary bacterial infections. The Old World cutaneous leishmaniasis is caused by *Leishmania topica*, which is found most commonly in children and young adults in regions bordering the Mediterranean, the Middle East, Southern Russia, and India. *Leishmania major* is endemic to desert areas in Africa, the Middle East, and Russia, whereas *Leishmania aethiopica* is found in the Kenyan highlands and Ethiopia. The New World disease caused by *Leishmania peruviana, Leishmania braziliensis,* and *Leishmania panamensis* is found in South and Central America, whereas *Leishmania mexicana* may be endemic to south-central Texas. The incubation period for cutaneous leishmaniasis ranges from a few weeks to several months. The slow-healing lesions may be seen on the skin in various regions of the body depending on the specific strain of organism. Usually, these conditions exhibit spontaneous healing, but this also may occur over an extended period of time (1–2 years).

## Malaria

Malaria is transmitted by the infected female *Anopheles* mosquito. The specific protozoan organisms causing malaria are from the genus *Plasmodium.* Only 4 of approximately 100 species cause malaria in humans. The remaining species affect birds, monkeys, livestock, rodents, and reptiles. The four species that affect humans are *Plasmodium falciparum, Plasmodium vivax, Plasmodium malariae,* and *Plasmodium ovale.* Concurrent infections by more than one of these species are seen in endemically affected regions of the world. Such multiple infections further complicate patient management and the choice of treatment regimens.

Malaria affects as many as 500 million humans globally and causes more than 2 million deaths annually. It is estimated that a third of these fatalities occur in children younger than 5 years. Although this disease is found primarily in the tropics and subtropics, it has been observed far beyond these boundaries.

Malaria has essentially been eradicated in most temperate-zone countries. However, more than 1,000 cases of malaria were documented recently in U.S. citizens returning from travel abroad. Today, malaria is found in most countries of Africa, Central and South America, and Southeast Asia. It is reported to be on the increase in Afghanistan, Bangladesh, Brazil, Burma, Cambodia, Colombia, China, Iran, India, Indonesia, Mexico, the Philippines, Thailand, and Vietnam. Infection from plasmodia can cause anemia, pulmonary edema, renal failure, jaundice, shock, cerebral malaria, and if not treated in a timely manner, even death.

### Types of Malaria

Malarial infections are known according to the species of the parasite involved.

**PLASMODIUM FALCIPARUM.** Infection with *Plasmodium falciparum* has an incubation period (time from mosquito bite to clinical symptoms) of 1 to 3 weeks (average, 12 days). The *P. falciparum* life cycle in humans begins with the bite of an infected female mosquito. The parasites in the sporozoite stage enter the circulatory system, through which they can reach the liver in approximately 1 hour. These organisms grow and multiply 30,000- to 40,000-fold by asexual division within liver cells in 5 to 7 days. Then, as merozoites, they leave the liver to reenter the blood stream and invade the erythrocytes, or red blood cells (RBCs), where they continue to grow and multiply further for 1 to 3 days. Specific receptors on the surface of the erythrocytes serve as binding sites for the merozoite. These infected RBCs rupture, releasing merozoites in intervals of approximately 48 hours. Chemicals released by the ruptured cell in turn cause activation and release of additional substances associated with the patient's symptoms. The clinical symptoms include chills, fever, sweating, headaches, fatigue, anorexia, nausea, vomiting, and diarrhea. Some of the released merozoites are sequestered in vital organs (brain and heart), where they continue to grow. Recurrence of the clinical symptoms on alternate days leads to the terminology of tertian malaria. The *P. falciparum* parasite also can cause RBCs to clump and adhere to the wall of blood vessels. Such a phenomenon has been known to cause partial obstruction and, sometimes, restriction of the blood flow to vital organs like the brain, liver, and kidneys. Reinfection of RBCs can occur, allowing further multiplication and remanifestation of the malaria symptoms. Some merozoites develop into male and female sexual forms, called gametocytes, which can then be acquired by the female mosquito after biting the infected human. Gametocytes mature in the mosquito's stomach to form zygotes. Growth of the zygotes leads to the formation of oocysts (spherical structures located on the outside wall of the stomach). Sporozoites develop from the oocysts, are released into the body cavity of the mosquito, and migrate to the salivary gland of the insect, from which they can be transmitted to another human following a mosquito bite. The life cycle of the malaria parasites is shown in the Figure 39.1. The genome of the *P. falciparum* is now known and is expected to provide potential new

Copyrighted material

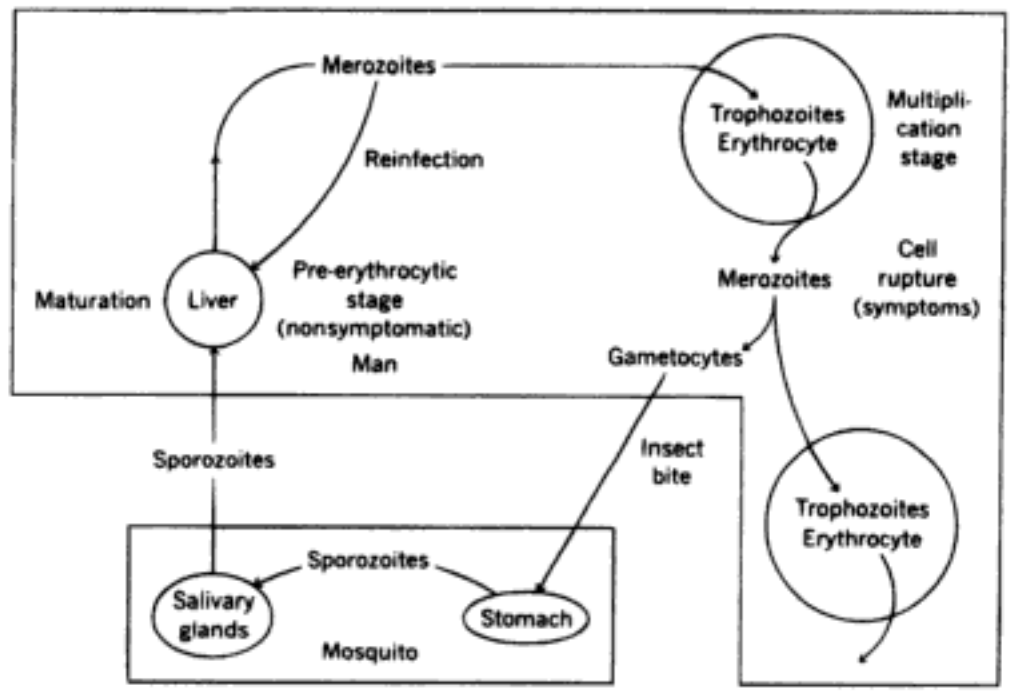

**Fig. 39.1.** Life cycle of malarial protozoa.

avenues for drug development. Genome information also is expected to give insight regarding the mechanisms of resistance and improve drug treatment.

**PLASMODIUM VIVAX.** *Plasmodium vivax* (benign tertian) is the most prevalent form of malaria. It has an incubation period of 1 to 4 weeks (average, 2 weeks). This form of malaria can cause spleen rupture and anemia. Relapses (renewed manifestations of erythrocytic infection) can occur. This results from the periodic release of dormant parasites (hypnozoites) from the liver cells. The erythrocytic forms generally are considered to be susceptible to treatment.

**PLASMODIUM MALARIAE.** *Plasmodium malariae* is responsible for quartan malaria. It has an incubation period of 2 to 4 weeks (average, 3 weeks). The asexual cycle occurs every 72 hours. In addition to the usual symptoms, this form also causes nephritis. This is the mildest form of malaria and does not relapse. The RBC infection associated with *P. malariae* can last for many years. The *P. malariae* is quite unlikely to become resistant.

**PLASMODIUM OVALE.** Infection with *Plasmodium ovale* has an incubation period of 9 to 18 days (average, 14 days). Relapses have been known to occur in individuals infected with this plasmodium. The relapse may be indicative of ovale tertian malaria and is associated with the ability of the organism to lie dormant in hepatic tissue for extended periods of time.

### Types of Chemotherapy

**TISSUE SCHIZONTICIDES.** These drugs eradicate the exoerythrocytic liver-tissue stages of the parasite, which prevents the parasite's entry into the blood. Drugs of this type are useful for prophylaxis. Some tissue schizonticides can act on the long-lived tissue form (hypnozoites of *P. vivax* and *P. ovale*) and, thus, can prevent relapses.

**BLOOD SCHIZONTICIDES.** These drugs destroy the erythrocytic stages of parasites and can cure cases of falciparum malaria or suppress relapses. This is the easiest phase to treat, because drug delivery into the blood stream can be accomplished rapidly.

**GAMETOCYTOCIDES.** Agents of this type kill the sexual forms of the plasmodia (gametocytes), which are transmittable to the *Anopheles* mosquito, thereby preventing transmission of the disease.

**SPORONTOCIDES (SPOROZOOITICIDES).** These drugs act against sporozoites and are capable of killing these organisms as soon as they enter the bloodstream following a mosquito bite.

It should be noted that antimalarials may operate against more than one form of the organism and may be effective against one species of plasmodium but lack efficacy against others. In addition, antimalarial drugs may be classified according to their structural types.

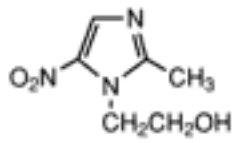
## GENERAL APPROACHES TO PROTOZOAL THERAPY

### Amebiasis and Giardiasis

The most appropriate approach for treatment of this type of protozoal infection is through prevention. Because the infection usually occurs by consumption of contaminated drinking water and food, avoidance is the key to prevention. Drinking bottled water, or boiling or disinfecting the water, will reduce the risk. Improvement in personal hygiene and general sanitation also are beneficial.

### Trypanosomiasis, Leishmaniasis, and Malaria

For these diseases that are spread by insect vectors, the use of insecticides, protective clothing, and insect repellents can greatly reduce the incidence of the disease. Unfortunately, many of these protozoal infections also



Copyrighted material

can infect other hosts beside humans; thus, even the most successful insect irradiation methods cannot destroy all the reservoirs of the protozoa. The use of insect repellents and protective clothing may be useful for visitors to regions with endemic infections, but these procedures may prove to be ineffective for those living in the area. For such individuals, early detection and drug therapy is the method of treatment.

## DRUG THERAPY FOR PROTOZOAL INFECTIONS

### Treatment of Amebiasis, Giardiasis, and Trichomoniasis

Metronidazole (Flagyl, Metryl, Satric)

Metronidazole

Metronidazole was initially introduced for the treatment of vaginal infections caused by *Trichomonas vaginalis* but has since been shown to be effective for treatment of amebiasis, giardiasis, and anaerobic bacterial infections, including *Clostridium difficile*.

**MECHANISM OF ACTION.** Despite the availability of metronidazole since the late 1950s, the mechanism of action of the drug is still unknown. It generally is agreed that metronidazole is a pro-drug and that anaerobic organisms reduce the nitro group in metronidazole to a hydroxylamine, as shown in Figure 39.2, during which a reactive derivative or reactive species are produced that cause destructive effects on cell components (i.e., DNA, proteins, and membranes). Specifically, DoCampo (5) has reported that nitroaryl compounds (nitroimidazoles, metronidazole; nitrofurans, nifurtomox) are reduced to nitro radical anions, which in turn react with oxygen to regenerate the nitroaryl and the superoxide radical anion (Fig. 39.3). Further reduction of superoxide radical anion leads to hydrogen peroxide and homolytic cleavage of the latter leads to hydroxyl radical formation. Superoxide radical anion, hydrogen peroxide, and hydroxyl radicals are referred to as reactive oxygen species (ROS) and are the reactive substances that are implicated in damage to critical cellular components of the parasite.

**METABOLISM.** Liver metabolism of metronidazole leads to two major metabolites: hydroxylation of the 2-methyl

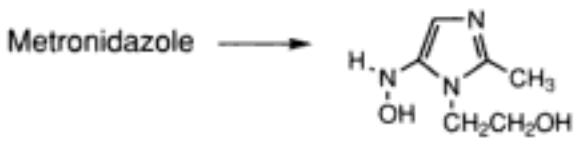


**Fig. 39.2.** Metabolic activation of metronidazole.

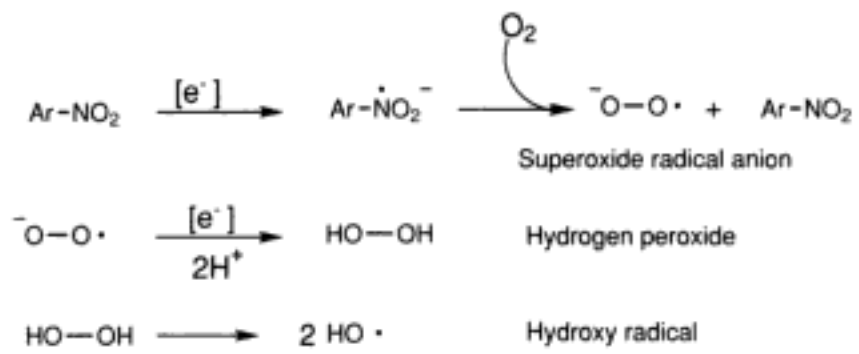

**Fig. 39.3.** Formation of ROS from nitroaryl compounds.

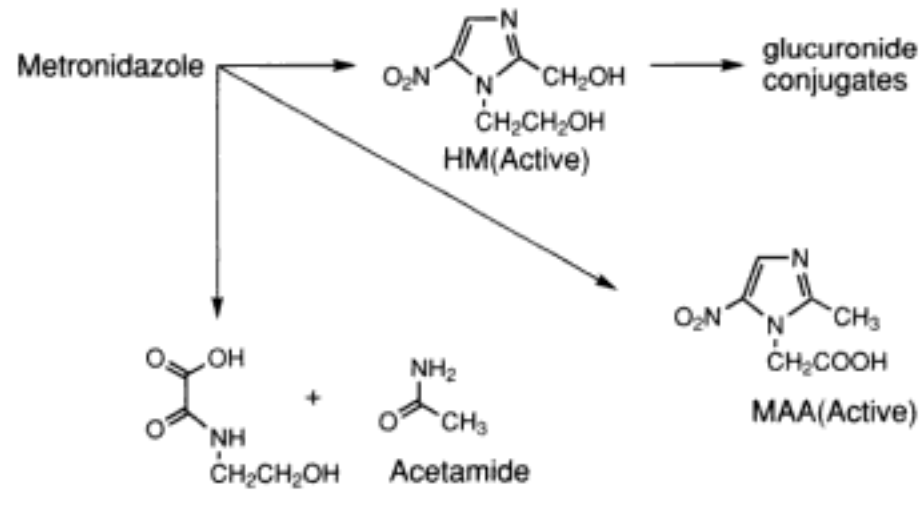
group to 2-hydroxymethylmetronidazole (HM), and oxidation to metronidazole acetic acid (6). Both compounds possess biological activity. Additionally, HM is found in the urine as glucuronide and sulfate conjugates. In addition, a small amount of metronidazole is oxidized to acetamide, a known carcinogen in rats but not in humans, and to the oxalate derivative shown in Figure 39.4 (7).

**PHARMACOKINETICS (6).** Metronidazole is available in a variety of dosage forms, including IV, oral, rectal, and vaginal suppositories. The bioavailability of metronidazole is nearly 100% when administered orally but is significantly less when administered via the rectal route (67–82%) or the vaginal route (19–56%). The drug is not bound to plasma protein. Distribution of the drug is fairly uniform through out the body, including mother's milk.

**THERAPEUTIC APPLICATION.** Metronidazole is considered to be the drug of choice for treatment for the protozoal infections amebiasis (intestinal and extraintestinal), giardiasis, and trichomoniasis (8). It is the drug of choice for treatment of the Gram-positive bacilli *Clostridium difficile* and in combination is an alternative therapy for *Helicobacter pylori* infections (9). The common side effects exhibited with metronidazole include abdominal distress, a metallic taste, and a disulfiram-like effect if taken with alcohol. The drug is reported to be carcinogenic in mice, possibly related to the metabolite acetamide, and as a result should not be used during the first trimester of pregnancy.



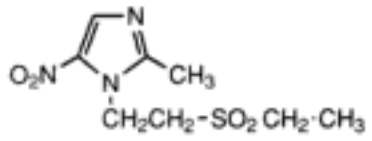


**Fig. 39.4.** Metabolism of metronidazole.

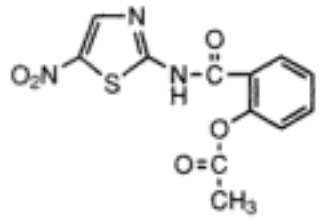
Copyrighted material



### Tinidazole (Tindamax)

Tinidazole

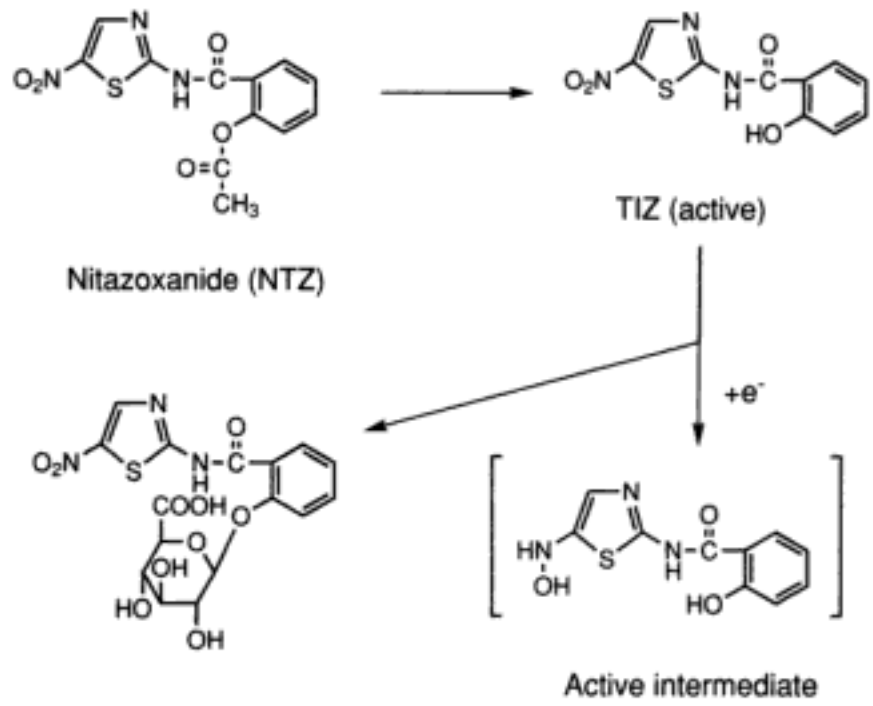
Tinidazole has recently been approved by the U.S. Food and Drug Administration (FDA) for the treatment of amebiasis, giardiasis, and trichomoniasis. It also appears to be highly effective against *Helicobacter pylori* infections, although it is not approved for this use. The drug is rapidly and completely absorbed following oral administration and can be administered with food to reduce GI disturbance. Tinidazole has a mechanism of action that parallels that of metronidazole as well as a similar metabolic pathway leading to hydroxylation at the 2-methyl group catalyzed by CYP3A4. Basically, tinidazole appears to mimic the actions of metronidazole, although there are reports that it is effective against some protozoa which are resistant to metronidazole.

### Nitazoxanide (Alinia)

Nitazoxanide

Nitazoxanide (NTZ) has been approved as an orphan drug for the treatment of diarrhea in children (age, 1–11 years) and is associated with giardiasis, but it also is approved for diarrhea caused by crytosporidiosis in patients with AIDS. Crytosporidiosis is a protozoal infection caused by *Cryptosporidium parvum*. The condition is uncommon in healthy individuals but can be life-threatening in immunosuppressed patients and those with HIV infections.

**Mechanism of action (10).** Nitazoxanide is a pro-drug that is metabolically converted into the deactylated drug tizoxanide (TIZ) (Fig. 39.5). The TIZ then undergoes a four-electron reduction of the 5-nitro group giving various short-lived intermediates, which may include the hydroxylamine derivative. It is these reduced products that represent the active form of NTZ. Whereas these intermediates would suggest that NTZ has the same mechanism of action as metronidazole, this does not appear to be the case. Nitazoxanide is thought to inhibit the enzyme pyruvate:ferredoxin oxidoreductase in *Trichomonas vaginalis, Entamoeba histolytica*, and *Clostridium perfingens*. The results of this inhibition is disruption of the bioenergetics of these organisms. Unlike metronidazole and tinidazole, which fragment DNA and are suspected mutagenic agents, NTZ and TIZ do not cause DNA fragmentation



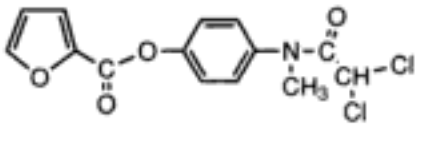


**Fig. 39.5.** Metabolic activation of nitazoxanide.

and are not considered to be mutagenic. This might be associated with the higher redox potential found for NTZ, a nitrothiazole, in comparison with very low redox potential found for the nitroimidazoles, such as metronidazole and tinidazole. Additional metabolites of TIZ also includes the glucuronide, which shows some biological activity, and small amounts of an aromatic hydroxylation product (Fig. 39.5).

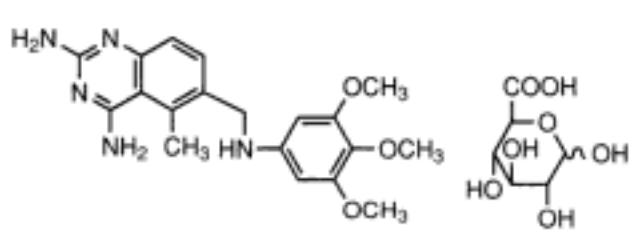
**Pharmacokinetics.** Nitazoxanide is available as powder that is reconstituted and dispensed as an oral suspension. The drug is well absorbed from the GI tract and rapidly metabolized, with elimination products appearing in the urine and feces. The only identified products in the plasma are TIZ and its glucuronide (11). The product can be taken with food.

**Therapeutic application.** Although NTZ has only been approved for treatment of diarrhea in children caused by *Giardia lamblia* and diarrhea caused by *Cryptosporidium parvum*, the drug may soon be approved for adults suffering from diarrhea caused *Giardia lamblia*. In addition, the drug has been shown to be effective against the protozoa *Entamoeba histolytica* and *Trichomonas vaginalis*, the bacteria *Helicobacter pylori* and *Clostridium perfringens*, and various helminths, including *Ascaris lumbricoides, Enterobius vermicularis, Ancylostoma doudenale,* and *Strongyloides stercoralis* (12).

### Diloxanide Furoate

Diloxanide furoate

Diloxanide furoate (available from the Centers for Disease Control and Prevention [CDC]) is prescribed for the treatment of asymptomatic amebiasis but is ineffective as a single agent for the extraintestinal form of the disease. The drug is



Copyrighted material

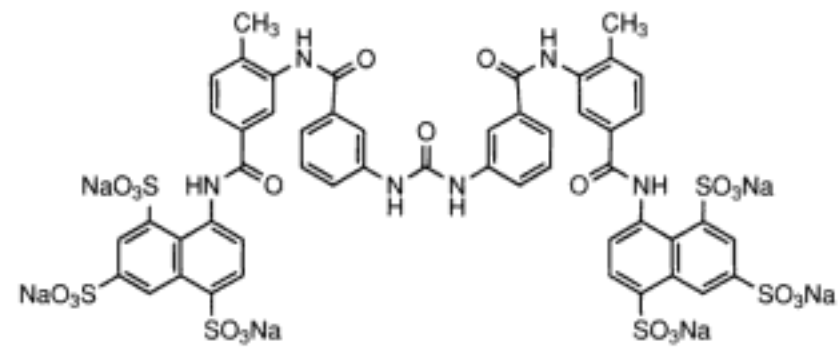
inhibit the mitochondrial respiratory chain. More specifically, atovaquone is a ubiquinone reductase inhibitor, inhibiting at the cytochrome $bc_1$ complex (15). This action leads to a collapse of the mitochondrial membrane potential. The compound shows stereospecific inhibition, with the *trans* isomer being more active than the *cis* isomer.

**PHARMACOKINETICS.** Atovaquone is poorly absorbed from the GI tract because of its poor water solubility and high fat solubility, but the absorption can be significantly increased if taken with a fat-rich meal. The drug is highly bound to plasma protein (94%) and does not enter the CNS in significant quantities. It is not significantly metabolized in humans and is exclusively eliminated in feces via the bile.

**THERAPEUTIC APPLICATIONS.** With as many as 70% of patients with AIDS developing pneumocystis and, of these, nearly 60% of the patients on cotrimoxazole developing serious side effects to this combination, atovaquone is an important alternative drug (16). Atovaquone also has been reported to be effective for the treatment of toxoplasmosis caused by *Toxoplasma gondii*, although it has not been approved for this use.

Trimetrexate Glucuronate (Neutrexin)

Trimetrexate glucuronate



Trimetrexate (TMQ) has been approved for the treatment of *Pneumocystis carinii* in patients with AIDS and also exhibits antiprotozoal activity against *Trypanosoma cruzi*. The drug is available as a single-ingredient medication, but it can be administered along with folinic acid in much the same way that methotrexate is administered with calcium leucovorin in cancer chemotherapy. Trimetrexate is a derivative of methotrexate.

**MECHANISM OF ACTION.** Trimetrexate is considered to be a nonclassical folate antagonist, whereas methotrexate, the structurally similar analogue of TMQ, is a classical folate antagonist. The difference between these two drugs is that methotrexate, with its polar glutamate side chain, is transported into the cell via a carrier-mediated transport system, whereas TMQ, without the glutamate moiety, is absorbed by the cell via a passive diffusion. Once in the cell, TMQ inhibits DHFR. Trimetrexate binds to *Pneumocystis carinii* DHFR 1,500 times more strongly than trimethoprim and somewhat more strongly than methotrexate. It also has been reported that TMQ readily enters the *P. carinii* cell because of the lipophilic nature of this drug (17). Methotrexate and leucovorin are not able to enter the cell, however, because the cell membrane of *P. carinii* does not possess the transporter protein (17).

**THERAPEUTIC APPLICATION.** Trimetrexate, when combined with the cytoprotective agent leucovorin, is more effective and better tolerated than pentamidine in the treatment of PCP (18). Because the first- and second-line agents are successful in only 50 to 75% of these cases, and because adverse reactions severely limit the use of some of the older agents, TMQ may offer some advantages in treatment. Trimetrexate is administered by IV infusion over 60 to 90 minutes and should be combined with the cytoprotective drug leucovorin. The leucovorin protects against bone marrow suppression and against renal and hepatic dysfunction. Leucovorin administration should continue for 72 hours after the last dose of TMQ. Additionally, TMQ has been reported to be effective in the treatment of Chagas' disease.

## Treatment of Trypanosomiasis (19)

Suramin Sodium (Available from the CDC)

Suramin Sodium

Introduced into therapy for the treatment of early trypanosomiasis in the 1920s, suramin, a bis-hexasulfonatednaphthylurea, is still considered to be the drug of choice for treatment of non-CNS-associated African trypanosomiasis.

**MECHANISM OF ACTION.** The mechanism of action of suramin is unproven, but the drug is known to have a high affinity for binding to a number of critical enzymes in the pathogen. Among the enzymes to which suramin has been shown to bind are several dehydrogenases and kinases. As a result of binding, suramin has been shown to be an inhibitor of DHFR, a crucial enzyme in folate metabolism, and thymidine kinase. In addition, suramin is an inhibitor of glycolytic enzymes in *Trypanosoma brucei*, with binding constants much lower than those seen in mammalian cells. Inhibition of glycolysis would be expected to block energy sources of the pathogen, leading to lysis. Whether one or more of these inhibitor actions represent the toxic action of suramin on the pathogen remains unproven.

**PHARMACOKINETICS.** Suramin sodium is a water-soluble compound that is poorly absorbed via oral administration and must be administered IV in multiple injections.

Copyrighted material

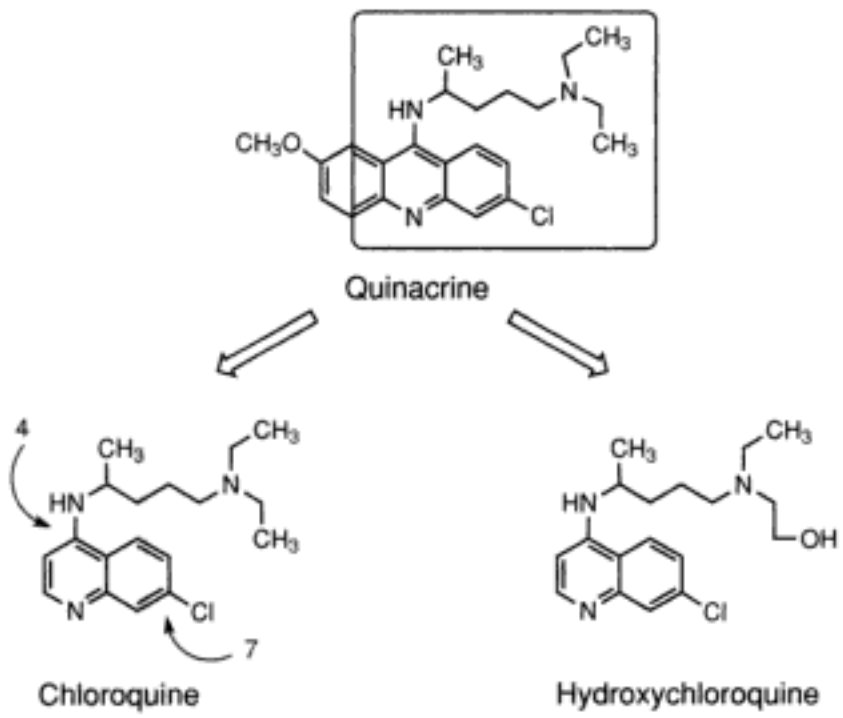


**Fig. 39.11.** Structural similarity between quinacrine and the 4-aminoquinolines.

primaquine, retain the methoxyquinoline nucleus of quinine and quinacrine (Fig. 39.12). The quinoline-4-methanols, mefloquine and halofantrine, show similarity to the 4-quinolinemethanol portion of quinine (Fig. 39.12).

### 4-Substituted Quinolines

Five compounds may be considered within this class of drugs: quinine, chloroquine and hydroxychloroquine, mefloquine, and halofantrine (Figs. 39.11 and 39.12). These compounds not only share a structural similarity but also are thought to have similar mechanisms of action, are effective on the same stage of the parasite, and may share similar mechanisms of resistance.

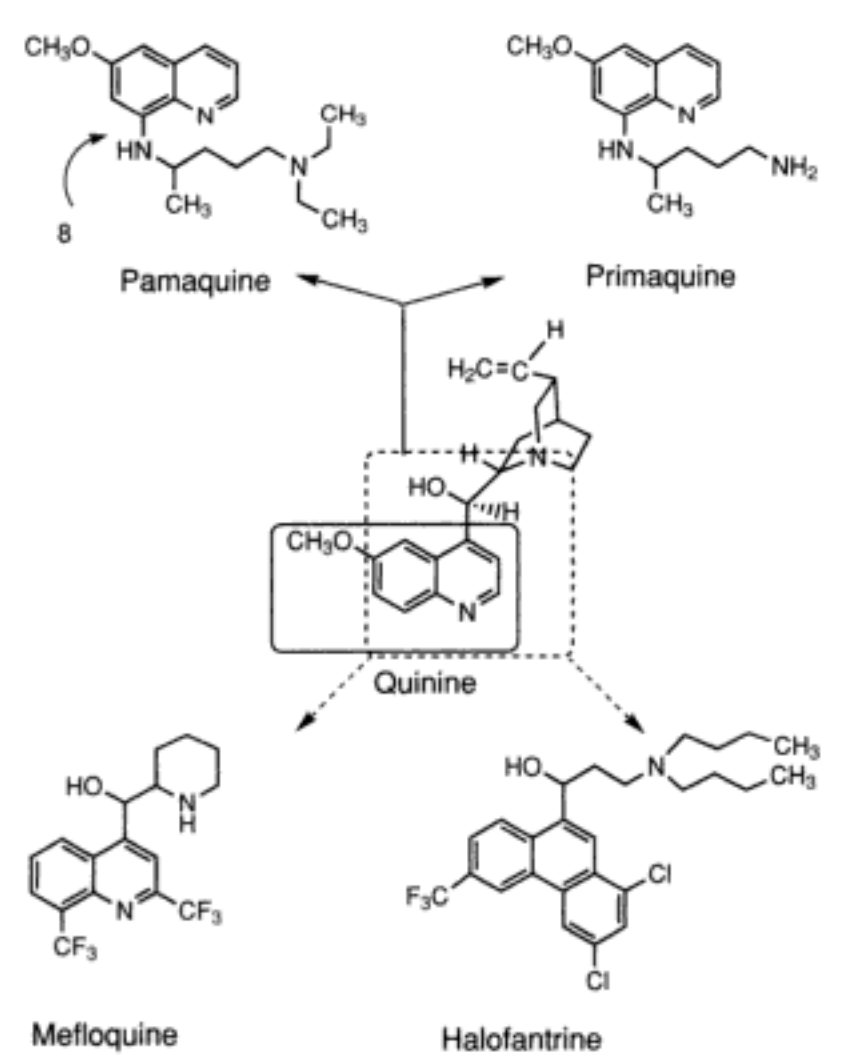

**Fig. 39.12.** Structural similarity between quinine and the 8-aminoquinolines (⟶) and between quinine and the quinoline-4-methanols (⇢).

**Mechanism of action.** The mechanism of action of chloroquine has been studied in depth, and the results of these studies have been assumed to be applicable to the other 4-substituted quinolines (33). Various mechanisms of actions have been offered to explain the action of this class of drugs, including the DNA intercalation mechanism, the weak base hypothesis, and the ferriprotoporphyrin hypothesis. The present understanding about the mechanism of action would appear to utilize various aspects of each of these previous mechanisms. It is known that hemoglobin is transported into the food vacuoles of the plasmodium, where digestion of the hemoglobin supplies the organism with a source of amino acids. One of the products of this digestion is free heme, a substance toxic to the plasmodium cells, which in the plasmodium vacuole is polymerized to hemozoin. It has been demonstrated that the quinolines bind to hemozoin through a drug–heme complex in which the aromatic quinoline ring π-bonds to the porphyrin nucleus (34). This drug–heme complex caps the growing hemozoin polymer, thus blocking further extension of the polymer. The result of this complexation is that newly formed, free toxic heme is now present, which leads to the death of the plasmodium. The accumulation of the 4-substituted quinolines in the acidic food vacuoles (pH 4.8–5.2) is based on the fact that these drugs are weak bases, as indicated by their $pK_a$ values. The extracellular fluid of the parasite is at pH 7.4, and as a result, the weak base will move toward the more acidic pH of the vacuoles, reaching concentrations hundreds of times those in the plasma. Additionally, the binding of the quinoline to the heme draws additional quantities into the vacuole.

**Mechanism of resistance.** A limiting factor for most of the antimalarial drugs is the development of resistant strains of plasmodium. It should be noted that resistance differs from region to region, and in some cases, a resistant strain may develop to a particular drug without that drug ever having been introduced to the region (possible cross-resistance). The development of resistance is thought to be a spontaneous gene mutation. Several mechanisms of resistance appear to be operating. One of these mechanisms is based on the *Plasmodium falciparium* chloroquine-resistance transporter (*pfrcrt*) mechanism, which is sufficient and necessary to impart resistance (35). A gene encodes for a transmembrane transporter protein found in the membrane of the food vacuole. Multiple mutations within a specific region this gene result in reduced accumulation of chloroquine, resulting from the increased efflux of the drug. Additional transporter proteins also may be involved in resistance.

Copyrighted material

***Chloroquine (Aralen).*** Chloroquine is the most effective of the hundreds of 4-aminoquinolines synthesized and tested during World War II as potential antimalarials. Structure–activity relationships demonstrated that the chloro at the 8-position increased activity, whereas alkylation at C-3 and C-8 diminished activity. The replacement of one of its N-ethyl groups with an hydroxyethyl produced hydroxychloroquine, a compound with reduced toxicity that is rarely used today except in cases of rheumatoid arthritis.

Chloroquine is commonly administered as the racemic mixture, because little is gained by using the individual isomers. The drug is well absorbed from the GI tract and distributed to many tissues, where it is tightly bound and slowly eliminated. The drug is metabolized by N-dealkylation by CYP2D6 and CYP3A4 isoforms. It has been reported that the level of metabolism correlates closely with the degree of resistance. The suggestion has been made to coadminister chloroquine with CYP2D6 and CYP3A4 inhibitors to potentate activity and reduce resistance. Although this may be possible, it is not commonly practiced.

Chloroquine is an excellent suppressive agent for treating acute attacks of malaria caused by *Plasmodium vivax* and *Plasmodium ovale.* The drug also is effective for cure and as a suppressive prophylactic for the treatment of *Plasmodium malariae* and susceptible *Plasmodium falciparum.*

Chloroquine generally is a safe drug, with toxicity occurring at high doses of medication if the drug is administered too rapidly via parenteral routes. With oral administration, the side effects primarily are GI effects, mild headache, visual disturbances, and urticaria.

***Mefloquine (Lariam) (37).*** Mefloquine, which was synthesized with the intent of blocking the site of metabolism in quinine with the chemically stable $CF_3$ group, exists as four optical isomers of nearly equal activity. The drug is active against chloroquine-resistant strains of plasmodium, yet cross-resistance is not uncommon. Metabolism is cited as the possible mechanism of resistance. Mefloquine is slowly metabolized through CYP3A4 oxidation to its major inactive metabolite, carboxymefloquine (Fig. 39.13). Most of the parent drug is excreted unchanged into the urine. Its coadministration with CYP3A4 inhibitors (e.g., ketoconazole) has increased the area under the curve for mefloquine by inhibiting its metabolism to carboxymefloquine.

Mefloquine is only available in an oral dosage form, which is well absorbed. The presence of food in the GI tract affects the pharmacokinetic properties of the drug, usually enhancing absorption. The lipophilic nature of the drug accounts for the extensive tissue binding and low clearance of total drug, although the drug does not accumulate after prolonged administration. The drug has a high affinity for erythrocyte membranes.

**Fig. 39.13.** *Plasmodium falciparum* metabolism of mefloquine.

Mefloquine is an effective suppressive prophylactic agent against *Plasmodium falciparum* both in nonimmune populations (travelers coming into regions of malaria) and in resident populations. The drug also has high efficacy against falciparum malaria, with a low incidence of recrudescence. The drug is ineffective against sexual forms of the organism.

The incidence of side effects with mefloquine is considered to be high. The effects are classified as neuropsychiatric, GI, dermatologic, and cardiovascular. The neuropsychiatric effects may be serious (e.g., suicidal tendencies or seizures) or minor (e.g., dizziness, vertigo, ataxia, and headaches). Gastrointestinal side effects included nausea, vomiting, and diarrhea, whereas the dermatologic effects include rash, pruritus, and urticaria. Finally, cardiovascular side effects may include bradycardia, arrhythmias, and extrasystoles.

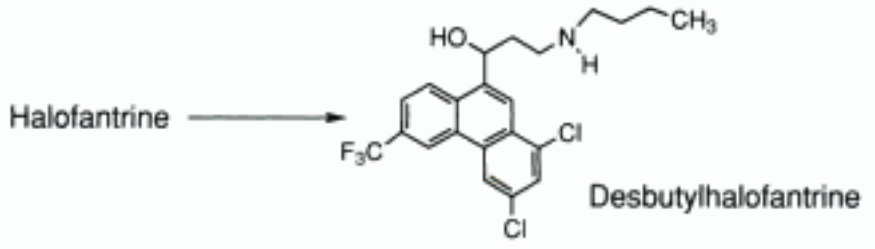
***Halofantrine (Hafan).*** Halofantrine (38,39), a member of the 9-phenanthrenemethanol class (Fig. 39.12), originally came out of a synthesis program dating to World War II, but this particular agent was not fully developed until the 1960s. Halofantrine has one chiral center and has been separated into its enantiomers. There appears to be little difference between the enantiomers; thus, the drug is used as a racemic mixture.

Halofantrine is considered to be an alternative drug for treatment of both chloroquine-sensitive and chloroquine-resistant *Plasmodium falciparum* malaria, but its efficacy in mefloquine-resistant malaria may be questionable. The drug is metabolized via N-dealkylation to desbutylhalofantrine by CYP3A4 (Fig. 39.14). The metabolite appears to be several-fold more active than the administered drug.

At present, halofantrine is only available in a tablet form, which has significant implications as it relates to its

**Additional Therapeutic Indications for Chloroquine**

Chloroquine also is prescribed for treatment of rheumatoid arthritis, discoid lupus erythematosus, and photosensitivity diseases.



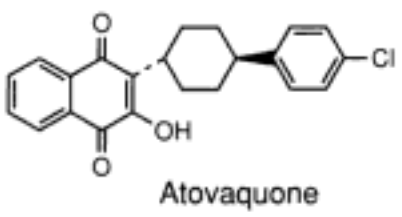


**Fig. 39.14.** Metabolism of halofantrine.

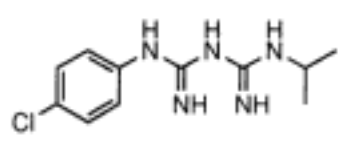
Copyrighted material



(a pyrophosphokinase) and the incorporation of PABA into dihydropteroic acid. A second bifunctional enzyme catalyzes the reduction of dihydropteroic acid and thymidylic acid synthesis. As a result, the drug combination (Fansidar) appears to have improved drug-mediated disruption of folic acid in *Plasmodium* sp. (35,43). This combination has been used with quinine for the treatment and prevention of chloroquine-resistant malaria (*Plasmodium falciparum, Plasmodium ovale, Plasmodium vivax,* and *Plasmodium malaria*). The combination therapy (Fansidar) has the added advantage of being inexpensive, which is essential for successful therapy in developing countries. When used on its own, pyrimethamine is a blood schizonticide without effects on the tissue stage of the disease.

The mechanism of resistance to the folate inhibitor combination has been shown to be associated with point mutations in both DHFR and the dihydropteroate synthase enzymes (35).

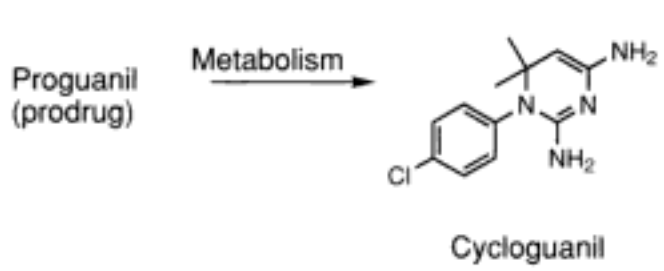
### ATOVAQUONE-PROGUANIL

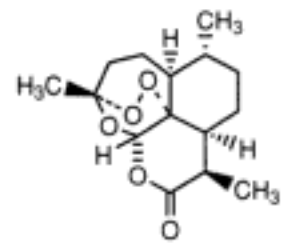
Atovaquone

Proquanil

Atovaquone was originally developed as an antimalarial, but because of the high failure rate (~30%), it is not prescribed as a single chemical entity but, rather, is used to treat pneumocystis (see page 1092). More recently, however, atovaquone has been combined with proquanil as an effective prophylactic and therapeutic antimalarial (35). The two drug together (Malarone) exhibit synergy in which proguanil reduces the effective concentration of atovaquone needed to damage the mitochondrial membrane and atovaquone increases the effectiveness of proguanil but not its active metabolite (for the mechanism of action of atovaquone, see page 1091). Proguanil was developed decades earlier as a folic acid antagonist and functions as a pro-drug. The active form of proguanil is cycloguanil, which acts as a DHFR inhibitor (Fig. 39.16). Later, this discovery led to the development of pyrimethamine.

Resistance to atovaquone used as a monotherapy may have been associated with the pharmacokinetics of the drug. Atovaquone is quite lipophilic and has slow uptake, resulting in the pathogen experiencing low concentrations of the drug over an extended period of time, both of which encourage the development of resistance. A single-point mutation appears to be sufficient for resistance (44). To date, resistance to the combination has not been reported.





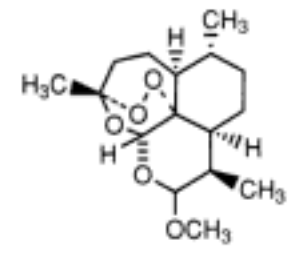


**Fig. 39.16.** Activation of proguanil leading to cycloguanil.

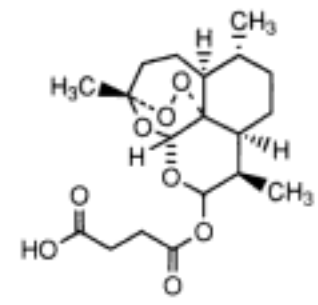
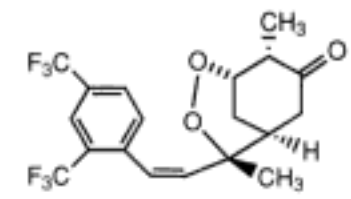


### ARTEMISININS (45–48)



Artemisinin

Artemether (Artenam)

Artesunate

Arteflene

The most recent additions to the drug therapy for malaria are artemisinin and its derivatives. Isolated from *Artemisia annua* (qinghao, sweetworm wood), this material has been used by Chinese herbalists since 168 BC. Artemisinin and the synthetic and semisynthetic derivatives, artemether, arteflene, and artesunate, are active by virtue of the endoperoxide.

***Mechanism of Action.*** The artemisinins appear to kill the parasite by a free radical mechanism—not by the generation of ROS but, rather, by virtue of a free radical associated with the endoperoxide, possibly involving a carbon radical. Evidence points toward activation of the endoperoxide via an iron-dependent mechanism. The resulting free radical selectively targets sarcoplasmic/endoplasmic reticulum $Ca^{2+}$-ATPase of the *Plasmodium falciparum* (PfATP6), altering calcium stores (49). The artemisinins actually may form covalent adducts to specific membrane-associated proteins after concentrating in infected erythrocytes.

**THERAPEUTIC APPLICATION.** The artemisinins are hydrophobic in nature with the exception of artesunate, which is available as a water-soluble hemisuccinate salt, and are partitioned into the membrane of the plasmodium. These compounds have gametocytocidal activity as well as activity against all asexual stages of the parasites. These agents are short acting, with relatively short half-lives. Little or no cross-resistance has been reported, with the drugs rapidly clearing the blood of parasites. The drugs have limited availability in the United States, but they are being utilized elsewhere as commercial or experimental agents, often in combination therapy. Combination therapy has the goal of reducing resistance with the hope for synergism and, when combined with longer-acting drugs,

Copyrighted material

meat, where the organism exists as an encysted larvae. Traditionally, the worm has been associated with domestic pork that feeds on untreated garbage. More recently, outbreaks have occurred in individuals eating infected game, such as wild boar, bear, or walrus. Trichinosis infections are more likely to occur after consumption of homemade pork or wild-game sausages. After ingestion, the larvae are released from the cyst form and then migrate into the intestinal mucosa. After maturation and reproduction, the newly released larvae penetrate the mucosal lining and are distributed throughout the body, where they enter skeletal muscle. During the adult intestinal stage, diarrhea, abdominal pain, and nausea are the most common symptom, whereas the muscular form of the disease has symptoms that may include muscle pain and tenderness, edema, conjunctivitis, and weakness.

### Filariasis

The term "filariasis" denotes infections with any of the Filarioidea, although it is commonly used to refer to lymphatic-dwelling filariae, such as *Wuchereria bancrofti, Brugia malayi,* and *Brugia timori.* Other filarial infections include *Loa loa* and *Onchocerca volvulus.* The latter two are known as the eyeworm and the river blindness worm, respectively. Elephantiasis is the most common disease associated with filariasis. These parasites vary in length from 6 cm for brugia to 50 cm for onchocerca. The incubation periods also vary from 2 months for brugia to 12 months for bancroftian filaria. It is estimated that 400 million persons are infected with human filarial parasites. Depending on the specific organism, various intermediate hosts are involved in spreading the infection. Mosquitoes are involved with the spread of *Wuchereria bancrofti, Brugia malayi,* and *Brugia timori,* whereas the female blackfly spreads river blindness. The larvae released by the female filaria are referred to as microfilariae and commonly may be found in the lymphatics.

## Cestode and Trematode Infections

### Cysticercosis or Tapeworm Infection

Helminths of this class that are of concern as potential parasites in humans include:

- **Beef tapeworm (*Taenia saginata*).** This worm is found worldwide and infects people who eat undercooked beef. The worm reaches a length of more than 5 m, and it contains approximately 100 segments/m. Each of these segments contains its own reproductive organs.
- **Pork tapeworm (*Taenia solium*).** Pork tapeworms sometimes are called bladder worms and occasionally are found in uncooked pork. The worm attaches itself to the intestinal wall of the human host. The adult worm reaches 5 m in length and, if untreated, survives in the host for many years.
- **Dwarf tapeworm (*Hymenolepis nana*).** This infection is transmitted directly from one human to another without an intermediate host. *Hymenolepis nana* reaches only 3 to 4 cm in length. It is found in temperate zones, and children are most frequently infected.
- **Fish tapeworm (*Diphyllobothrium latum*).** The fish tapeworm reaches a length of 10 m and contains approximately 400 segments/m. These tapeworms attach themselves to the intestinal wall and rob the host of nutrients. They especially absorb vitamin $B_{12}$ and folic acid. Depletion of these critical nutrients, especially vitamin $B_{12}$, can lead to pernicious anemia. Tapeworm eggs are passed in the patient's feces, and contamination of food and drink may result in transmission of the infection.

### Schistosomiasis or Blood Flukes

Three primary trematode species cause schistosomiasis in humans: *Schistosoma hematobium, Schistosoma mansoni,* and *Schistosoma japonicum.* Infections result from the penetration of normal skin by living (free-swimming) cercaria (the name given to the infectious stage of the parasite) with the aid of secreted enzymes. The cercaria develop to preadult forms in the lungs and skin. Then, these parasites travel in pairs via the bloodstream and invade various tissues. The adult worm reaches approximately 2 cm in length. The female deposits her eggs near the capillary beds, where granulomas form. Some of the eggs will move into the lumen of the intestines, bladder, or ureters and are released into the environmental surrounding, where the parasite will seek out the intermediate snail vector. Asexual reproduction occurs in the snail. After a period of time, the cercaria are again released from the snail to continue the cycle. The patients might experience headache, fatigue, fever, and GI disturbances during the early stages of the disease. Hepatic fibrosis and ascites occur during later stages. Untreated patients can harbor as many as 100 pairs of worms. Untreated worms can live 5 to 10 years within the host. It is estimated that as many as 200 million persons worldwide are infected with schistosomes. Depending on the species of schistosome, the disease is found in parts of South America, the Caribbean Islands, Africa, and the Middle East.

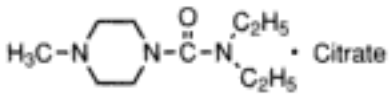
## Drug Therapy for Helminth Infections (51)

Helminths represent a biologically diverse group of parasitic organisms differing in size, life cycle, site of infection (local and systemic), and susceptibility to chemotherapy. With such variation in infectious organisms, it is not surprising that the drugs used to control helminth infections also represent a varied group of chemical classes. As indicated in Table 39.3, the drugs may have fairly narrow spectra of activity (pyrantel pamoate) or a broad spectra of activity (benzimidazoles).

### Benzimidazoles

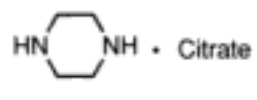
The benzimidazoles (Table 39.4) are a broad-spectrum group of drugs discovered in the 1960s with activity against GI helminths. Several thousand benzimidazoles have been synthesized and screened for anthelmintic

Copyrighted material



Albendazole is unique in two ways. First, the presence of a thioether substituent at the five position increases the likelihood of sulfur oxidation. Second, the initial metabolite, albendazole sulfoxide, is a potent anthelmintic. This initial oxidation is catalyzed principally (70%) by CYP3A4 and CYP1A2 and(30%) by flavin-containing monooxygenase, giving rise to a compound that is bound to plasma protein. This intermediate has an expanded utility in that it has been shown to be active against the hydatid cyst found in echinococciasis, a tapeworm disease (58). Further oxidation by cytochrome P450 leads to the inactive sulfone. Additional metabolites of the sulfone have been reported that include carbamate hydrolysis to the amine and oxidation of the 5-propyl side chain. These reactions occur only to a minor extent.

Metabolism of mebendazole occurs primarily by reduction of the 5-carbonyl to a secondary alcohol, which greatly increases the water solubility of this compound. An additional Phase I metabolite resulting from carbamate hydrolysis has been reported as well. Both the secondary alcohol and the amine are readily conjugated (a Phase II metabolism). Evidence would suggest that the anthelmintic activity of mebendazole resides in the parent drug and none of the metabolites.



Thiabendazole is metabolized through aromatic hydroxylation at the five position catalyzed by CYP1A2. The resulting phenol is conjugated to 5-hydroxythiabendazole glucuronide and 5-hydroxythiabendazole sulfate, respectively. The initial metabolite, along with minor amount of $N_1$-methylthiabendazole (from a methylation Phase II reaction), have been reported to be teratogenic in mice and rats.

**THERAPEUTIC APPLICATION.** As indicated in Table 39.3, mebendazole and albendazole have a wide spectrum of activity against intestinal nematodes. The drugs are useful and effective against mixed infections. The adverse reactions commonly are GI in nature (nausea, vomiting, and diarrhea). Both drugs have been reported to be teratogenic in rats and, therefore, should not be used during the first trimester of pregnancy. A third drug of this class is thiabendazole, which remains of some value in treatment of strongyloidiasis, as an alternate drug, and cutaneous larva migrans (creeping eruption), for which it is the drug of choice. Thiabendazole commonly is used in veterinary medicine. The drug is less commonly used because of associated toxicity. Thiabendazole has been reported to cause Stevens-Johnson syndrome and has the potential for hepatotoxicity and crystalluria.

## Diethylcarbamazine (Hetrazan)

Diethylcarbamazine citrate

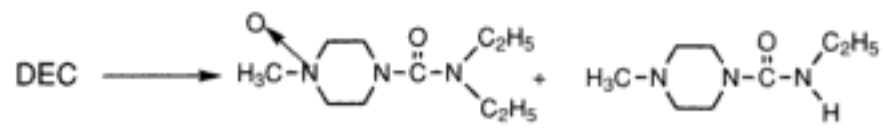
Piperazine citrate

Discovered in the 1940s, diethylcarbamazine (DEC) has proven to be especially effective as a filaricidal agent. The incidence of filariasis among American troops during World War II necessitated a search for drugs with an antifalarial spectrum of activity. The once-popular piperazine also was discovered during these initial screenings. Although chemically similar, the activity again helminths is quite different. Piperazine is active against nematodes, whereas DEC is active against falaria and microfalaria (59).

**MECHANISM OF ACTION.** Although studied extensively, the mechanism of action of DEC remains unknown. Diethylcarbamazine appears to be the active form of the drug, with a very rapid onset of action (within minutes), but of interest is the fact that the drug is inactive in vitro, suggesting that activation of a cellular component is essential to the filaricidal action. Three mechanisms have been suggested. The first is involvement of blood platelets triggered by the action of filarial excretory antigens. A complex reaction is thought to occur between the drug, the antigen, and platelets (60). Although these authors were unable to show a direct action of the drug on the microfalaria, a more recent study showed that DEC produced morphological damage to the microfalaria. The damage consisted of the loss of the cellular sheath, exposing antigenic determinants to immune defense mechanisms. Severe damage then occurred to microfalaria organelles, leading to death (61). The second is inhibition of microtubule polymerization and disruption of preformed microtubules (62). The third is interference with arachidonic acid metabolism (63). Diethylcarbamazine is known to have anti-inflammatory action, which appears to involve blockage at cyclooxygenase and leukotriene $A_4$ synthase (leukotriene synthesis). This action appears to alter vascular and cellular adhesiveness and cell activation. This latter action would suggest a possible relationship between the first and third mechanism.

**METABOLISM.** The metabolism of DEC leads to the compounds shown in Figure 39.18 plus trace amounts of methylpiperazine and piperazine. Nearly all of the metabolites appear in the urine. As much as 10 to 20% of the drug is excreted unchanged. As indicated by the rapid action of the drug, it would appear that none of the metabolites are involved in the therapeutic action of DEC.

**THERAPEUTIC APPLICATION.** Diethylcarbamazine citrate is freely soluble in water, is rapidly absorbed, and is effective against microfalariae. The drug does not appear to be effective against the adult worm. In general, the drug has mild adverse effects, but under some conditions, it



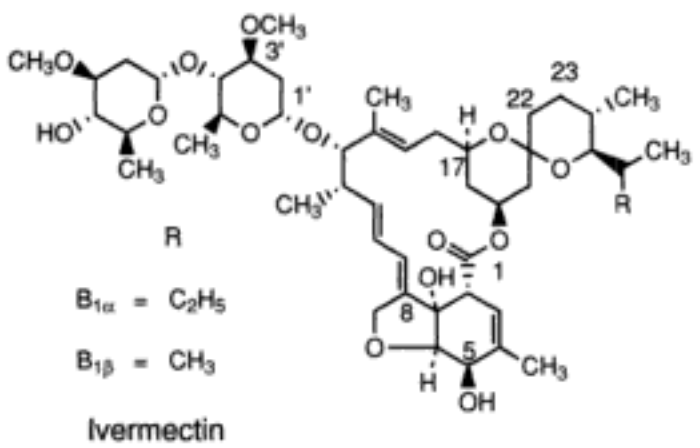


**Fig. 39.18.** Metabolism of diethylcarbamazine (DEC).

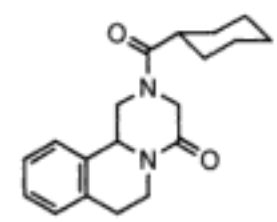
Copyrighted material

may produce serve adverse reactions, including anaphylactic reactions, intense pruritus, and ocular complications (64). The severe anaphylactic reaction is known as the Mazzotti reaction, and it appears to be an immune response related to the presence of dead microfilariae. This reaction is more common in individuals who have a high-load microfilarial infection, and it may preclude the use of DEC in some patient populations (51).

### Ivermectin (Mectizan)

Ivermectin

Extracted from the soil actinomycete *Streptomyces avermitilis,* the natural avermectins are 16-membered macrocyclic lactones that, on reduction of the $C_{22\text{-}23}$ double bond, give rise to ivermectin (IVM), which is an 80:20 mixture of dihydroavermectin $B_{1\alpha}$ and $B_{1\beta}$, respectively. The natural avermectins have minimal biological activity, but IVM has proven to be quite beneficial in the treatment of various nematode infections.



**MECHANISM OF ACTION.** Two mechanisms of action are thought to be involved in the action of IVM (51,65). The first is an indirect action in which motility of microfalaria is reduced, which in turn allows cytotoxic cells of the host to adhere to the parasite, resulting in elimination from the host. This action may occur by virtue of the ability of IVM to act either as a γ-aminobutyric acid (GABA) agonist or as an inducer of chloride ion influx, leading to hyperpolarization and muscle paralysis. The chloride ion influx appears to be the more plausible mechanism (66). Recently, it has been shown that IVM binds irreversibly to the glutamate-gated chloride channel of the nematode *Haemonchus contortus,* whereas the channel is in an open conformation. The binding then remains locked in the open conformation, allowing ions to cross the membrane, leading to the paralytic action of IVM (67). The result of this action is a rapid decrease in microfilarial concentrations.

A second action of IVM leads to the degeneration of microfilariae in utero. This action would result in fewer microfilariae being released from the female worms, and it occurs over a longer period of time. The presence of degenerated microfilariae in utero prevents further fertilization and production of microfilariae.

**METABOLISM.** Ivermectin is rapidly absorbed, is bound to a great extent to plasma protein, and is excreted in the urine or feces either unchanged or as the 3′-O-demethyl-22,23-dihydroavermectin $B_{1\alpha}$ or as the dihydroavermectin $B_{1\alpha}$ monosaccharide. The absorption of IVM is significantly affected by the presence of alcohol. Administration of IVM as an alcoholic solution may result in as much as a 100% increase in absorption.

**THERAPEUTIC APPLICATION.** Although IVM has activity against a variety of microfalaria, including *Wuchereria bancrofti, Brugia malayi, Loa loa,* and *Mansonella ozzardi,* as well as activity against *Strongyloides stercoralis,* the drug is used primarily in the treatment of onchocerciasis (African river blindness) caused by *Onchocerca volvulus.* It is estimated that 20 million people are affected by this condition and an additional 123 million are at risk of the infection. The drug is effective against both the eyeworm as well as skin infections of *O. volvulus.* Ivermectin has the distinct advantage over DEC in that IVM can be used as a single dose (150 μg/kg) once a year (although there is support for dosing every 6 months), has far less likelihood of causing the potentially fatal anaphylactic reaction (Mazzotti reaction), and can be used for mass treatment programs.

### Praziquantel (Biltricide)

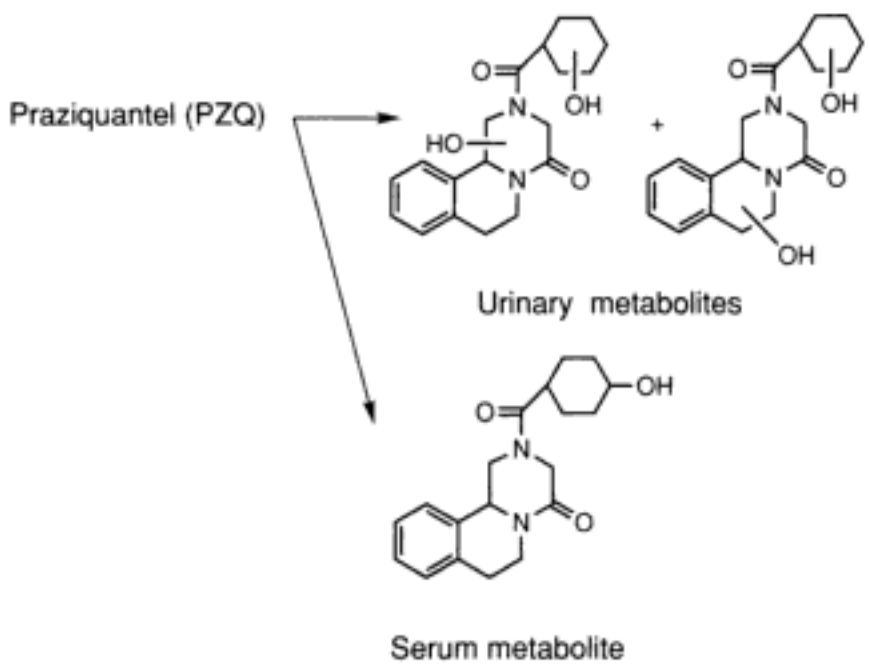
Praziquantel

Praziquantel (PZQ) is an isoquinoline derivative with most of the biological activity found in the levo enantiomer. The compound has no activity against nematodes, but it is highly effective against cestodes and trematodes.

**MECHANISM OF ACTION.** More than one mechanism of action may exist for PZQ, possibly depending on the type of parasite being treated. The mechanism of action appears to involve $Ca^{2+}$ redistribution either directly or indirectly. In the case of helminths found in the lumen of the host (cestode infection), the drug leads to muscle contraction and paralysis, leading in turn to worm expulsion. Additionally, PZQ has been shown to inhibit phosphoinositide metabolism, which by an undetermined mechanism leads to the worm paralysis (68). With intravascular-dwelling schistosomes, PZQ leads to drug-induced damage of the tegument of the worm. As a result, antigens in the helminth are subject to attack by immune antibodies of the host (69,70). An antigen–antibody immunological reaction leads to the death of the parasite. Finally, PZQ affects glycogen content and energy metabolism (71,72).

**METABOLISM.** Praziquantel is rapidly absorbed and undergoes hepatic first-pass metabolism. The metabolites are

Copyrighted material



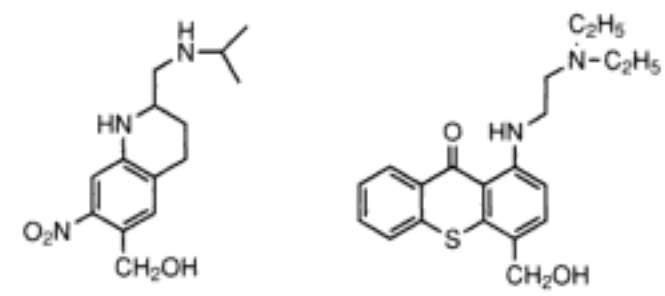


**Fig. 39.19.** Metabolism of praziquantel (PZQ).

either less active or inactive and consist of hydroxylated compounds. In the serum, the major metabolite appears to be the monohydroxylated 4-hydroxycyclohexylcarboxylate, whereas in the urine, 50 to 60% of the initial PZQ exists as dihydroxylated products (Fig. 39.19) (73). These hydroxylation reactions are catalyzed by CYP2B6 and CYP3A4. The metabolites would be expected to exist in the conjugated form in the urine.

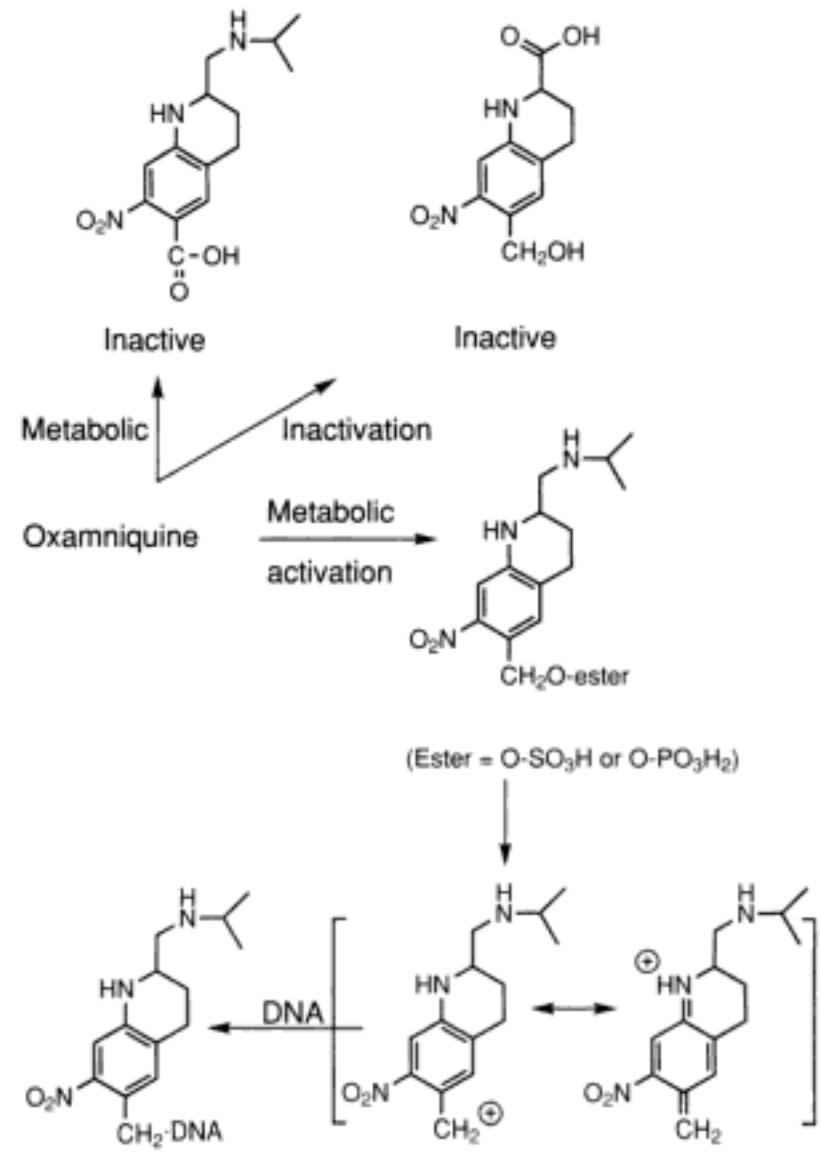
**THERAPEUTIC APPLICATION.** PZQ is the drug of choice for treatment of schistosomiasis and liver flukes (trematode and cestode infections). The drug is stage specific, with activity against the invasive stages, which includes the cercariae and young schistosomula and the mature worms, but not against the liver stages. Although an approved drug, PZQ is considered to be an investigational drug by the U.S. FDA in the treatment of schistosomiasis and liver flukes. The drug has a bitter taste and, therefore, should not be chewed. The side effects usually are not severe and consist of abdominal discomfort (pain and diarrhea). Mounting evidence suggests that resistance may become a significant problem.

### Oxamniquine (Mansil, Vansil)

Oxamniquine was originally investigated in the 1960s and was found to have limited antiprotozoal activity, with activity against *Schistosoma mansoni* but no activity against the other two schistosomal organisms. In addition, the drug is stage specific, with activity against cercariae and very young schistosomula and adult worms. For reasons that remain unknown, the drug is more effective against adult male worms than against female worms. The drug has structural similarity to hycanthone, which is no longer used because of severe toxicity and teratogenic effects.

**MECHANISM OF ACTION.** Oxamniquine is activated via esterification to a biological ester that spontaneously dissociates to an electrophile, which alkylates the helminth DNA, leading to irreversible inhibition of nucleic acid metabolism (Fig. 39.20) (72). Resistant helminths do not esterify oxamniquine; therefore, activation does not occur. Other metabolic reactions consist of oxidative reactions, leading to inactivation (Fig. 39.20). The metabolites are excreted primarily in the urine.

**THERAPEUTIC APPLICATION.** Oxamniquine is readily absorbed following oral administration and has a relatively short half-life. The drug has been highly effective against *Schistosoma mansoni* native to Brazil, where it is marketed under the trade name Mansil. It also is beneficial against West African *S. mansoni* and is supplied under the trade name Vansil. Side effects are minimal, with transient dizziness being reported. The major drawback is high cost. Encouraging outcomes have been reported with the combination of oxamniquine and PZQ.



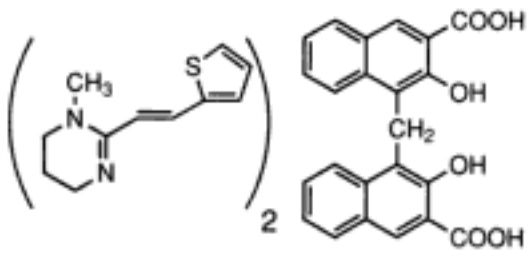


**Fig. 39.20.** Metabolism of oxamniquine accounting for the mechanism of action and inactivation.

Copyrighted material

### Pyrantel Pamoate (Antiminth)

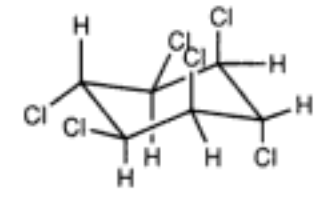
Pyrantel pamoate

Pyrantel was first reported for its anthelmintic activity in 1966 (74). Although it has activity against most intestinal roundworm infections, it has not been approved by the U.S. FDA for several of these infestations. It is considered to be the drug of choice in the treatment of pinworms. The drug is used as the pamoate salt, which is quite insoluble and, as a result, is not readily absorbed. This property improves the usefulness of the drug for treatment of intestinal helminths. In addition to its value in treating enterobiasis, the drug is effective for hookworm and roundworm (ascariasis) infections. Pyrantel acts as a depolarizing neuromuscular blocking agent that activates nicotinic receptors and inhibits cholinesterase, ultimately leading to worm paralysis.

## ECTOPARASITIC INFECTIONS

Two parasitic organisms that cause common topical infections are *Sarcoptes scabiei*, which is responsible for scabies, and *Pediculus humanus*, which is responsible for lice infections.

### Scabies



Scabies, commonly referred to as the "seven year itch," is a condition caused by *Sarcoptes scabiei*, or the itch mite. The condition commonly is spread by direct, person-to-person contact, although the organism is capable of living for 2 to 3 days in clothing, bedding, or house dust. Sharing of clothing is a common means whereby the condition spreads. The organism burrows into the epidermis, usually in the folds of the skin of the fingers, the elbows, female breast, penis, scrotum, and buttocks. The female parasite lays eggs in the skin, which then hatch and mature to adults. The itch mite can live for 30 to 60 days. The infections are most common in children, but they also may be found in adults in institutional settings. The primary symptom of severe itching may foster secondary infections at the site of scratching. Because of the potential for spread to other members of a family, it is common to treat all members of the family. This will prevent reinfection from a second family member after successful therapy of the first family member.

### Lice

Pediculosis or lice is caused by any of the parasites *Pediculus humanus capitis*, the head louse; *Pediculus humanus corporis*, the body louse; or *Phthirius pubis*, the crab louse (found in the genital area). Lice are bloodsucking insects that live for 30 to 40 days on the body of the host. The organisms reproduce, and the female lays her eggs, the nits, which become attached to hair. The nits are white in color and hatch in 8 to 10 days. For the parasite to live, it must feed on blood, which it sucks through punctures in the skin. A hypersensitivity reaction occurs at these puncture sites, which then leads to pruritus, host scratching, and possible secondary infection. In addition to the scalp and skin, the eyebrows, eyelids, and beard may become sites of infection. The transfer of infection can occur through person-to-person contact and from infected clothing, on which the organism can survive for up to 1 week. The sharing of clothing is a common means for the spread of body lice. Head lice are quite common among children in grade school, whereas crab lice are common among individuals who are sexually active. Treatment of family members is recommended, and clothing and bed linen should be removed and washed in very hot water.

### Drug Therapy for Scabies and Pediculosis

#### Lindane (Kwell)

γ-Benzene hexachloride

Chlorination and reduction of benzene leads to a mixture of hexachlorocyclohexanes. The insecticidal activity resides primarily in the γ-isomer of hexachlorocyclohexane (γ-benzene hexachloride). The compound is thought to produce its insecticidal action by virtue of a CNS stimulatory action that occurs by blockage of GABA. The compound is readily absorbed through the chitinous exoskeleton of the parasite. Unfortunately, lindane also is readily absorbed through intact human skin, especially the scalp, and has the potential for systemic neurotoxicity in the host. Infants and children and, possibly, the elderly are most prone to the neurotoxic effects of the drug. Because the lindane is quite lipophilic and, is applied to the scalp as a shampoo, it may be absorbed where upon it can readily enter the CNS of the patient producing signs of neurotoxicity (convulsions, dizziness, clumsiness, and unsteadiness).

The drug is available in a lotion and a shampoo and is recommended for the treatment of both pediculosis and scabies. When using the lotion topically, it should be applied to dry skin, covering the entire surface and being left in place for 8 hours. The lindane then should be removed by washing thoroughly. If the shampoo is used for *Pediculosis capitis*, the hair should be cleaned of oil and dried before application of the lindane shampoo. The shampoo is then worked into the hair and scalp, being applied in such a way as to prevent other parts of the body from coming into contact with the drug. After approximately 4 minutes, the drug is removed by washing with

Copyrighted material

water, and the hair is dried and then combed with a fine-toothed comb to remove nits.

### Pyrethrum and Pyrethroids

The naturally occurring pyrethrums have been used as insecticides since the 1800s. These compounds are extracted from the flowering portion of the Chrysanthemum plant. The flowers produced in Kenya have, on average, 1.3% pyrethrins. These pyrethrum extracts are a major agricultural product for that country.

**Chemistry.** The Chrysanthemum extract is a mixture of ester consisting of the acids chrysanthemic and pyrethric and the alcohols pyrethrolone and cinerolone (Fig. 39.21). The esters are prone to hydrolysis and oxidation and, as a result, should be stored in the cold and protected from light. Because of the high cost, limited availability, and rapid degradation, synthetic derivatives have been investigated. The result has been the preparation of pyrethroids, the synthetic derivatives of pyrethrins. The compound used therapeutically is permethrin, which exists as a 60:40 mixture of *trans:cis* isomers.

**Mechanism of action (75–78).** The pyrethrins and pyrethroids (permethrin) are nerve membrane sodium channel toxins that do not affect potassium channels. The compounds bind to specific sodium channel proteins and slow the rate of inactivation of the sodium current elicited by membrane depolarization and, as a result, prolong the open time of the sodium channel. At low concentrations, the pyrethroids produce repetitive action potentials and neuron firing; at high concentrations, the nerve membrane is depolarized completely and excitation blocked.

The receptor interaction of the pyrethrums with the sodium channel complex is stereospecific and dependent on the stereochemistry of the carboxylic acid. In the case of the pyrethroids, the most active isomers are the 1R,3-*cis*- and 1R,3-*trans*-cyclopropanecarboxylates. The 1S-*cis*- and -*trans*-isomers are inactive and actually are antagonists to the action of the 1R-isomers.

**Metabolism.** A property that enhances the usefulness of the pyrethrums and pyrethroids is that these compounds are highly toxic to the ectoparasites but relatively nontoxic to mammals if absorbed. The apparent lack of toxicity is associated with the rapid metabolism of these drugs through hydrolysis and or oxidation (Fig. 39.22) (79,80). The nature of the metabolism (i.e., hydrolysis versus oxidation) is dependent on the structure of the pyrethrins or pyrethroids. Oxidation of the *trans*-methyl of the isobutylene in the carboxyl moiety initially gives an alcohol, which then proceeds to the carboxylic acid, whereas epoxidation of the terminal alkene of the alcohol portion of pyrethrin I gives either the 1,2-diol or the 1,4-diol. No ester hydrolysis is reported. Permethrin is hydroxylated on the terminal aromatic ring at either the 4- or 2-position, is oxidized on the methyl group of the dimethylcyclopropane, and is hydrolyzed at the ester moiety. The rapid breakdown of these agents also accounts for their low persistence in the environment.

### Therapeutic Application

***Pyrethrins (A-200, RID).*** Because of the high cost and rapid degradation of the pyrethrins, they usually are combined with piperonyl butoxide, a synergist (Fig. 39.21). Piperonyl butoxide has no insecticidal activity in it own right but is thought to inhibit the cytochrome P450 enzyme of the insect, thus preventing an oxidative inactivation of the pyrethrins by the parasite. The combination is used in a 10:1 ratio of piperonyl butoxide to pyrethrins. The mixture is used for treatment of *Pediculus humanus capitis*, *Pediculus humanus corporis*, and *Phthirius pubis*. Various dosage forms are available, including a gel, shampoo, and topical solution.

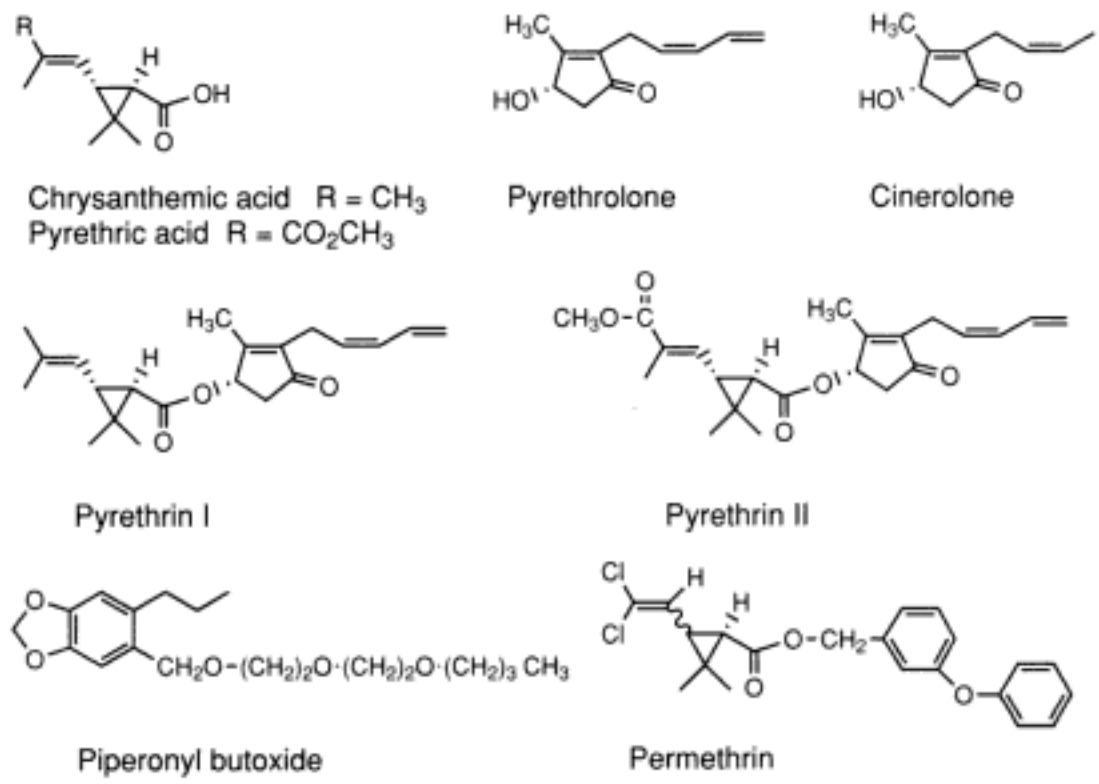


**Fig. 39.21.** Structures of pyrethrum and pyrethroid.

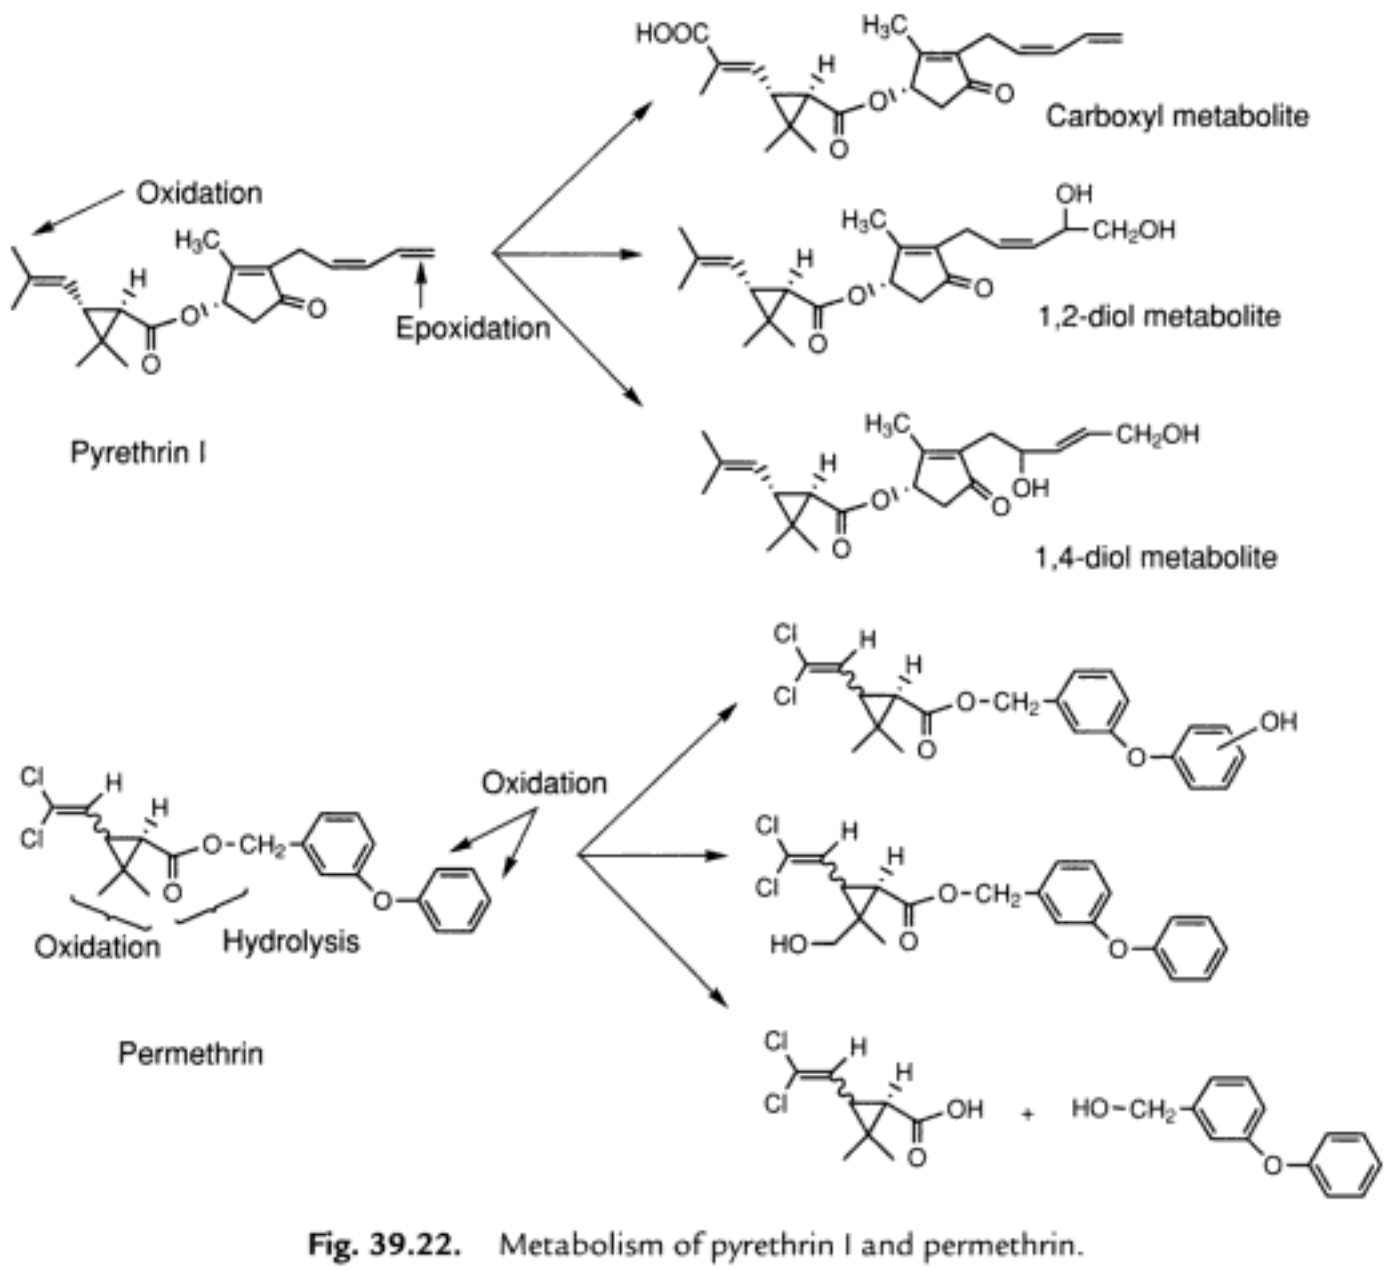
Copyrighted material



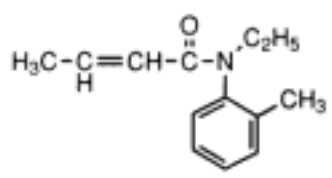


**Fig. 39.22.** Metabolism of pyrethrin I and permethrin.

***Permethrin (Nix-1% lotion, Elimite-5% Cream).*** Permethrin, because of its increased stability and its availability synthetically, is not used with a synergist. The compound is used in a 1% lotion for the treatment of pediculosis capitis and in a 5% cream as a scabicide.

### Crotamiton

Crotamiton

Crotamiton is available as a 10% cream for the treatment of scabies, although it is less effective than pyrethrins or permethrin (81,82). Because crotamiton may need to be applied a second time for successful treatment of scabies but the pyrethrins or permethrin require a single application, poor patient compliance with crotamiton may reduce its effectiveness. The advantage of crotamiton over lindane comes from the fact that lindane has potential neurotoxicity if absorbed especially in infants and children, whereas crotamiton has less systemic neurotoxicity. The most common side effect reported for crotamiton is skin irritation.

- Caspofungin
- Micafungin

CICLOPIROX

FLUCYTOSINE

GRISEOFULVIN

HALOGROGIN

TOLNAFTATE

UNDECYLENIC ACID

## INTRODUCTION

Until recently, chemotherapy of fungal infections has lagged far behind chemotherapy of bacterial infections. This lack of progress has resulted, in part, because the most common fungal infections in humans have been relatively superficial infections of the skin and mucosal membranes and potentially lethal deep-seated infections have been quite rare. Because most humans with a normally functioning immune system are able to ward off invading fungal pathogens with little difficulty, the demand for improvements in antifungal therapy has been small. Immunocompromised patients, however, are very susceptible to invasive fungal infections. The onset of the AIDS epidemic, combined with the increased use of powerful immunosuppressive drugs for organ transplants and cancer chemotherapy, has resulted in a greatly increased incidence of life-threatening fungal infections and a corresponding increase in demand for new agents to treat these infections. The number of effective antifungal agents available is quite small compared to those available to treat bacterial infections, but research in this area is quite active. Several new agents have been introduced in the last few years.

## FUNGAL DISEASES

The fungal kingdom includes yeasts, molds, rusts, and mushrooms. Most fungi are saprophytic, which means that they live on dead organic matter in the soil or on decaying leaves or wood. A few of these fungi can cause opportunistic infections if they are introduced into a human through wounds or by inhalation. Some of these infections can be fatal. There are relatively few obligate animal parasites (i.e., microorganisms that can only live on mammalian hosts) among the fungi, although *Candida albicans* is commonly found as part of the normal flora of the gastrointestinal tract and vagina. The obligatory parasites are limited to dermatophytes that have evolved to live on/in the keratin-containing hair and skin of mammals, where they cause diseases such as ringworm and athletes foot. (Ringworm is not caused by a parasitic worm but, rather, is named for the ring-like appearance of this fungal infection of the skin.) A detailed description of fungal infections is beyond the scope of this book, but comprehensive treatises are available (1).

Most fungal infections are caused primarily by various yeasts and molds. Yeasts, such as the opportunistic pathogen *Candida albicans* and the bakers' yeast *Saccharomyces cerevisiae*, typically grow as single oval cells and reproduce by budding. *Candida albicans* and some other pathogenic yeasts also can grow in multicellular chains called hyphae. Infection sites may contain both yeast and hyphal forms of the microorganism. Molds, such as *Trichophyton rubrum*, one of the causative agents of ringworm, grow in clusters of hyphae called a mycelium. All fungi produce spores, which may be transported by direct contact or through the air. Although most topical fungal infections are readily treated, the incidence of life threatening systemic fungal infections, including those caused by yeasts such as *Candida albicans* and molds such as *Aspergillus fumigans* are increasing, and mortality remains high (2).

### Dermatophytes

Dermatophytes are fungi causing infections of skin, hair, and nails (3). The dermatophytes obtain nutrients from attacking the cross-linked structural protein keratin, which other fungi cannot use as a food source. Dermatophytic infections, known as tinea, are caused by various species of three genera (*Trichophyton*, *Microsporum*, and *Epidermophyton*) and are named for the site of infection rather than for the causative organism. Tinea capitis is a

## CLINICAL SIGNIFICANCE

Antifungal agents include diverse compounds with varied actions. A few key examples can highlight the importance of medicinal chemistry to clinical practice. Knowledge regarding the molecular structure of polyene antifungal agents, such as amphotericin B, is essential in understanding how they work. These agents are macrocyclic lactones with distinct hydrophilic and lipophilic regions. One of the putative mechanisms of polyene action involves the formation of pores in the fungal cell membrane. The lipophilic regions of the polyene molecules facilitate the binding to the cell membrane sterols. The hydrophilic portions of the molecule align to create a hydrophilic pore in the sterol-containing cell membrane. As a result, there is membrane depolarization and increased membrane permeability and, eventually, fungal cell death. The lipophilic regions of amphotericin B also contribute to its poor solubility in aqueous solutions. The traditional intravenous formulation of amphotericin B includes a dispersing agent, deoxycholate, which facilitates formation of the required micellular dispersion when administered in a 5% dextrose in water solution.

5-Flucytosine (5-FC) is an analogue of the natural pyrimidine cytosine that is converted to 5-fluorouracil (5-FU) in susceptible fungi. Formation of 5-FU is essential to the antimycotic effect of 5-FC; 5-FU acts as a pyrimidine antimetabolite and is phosphorylated to the cytotoxic agent 5-fluorodeoxyuridine monophosphate. All of these facts are commonly emphasized in a medicinal chemistry sequence, and readers probably are aware that 5-FU is a chemotherapeutic agent that causes myelosuppression as its major toxicity. Therefore, it should not be surprising that the same side effect can be seen in patients receiving 5-FC.

The newest antifungals, the echinocandins, are macromolecular structures with high molecular weights (>1,000 dalton), which a student can easily visualize by looking at the chemical structure. Their relatively low volume of distribution in the body can be partially explained by their size. Clinically, these agents have not achieved high concentrations in the central nervous system and the vitreous chamber of the eye, two compartments that are subject to fungal invasion.

**Douglas Slain, Pharm.D. BCPS**
*Associate Professor*
*College of Pharmacy*
*West Virginia University*

fungal infection of the hair and scalp. Tinea pedis refers to infections of the feet, including athlete's foot, tinea manuum to fungal infection of the hands, tinea cruris to infection of the groin (jock itch), and tinea unguium to infection of the fingernails. Athlete's foot in particular may be an infection involving several different fungi, including yeasts. Tinea unguium, also known as onychomycosis, whether of the fingernails or toenails, can be particularly difficult to treat, because the fungi invade the nail itself. Appropriate drug therapy prevents the fungus from spreading to the newly formed nail. Penetration of drugs into previously existing nail is problematic, however, and with some drug regimens, the infection is not cured until an entirely new, fungus-free nail has grown in. Because this can take months, patient compliance with a lengthy drug regimen can be a problem.

### Yeasts

The most common cause of yeast infections is *Candida albicans*, which is part of the normal flora in a significant portion of the population where it resides in the oropharynx, gastrointestinal tract, vagina, and surrounding skin (4). It is the principal cause of vaginal yeast infections and oral yeast infections (thrush). These commonly occur in mucosal tissue when the normal population of flora has been disturbed by treatment of a bacterial infection with an antibiotic or when growth conditions are changed by hormonal fluctuations, such as occur in pregnancy. *Candida albicans* can cause infections of the skin and nails, although the latter are not common. In persons with healthy immune systems, *Candida* infections are limited to superficial infections of the skin and mucosa. In persons with impaired immune systems, however, *Candida albicans* also may cause deep-seated systemic infections, which can be fatal. Several other infections with *Candida* species occur, including *C. tropicalis*, *C. krusei*, *C. parapsilosis*, and *C. glabrata* (also known as *Torulopsis glabrata*). These organisms are becoming more common and often do not respond to antifungal therapy as readily as *Candida albicans*.

*Cryptococcus neoformans* is a yeast commonly found in bird droppings, particularly pigeon droppings (5). When dust contaminated with spores is inhaled by persons with a competent immune system, the organism causes a minor, self-limiting, lung infection. Such infections frequently are mistaken for a cold, and medical treatment is not sought. In immunocompromised persons, however, the organism can be carried by the circulatory system from the lungs to many other organs of the body, including the central nervous system (CNS). Infection of the CNS is uniformly fatal unless treated.

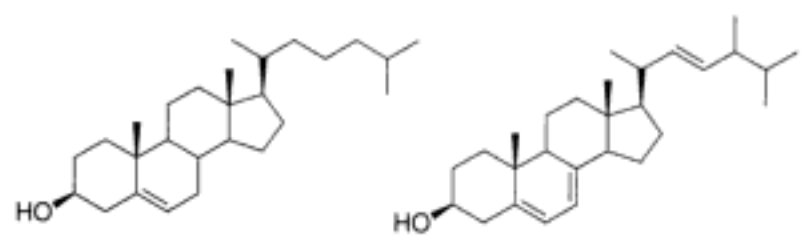
Although most yeast infections are caused by various species of *Candida* or *Cryptococcus*, other yeasts also can cause infections in humans, including *Malassezium furfur*, *Trichosporon beigelii*, and *Blastoschizomyces capitatus* (6). These infections are relatively rare, and they are difficult to treat.

### Thermally Dimorphic Fungi (Endemic Mycoses)

Thermally dimorphic fungi are saprophytes that grow in one form at room temperature and in a different form in

Copyrighted material

a human host at 37°C (7). The most common infectious agents are *Blastomyces dermatitidus, Paracoccidiodes brasiliensis, Coccidioides immitus,* and *Histoplasma capsulatum,* the causative agents of blastomycosis, paracoccidiomycosis, coccidiomycosis (valley fever), and histoplasmosis, respectively. All these organisms live in soil and cause disease through inhalation of contaminated dust. The resulting lung infections are often mild and self-limiting, but they may progress on to a serious lung infection. The circulatory system may transport the organisms to other tissues, where the resulting systemic infection may be fatal. *Blastomyces dermatitidus* is endemic to southcentral United States and *P. brasiliensis* to Central and South America, where it is the most common cause of fungal pulmonary infections. *Coccidioides immitus* is endemic to the dry areas of the southwestern United States and northern Mexico. It is particularly prevalent in the San Joaquin Valley of California, hence the name valley fever. *Histoplasma capsulatum* is endemic to the Mississippi and Ohio River valleys of the United States, where nearly 90% of the population tests positive for exposure to the organism.



### Molds

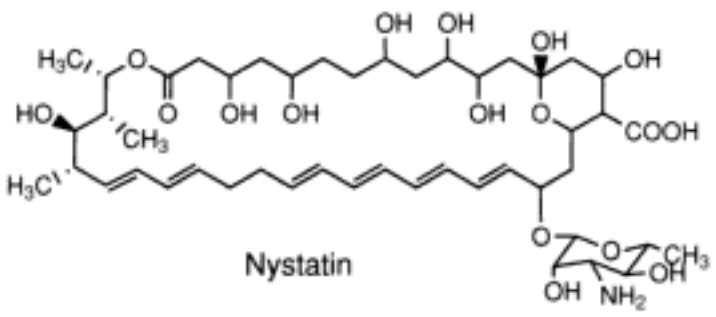
Various *Aspergillus* species are found worldwide and are virtually ubiquitous in the environment. The most common organisms causing disease are *A. fumigatus, A. niger,* and *A. flavus.* Several other *Aspergillus* species are known to cause infection, and some, such as *A. nidulans,* are becoming more common. *Aspergillus* spp. very rarely cause disease in persons with normal immune systems but are very dangerous to persons with suppressed immune systems. Because *Aspergillus* spores are everywhere, inhalation is the most common route of inoculation, but infection through wounds, burns, and implanted devices (e.g., catheters) also is possible. Nosocomial (hospital-derived) aspergillosis is a major source of infection in persons with leukemia and in those receiving organ or bone marrow transplants. Aspergillosis of the lungs may be contained, but systemic aspergillosis has a high mortality rate.

Zygomycosis (mucormycosis) is a term used to describe infections caused by the genera *Rhizopus, Mucor,* and *Absidia* of the fungal order Mucorales (8). As with several other opportunistic fungal pathogens, these soil microorganisms generally are harmless to those with a competent immune system but can cause rapidly developing, fatal infections in an immunosuppressed patient. These organisms can infect the sinus cavity, from which they spread rapidly to the CNS. Blood vessels also may be attacked and ruptured. Zygomycoses spread rapidly and are often fatal.

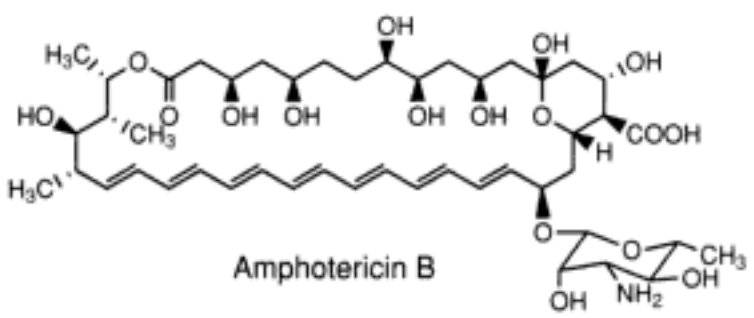
## BIOCHEMICAL TARGETS FOR ANTIFUNGAL CHEMOTHERAPY

Antifungal chemotherapy depends on biochemical differences between fungi and mammals (9,10). Unlike bacteria, which are prokaryotes, both fungi and mammals are eukaryotes, and the biochemical differences between them are not as great as one might expect. At the cellular level, the greatest difference between fungal cells and mammalian cells is that fungal cells have cell walls but that mammalian cells do not. Inhibitors of bacterial cell wall biosynthesis, such as penicillins and cephalosporins, have provided many powerful antibacterial agents with little toxicity to humans. The fungal cell wall therefore is a logical target for a similar class of drugs, which would be expected to be potent antifungals yet have little human toxicity. Only recently, however, have a few potent inhibitors of fungal cell wall biosynthesis become available for clinical use (11). Other targets for antifungal agents include inhibitors of DNA biosynthesis, disruption of mitotic spindles, and general interference with intermediary metabolism. The difference between fungal and mammalian cells that is most widely exploited, however, is that the cell membranes of fungi and mammals contain different sterols. Sterols are important structural components of fungal and mammalian cell membranes and are critical to the proper functioning of many cell membrane enzymes and ion-transport proteins. Mammalian cell membranes contain cholesterol as the sterol component, whereas fungi contain ergosterol (12).

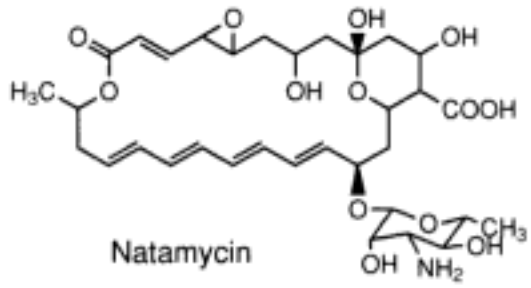
Cholesterol Erogosterol



Although the two sterols are quite similar, the side chains are slightly different, and when three-dimensional models are constructed, the ring system of ergosterol is slightly flatter because of the additional double bonds in the B ring. Nevertheless, with only a few exceptions, this difference in sterol components provides the biochemical basis of selective toxicity for most of the currently available antifungal drugs.



### Polyene Membrane Disruptors—Amphotericin B, Nystatin, and Congeners



Before the mid-1950s, effective antifungal therapy was limited to topical applications of undecylenic acid derivatives, mixtures of benzoic acid and salicylic acid, and a few other agents of modest efficacy. No reliable treatments existed for the few cases of deep-seated systemic fungal infections that did occur. The discovery of the polyene antifungal agents, however, provided a breakthrough into both a new class of antifungal agents and the first drug to be effective against deep-seated fungal infections. The polyenes are macrocyclic lactones with distinct hydrophilic and lipophilic regions. The hydrophilic region contains several alcohols, a carboxylic acid, and usually, a sugar. The

Copyrighted material

lipophilic region contains, in part, a chromophore of four to seven conjugated double bonds. The number of conjugated double bonds correlates directly with antifungal activity in vitro and, inversely, with the degree of toxicity to mammalian cells. That is, not only are the compounds with seven conjugated double bonds, such as amphotericin B, approximately 10-fold more fungitoxic, they are the only ones that may be used systemically.

### Mechanism of Action

The polyenes have an affinity for sterol-containing membranes, insert into the membranes, and disrupt membrane functions. The membranes of cells treated with polyenes become leaky, and eventually, the cells die because of the loss of essential cell constituents, such as ions and small organic molecules. Polyenes have a demonstrably higher affinity for membranes containing ergosterol over cholesterol-containing membranes. This is the basis for their greater toxicity to fungal cells. Some evidence suggests that the mechanism of insertion differs between the types of cells. Polyene molecules may insert individually into ergosterol-containing membranes but require prior formation of polyene micelles before inserting into cholesterol-containing membranes.

### Specific Drugs

**NYSTATIN.** Nystatin, the first clinically useful polyene antifungal antibiotic, is a conjugated tetraene isolated from cultures of the bacterium *Streptomyces noursei* in 1951. Nystatin is an effective topical antifungal against a wide variety of organisms and is available in a variety of creams and ointments. Nystatin is too toxic to be used systemically, but because very little drug is absorbed following oral administration, it may be administered by mouth to treat fungal infections of the mouth and gastrointestinal tract (Table 40.1). Although nystatin itself was not a breakthrough in systemic antifungal therapy, the search for other polyenes led to the discovery of a polyene that can be used systemically.

**AMPHOTERICIN B.** Amphotericin B, which as a heptaene has low enough toxicity to mammalian cells to permit intravenous (IV) administration, was discovered in 1956. Amphotericin B is, nevertheless, a very toxic drug and must be used with caution. Adverse effects include fever, shaking chills, hypotension, and severe kidney toxicity. Despite its toxicity, amphotericin B is considered to be the drug of choice for many systemic, life-threatening fungal infections. The drug cannot cross the blood-brain barrier and must be administered intrathecally for treatment of fungal infections of the CNS. Closely related heptaenes are candicidin, hamycin, and trichomycin.

The nephrotoxicity of amphotericin B has been a serious drawback to the use of this drug since its introduction. Recently, however, the toxicity of the drug has been decreased substantially by changes in formulation (Table 40.2). The polyenes are only sparingly soluble in water, and amphotericin B has long been formulated as a complex with deoxycholic acid for IV administration. More recently developed formulations of amphotericin B, such as liposomal encapsulation and lipid complexes, have dramatically decreased the toxicity of the drug to humans, which permits higher plasma levels to be employed. The mechanisms by which the new formulations decrease the toxicity are not entirely clear, but altered distribution is clearly a factor. Because the blood vessels at the site of infection are more permeable than those of normal tissue, the large suspended particles of the lipid formulations can penetrate the site of infection more readily than they can penetrate healthy tissue. The result is selective delivery of drug to the site of infection. Some evidence also indicates that the newer formulations transfer amphotericin B to ergosterol-containing fungal cells more efficiently than to cholesterol-containing mammalian cells.

**NATAMYCIN.** Natamycin, a tetraene, is available in the United States as a 5% suspension applied topically for the treatment of fungal infections of the eye (Table 40.1).

## Ergosterol Biosynthesis Inhibitors

A schematic of fungal ergosterol biosynthesis starting from squalene is shown in Figure 40.1. The biosynthetic pathway has been simplified to emphasize steps important to the action of currently employed antifungal drugs. The last nonsteroidal precursor to both ergosterol and cholesterol is the hydrocarbon squalene. Squalene is converted to squalene epoxide by the enzyme squalene epoxidase. Squalene epoxide is then cyclized to lanosterol, the first steroid in the biosynthetic pathway. The

## Table 40.2. Systemic Antifungal Agents

| Chemical Class | Generic Name | Trade Name | Dosage Form |
|---|---|---|---|
| Allylamine | Terbinafine | Lamisil | 250-mg tablets |
| Imidazole | Ketoconazole | Various | 200-mg tablets |
| | | Nizoral | 200-mg tablets |
| Triazole | Fluconazole | Diflucan | 50-, 100-, 150-, and 200-mg tablets; 350-mg (10 mg/mL reconst.) powder for oral suspension; 100- and 200-mL (2 mg/mL) solution for injection |
| | Voriconazole | Vfend | 50- and 200-mg tablets; 200-mg powder for injection; 45-g (40 mg/mL reconst.) powder for oral suspension |
| | Itraconazole | Various | 100-mg capsules |
| | | Sporanox | 100-mg capsules; 10 mg/mL injection solution; 10 mg/mL oral solution |
| Echinocandins | Caspofungin | Cancidas | 50- and 70-mg powder for injection |
| | Anidulafungin | Eraxis | 50-mg powder for injection |
| | Micafungin | Mycamine | 50-mg powder for injection |
| Polyene | Amphotericin B | Amphocin (desoxycholate) | 50-mg powder for injection |
| | | Fungizone (desoxycholate) | 50-mg powder for injection |
| | | Abelcet (lipid complex) | 100 mg/20 mL suspension, single-use vials |
| | | Amphotec (cholesteryl) | 50 mg/20 mL and 100 mg/50 mL powder, single-use vials |
| | | AmBisome (liposomal) | Powder, single-use vials |
| Misc. | Flucytosine | Ancobon | 250- and 500-mg capsules |
| | Griseofulvin | Fulvicin, Grifulvin, Grisactin | 250- and 500-mg microsize tablets; 125- to 330-mg ultramicrosize tablets |

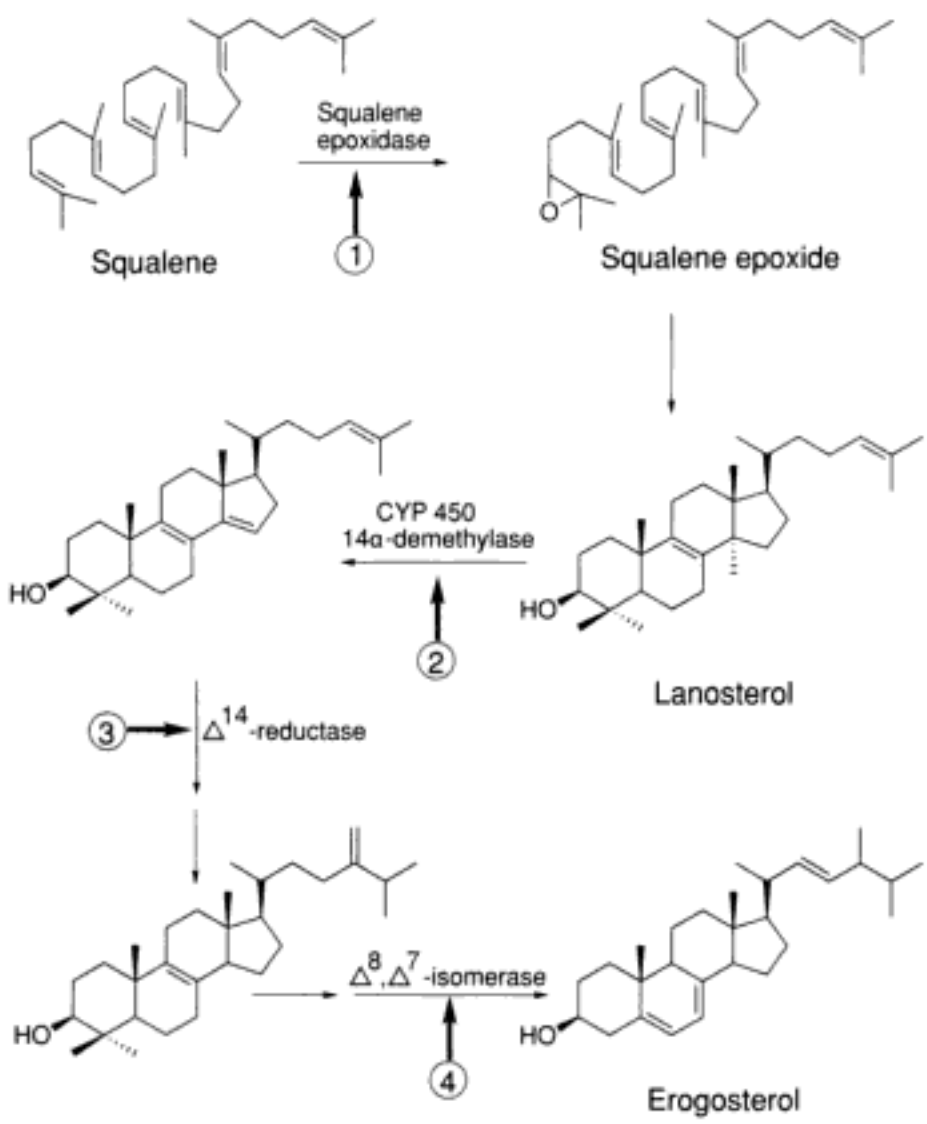

**Fig. 40.1.** Ergosterol biosynthesis from squalene, with key steps shown in the simplified figure. Enzymatic steps known to be the site of action of currently employed antifungal agents are indicated by a heavy black arrow and a number.

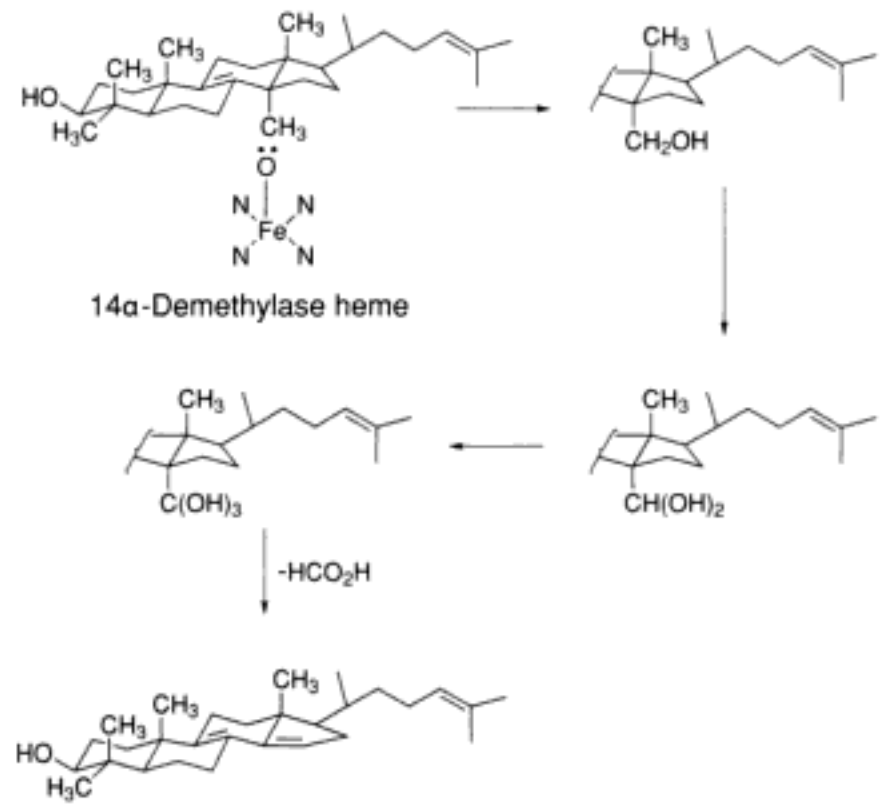

**Fig. 40.2.** Demethylation of the 14α-methyl group from lanosterol carried out by the cytochrome P450 enzyme sterol 14α-demethylase (CYP51). The mechanism involves three successive heme-catalyzed insertions of activated oxygen into the three carbon-hydrogen bonds of the 14α-methyl group, which raises the oxidation state of the methyl group to a carboxylic acid. The group is finally eliminated as formic acid to create a double bond between carbons 14 and 15.

interaction (see box). Ketoconazole is a weak inhibitor of CYP2C9, which is the enzyme responsible for the metabolism of several narrow therapeutic index drugs, such as warfarin and phenytoin. As better systemic agents have become available, ketoconazole's clinical use has become limited to topical applications in a variety of dosage forms, including creams, lotions, suppositories, and shampoos.

***Itraconazole.*** Itraconazole was, along with fluconazole, one of the first triazoles introduced into clinical use (Fig. 40.6) (14). Itraconazole's oral bioavailability is variable and is influenced by food and stomach pH, a strongly acidic pH being required for good absorption. Like ketoconazole, itraconazole is extensively metabolized by CYP3A4 following oral administration, and levels are markedly reduced by coadministration of the CYP3A4-inducers phenytoin, carbamazepine. and rifampin (13). Additionally, like ketoconazole, itraconazole has been demonstrated to be a strong inhibitor of CYP3A4 (15). This interaction has proven to be of clinical significance because the risk of developing rhabdomyolysis following lovastatin or simvastatin therapy with coadministration of itraconazole (16–18). Itraconazole therefore is likely to have serious interactions with any other drug metabolized by CYP3A4. Again like ketoconazole, itraconazole appears to have little or no effect on CYP2C9-mediated metabolism of warfarin and phenytoin.

***Terconazole.*** Terconazole (Fig. 40.6) is a close analogue of ketoconazole and itraconazole. It is approved only for the treatment of vaginal candidiasis and is not used systemically (Table 40.1) (19,20).

***Fluconazole.*** Fluconazole (Fig. 40.6), which was introduced at the same time as itraconazole, differs from ketoconazole and itraconazole in that it is equally bioavailable when given orally or IV. Two major advantages of fluconazole over other antifungal agents are that it can cross the blood-brain barrier and has efficacy against *Cryptococcus neoformans* (21). Fluconazole also differs in that it is only a weak inhibitor of CYP3A4 but a strong inhibitor of CYP2C9 (22). For instance, fluconazole doubles the AUC of (*S*)-warfarin (the active enantiomer) and greatly prolongs the prothrombin time in patients receiving warfarin anticoagulant therapy (23). Because warfarin has such a narrow therapeutic index and excessive anticoagulation can be extremely harmful, this interaction is considered to be of major clinical significance. Fluconazole also decreases the metabolism of the CYP2C9 substrate phenytoin, an antiepileptic agent that also has a narrow therapeutic index (24). Depending on the dose of fluconazole, coadministration with phenytoin can result in a 75 to 150% increase in the phenytoin AUC, and numerous case reports have documented substantial adverse effects following this regimen. Fluconazole also will inhibit CYP3A4, though not to the same degree as ketoconazole and itraconazole. Fluconazole exhibits a dose-dependent inhibition of triazolam metabolism (a CYP3A4 reaction) causing as much as a fourfold increase in triazolam AUC.

***Voriconazole.*** Voriconazole (Fig. 40.6) is a fluconazole analogue that was developed to overcome some of the limitations of fluconazole (25) and does, indeed, have a broader spectrum of activity than fluconazole, having activity against *Aspergillus* and fluconazole-resistant strains of *Candida* and *Cryptococcus* (26). Voriconazole is orally absorbed and penetrates the blood-brain barrier. Unfortunately, voriconazole is extensively metabolized CYP450 enzymes (Fig. 40.7) and is an inhibitor of CYP2C19, CYP2C9, and CYP3A4, leading to many drug interactions (27,28). Voriconazole exhibits nonlinear, saturable kinetics, and because CYP2C19 exhibits genetic polymorphisms, plasma levels can be higher in poor metabolizers versus extensive metabolizers (29,30).

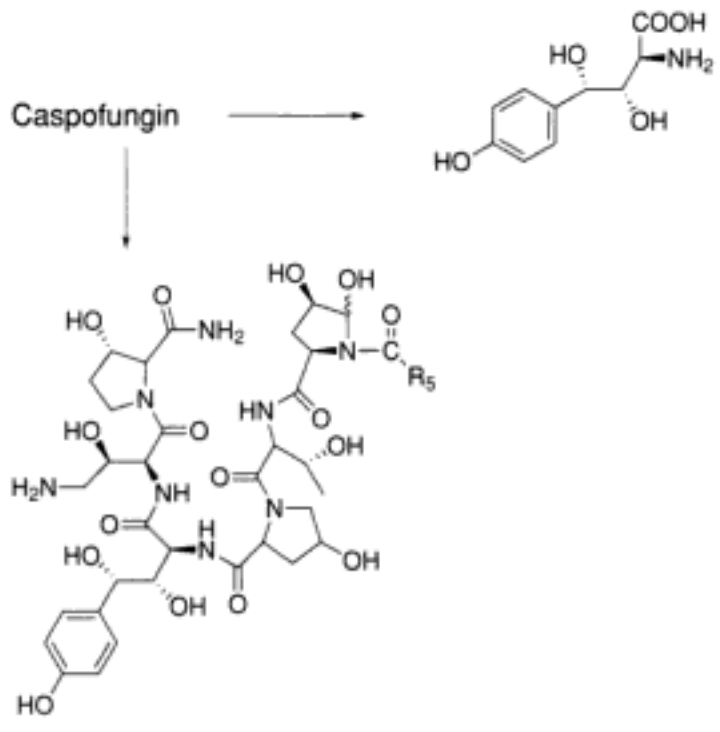
### Caspofungin, Anidulafungin, and Micafungin

Recently, three semisynthetic echinocandins have been approved for use in treating life-threatening systemic fungal infections (47). These are caspofungin, anidulafungin, and micafungin (Fig. 40.9). These drugs represent the first class of antifungal agents with a novel mechanism of action to be marketed in more than 30 years and are a very valuable contribution to therapy for systemic fugal infections. They are effective against a variety of *Candida* species that have proven to be resistant to other agents as well as effective against azole-resistant *Aspergillus*. Therefore, these drugs are truly life-saving for those afflicted with these previously resistant fungi. Unfortunately these echinocandins are not effective against *Cryptococcus neoformans*. None of these drugs is orally active, and all must be administered by IV infusion. Because of limited hepatic metabolism, drug–drug interactions are not a problem. Caspofungin is metabolized by hydrolysis in two portions of the hexapeptide ring (Fig. 40.10) (48), whereas anidulafungin does not appear to be actively metabolized but rather slowly degrades (49). Micafungin is metabolized by a sulfotransferase and by catechol-O-methyltransferase (COMT), but no significant drug interactions are known (50).



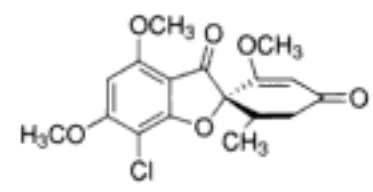


**Fig. 40.10.** Metabolic products formed from caspofungin.

## Drugs Acting Through Other Mechanisms

### Flucytosine

Flucytosine is a powerful antifungal agent used in the treatment of serious systemic fungal infections, such as *Cryptococcus neoformans* and *Candida* spp (Table 40.2). Flucytosine itself is not cytotoxic but, rather, is a pro-drug that is taken up by fungi and metabolized to 5-fluorouracil (5-FU) by fungal cytidine deaminase (Fig. 40.11) (51). Then, 5-FU is converted to 5-fluorodeoxyuridine, which as a thymidylate synthase inhibitor interferes with both protein and RNA biosynthesis. 5-Fluorouracil is cytotoxic and is employed in cancer chemotherapy (see Chapter 42). Human cells do not contain cytosine deaminase and, therefore, do not convert flucytosine to 5-FU. Some intestinal flora, however, do convert the drug to 5-FU, so human toxicity does result from this metabolism. Resistance rapidly develops to flucytosine when used alone, so it is almost always used in conjunction with amphotericin B. Use of flucytosine has declined since the discovery of fluconazole.

### Griseofulvin

Griseofulvin

Griseofulvin is an antifungal antibiotic produced by an unusual strain of *Penicillium* (52). It is used orally to treat

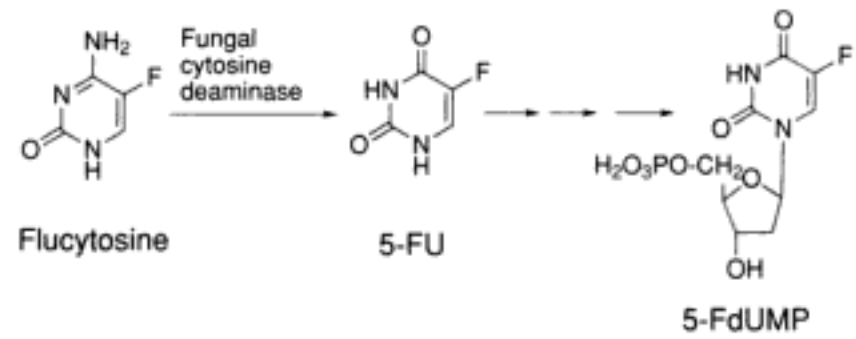

**Fig. 40.11.** Flucytosine, a pro-drug, is converted by fungal cytosine deaminase to 5-fluorouracil (5-FU). This reaction does not occur in mammalian cells. A further transformation of 5-FU to the actual cytotoxic agent, 5-fluorodeoxyuridine monophosphate (5-FdUMP), also occurs.

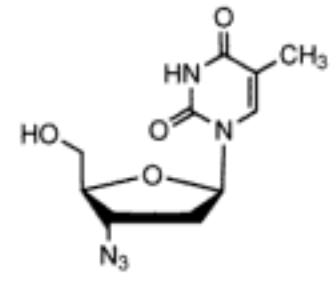
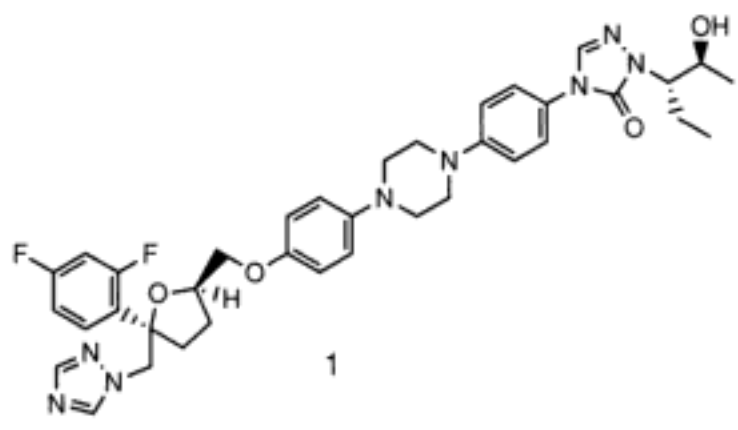
## CASE STUDY

***Victoria F. Roche and S. William Zito***



KK is a 42-year-old, Brazilian-born executive who works for Ronald Stump, an internationally famous investment mogul and entrepreneur who mentors (and generously rewards) go-getters like KK. KK's career potential seemed unlimited until he acquired AIDS from a previous partner who was unaware of his HIV-positive status at the time of their relationship. The last year has been tough for KK, who has always been athletic, adventurous, and seemingly indestructible, but he has fallen ill several times in the past 12 months with bacterial and viral infections, including a particularly nasty case of poststreptococcal nephritis. He is currently on antiviral therapy that includes indinavir sulfate (Crixivan, 800 mg every 8 hours) and zidovudine (Retrovir, 300 mg b.i.d.). Although he is still able to work and is managing fairly well, he is fearful about the anticipated final outcome of his disease and is employing spiritual and nontraditional strategies in an attempt to heal.

As part of this holistic approach to healing, KK flew to the Amazon and spent two nights alone on the edge of the jungle, seeking insight and peace through reflection and prayer. All he took in with him was his medication and a sufficient amount of food and water to last for 48 hours. He felt safe, however, because he was within a 20-minute walk of a tribal community and could sound an alarm that would alert people in case of danger or an emergency. He slept under the stars, pulling up ground vegetation into a "natural" bed each night. He felt emotionally restored after the experience—until it became known that he had inhaled dust contaminated with the soil fungus *P. brasiliensis* and a species of *Aspergillus* mold. He is now in the critical care wing of your hospital with a disseminated fungal infection. The therapeutic plan is to start him on an appropriate IV antifungal agent supplemented with oral therapy. Consider the structures of the antifungal agents drawn below, and identify suitable parenteral and oral antifungal drug products for KK.



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

THOMAS L. LEMKE

**DRUGS COVERED IN THIS CHAPTER:**

ANTIMYCOBACTERIAL AGENTS

ANTITUBERCULIN DRUGS

- Capreomycin
- Cycoserine
- Ethambutol
- Ethionamide
- Isoniazid
- Kanamycin
- Para aminobenzoic acid
- Pyrazinamide
- Rifampin
- Rifapentine
- Streptomycin

MAC THERAPY

- Azithromycin
- Clarithromycin

LEPROSTATIC DRUGS

- Clofazimine
- Dapsone
- Rifampin
- Thalidomide

## GENERAL CONSIDERATIONS

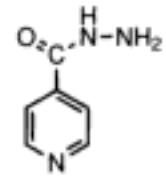
Mycobacteria are a genus of acid-fast bacilli belonging to the Mycobacteriaceae, which include the organisms responsible for tuberculosis and leprosy as well as a number of other, less common diseases. Characteristic of mycobacteria is the fact that these organisms tend to be slow-growing, difficult to stain, and when they are stained with basic dye, can resist decolorization with acid alcohol. The staining characteristics relate to the abnormally high lipid content of the cell wall. In fact, the cell wall or cell envelope of the mycobacterium holds the secret to many of the characteristics of this genus of organisms. The cell envelope is unique in both structure and complexity. It has been suggested that the cell envelope is responsible for mycobacterium pathogenicity or virulence, multiple drug resistance, cell permeability, immunoreactivity and inhibition of antigen responsiveness, as well as disease persistence and recrudescence. In addition, several of the successful chemotherapeutic agents are know to inhibit the cell envelope synthesis as their mechanism of action. It is no wonder that significant effort has been put forth to define the chemical structure of the mycobacterium cell envelope.

A series of papers were presented and reported in 1991 dealing with the topic of the structure and functions of the cell envelope of mycobacterium (1). As illustrated in Figure 41.1, the mycobacterial cell envelope contains, on the interior surface, a plasma membrane similar to that found in most bacteria. A conventional peptidoglycan layer affording the organism rigidity appears next. This layer is composed of alternating N-acetyl-D-glucosamines (Glu) linked to N-glycoyl-D-muramic acids (Mur) through 1–4 linkages that, in turn, is attached to the peptido chain of D-alanine (A), D-glutamine (G), meso-diaminopimelic acid (DP), and L-alanine (A). A novel disaccharide phosphodiester linker made up of N-acetyl-D-glucosamine and rhamnose connects the muramic acid to a polygalactan and polyarabinose chain. The latter polysaccharides are referred to as the arabinogalactan (AG) portion of the cell envelope. The manner in which the arabinosyl and galactosyl resides are arranged is still under investigation. It is known that the arabinosyl chains terminate in mycolic acid residues. (The mycolates will be discussed in more detail later in this chapter.) Noncovalently bound to the mycolates are a number of free nonpolar and polar lipids (the phthiocerol lipids and the glycopeptidolipids, respectively). Finally, spanning from the interior, embedded in the plasma membrane, to the exterior is the lipoarabinomannan (LAM) polymer. As indicated, this unit is composed of polyarabinose, polymannan, and various lipids attached through a phosphatidylinositol moiety (2,3).

## SPECIFIC DISEASES

### Leprosy (Hansen's Disease)

Throughout the Bible, one finds reference to the condition of leprosy, such as that described in *Leviticus*: "[I]s there any flesh in the skin of which there is a burn by fire, and the quick flesh of the burn becomes a bright spot, reddish white or white, . . . and if the hair in the bright spot is turned white, and it appears deeper than the skin, it is leprosy broken out in the burn." Associated with the disease was a belief that individuals suffering from this disease were unclean. Today, leprosy (Hansen's disease) is recognized as a chronic granulomatous infection caused by *Mycobacterium leprae*. The disease may consist of lepromatous leprosy, tuberculoid leprosy, or a condition with characteristics between these two poles and referred to as borderline leprosy. The disease is more common in tropical countries but is not limited to warm climate regions. It is thought to afflict some 10 to 20 million individuals. Children appear to be the most susceptible population, but the signs and symptoms usually do not occur until much later in life. The incubation period usually is



successful chemotherapy calls for drugs with bactericidal action against all stages of the organisms—but especially against the persisters. The use of combination therapy over an extended period of time is one answer to successful treatment.

## DRUG THERAPY FOR TUBERCULOSIS

Drug therapy for the treatment of TB has been greatly hampered by the development of MDR-TB and the lack of new classes of drugs. In fact, no new drugs have been developed in the last 40 years. The only change in the treatment of TB has been the strategy of using direct observed treatment (DOT), with an emphasis on patient-centered care (7). Additionally, whereas the course of treatment has been reduced, through the use of drug combinations, to 6 months, patient compliance continues to be a serious problem, which in turn may be associated with the development of bacterial resistance.

### First-Line Agents

#### Isoniazid (Isonicotinic Acid Hydrazide, Nydrazid, Laniazid)

Isoniazid (INH) is a synthetic antibacterial agent with bactericidal action against *M. tuberculosis*. The drug was discovered in the 1950s as a beneficial agent effective against intracellular and extracellular bacilli, and it generally is considered to be the primary drug for treatment of *M. tuberculosis*. Its action is bactericidal against replicating organisms, but it appears to be only bacteriostatic at best against semidormant and dormant populations. After treatment with INH, *M. tuberculosis* loses its acid fastness, which may be interpreted as indicating that the drug interferes with cell wall development.

**MECHANISM OF ACTION.** Although extensively investigated, the mechanism of action of INH has remained unknown until recently. New investigations into mechanisms of bacterial resistance have shed light on the molecular mechanism of action of INH (8). It generally is recognized that INH is a pro-drug that is activated through an oxidation reaction catalyzed by an endogenous enzyme (9). This enzyme, katG, which exhibits catalase-peroxidase activity, converts INH to a reactive species capable of acylation of an enzyme system found exclusively in *M. tuberculosis*. Evidence in support of the activation of INH reveals that INH-resistant isolates have decreased catalase activity and that the loss of catalase activity is associated with the deletion of the catalase gene, *katG*. Furthermore, reintroduction of the gene into resistant organisms results in restored sensitivity of the organism to the drug. Reaction of INH with catalase-peroxidase results in formation of isonicotinaldehyde, isonicotinic acid, and isonicotinamide, which can be accounted for through the reactive intermediate isonicotinoyl radical or isonicotinic peroxide, as shown in Figure 41.2 (10). Evidence has been offered both for and against the reaction of catalase-peroxidase activated INH with a portion of the enzyme inhA, which is involved in the biosynthesis of the mycolic acids (Fig. 41.3) (11–13). The mycolic acids are important constituents of the mycobacterial cell wall in that they provide a permeability barrier to hydrophilic solutes. The enzyme inhA, produced under the control of the *inhA* gene, is an NADH-dependent, enoyl reductase protein thought to be involved in double-bond reduction during fatty acid elongation (Fig. 41.4). Isoniazid specifically inhibits long-chain fatty acid synthesis (>26 carbon atoms). It should be noted that the mycolic acids are α-branched lipids having a "short" arm of 20 to 24 carbons and a "long" arm of 50 to 60 carbons. It has been proposed that INH is activated to an electrophilic species that acylates the four position of the NADH (Fig. 41.5, on page 1132). The acylated NADH is no longer capable of catalyzing the reduction of unsaturated fatty acids, which are essential for the synthesis of the mycolic acids (14–16).

aliphatic chain forming a bridge between two nonadjacent positions of an aromatic moiety. While investigating the biological activity of the naturally occurring rifamycins (B, O, and S), a spontaneous reaction gave the biologically active rifamycin SV, which was later isolated from natural sources. Rifamycin SV was the original rifamycin antibiotic chosen for clinical development (27). Semisynthetic derivatives are prepared via conversion of the natural rifamycins to 3-formylrifamycin, which is derivatized with various hydrazines to give products such as rifampin (RIF) and rifapentine. Rifampin and rifapentine have significant benefit over previously investigated rifamycins in that they are orally active, are highly effective against a variety of both Gram-positive and Gram-negative organisms, and have high clinical efficacy in the treatment of TB. The rifamycin antibiotics are active against both growing and slow-metabolizing, nongrowing bacilli.

**MECHANISM OF ACTION.** The rifamycins inhibit bacterial DNA-dependent RNA polymerase (DDRP) by binding to the β-subunit of the enzyme and are highly active against rapidly dividing intracellular and extracellular bacilli. Rifampin is active against DDRP from both Gram-positive and Gram-negative bacteria, but because of poor penetration of the cell wall of Gram-negative organisms by RIF, the drug has less value in infections caused by such organisms. Inhibition of DDRP leads to blocking the

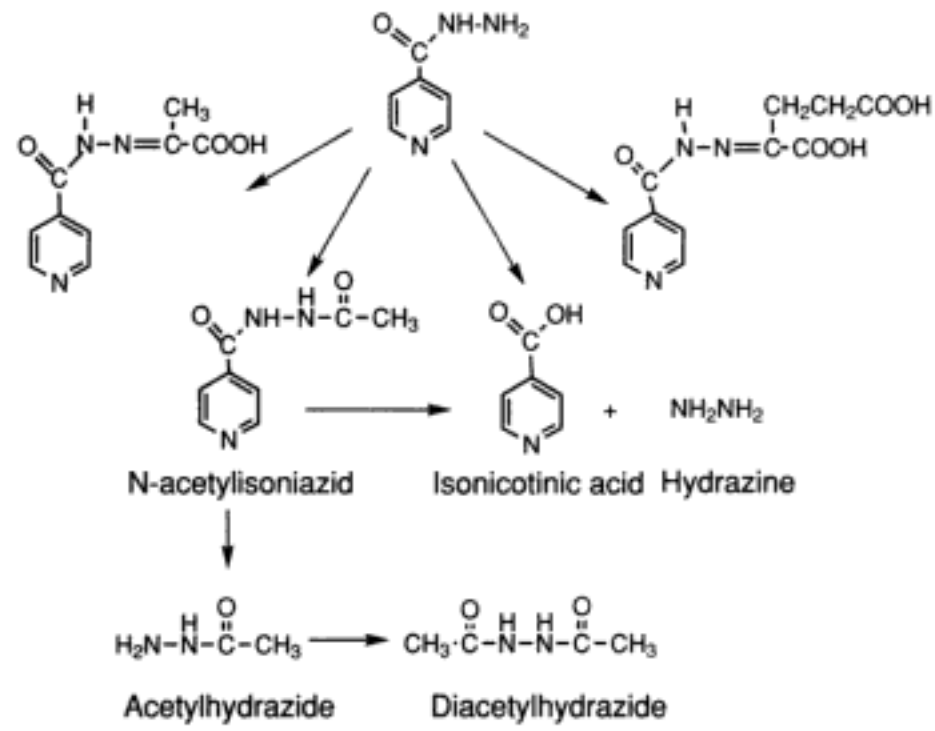

**Fig. 41.6.** Metabolism of isoniazid.

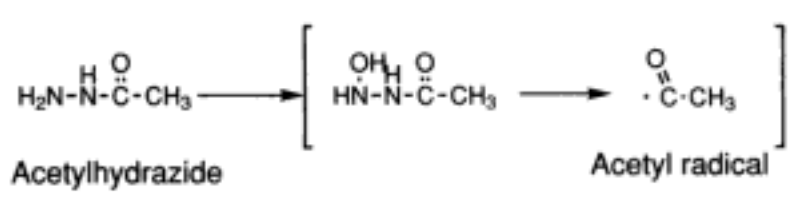
initiation of chain formation in RNA synthesis. It has been suggested that the naphthalene ring of the rifamycins π-π bonds to an aromatic amino acid ring in the DDRP protein (28). The DDRP is a metalloenzyme that contains two zinc atoms. It is further postulated that the oxygens at C-1 and C-8 of a rifamycin can chelate to a zinc atom, which increases the binding to DDRP, and finally, the oxygens at C-21 and C-23 form strong hydrogen bonds to the DDRP. The binding of the rifamycins to DDRP results in the inhibition of the RNA synthesis. Specifically, RIF has been shown to inhibit the elongation of full-length transcripts, but it has no effect on transcription initiation (8). Resistance develops when a mutation occurs in the gene responsible for the β-subunit of the RNA polymerase (*rpoB* gene), resulting in an inability of the antibiotic to readily bind to the RNA polymerase (29).

**STRUCTURE–ACTIVITY RELATIONSHIP.** A large number of derivatives of the naturally occurring rifamycins have been prepared (30). From these compounds, the following generalizations can be made concerning the structure–activity relationship (SAR): 1) Free -OH groups are required at C-1, C-8, C-21, and C-23; 2) these groups appear to lie in a plane and to be important binding groups for attachment to DDRP, as previously indicated; 3) acetylation of C-21 and/or C-23 produces inactive compounds; 4) reduction of the double bonds in the macro ring results in a progressive decrease in activity; and 5) opening of the macro ring also gives inactive compounds. These latter two changes greatly affect the conformational structure of the rifamycins, which in turn



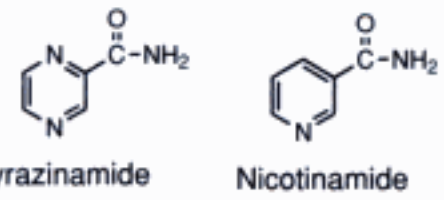


**Fig. 41.7.** Acylating metabolite of isoniazid.

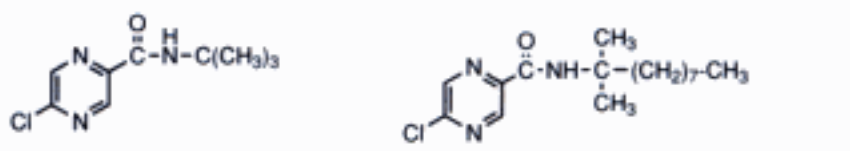
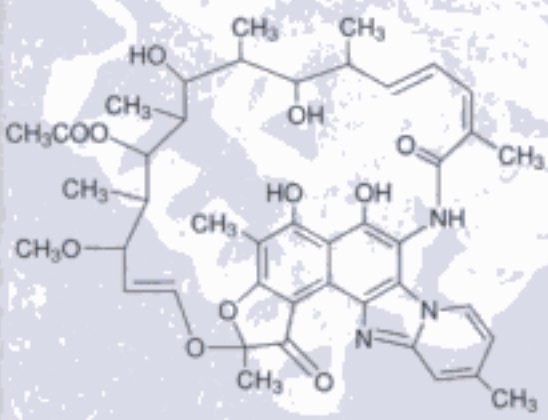
Copyrighted material

Rifapentine is readily absorbed following oral administration and is highly bound to plasma protein (97.7% vs. 80% for RIF). Related to the higher plasma binding, refapentine has a longer mean elimination half-life (13.2 hours in healthy male volunteers) in comparison with the half-life reported for RIF (~2–5 hours). Greater than 70% of either drug is excreted in the feces. Rifapentine generally is considered to be more active than rifampin and can be used in patients with varying degrees of hepatic dysfunction without the need for dose adjustment (34). This drug, similar to what is seen with RIF, induces hepatic microsomal enzymes (cytochrome P450 3A4 and 2C8/9). Rifapentine has been reported to be teratogenic in rats and rabbits (31).



### Pyrazinamide

Pyrazinamide (pyrazinecarboxamide) was discovered while investigating analogues of nicotinamide. Pyrazinamide is a bio-isoster of nicotinamide and possesses bactericidal action against *Mycobacterium tuberculosis*. Pyrazinamide has become one of the more popular antituberculin agents despite the fact that resistance develops quickly. Combination therapy, however, has proven to be an effective means of reducing the rate of resistant strain development. The activity of pyrazinamide is pH dependent with good in vivo activity at pH 5.5, but the compound is nearly inactive at neutral pH.



**MECHANISM OF ACTION.** The mechanism of action of pyrazinamide is unknown, but recent findings suggest that pyrazinamide may be active either totally or in part as a pro-drug. Susceptible organisms produce pyrazinamidase, which is responsible for conversion of pyrazinamide to pyrazinoic acid intracellularly (8). Mutation in the pyrazinamidase gene (*pncA*) results in resistant strains of *M. tuberculosis* (36). Pyrazinoic acid has been shown to possess biological activity at a pH 5.4 or lower, in contract in vitro tests that show pyrazinoic acid is 8- to 16-fold less active than pyrazinamide (37). Pyrazinoic acid may lower the pH in the immediate surroundings of the *M. tuberculosis* to such an extent that the organism is unable to grow, but this physicochemical property appears to account for only some of the activity. The protonated pyrazinoic acid also can permeate the mycobacterial membrane to lower the pH of the cytoplasm. Recent evidence suggests that pyrazinoic acid decreases membrane potential in older, nonreplicating bacilli, thus decreasing membrane transport, and interferes with the energetics of the membrane (38).

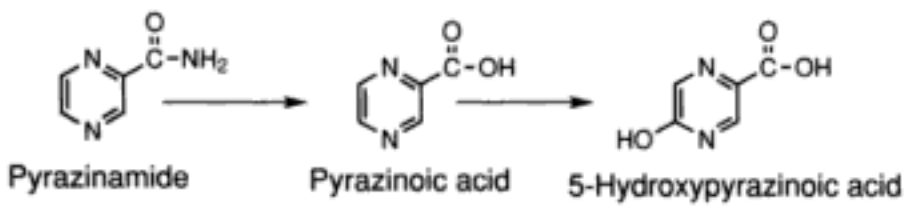
**STRUCTURE–ACTIVITY RELATIONSHIP.** Previous structural modification of pyrazinamide has proven to be ineffective in developing analogues with increased biological activity. Substitution on the pyrazine ring or use of alternate heterocyclic aromatic rings have given compounds with reduced activity (39). More recently, using quantitative SAR, a series of analogues have been prepared with improved biological activity. The requirements for successful analogues include 1) provision for hydrophilicity to allow sufficient plasma concentrations such that the drug can be delivered to the site of infection, 2) lipophilicity to allow penetration into the mycobacterial cell, and 3) susceptibility to hydrolysis such that the prodrug is unaffected by the "extracellular" enzymes but is readily hydrolyzed at the site of action. Two compounds have been found that meet these criteria: tert-butyl 5-chloropyrazinamide, and 2′-(2′-methyldecyl) 5-chloropyrazinamide (40).

**METABOLISM.** Pyrazinamide is readily absorbed after oral administration, but little of the intact molecule is excreted unchanged (Fig. 41.9). The major metabolic route consists of hydrolysis by hepatic microsomal pyrazinamidase to pyrazinoic acid, which may then be oxidized by xanthine oxidase to 5-hydroxypyrazinoic acid. The latter compound may appear in the urine either free or as a conjugate with glycine (23).

**Rifaximin (Xifaxan)**

Recently, the U.S. Food and Drug Administration (U.S. FDA) has approved the release of rifaximin, a rifamycin antibiotic, for the treatment of travelers' diarrhea (TD) caused by enterotoxigenic *Escherichia coli*. Although the drug is not intended for the treatment of TD, there are indications that the drug may be effective as a prophylactic agent. Rifaximin is administered orally, with less than 0.4% absorption; therefore, its actions are limited to the GI tract. Its mechanism of action is essentially the same as that of other reifamcyin antibiotics (35).

Copyrighted material



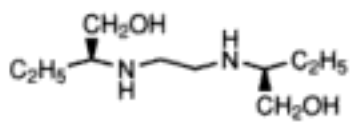


**Fig. 41.9.** Metabolism of pyrazinamide.

**THERAPEUTIC APPLICATION.** Pyrazinamide has gained acceptance as an essential component in combination therapy for the treatment of TB (component of Rifater with INH and RIF). The drug is especially beneficial in that it is active against semidormant intracellular tubercle bacilli that are not affected by other drugs (7,34). Evidence suggests that pyrazinamide is active against nonreplicating persister bacilli. The introduction of pyrazinamide combinations has reduced treatment regimens to 6 months from the previous 9-month therapy. The major serious side effect of pyrazinamide is the potential for hepatotoxicity. This effect is associated with dose and length of treatment. Pyrazinamide is not affected by the presence of food in the GI tract or by the use of aluminum-magnesium antacids (41).

### Ethambutol (Myambutol)

Ethambutol (EMB), an ethylenediiminobutanol, is administered as its (+)-enantiomer, which is 200- to 500-fold more active than its (−)-enantiomer. The difference in activity between the two isomers suggests a specific receptor for its site of action. Ethambutol is a water-soluble, bacteriostatic agent that is readily absorbed (75–80%) following oral administration.

**MECHANISM OF ACTION.** The mechanism of action of EMB remains unknown, although mounting evidence suggests a specific site of action for EMB. It has been known for some time that EMB affects mycobacterial cell wall synthesis; however, the complicated nature of the mycobacterial cell wall has made pinpointing the site of action difficult. In addition to the peptidoglycan portion of the cell wall, the mycobacterium have a unique outer envelop consisting of arabinofuranose and galactose (AG), which is covalently attached to the peptidoglycan and an intercalated framework of lipoarabinomannan (LAM) (Fig. 41.1). The AG portion of the cell wall is highly branched and contains distinct segments of galactan and distinct segments of arabinan. At various locations within the arabinan segments (terminal and penultimate), the mycolic acids are attached to the C-5′ position of arabinan (42,43). Initially, Takayama et al. (44) reported that EMB inhibited the synthesis of the AG portion of the cell wall. More recently, it has been reported that EMB inhibits the enzymes arabinosyl transferase. One action of arabinosyl transferase is to catalyze the polymerization of D-arabinofuranose,

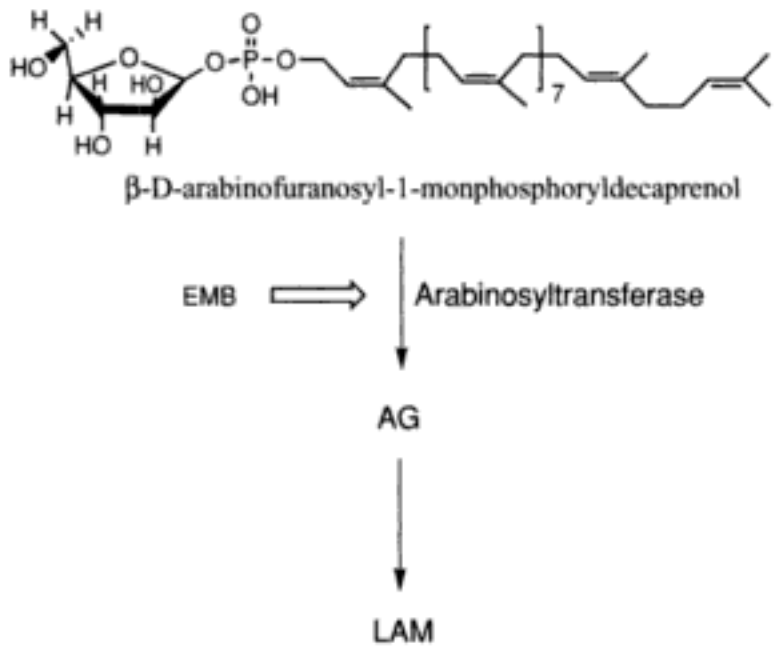

**Fig. 41.10.** Site of action of ethambutol (EMB) in cell wall synthesis.

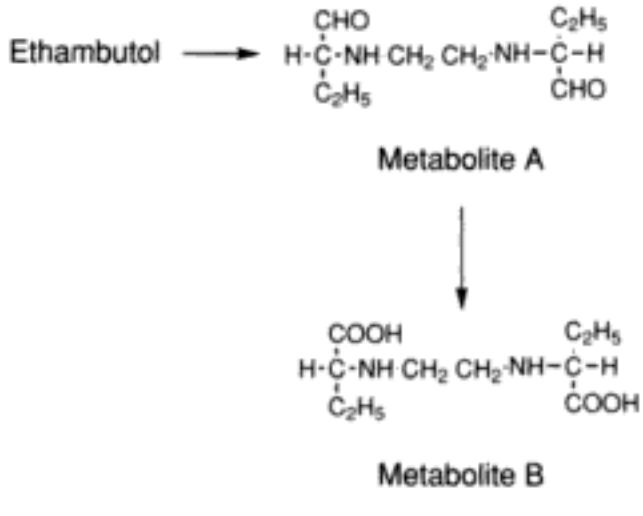
leading to AG (45,46). Ethambutol mimics arabinan, resulting in a buildup of the arabinan precursor β-D-arabinofuranosyl-1-monophosphoryldecaprenol and, as a result, a block of the synthesis of both AG and LAM (Fig. 41.10) (47). The mechanism of resistance to EMB involves a gene overexpression of arabinosyl transferase, which is controlled by the *embAB* gene (48).

This mechanism of action also accounts for the synergism seen between EMB and intracellular drugs, such as RIF. Damage to the cell wall created by EMB improves the cell penetration of the intracellular drugs, resulting in increased biological activity.

**STRUCTURE–ACTIVITY RELATIONSHIP.** An extensive number of analogues of EMB have been prepared, but none has proven to be superior to EMB itself. Extension of the ethylene diamine chain, replacement of either nitrogen, increasing the size of the nitrogen substituents, and moving the location of the alcohol groups are all changes that drastically reduce or destroy biological activity.

**METABOLISM.** The majority of the administered EMB is excreted unchanged (73%), with no more than 15% appearing in the urine as either Metabolite A or Metabolite B (Fig. 41.11). Both metabolites are devoid of biological activity.



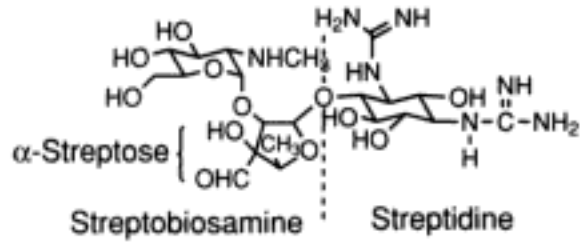


**Fig. 41.11.** Metabolism of ethambutol.

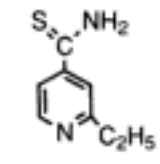
### Streptomycin

Streptomycin

Streptomycin (STM) was first isolated by Waksman and coworkers in 1944 and represented the first biologically active aminoglycoside. The material was isolated from a manure-containing soil sample and, ultimately, was shown to be produced by *Streptomyces griseus*. The structure was proposed and later confirmed by Kuehl et al. (49) in 1948. Streptomycin is water soluble, with basic properties. The compound usually is available as the trihydrochloride or sesquisulfate salt, both of which are quite soluble in water. The hydrophilic nature of STM results in very poor absorption from the GI tract. Orally administered STM is recovered intact from the feces, indicating that the lack of biological activity results from poor absorption and not chemical degradation.

**Mechanism of action.** The mechanism of action of STM and the aminoglycosides in general has not been fully elucidated. It is known that the STM inhibits protein synthesis, but additional effects on misreading of an mRNA template and membrane damage may contribute to the bactericidal action of STM. Streptomycin is able to diffuse across the outer membrane of *Mycobacterium tuberculosis* and, ultimately, to penetrate the cytoplasmic membrane through an electron-dependent process. Through studies regarding the mechanism of drug resistance, it has been proposed that STM induces a misreading of the genetic code and, thus, inhibits translational initiation. In STM-resistant organisms, two changes have been discovered: First, S12 protein undergoes a change in which the lysine present at amino acids 43 and 88 in ribosomal protein S12 is replaced with arginine or threonine, and second, the pseudoknot conformation of 16S rRNA, which results from intramolecular base pairing between GCC bases in regions 524 to 526 of the rRNA to CGG bases in regions 505 to 507, is perturbed (50). It is thought that S12 protein stabilizes the pseudoknot, which is essential for 16S rRNA function. By some yet-to-be-defined mechanism, STM interferes with one or both of the normal actions of the 16S protein and 16S rRNA.



**Structure–activity relationship.** All the aminoglycosides have very similar pharmacologic, pharmacodynamic, and toxic properties, but only STM and, to a lesser extent, kanamycin are used to treat TB. This is an indication for the narrow band of structurally allowed modifications giving rise to active analogues. Modification of the α-streptose portion of STM has been extensively studied. Reduction of the aldehyde to the alcohol results in a compound, dihydrostreptomycin, that has activity similar to STM but with a greater potential for producing delayed, severe deafness. Oxidation of the aldehyde to a carboxyl group or conversion to Schiff base derivatives (oxime, semicarbazone, or phenylhydrazone) results in inactive analogues. Oxidation of the methyl group in α-streptose to a methylene hydroxy gives an active analogue that has no advantage over STM. Modification of the aminomethyl group in the glucosamine portion of the molecule by demethylation or by replacement with larger alkyl groups reduces activity; removal or modification of either guanidine in the streptidine nucleus also decreases activity.

**Metabolism.** No human metabolites of STM have been isolated in the urine of patients who have been administered the drug, with approximately 50 to 60% of the dose being recovered unchanged in the urine (24). Metabolism appears to be insignificant on a large scale, but it is implicated as a major mechanism of resistance. One problem with STM that was recognized early was the development of resistant strains of *Mycobacterium tuberculosis*. Combination drug therapy was partially successful in reducing this problem, but over time, resistance has greatly reduced the value of STM as a chemotherapeutic agent for treatment of TB. Various mechanisms may lead to the resistance seen in *M. tuberculosis*. Permeability barriers may result in STM not being transported through the cytoplasmic membrane, but the evidence appears to suggest that enzymatic inactivation of STM represents the major problem. The enzymes responsible for inactivation are adenyltransferase, which catalyzes adenylation of the C-3 hydroxyl group in the N-methylglucosamine moiety to give the O-3-adenylated metabolite, and phosphotransferase, which phosphorylates the same C-3 hydroxyl to give O-3-phosphorylate metabolite (Fig. 41.12). This latter reaction appears to be the most significant clinically. The result of these chemical modifications is that the metabolites produced will not bind to ribosomes.

## Second-Line Agents

A number of drugs, including ethionamide, *p*-aminosalicylic acid, cycloserine, capreomycin, and kanamycin, are considered to be second-line agents (it should be noted that some authorities classify STM as a second-line agent). These agents are active antibacterial agents, but they usually are less well tolerated or have a higher incidence of adverse effects. These agents are utilized in cases of resistance, retreatment, or intolerance to the first-line drugs.

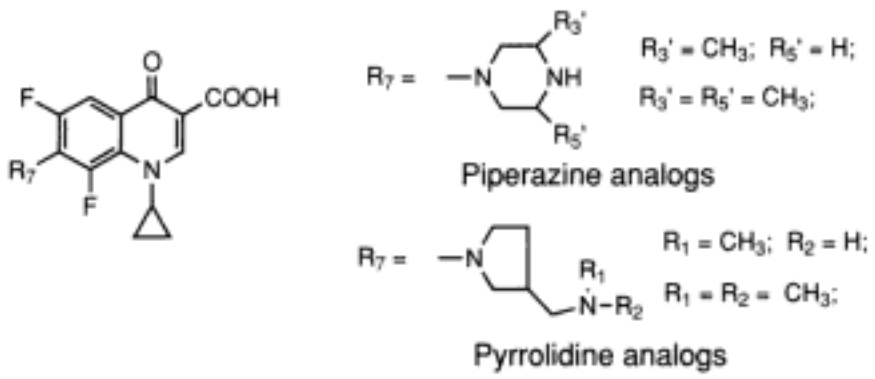

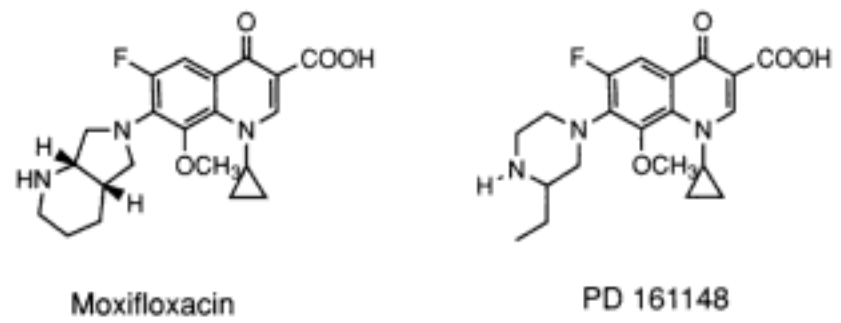

**Fig. 41.16.** 4-Quinolones demonstrating high activity against mycobacteria.

*Mycobacterium kansasii, Mycobacterium xenopi, Mycobacterium fortuitum,* MAC, and *Mycobacterium leprae.* The quinolones are attractive in that they are active at low concentrations, concentrate within macrophages, and have a low frequency of side effects.

**MECHANISM OF ACTION.** The mechanism of action of the fluoroquinolones is reported in detail in Chapter 38 and basically involves binding to DNA gyrase–DNA complex (GyrA and GyrB), inhibiting bacterial DNA replication and transcription. As a result, these drugs exhibit bactericidal activity.

**STRUCTURE–ACTIVITY RELATIONSHIP.** The structural requirements for activity against mycobacterium and, specifically, for activity against the MAC has been explored (56,57). It is known that nonfluorinated quinolones are inactive against mycobacteria. In addition, it has been reported that certain fragments or substructures within the quinolones improve activity toward the MAC (biophores), whereas other fragments deactivate the quinolones (biophobes). The important structural features acting as biophores include: 1) a cyclopropyl ring at the N-1 position, 2) fluorine atoms at positions C-6 and C-8, and 3) a C-7 heterocyclic substituent. Excessive lipophilicity at N-1 can decrease activity (i.e., 2,4-difluorobenzene). The C-7 substituents with greatest activity against mycobacteria include the substituted piperazines and pyrrolidines (Fig. 41.16). Two biophobes also have been reported and are shown in Fig. 41.17.

Several C-8 methoxy–substituted fluoroquinolones have been reported with superior activity over earlier quinolones (58,59). Moxifloxacin (BAY-12-8039) is reported to be active against *Mycobacterium tuberculosis* when combined with INH, and PD 161148 has been reported to have three to fourfold times the activity of ciprofloxacin as well as to demonstrate activity in GyrA-mutated resistant strains.

**THERAPEUTIC APPLICATION.** Fluoroquinolone therapy for TB is predominantly used in patients infected with multidrug-resistant organisms. Resistance to the quinolones has been reported and appears to be associated with mutations in the *gyrA* and *gyrB* genes, leading to single-amino-acid substitution in the DNA gyrase protein (8). As a result, use of the fluoroquinolones must be monitored in the treated patient population. The most active floroquinolones available for treatment of TB are ciprofloxacin (Cipro), sparfloxacin (Zagam), and ofloxacin (Floxin) (Fig. 41.18) (60).

## DRUG THERAPY FOR MAC

Drug therapy for the treatment of MAC is complicated. It underwent significant changes in the early 1990s, but little has changed during the last 10 years. Recommendations for treatment are presently based on small and, in some cases, incomplete studies; more changes can be expected in the future. For the most up-to-date information, the reader is referred to the CDC's homepage (http://www.cdc.gov). The 1997 guidelines for prophylaxis of MAC advise that all adults and adolescents with HIV infection and a CD4 lymphocyte count of less than 50 cells/mL receive clarithromycin, 500 mg b.i.d., or azithromycin, 1200 mg once a week. This recommendation is considered to be a standard of care (61–63). For treatment of MAC, it is recommended that a combination therapy be used that includes at least two drugs (either clarithromycin or azithromycin plus EMB for life). Other drugs that can be added to the combination consist of rifabutin, fluoroquinolones, and amikacin. It should be noted that INH and pyrazinamide are ineffective in the treatment of disseminated MAC.

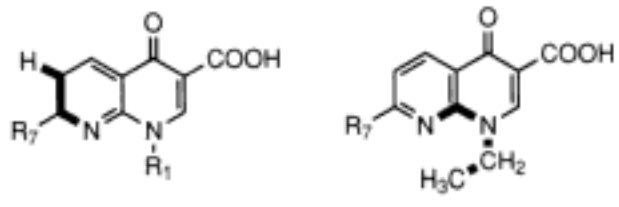

**Fig. 41.17.** Biophobes (bold) that inactivate 4-quinolones toward mycobacteria.

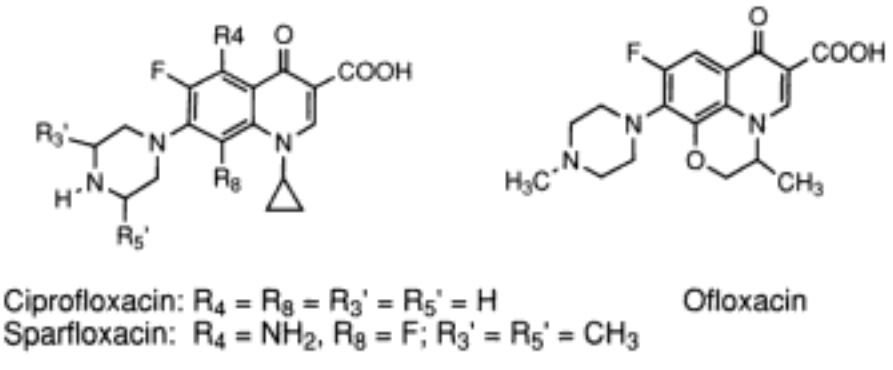

**Fig. 41.18.** Fluoroquinolones active against *Mycobacterium tuberculosis.*

Copyrighted material

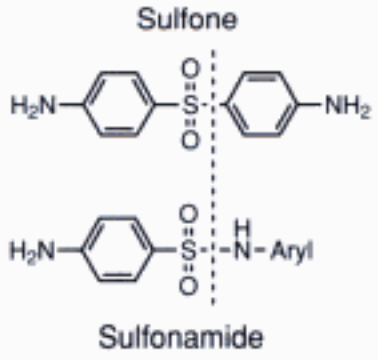

**Fig. 41.19.** Structural comparison of sulfones versus sulfonamide.

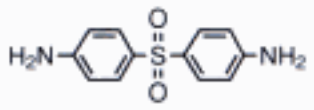
32-hydroxyrifabutin, and 32-hydroxy-25-desacetylrifabutin. The metabolites appear in the urine (50%) and in the feces (30%). Based on the activity of other rifamycins, it might be expected that one or more of the metabolites possess antimycobacterial activity.

### Additional Drugs

Various other agents have been combined with the macrolides or RIF for the prophylaxis and treatment of MAC. As indicated above, the effectiveness of each component in multidrug treatment is not easily defined. The additional drugs utilized include EMB, ciprofloxacin, amikacin, and clofazimine. Ethambutol and ciprofloxacin appear to have good activity against MAC, but clofazimine has shown unfavorable results. The U.S. FDA has advised against the use of clofazimine during initial therapy for MAC (62).



## LEPROSY

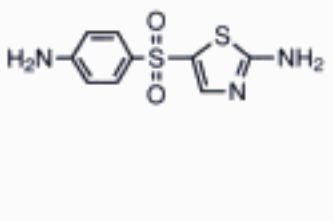
### Sulfones

The diaryl sulfones represent the major class of agents used to treat leprosy. The initial discovery of the sulfones came about as a result of studies directed at exploring the SAR of sulfonamides (Fig. 41.19). A variety of additional chemical modifications have produced several other active agents, but none has proved to be more beneficial than the original lead, 4,4′-diaminodiphenylsulfone. Dapsone was first introduced into the treatment of leprosy in 1943.

> Dapsone has a variety of uses in addition to the treatment of leprosy. These include the treatment of dermatitis herpetiformis as well as an unlabeled use in the treatment of brown recluse spider bites, inflammatory bowel disorders, leishmaniasis, malaria prophylaxis, relapsing polychondritis, rheumatic and connective tissue disorders, and prophylaxis of *Pneumocystis carinii* pneumonia in HIV-infected patients and organ transplant patients. Recently, dapsone has been approved for the treatment of acne. Under the trade name of Aczone, the drug is available as a 5% gel. Glucose-6-phosphate dehydrogenase (G6PD) levels, blood hemoglobin, and reticulocyte counts should be followed in patients with G6PD deficiency anemia and predisposed to increased hemolytic effects.

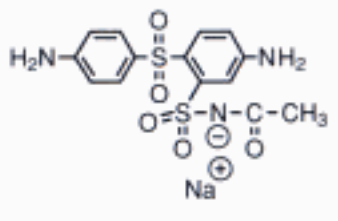
### Dapsone

4,4'-Diaminodiphenylsulfone (Dapsone)



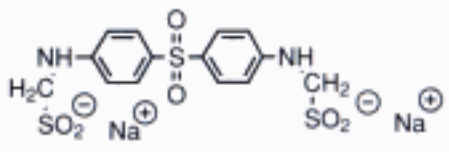
Dapsone, a diaminodiphenyl sulfone, is a nearly water-insoluble agent that is very weakly basic ($pK_a \sim 1.0$). The lack of solubility may account, in part, for the occurrence of GI irritation. Despite the lack of solubility, the drug is efficiently absorbed from the GI tract. Although dapsone is bound to plasma protein (~70%), it is distributed throughout the body.

#### Mechanism of Action



Dapsone, a bacteriostatic agent, is thought to act in a manner similar to that of the sulfonamides—namely, through competitive inhibition of *p*-aminobenzoic acid incorporation into folic acid (see *Sulfonamides* in Chapter 38). Bacteria synthesize folic acid, but host cells do not. As a result, coadministration of dapsone and *p*-aminobenzoic acid will inactivate dapsone. Both dapsone and clofazimine have significant anti-inflammatory actions, which may or may not play a role in the antimicrobial action. The anti-inflammatory action also may be a beneficial side effect, offsetting the complication of erythema nodosum leprosum seen in some patients. The anti-inflammatory action may come about by inhibition of myeloperoxidase-catalyzed reactions (64).

#### Structure–Activity Relationship



Several derivatives of dapsone have been prepared in an attempt to increase the activity. Isosteric replacement of one benzene ring resulted in the formation of thiazolsulfone. Although still active, it is less effective than dapsone. Substitution on the aromatic ring, to produce acetosulfone, reduced activity while increasing water solubility and decreasing GI irritation. A successful substitution consists of adding methanesulfinate to dapsone to give sulfoxone sodium. This water-soluble form of dapsone is hydrolyzed in vivo to produce dapsone. Sulfoxone sodium is used in individuals who are unable to tolerate dapsone because of GI irritation, but it must be used in a dose threefold that of dapsone because of inefficient metabolism to dapsone. The chemical modification of

Thiazolsulfone

Acetosulfone

Sulfoxone sodium

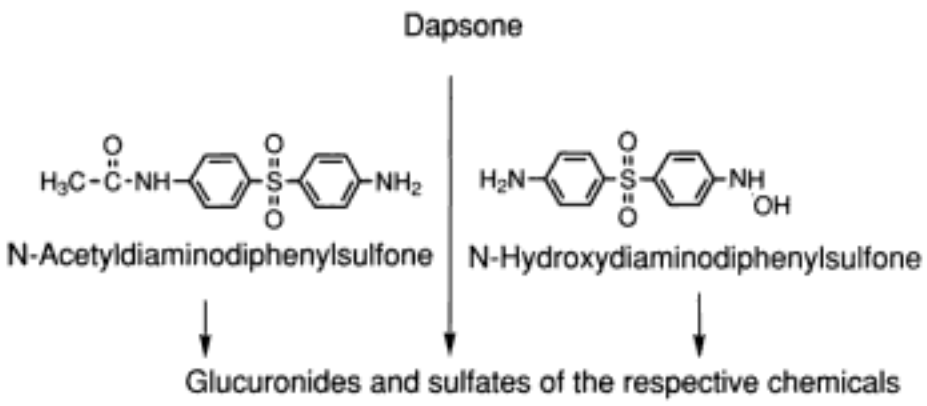


**Fig. 41.20.** Metabolites of dapsone.

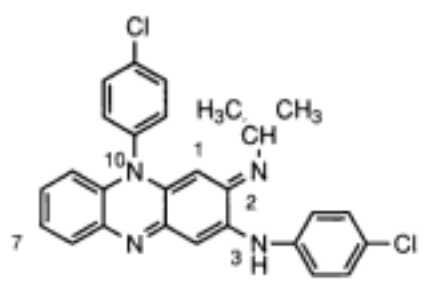


dapsone derivatives continues to be pursued with the intent of finding newer agents useful for the treatment of resistant strains of *Mycobacterium leprae* (65).

### Metabolism

The major metabolic product of dapsone results from N-acetylation in the liver by N-acetyltransferase. Dapsone also is N-hydroxylated to the hydroxylamine derivative. These metabolic reactions are catalyzed by CYP3A4 isoforms. Neither of these compounds possess significant leprostatic activity, although N-acetyldiaminodiphenylsulfone may be deacetylated back to dapsone. Products found in the urine consist of small amounts of dapsone, the metabolites N-acetyldiaminodiphenylsulfone and N-hydroxydiaminodiphenylsulfone, as well as glucuronide and sulfates of each of these substances (Fig. 41.20).

Although the acetylated metabolites of dapsone are inactive, there is growing concern over the adverse hematologic effects of the hydroxylated metabolite. The specific adverse effect reported for the N-hydroxydiaminodiphenylsulfone metabolite is methemoglobinemia (66).

## Clofazimine (Lamprene)

Clofazimine

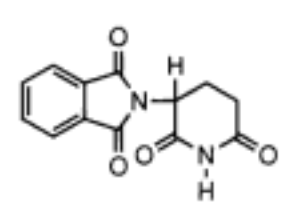
Although classified as a secondary drug for the treatment of leprosy and commonly used as a component of multidrug therapy, clofazimine appears to be increasing in use. Clofazimine was first used to treat advanced leprosy unresponsive to dapsone or STM in 1966. The chemical, a phenazine derivative, is a water-insoluble dye (dark-red crystals) that leads to pigmentation of the skin. In addition, discoloration (pink, red, or brownish-black) of the feces, eyelid lining, sputum, sweat, tears, and urine is seen.

### Mechanism of Action

The mechanism of action remains unclear at the present time. The molecule possess direct antimycobacterial and immunosuppressive properties. It has been shown that clofazimine increases prostaglandin synthesis and the generation of antimicrobial reactive oxidants from neutrophils, which may play a role in the antileprosy effects. The host cell defense may be stimulated by clofazimine, resulting in the generation of oxidants, such as the superoxide anion, which in turn could have a lethal effect on the organism (67,68).

### Structure-Activity Relationship

Several investigators have reported studies directed toward an understanding of the SAR of clofazimine (69–71). Substituents on the imino group at position 2, *p*-chloro substitution on the phenyls at C-3 and N-10, as well as substituents at position 7 have been investigated. The imino group at C-2 appears to be essential, with activity increased when the imino group is substituted with alkyl and cycloalkyl groups. Halogen substitution on the para position of the two phenyls at C-3 and N-10 enhance activity but are not essential to activity. The following order of activity has been reported: Br > Cl > $CH_3$ > EtO > H or F. In the analogues studied, the increased activity correlates well with pro-oxidative activities of the molecule (e.g., ability to generate superoxide anion) as well as increased lipophilicity.



### Metabolism

Various metabolites of clofazimine have been identified, but these account for less than 1% of the administered dose. The lack of higher concentrations of the metabolites may, in part, result from the very slow elimination of clofazimine from the body, which has an estimated half-life of from 8.8 to 69 days. The lipophilic nature of clofazimine results in distribution and storage of the drug in fat tissue. There appears to be some discrepancy as to the structures of the metabolites (71,72). The most recent studies suggest the presence of two conjugates, with the possibility of intermediates (Fig. 41.21). Clofazimine is thought to undergo hydroxylic dehalogenation on the 3-chloroaniline, followed by sulfate conjugation and 4-hydroxylation, followed by glucuronic acid conjugation.

## Rifampin (Rifadin, Rimactane)

Rifampin, an antituberculin drug, has already been discussed. Its actions against *Mycobacterium leprae* parallel those effects reported for *Mycobacterium tuberculosis*. Today, RIF is considered to be an effective antileprosy agent when used in combination with the sulfones.

## Thalidomide(Thalomid)

Thalidomide

Copyrighted material

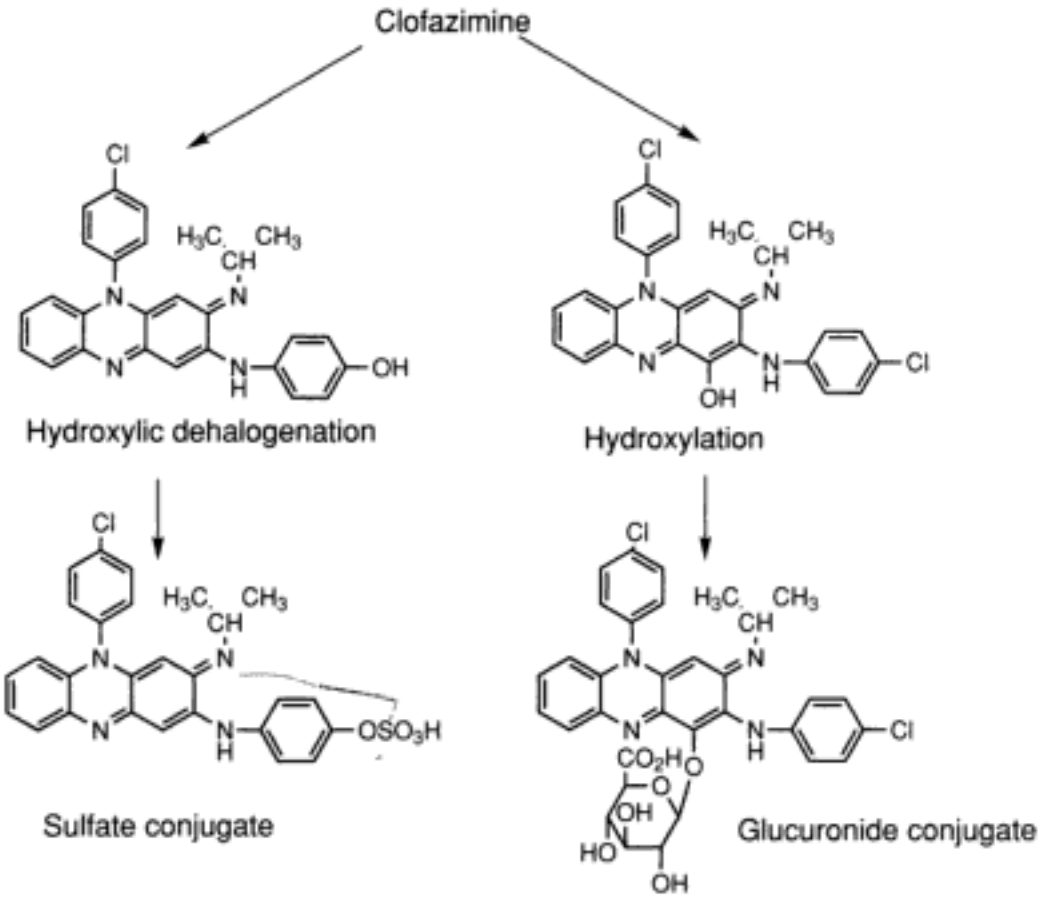


**Fig. 41.21.** Human metabolic products of clofazimine.

The development of painful, tender, inflamed, subcutaneous nodules that may last a week or two but may reappear and last for long periods is seen in a number of diseases. In the case of leprosy, the condition is referred to as erythema nodosum leprosum (ENL). The condition appears to by a hypersensitivity reaction, and although it may appear in nontreated patients, it commonly is seen as a complication of the chemotherapy of leprosy. In addition to painful nodules, the patient may experience fever, malaise, wasting, vasculitis, and peripheral neuritis. This condition has been successfully treated with thalidomide. Recently, thalidomide has been approved by the U.S. FDA for treatment of ENL and is considered to be the drug of choice (73,74). The mechanism whereby thalidomide produces relief is thought to be associated with the drug's ability to control inflammatory cytokines. Specifically, thalidomide inhibits the synthesis and release of tumor necrosis factor α, which is synthesized and released by blood mononuclear cells and appears in the serum during ENL; concentrations drop when the patient is treated with thalidomide. In addition to the treatment of ENL, thalidomide has been reported to exhibit beneficial effects in the treatment of aphthous ulcers in HIV-positive patients, Behcet's disease, chronic graft-versus-host disease, rash caused by systemic or cutaneous lupus erythematosus, pyoderma gangrenosum, and multiple myeloma.

Thalidomide is a very potent teratogenic agent, with a history of an estimated 10,000 deformed infants born to mothers who used the drug during pregnancy. It can be used safely in postmenopausal women, but strict controls are required for women of childbearing age. Additionally, although no evidence suggests that men can transmit the drug during sex, the use of condoms by male patients will be required.

### Therapeutic Considerations

Since its introduction into the chemotherapy of leprosy in 1947, dapsone has proved to be the single most effective agent. This drug was used as a monotherapeutic agent despite the recognition that resistant strains were beginning to emerge. Since 1977, monotherapy with dapsone is no longer recognized as an acceptable method for the treatment of leprosy. Today, combination chemotherapy is the method of choice. The combination consists of RIF (600 mg monthly), dapsone (100 mg daily), and clofazimine (300 mg monthly, with 50 mg daily added for patients with multibacillary leprosy, which is defined as five or more skin lesions). Therapy is usually continued for at least 2 years or as long as skin smears are positive. The patient is kept under supervision for 5 years following completion of chemotherapy. A similar treatment regimen is recommended for treatment of paucibacillary leprosy (defined as five or fewer skin lesions) except that treatment is continued for 6 months and the patient kept under observation for an additional 2 years (75,76). It should be noted that the patient is noninfectious within 72 hours of starting treatment. Other combinations that have been reported include RIF plus ofloxacin and minocycline or ofloxicin plus minocycline. The new regimens allow a shortened treatment period and a reduced rate of relapse.

An important aspect of therapy for leprosy involves the treatment of peripheral nerve damage. This nerve damage can be treated with steroids, such as prednisolone. For severe cases, however, thalidomide is used.

## DRUGS COVERED IN THIS CHAPTER:

DNA ALKYLATING AGENTS
- Chlorambucil
- Cyclophosphamide
- Estramustine
- Ifosfamide
- Mechlorethamine
- Melphalan
- Thiotepa

NITROSOUREAS
- Carmustine
- Lomustine
- Streptozocin

PROCARBAZINE AND TRIAZENES
- Dacarbazine
- Procarbazine
- Temozolomide

MISCELLANEOUS ALKYLATING AGENTS
- Altretamine
- Busulfan

ORGANOPLATINUM COMPLEXES
- Carboplatin
- Cisplatin
- Oxaliplatin
- Satraplatin

ANTIBIOTICS
- Bleomycin
- Dactinomycin
- Daunorubicin
- Doxorubicin
- Epirubicin
- Idarubicin
- Mitoxantrone
- Mitomycin
- Valrubicin

ANTIMETABOLITES
- DNA polymerase inhibitors
  - Cladribine
  - Clofarabine
  - Cytarabine
  - Fludarabine
  - Gemcitabine
- Pyrimidine antagonists
  - Capecitabine
  - Floxuridine
  - Fluorouracil
  - Methotrexate
  - Pemetrexed
- Purine antagonists
  - Mercaptopurine
  - Thioguanine
- Miscellaneous antimetabolites
  - Hydroxyurea
  - Pentostatin

MITOSIS INHIBITORS
- Docetaxel
- Etoposide
- Irinotecan
- Paclitaxel
- Teniposide
- Topotecan
- Vinblastine
- Vincristine
- Vinorelbine

MISCELLANEOUS ANTICANCER AGENT
- Azacitidine

## INTRODUCTION

### Overview

Healthy cells are under strict biochemical control for growth and differentiation. Cells divide and proliferate under the influence of various growth stimulators and are subject to arrested growth (senescence) and programmed cell death (apoptosis). In cancer, these regulatory processes have gone awry, and cells grow and divide uncontrollably, consuming energy and losing both structure and function because of an inability to adequately differentiate. To add insult to injury, rampant cell division is accompanied by disabled cell-death processes, leading first to cellular immortality and, eventually, to genetic instability. The causes of cancer are many and varied (e.g., chemical, environmental, viral, and mutagenic), but all ultimately lead to an aberration in the expression of proto-oncogenes, the products of which control normal cell life. When these genes mutate to become oncogenes in a sequential, multistep process, cancer results. Oncogenes (e.g., *myc* and *ras*) can either overexpress or underexpress regulatory biochemicals, resulting in preferential and accelerated cellular growth. Concomitantly, tumor suppressor genes (e.g., anti-oncogenes like *p53*, *p21*, $p^{INK4A}$, and *retinoblastoma*) can be inhibited (1).

Initially, tumors grow exponentially, taking a consistent amount of time for every doubling of the tumor cell population size. In fact, the majority of a cancer cell's lifetime is spent before the tumor presents clinically. Initially, growth is very rapid (doubling time measured in days), but doubling time can slow to weeks or months as the tumor ages (2) because of increasingly poor vascularization and the resulting decrease in access to blood and essential nutrients.

### Selected Definitions

#### Oncogenes and Tumor Suppressor Genes

Oncogenes are regulators of cellular communication with the outside environment. They are derived through the mutation of proto-oncogenes, which are normal and ubiquitous genes involved in the regulation of homeostatic cellular functions. Mutations in proto-oncogenes can occur as spontaneous point mutations, inherited germline mutations, chromosomal rearrangements or through augmentation of gene expression. Regardless of the mutational mechanism, when the mutated oncogenes are

## CLINICAL SIGNIFICANCE

Chemotherapy has significantly changed the treatment of cancer since the first agents were studied in the 1940s. Understanding the chemical mechanism of action for traditional chemotherapeutic agents, including whether the agent is cell-cycle specific or cell-cycle nonspecific, is important so that administration can be planned accordingly and coadministration of agents with similar toxicities can be avoided.

The disadvantage of traditional chemotherapeutic agents is the inability of the agent to recognize the difference between normal cells and cancer cells. So, although the agents may shrink or eliminate the tumor, the treatment is accompanied by many unwanted side effects. There are numerous examples in which a chemical understanding of the chemotherapeutic agent is needed. For example, hydration with chloride-containing fluid is necessary with cisplatin to keep cisplatin in its inactive form in the kidneys and to avoid renal toxicity. Another example can be found when using cyclophosphamide or ifosfamide. The dissociation of aldophosphamide produces the active compound phophoramide mustard, but it also produces acrolein, which can cause significant damage to the bladder. This bladder damage, or hemorrhagic cystitis, can be prevented with the use of mesna, which inactivates the effects of acrolein in the bladder. Understanding the chemical basis for the toxicities seen with chemotherapy is imperative in managing or preventing them in clinical practice.

*Creighton University*

stimulated by exposure to chemical, environmental, or viral carcinogens, they produce proteins that are either wrongly expressed within their normal cell or expressed in inappropriate tissues. In either case, cellular proliferation leading to cancer results (1,3).

Tumor suppressor genes are intended to keep oncogenes in check by halting uncontrolled cellular growth. In direct opposition to oncogenes, which induce cancer when stimulated or amplified, tumor suppressor genes promote cancer when inactivated or attenuated. Two of the most prevalent tumor suppressor genes involved in the generation of cancer are *p53* and *retinoblastoma*, or *Rb*. When either of these two suppressor genes loses function, the negative control on cellular proliferation is lifted and cells gain immortality (an essential quality of a cancer cell). The loss or disruption of function of the *p53* tumor suppressor gene is found in approximately half of human cancers and is a harbinger of a poor prognosis.

Oncogenes and tumor suppressor genes that have been linked to specific types of cancer are identified in Table 42.1. Table 42.2 relates oncogenic markers of selected cancers to disease prognosis and treatment strategy.

### Cell Cycle

When cells reproduce, they do so via a very specific game plan known as the cell cycle. Cell division (mitosis) kicks off the cycle, and after a period of 30 to 60 minutes, the cells go into either a resting phase (called $G_0$) or a presynthetic (gap) phase (called $G_1$), in which enzyme production occurs in preparation for de novo nucleic acid synthesis. Production of DNA then occurs in an S phase that can last up to 20 hours. The S phase is followed by a gap phase ($G_2$), in which RNA, critical proteins, and the mitotic spindle apparatus are generated for the next mitotic (M) phase (3,4).

This is important to our discussion, because some anticancer agents are specific for a certain phase of the cell cycle. For example, antimetabolite antineoplastics damage cells in the S phase, whereas mitosis inhibitors pack their greatest cell-killing punch in the M phase. The administration of cell-cycle phase–specific antineoplastics is carefully planned so that the drug encounters cancer cells at their most vulnerable moments. Other antineoplastic agents are toxic to cells regardless of cycle phase (e.g., DNA alkylating agents and most antineoplastic antibiotics). These cell-cycle phase–nonspecific agents can be administered at any time that is feasible for the provider and convenient for the patient.

In general, cancer cells undergoing rapid division are most vulnerable to the cytotoxic action of antineoplastic agents, and antineoplastic therapy holds its greatest

Table 42.1. Oncogenic Origin of Selected Cancers (1,3)

| Cancer Type | Common Oncogenic or Tumor Suppressor Gene Origin |
|---|---|
| Chronic myelogenous leukemia | *bcr-abl* proto-oncogene translocation |
| Follicular lymphoma | *bcl-2* amplification, *myc* mutation |
| Sporadic thyroid cancer | *ret* mutation |
| Colorectal and gastric cancer | *APC* gene mutation |
| Familial breast and ovarian cancer | *BRCA1*, *BRCA2* mutation |
| Invasive ductal breast cancer | *HER-2* amplification |
| Familial melanoma | $p16^{INK4A}$ mutation |
| Childhood neuroblastoma and small cell lung cancer | N-*myc* amplification |
| Leukemia, breast, colon, gastric, and lung cancer | *c-MYC* amplification |
| Renal cell cancer | Von Hippel-Lindaugene (VHL) dysfunction |

Copyrighted material

Table 42.2. Oncogenic Markers and Therapeutic Strategies in Selected Cancers (1)

| Cancer Type | Oncogenic Marker | Prognosis/Responsiveness to Chemotherapy | Approach |
|---|---|---|---|
| Breast cancer | HER-2 amplification | Poor | Aggressive chemotherapy, targeted therapy |
| Acute myelogenous leukemia | t(8;21) or inv(16) translocation | Good | Standard chemotherapy |
| Acute lymphocytic leukemia | *bcr-abl* rearrangement | Poor | Bone marrow transplantation |

promise for positive outcomes if initiated when the tumor is small but growing aggressively. Conversely, slow-growing tumors with a high percentage of cells remaining in the $G_0$ phase (e.g., nonsmall cell lung cancer) often are nonresponsive to standard chemotherapy (4). If the tumor is not detected until it is quite large, therapy also can be compromised by inefficient or substandard drug delivery because of poor tumor vascularization.

### Metastasis

Metastasis refers to the process by which malignant cells leave the parent tumor, migrate to distant sites, and invade new tissue. The primary metastatic "highways" utilized by meandering cancer cells are the blood and lymph fluids. Sloughed cells must find a biological environment with all of their essential growth factors in place before they can put down roots and evolve into a full-fledged metastatic tumor. Because many distinct and interdependent steps must be accomplished to establish metastatic disease, the process has been termed the "metastatic cascade" (5). Fortunately, there are many opportunities within the cascade for the body to mount a successful defense and destroy the potential invaders.

### Cancer Staging

Clinicians need to have a common language through which to communicate about disease severity to make the best team-based decisions about the relative risks and benefits of treatment options. In the TNM cancer staging classification, the severity of solid tumor neoplastic growth is characterized by the size of the tumor mass ($T_1$–$T_4$), the extent of lymph node involvement ($N_1$–$N_3$), and whether distant metastasis has occurred ($M_0$ or $M_1$). The higher the subscripted number in each of these parameters, the more advanced and/or disseminated the disease. Taken together, the TNM characteristics of a tumor can be translated into a comprehensive staging scale ranging from I (localized) to IV (metastatic). The intermediate disease severity stages indicate local (Stage II) or regional (Stage III) tissue invasion (3). Staging is an essential prerequisite for the prediction of prognosis and the identification of the most appropriate treatment plan and optimal dosing regimen (2).

### Response Criteria

In this era of patient-centered, team-based care, it is equally beneficial to quantify a patient's clinical response to therapy in a manner that is consistent and universally understood by all health care providers. Five discrete anticancer therapy response categories have been defined, with criteria established for each (3). Whereas "cure" is obviously the most noble goal, it is very difficult to achieve in most types of cancer. "Cure" for all cancers except breast and melanoma equates to no evidence of disease for a minimum of 5 years. More commonly, the response category viewed as the pinnacle is "complete response," in which the patient has no evidence of cancer for at least 1 month following the cessation of therapy but where relapses are still possible. A "partial response" is claimed when tumor size or disease severity has been cut at least in half and there is no evidence of new lesions at the primary site or elsewhere. If this level of clinical improvement is not reached, yet the patient has experienced significant attenuation of symptoms and/or enhancement of quality of life, the response is termed "clinical benefit." A less optimistic response category is "stable disease," in which tumor size or disease severity has changed by 25% or less in either direction. Most dire is "progression," a category that is characterized by tumor growth or worsening disease severity at the 25% or higher level.

## Historical Background (6)

> "Those who have not been trained in chemistry or medicine, which after all is only applied chemistry, may not realize how difficult the problem of [cancer] treatment really is. It is almost, not quite, but almost as hard as finding some agent that will dissolve away the left ear, say, yet leave the right ear unharmed: so slight is the difference between the cancer cell and its normal ancestor."

Thus wrote noted cancer researcher and physician Dr. William H. Woglom in a monograph published by the American Association for the Advancement of Science in 1947 (7). Although somewhat predictive of what we now know to be true regarding the relationship between resident genes and oncogenes, Dr. Woglom's rather gloomy prognosis of our ability to meet cancer on its own ground and beat it was underpinned by centuries of unsuccessful attempts to treat neoplastic disease with toxic metals, including lead, arsenic, silver, zinc, antimony, mercury, and bismuth. The era of more promising chemotherapy was just on the horizon, however, even as Woglom penned his words of therapeutic woe.

Copyrighted material

Among the first nonmetallic therapeutic agents to show benefit in the treatment of cancer was cortisone and, later, prednisone. In the 1940s, these glucocorticoids were shown to induce tumor regression in a laboratory cancer model (murine lymphosarcoma) and in acute leukemia. In the same decade, the retrospective recognition that World War I soldiers exposed to sulfur mustard gas, used as an agent of war, suffered from damaged lymphoid tissue and bone marrow led to the development of the cytotoxic nitrogen mustards for the treatment of lymphoma. Chemists then used their scientific understanding of mustard reactivity to design agents that were either "superpotent" and nonselective (e.g., highly toxic) or of lower reactivity so as to provide oral activity and less systemic toxicity.

The discovery in 1940 that *p*-aminobenzenesulfonamide was effective against streptococcal infections ushered in the era of antimetabolite chemotherapy. The development of antifolate antineoplastics, which were shown to be effective in combating childhood leukemias, got its start in the late 1940s. In the mid- to late-1950s, on the heels of the success of antifolates, came the development of antimetabolites based on the structures of endogenous purine and pyrimidine bases. Perhaps the most exciting discovery in this regard was the recognition that a very simple analogue of the endogenous pyrimidine uracil (5-fluorouracil) was a potent inhibitor of deoxythymidine monophosphate biosynthesis and that inhibiting the production of this essential nucleotide produced positive results in patients suffering from colon, stomach, pancreatic, and breast cancers. Antimetabolites that target DNA polymerase (e.g., cytarabine) were conceptualized and synthesized in the late 1950s and subsequently shown to be effective in acute myeloblastic leukemia.

The antibiotic antineoplastics came into clinical utility when the highly toxic actinomycin (discovered in the 1940s) was found to be effective in the treatment of human testicular cancer and uterine choriocarcinoma. Other natural anticancer antibiotics, such as bleomycin, subsequently were found to be active against various hematological cancers and solid tumors (1960s), which led to the development of semisynthetic analogues with both high potency and wider margins of safety in more recent times. The antimitotic vinca alkaloids vincristine and vinblastine were shown to have activity against Hodgkin's disease and acute lymphoblastic leukemia around the same time that the antibiotic antineoplastics were being developed.

Cancer chemotherapy appears to have come full circle since the "metal-intense Renaissance," because some of the newest anticancer drugs to join the U.S. market are organometallic platinum complexes. The activity of cisplatin (the first such complex to be commercially available) against lymphosarcoma and solid tumors of the head, neck, and reproductive organs was first noted in the early 1970s. The fortuitous discovery of organoplatinum complexes in the treatment of cancer is attributed to Dr. Barnett Rosenberg, who was studying the impact of electromagnetic radiation on bacterial cell growth using platinum electrodes. He followed up on the astute observation that the bacteria exposed to the electrodes experienced profound changes in cellular structure, which ultimately were attributed to the in situ generation of cisplatin. Both Pt(II) and Pt(IV) analogues of cisplatin, which offer high potency coupled with lower resistance potential and fewer use-limiting side effects (e.g., oto-, nephro-, and hematotoxicity), are currently on the market and in clinical trials. In addition to organometallics, the efficacy of sex hormones and hormone antagonists in fighting hormone-dependent cancers (e.g., estrogen receptor–positive breast cancer or prostate cancer) and the advent of therapeutic biological response modifiers with direct antiproliferative effects (e.g., interferons) has added significantly to the therapeutic options available to providers and the cancer patients for whom they care.

Despite the wide range of antineoplastic agents currently available, it has been estimated that more than half of all patients with cancer ultimately succumb to their disease (8). Novel therapies based on an in-depth understanding of the molecular mechanisms involved in the complex cascade of events we call cancer are urgently needed. Fortunately, molecular targets for focused chemotherapeutic interventions are being discovered with increasing regularity, opening the door for the scientifically grounded development of new drugs. The critical role of computer-based technology in facilitating the ability of chemists to conceptualize and visualize molecular interactions between potential drugs and putative receptor targets that lead to rational drug design and development, as well as in analyzing and managing the overwhelming amounts of data that are generated from these studies, cannot be underestimated. Likewise, the availability of viable tumor cell lines has facilitated a disease-specific orientation to the hunt for more effective therapies. Currently, there are tumor cell lines for lung, colon, breast, and kidney cancers, as well as for melanoma and leukemia (8).

Several monoclonal antibodies targeted to tumor cell antigens or proteins critical to cellular proliferation (e.g., human epidermal growth factor, vascular endothelial growth factor, tyrosine kinase, and proteasomes) have found their way to the U.S. market. In addition, several new targets for anticancer drug development currently are being actively explored by biomedical scientists (1,3). For example, cancer cells overexpress the enzyme telomerase, which inhibits the natural destruction of chromosomal telomeres (DNA caps), leading to unwanted cellular immortality. Telomerase inhibitors would be expected to reestablish cellular senescence and to halt uncontrolled cell division by maintaining the integrity of the telomeres and are being pursued as a new biochemical approach to disease attenuation or control. Other potential antineoplastic drug targets being seriously investigated are aberrant genes or enzymes unique to specific tumors and P-glycoprotein, which is overexpressed in

Table 42.3. Estimated 2005 Incidence and Mortality of Common Cancers (3)

| | Prostate/Breast | | Lung | | Colorectal | |
|---|---|---|---|---|---|---|
| | Men | Women | Men | Women | Men | Women |
| **Incidence** | 232,090 (33%) | 211,240 (32%) | 93,010 (13%) | 79,560 (12%) | 71,820 (10%) | 73,470 (11%) |
| **Mortality** | 30,350 (10%) | 40,410 (15%) | 90,490 (31%) | 73,020 (27%) | 28,540 (10%) | 27,750 (10%) |

many cancers as a result of an amplified *mdr-1* gene and responsible for the rapid ejection of antineoplastic agents from target cells. Other multidrug resistance–associated proteins (the MRP family) involved in this devastating rebound of the cancer cell also are being investigated as potential sites of therapeutic intervention. The intense focus on resistance molecules such P-glycoprotein is warranted, because patients whose tumors express this efflux-promoting protein respond poorly to chemotherapy and have a poor prognosis (2).

In the future, it is hoped that clinicians will be able to generate a genetic expression profile for each patient with cancer to help them predict response to all possible therapies and to guide pharmacotherapy selection.

## DISEASE STATE

Cancers generally can be classified as lymphatic, epithelial, nerve, or connective tissue related, and tumor nomenclature is based on tissue of origin as follows: carcinoma (epithelial origin), sarcoma (muscle or connective tissue origin), leukemia and lymphoma (lymphatic or hematologic origin), and glioma (neural origin). The risk of developing epithelial-derived cancers increases with age.

### Incidence

Approximately 1.3 million cases of cancer are diagnosed each year in the United States, resulting in an estimated 570,280 annual deaths (3). The most commonly acquired cancers include those of the prostate, breast, lung, colon, and rectum. Lung cancer is the most fatal and is responsible for approximately 160,000 deaths each year. These prominent cancers (prostate/breast, lung, and colorectal) occur with very similar frequency in men and women, and little gender-related differences in mortality are noted (Table 42.3). Some geographical differences in incidence have been noted, with lung cancer being more prevalent in rural southern U.S. states, and breast and colon cancer more commonly diagnosed in the "northeast corridor" of the United States (9).

### Signs and Symptoms

The clinical manifestations of cancer can vary widely depending on type and stage of neoplastic disease. The American Cancer Society has been promulgating its list of the major warning signs of cancer for decades (Table 42.4) (10,11). Patients are well-served by being familiar with these early warning signs, because cancer is most effectively treated when diagnosed before more life-threatening symptoms appear. One readily recognized symptom of cancer is persistent weight loss (especially in children), and severe, unrelenting pain is a hallmark symptom of cancer in the later stages. Solid tumors can become palpable or observable masses when the cancer is advanced.

### Biochemical Bases and Causes of Cancer

Currently, it is understood that cancer is caused by mutations in "resident" or normal genes rather than by the introduction of foreign genes into otherwise healthy systems (1,3). The single-gene theory of cancer (where a single mutation could result in neoplastic disease) has been abandoned in favor of the multiple mutation prerequisite, and complex gene pathways, interactions, and communications are now the focus of study in the understanding of

Table 42.4. The American Cancer Society's Major Warning Signs of Cancer (10,11)

| Cancer Warning Signs in Adults | Cancer Warning Signs in Children |
|---|---|
| Change in bowel or bladder habits | Continued, unexplained weight loss |
| A sore that does not heal | Frequent headaches, with vomiting |
| Unusual bleeding or discharge | Localized pain or persistent limping |
| Thickening or lump in breast or elsewhere | Any unusual mass or swelling |
| Indigestion or difficulty in swallowing | Sudden eye or vision changes |
| Obvious change in a wart or mole | Recurrent or unexplained fever |
| Nagging cough or hoarseness | Excessive bruising or bleeding |
| | Noticeable paleness or loss of energy |

because of the strong negative inductive effect of the positively charged nitrogen atom.

In step 2, a DNA nucleophile conducts an intermolecular nucleophilic attack, which breaks the aziridine ring and alkylates DNA. Although guanine is the preferred nucleic acid base involved in the alkylation reaction, adenine also is known to react. Of critical importance is the fact that the lone pair of electrons on the mustard nitrogen is regenerated when the aziridine ring cleaves.

Steps 3 and 4 are simply repetitions of steps 1 and 2, respectively, involving the second arm of the mustard and a second molecule of DNA. Ultimately, two molecules of DNA will be cross-linked through the carbon atoms of what was once the nitrogen mustard. Finally, hydrolytic depurination (step 5) cleaves the bound guanine residues from the DNA strand. This is an attempt to liberate the DNA from the mustard's covalent "stranglehold," but the DNA released from this mustard trap is damaged and unable to replicate. Cell death is the inevitable result. If this is happening in a tumor cell, the therapeutic goal has been accomplished. If it is happening in a healthy cell, particularly one with a short half-life, then the patient may experience side effects that can be use-limiting.

**STRUCTURE–ACTIVITY RELATIONSHIPS.** The structure of nitrogen mustards differs only in the nature of the third group (R) attached to the amino nitrogen. This group, which can be either aliphatic or aromatic, is the prime determinant of chemical reactivity, oral bioavailability, and the nature and extent of side effects.

An aliphatic nitrogen substituent (e.g., $CH_3$) will push electrons to the amine through σ bonds. This electronic enrichment enhances the nucleophilic character of the lone pair of electrons and increases the speed at which the $\delta^+$ β-carbon of the mustard will be attacked. Whether in a tumor cell or a healthy cell, the aziridinium ion, as soon as it forms, will react with unpaired DNA and/or other cell nucleophiles, such as electron-rich SH, OH, and NH groups of amino acids on enzymes or membrane-bound receptors. The body's water also can react with (and inactivate) the aziridinium ion. The intra- and intermolecular reactions designated as steps 1 through 4 in Figure 42.1 happen so rapidly that almost no chance exists for tissue or cell specificity, which means a greatly increased risk of serious side effects and use-limiting toxicity.

Conversely, an aromatic nitrogen substituent (e.g., phenyl) conjugated with the mustard nitrogen will stabilize the lone pair of electrons through resonance. Resonance delocalization significantly slows the rate of intramolecular nucleophilic attack, aziridinium ion formation, and DNA alkylation. Aromatic mustards have a reactivity sufficiently controlled to permit oral administration and attenuate the severity of side effects. The higher stability also provides the chance for enhanced tissue selectivity by giving the intact mustard time to reach malignant cells before generating the electrophilic aziridinium ion.

Nitrogen mustards can decompose in aqueous media through formation of the inactive dehalogenated diol

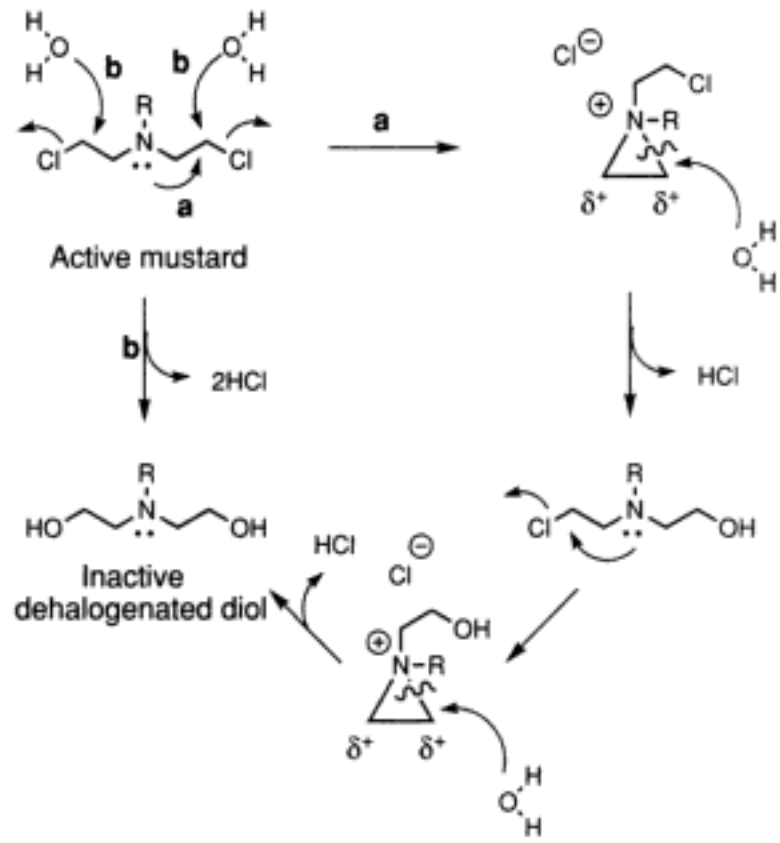

**Fig. 42.2.** Aqueous decomposition of nitrogen mustards.

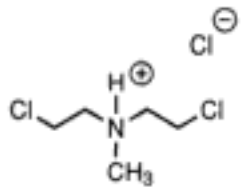
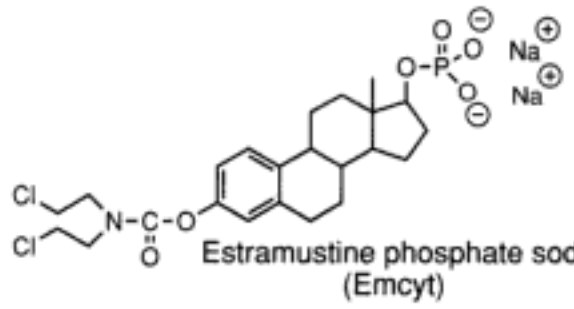
shown in Figure 42.2. Both the mustard nitrogen (pathway a) and the oxygen of water (pathway b) can act as nucleophiles to advance this degradative process. The decomposition reactions can be inhibited if the nucleophilic character of these atoms is eliminated through protonation, so buffering solutions to a slightly acidic pH helps to enhance stability in aqueous solution.



### SPECIFIC DRUGS

***Mechlorethamine Hydrochloride.*** Mechlorethamine is the only aliphatic nitrogen mustard currently on the U.S. market (Fig. 42.3). Its use is limited by extremely high reactivity, which leads to rapid and nonspecific alkylation of cellular nucleophiles and excessive toxicity. It is a severe vesicant, and if accidental skin contact occurs, the drug must be inactivated with 2% sodium thiosulfate ($Na_2S_2O_3$) solution. This reagent reacts with the mustard to create an inactive, highly ionized, and water-soluble thiosulfate ester that can be washed away (Fig. 42.4). The affected tissue also should be treated with an ice compress for 6 to 12 hours.



Mechlorethamine is marketed in hydrochloride salt form to provide water solubility for intravenous (IV) or intracavitary administration. The strong electron-withdrawing effect of the two chlorine atoms reduces the $pK_a$ of mechlorethamine to 6.1, which gives a ratio of unionized to ionized drug forms of approximately 20:1 at pH 7.4. This agent is too reactive for oral administration and too toxic to use alone. In addition to severe nausea and vomiting, myelosuppression (lymphocytopenia and granulocytopenia), and alopecia, it can cause myelogenous leukemia with extended use because of its mutagenic/carcinogenic effects on bone marrow stem cells. Mechlorethamine is still used in regimens for cancers of the blood (e.g., Hodgkin's disease, chronic myelocytic, or chronic lymphocytic leukemia); fortunately, however, safer and still highly potent antineoplastic agents are now available.

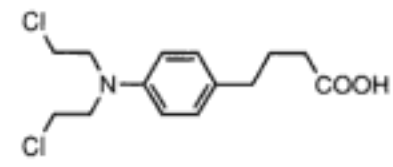
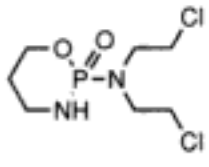
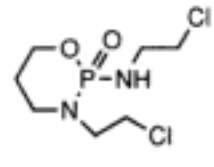
**Nitrogen mustards and aziridine-mediated alkylators:**



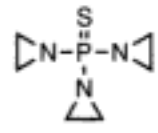
Mechlorethamine hydrochloride (Mustargen)



Estramustine phosphate sodium (Emcyt)

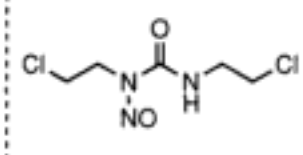


Melphalan (Alkeran)

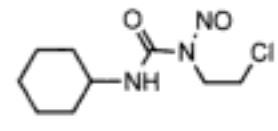


Chlorambucil (Leukeran)

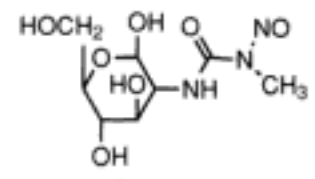
Cyclophosphamide (Cytoxan)



Ifosfamide (Ifex)

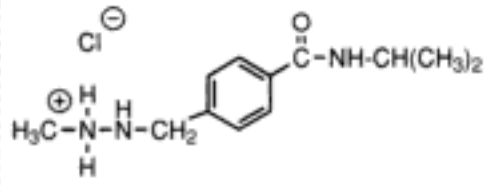


Thiotepa (Thioplex)

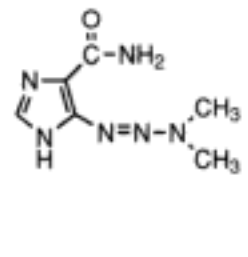


**Nitrosoureas:**

Carmustine (BiCNU)

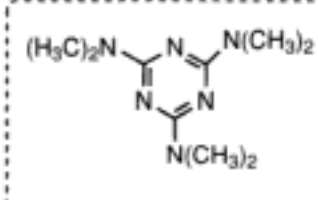


Lomustine (CeeNU)

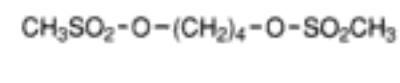


Streptozocin (Zanosar)

**DNA methylators:**



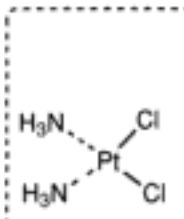
Procarbazine hydrochloride (Matulane)



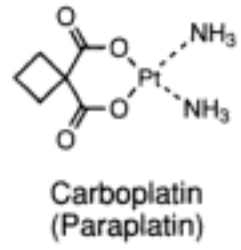
Dacarbazine (DTIC-Dome)

Temozolomide (Temodar)

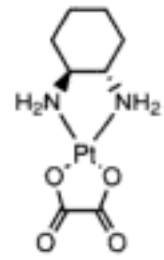
**Miscellaneous DNA alkylators:**



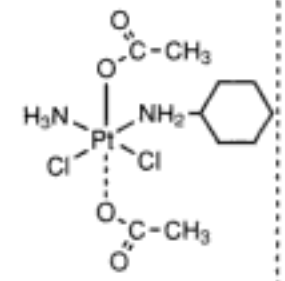
Altretamine (Hexalen)



Busulfan (Myleran)



**Organoplatinum complexes:**



Cisplatin (Platinol-AQ)

Carboplatin (Paraplatin)

Oxaliplatin (Eloxatin)

Satraplatin (investigational)

**Fig. 42.3.** DNA cross-linking agents.

***Melphalan.*** This aromatic mustard, used primarily in the treatment of multiple myeloma, is able to stabilize the lone pair of electrons on the mustard nitrogen through resonance with the conjugated phenyl ring, slowing the formation of the reactive aziridinium ion. The L-isomer of the amino acid Phe was purposefully incorporated into this antineoplastic agent (Fig. 42.3), because naturally occurring L–amino acids are preferentially transported into cells by the action of specific amino acid carrier proteins. It was assumed that the L-Phe would act as a homing device and actively transport the toxic mustard inside the tumor cells, but some studies indicate that melphalan enters cells through facilitated diffusion rather than by active transport (15).

Because the lone pair of electrons of melphalan (and other aromatic mustards) is less reactive, there is a greater opportunity for distribution to cancer cells and a decreased incidence of severe side effects. There is a lower incidence of nausea and vomiting compared to mechlorethamine, but patients still experience myelosuppression, which can

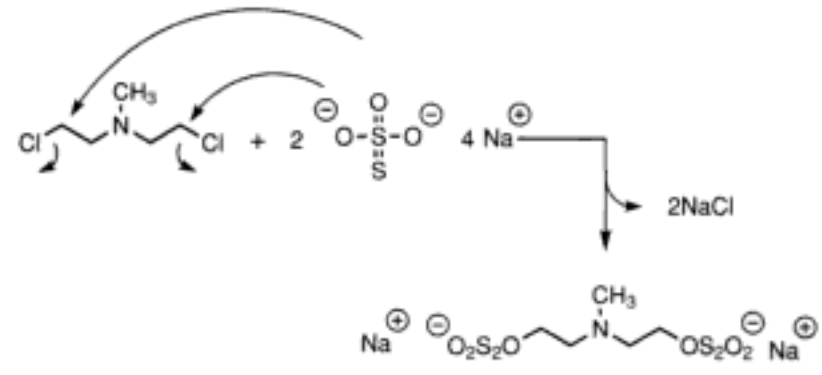


**Fig. 42.4.** Mechlorethamine inactivation by sodium thiosulfate.

Copyrighted material

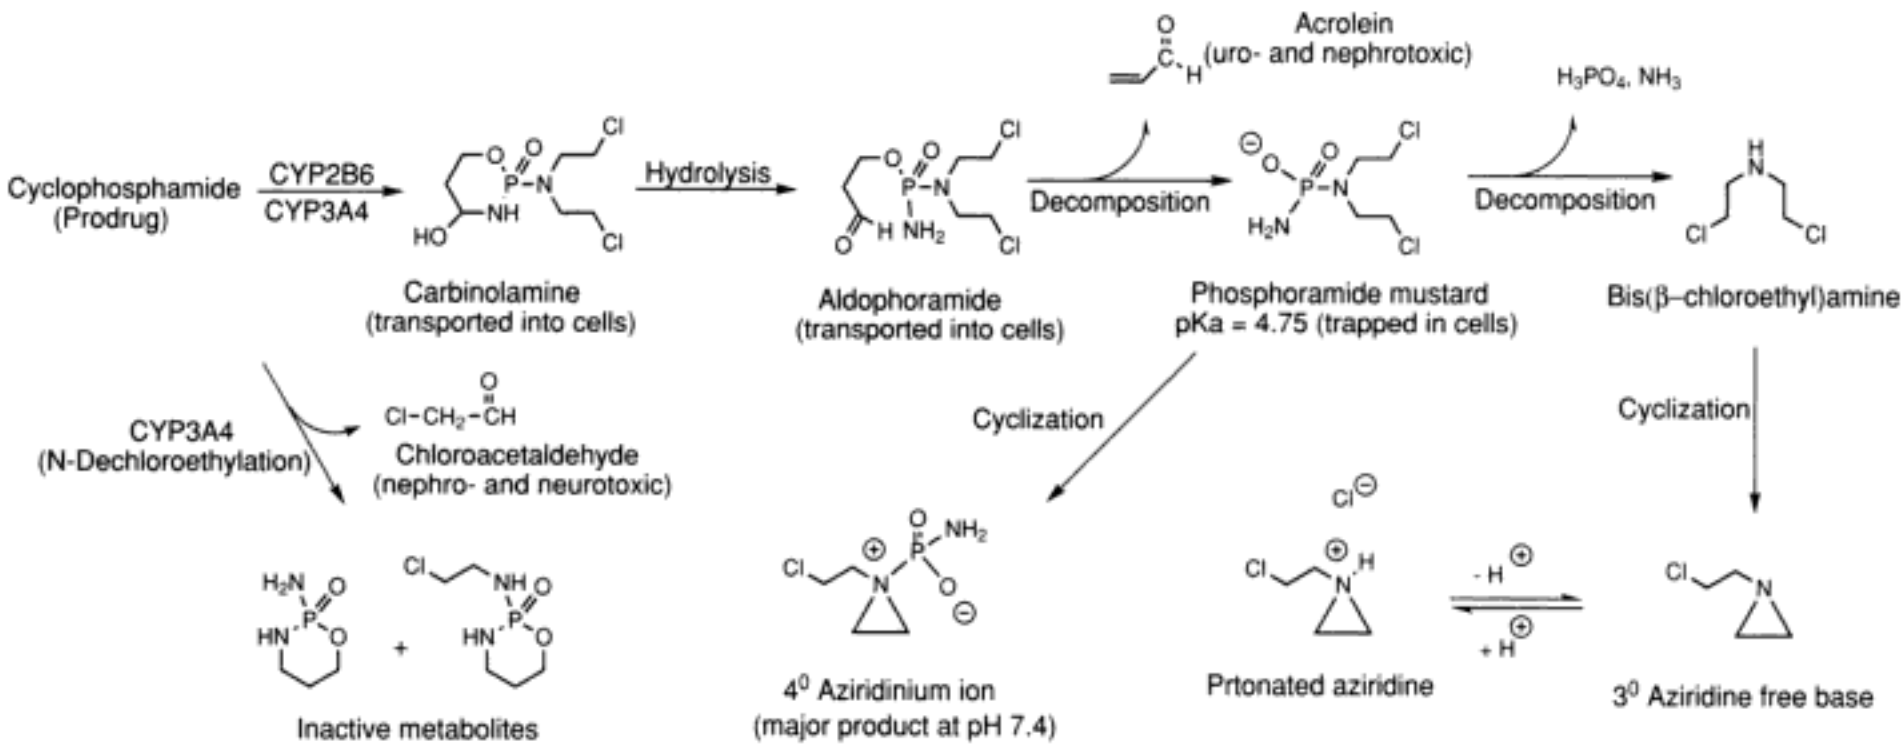

**Fig. 42.6.** Cyclophosphamide metabolism.

and ammonia ($NH_3$) and leaving the naked bis(β-chloroethyl)amine mustard. This secondary amine cyclizes in a manner similar to the tertiary phosphoramide mustard, forming a tertiary aziridine (rather than a quaternary aziridinium) species. The free tertiary aziridine can protonate at intracellular pH to provide the cationic aziridine species, which is in equilibrium with the free-base form. Some electrophilic character is lost, but the carbon atoms in both forms are still $\delta^+$ enough to attract DNA nucleophiles, albeit less vigorously. The net result of this attack is DNA alkylation and cell death.

The need for metabolic activation in the liver means lowered GI toxicity and less nonspecific toxicity for cyclophosphamide compared with other DNA alkylating agents, but cyclophosphamide is not without its toxic effects. Acrolein, generated during the formation of phosphoramide mustard, is a very electrophilic and highly reactive species and causes extensive damage to cells of the kidney and bladder. Potentially fatal acute hemorrhagic cystitis is a significant risk of cyclophosphamide therapy.

Bladder damage from acrolein results from attack by Cys sulfhydryl groups at the $\delta^+$ terminal carbon of the acrolein structure, resulting in renal cell alkylation and cell death. Physiological results can include severe hemorrhage, sclerosis, and on occasion, induction of bladder cancer. Acrolein also damages the nephron, particularly when used in high doses, in children, in patients with only one kidney, or when coadministered with other nephrotoxic agents (e.g., cisplatin). To minimize the risk of bladder toxicity from acrolein, fluids should be forced and the bladder irrigated. Mesna (Mesnex) also is available as adjuvant therapy in case of overt toxicity or as a prophylactic protectant. A sulfhydryl reagent, mesna competes with Cys residues for the alkylating arolein, as shown in Figure 42.7. Mesna concentrates in the bladder and will prevent damage to those cells. It does not concentrate to any appreciable extent in the nephron and, therefore, is not good protection against cyclophosphamide-induced nephrotoxicity.

As effective as mesna is for preventing acrolein-induced urotoxicity, it does little to spare the kidney and nerve cells from chloroacetaldehyde, the other toxic by-product of cyclophosphamide metabolism (18). Luckily, only approximately 10% of a standard dose of cyclophosphamide undergoes the dechloroethylation reaction, although this percentage can rise if higher doses are used (16).

Cyclophosphamide most commonly is used in combination with other antineoplastic agents to treat a wide range of neoplasms, including leukemias and malignant lymphomas, multiple myeloma, ovarian adenocarinoma, and breast cancer. The drug is metabolized in the liver

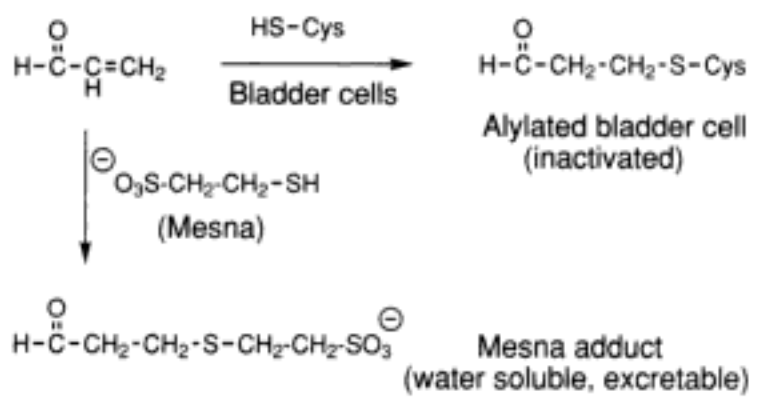

**Fig. 42.7.** Sulfhydryl alkylation by acrolein.

Copyrighted material

and is eliminated via the kidney, with approximately 15% of a given dose being excreted unchanged. Doses should be reduced in patients with levels of creatinine clearance less than 30 mL/min. Interestingly, hepatic dysfunction does not seem to alter metabolism of this drug, but caution should be exercised in patients with inhibited cytochrome P450 (CYP450) enzymes or with a combination of factors that could negatively impact drug activation/inactivation pathways.

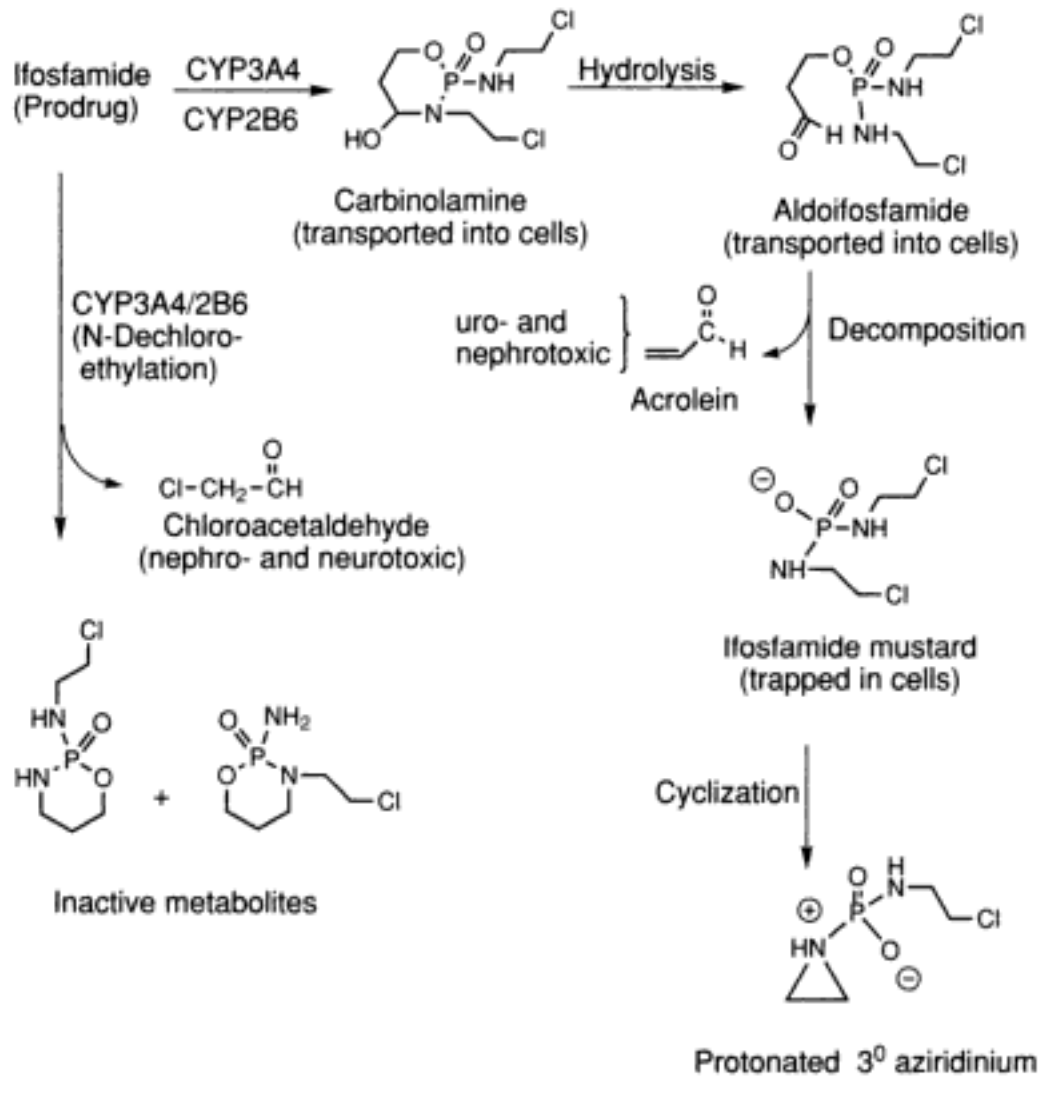
***Ifosfamide.*** This cyclophosphamide analogue has the two arms of the mustard on different nitrogen atoms (Fig. 42.3). Ifosfamide also requires metabolic activation (Fig. 42.8), but this time it is the CYP3A4 isoform that converts the majority of the dose to the carbinolamine, with CYP2B6 taking on a minor, supporting role (19). Because ifosfamide has a lower affinity for the hydroxylating CYP3A4 and CYP2B6 enzymes, presumably as a result of steric hindrance, bioactivation proceeds at a slower rate (20). Doses three- to fourfold higher than cyclophosphamide are required to achieve the same antineoplastic result.

Unlike cyclophosphamide, dechloroethylation is a significant metabolic pathway for ifosfamide, and approximately 45% of a standard dose will undergo this inactivating and toxicity-inducing biotransformation. CYP3A4 catalyzes approximately 70% of ifosfamide dechloroethylation, with CYP2B6 taking care of the remainder (16). The fact that this reaction can occur in the renal tubule, generating chloroacetaldehyde right in the nephron, contributes to its significantly higher nephrotoxicity (20). Ultimately, both chloroalkyl groups are lost before the compound is excreted.

It bears repeating that there is a significantly higher risk of bladder toxicity and nephrotoxicity with ifosfamide than with cyclophosphamide. This is because:

- Significantly more chloroacetaldehyde is generated through CYP3A4- and CYP2B6-mediated dechloroethylation. This biotransformation can take place in the nephron, which places the toxic by-product right where it will do the most damage.
- Ifosfamide is more water soluble than cyclophosphamide and will concentrate in the renal system. Between 20 and 50% of a dose is excreted unchanged in the urine.
- Acrolein also is formed when this alkylator generates the cytotoxic aziridiniun ion.
- Higher doses must be administered to achieve the same degree of antineoplastic action, so more molecules of acrolein and chloroacetaldehyde will be produced.

Because acrolein is formed, the same precautions against hemorrhagic cystitis that were previously outlined for cyclophosphamide must be taken: hydrate well, irrigate thoroughly, and administer with mesna. As previously stated, mesna will not prevent chloroacetaldehyde-induced toxicity.



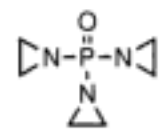


**Fig. 42.8.** Ifosfamide metabolism.

Copyrighted material

Ifosamide currently is used as "third-line" therapy against testicular cancer, although it also has shown activity in a number of solid tumors and hematologic cancers. Patients on ifosfamide (but not cyclophosphamide) commonly exhibit central nervous system (CNS) toxicity. In severe forms, CNS depression can progress to coma and death.

***Thiotepa.*** Thiotepa (Fig. 42.3), a tertiary aziridine, is less reactive than quaternary aziridinium compounds and is classified as a weak alkylator. It is possible for the nitrogen atoms to be protonate before reacting with DNA (a positively charged aziridine is more reactive than the un-ionized aziridine), but the electron-withdrawing effect of the sulfur atom decreases the $pK_a$ to approximately six, which keeps the percentage ionized at pH 7.4 relatively low. Thiotepa undergoes oxidative desulfuration, forming an active cytotoxic metabolite known as TEPA (triethylenephosphoramide). This antineoplastic agent is most commonly employed in the treatment of ovarian and breast cancers, as well as papillary carcinoma of the bladder.

Triethylenephosphoramide
(an active thiotepa metabolite)

Thiotepa and the TEPA metabolite readily enter the CNS after systemic administration, leading to dizziness, blurred vision, and headaches. More critically, these agents also are severe myelosuppressants and can induce leukopenia, thrombocytopenia, and anemia. Patients treated with thiotepa are at high risk for infection and hemorrhage. Oral absorption is unreliable, so thiotepa is given IV or can be instilled intravesically in the treatment of bladder cancer. Even when administered locally in bladder cancer, high levels of this lipophilic drug reach the systemic circulation, resulting in bone marrow depression. Patients have died from myelosuppression after intravesically administered thiotepa. The drug also causes damage to the hepatic and renal systems. Dose and/or administration frequency should be increased slowly, even if the initial response to the drug is sluggish, or unacceptable toxicity may result.

## Nitrosoureas

**MECHANISM OF ACTION.** The nitrosoureas are unstable structures that decompose readily in the aqueous environment of the cell. Nonenzymatic fragmentation is stimulated by the loss of proton from the urea moiety. Cyclization of the resultant anion to an unstable oxazolidine (pathway A) is followed by decomposition to vinyl diazotic acid and a substituted isocyanate, both of which release a gaseous fragment (nitrogen and carbon dioxide, respectively) to generate cytotoxic electrophiles (Fig. 42.9). Vinyl carbocation, acetaldehyde, and 2-chloroethylamine generated from the 2-chloroethylisocyanate moiety of carmustine are all capable of alkylating DNA in

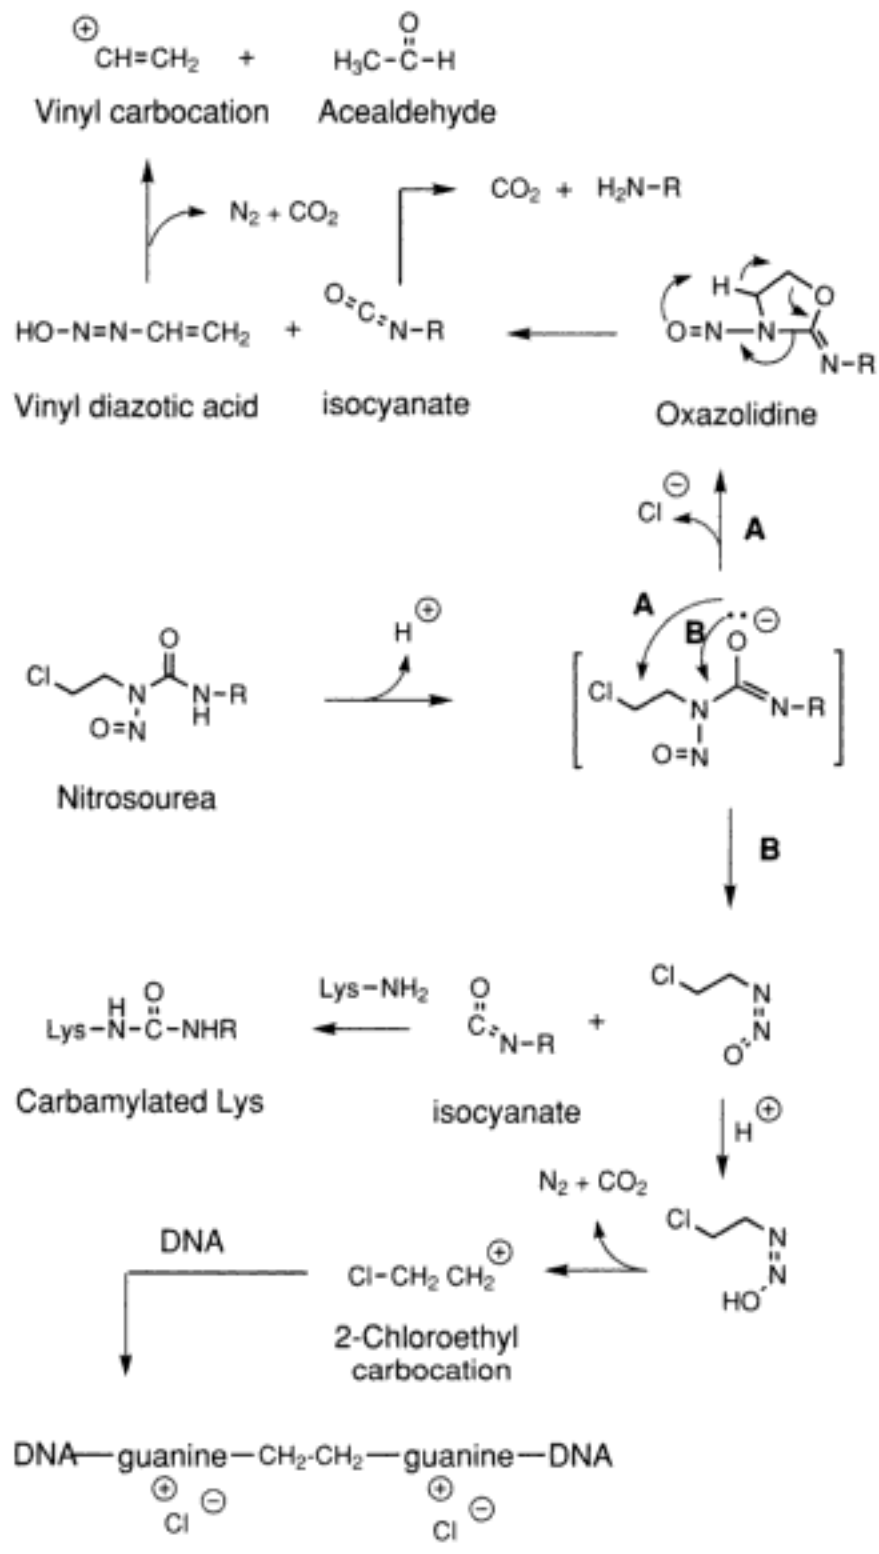

**Fig. 42.9.** Nitrosourea decomposition to active electrophiles.

the standard manner (21). A second decomposition mechanism (pathway B) ultimately produces an electrophilic 2-chloroethylcarbocation capable of DNA alkylation at guanine-$N^7$ and $O^6$ as well as an isocyanate that can carbamylate amino acid residues (e.g., Lys).

### SPECIFIC DRUGS

***Carmustine and Lomustine.*** Carmustine and lomustine are both highly lipophilic chloroethylnitrosourea analogues marketed for use in brain tumors and Hodgkin's disease. Carmustine also has shown value in the treatment of non-Hodgkin's lymphoma and multiple myeloma, and it is given IV or incorporated into biodegradable wafers that are implanted directly into the CNS after tumor resection. The high lipophilicity of carmustine precludes a totally aqueous IV formulation, and the drug is administered in 10% ethanol. Although carmustine degrades within 15 minutes of IV administration, lomustine is stable enough for oral use and is marketed in capsule form. Carmustine also can

Copyrighted material

decompose in vitro if exposed to temperatures around 90°F. Pure carmustine is a low-melting solid, but the decomposed product is an oil and, therefore, is readily detected. Vials of carmustine that appear oily should be discarded.

Both carmustine and lomustine can induce thrombocytopenia and leukopenia, leading to hemorrhage and massive infection. Acute (as well as potentially fatal delayed) pulmonary toxicity also is a risk. Pulmonary toxicity is dose-related, and individuals who received the drug in childhood or early adolescence are at higher risk for the delayed reaction. The grand mal seizures that are possible from the wafer formulation of carmustine appear to result from the wafer rather than from the nitrosourea.

***Streptozocin.*** The glucopyranose moiety of streptozocin confers both islet cell specificity and high water solubility to this nitrosourea-based antineoplastic. As a result, it is used exclusively in metastatic islet cell carcinoma of the pancreas and is administered IV in D5W or normal saline. Lacking the 2-chloroethyl substituent of carmustine and lomustine, it is much less reactive as a DNA alkylating agent, and myelotoxicity is relatively rare but not unknown. Cumulative, dose-related renal toxicity can be severe or fatal, however, and 67% of patients receiving this drug will exhibit some kidney-related pathology. Good hydration is essential to successful therapy, and kidney function should be monitored weekly.

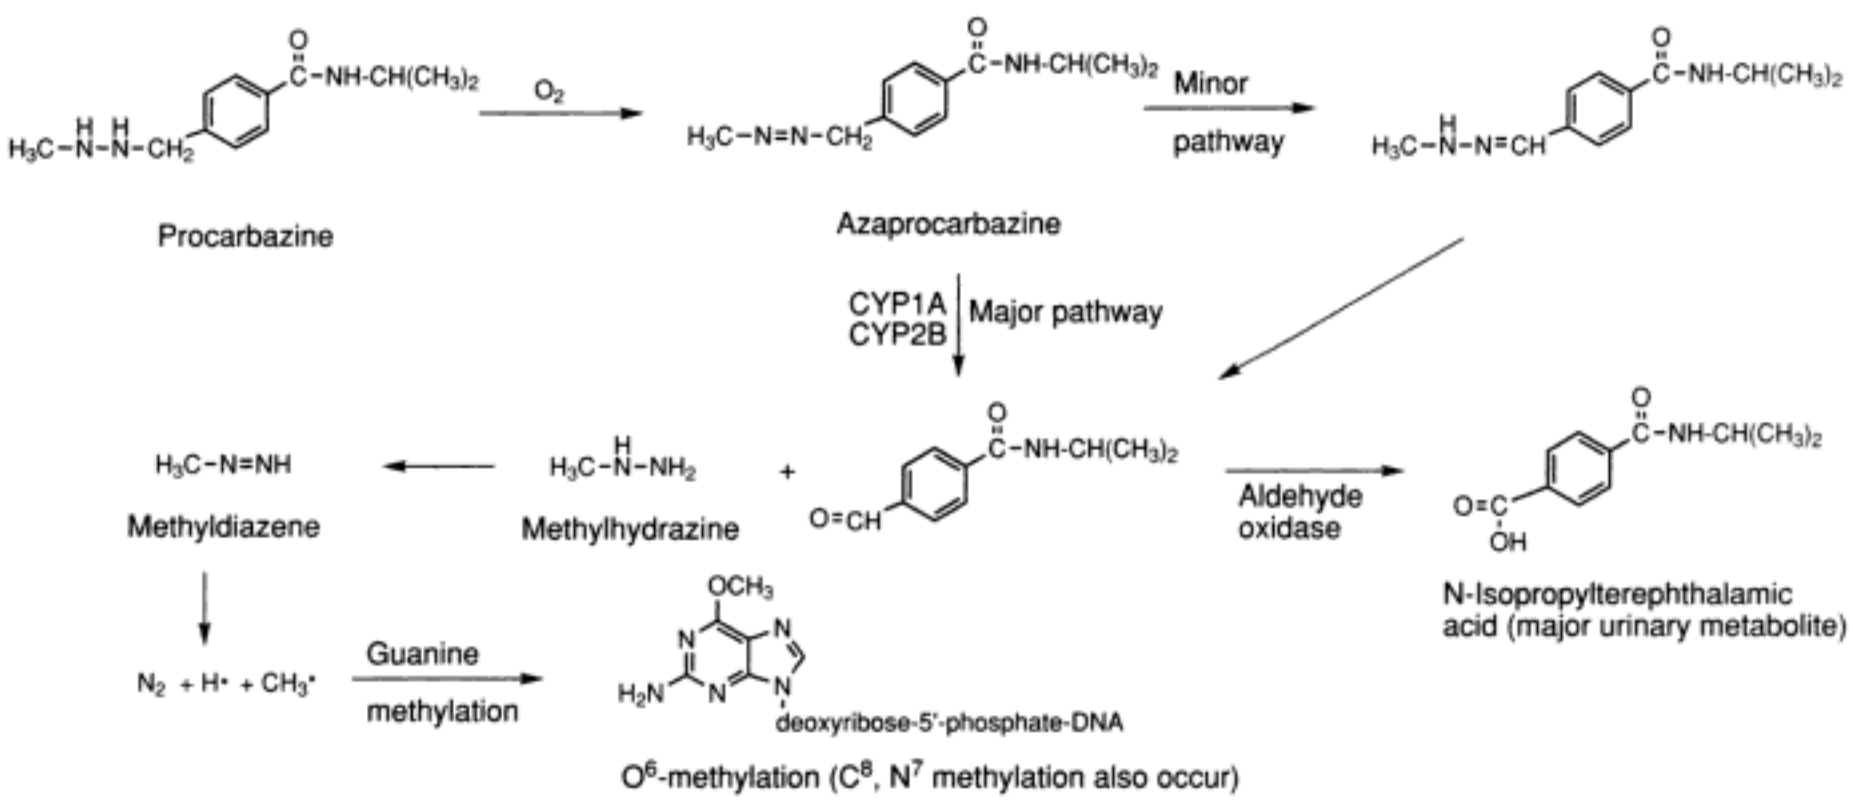
## Procarbazine and Triazenes

**MECHANISM OF ACTION.** Procarbazine and the triazenes dacarbazine and temozolomide act by different mechanisms, but they all exert an antineoplastic effect through the $O^6$-methylation of guanine nucleotides. $O^6$-methylguanine pairs preferentially with thymine, and these "mispairs" prompt point mutations during subsequent DNA replication cycles and trigger cell destruction through the activation of the normal postreplication mismatch repair (MMR) system. Patients who are able to repair this damage through the action of $O^6$-alkylguanine-DNA-alkyltransferase, which transfers the offending $CH_3$ group to a Cys residue on the alkyltransferase protein, will exhibit resistance to these agents, whereas those who underexpress this protein should respond well (22). Because the alkyltransferase is irreversibly inactivated in the DNA rescue process, enzyme depletion (and subsequent loss of DNA repair capability) is a significant risk.

Procarbazine metabolism involves CYP1A and CYP2B enzymes (23), and DNA alkylation operates through a free radical mechanism (Fig. 42.10). The major degradation pathway involves benzylic oxidation of azoprocarbazine, producing methylhydrazine that generates a methyl radical through an unstable diazene intermediate (24,25) In addition to $O^6$, the reactive methyl radical formed can alkylate the $C^8$ and $N^7$ positions of guanine. In contrast, the triazenes methylate DNA guanine via diazomethane and/or methyl carbocation generated in situ. Although temozolomide is converted to the diazomethane precursor 3-methyl-(triazen-l-yl) imidazole-4-carboxamide (MTIC) through nonenzymatic mechanisms, the conversion of dacarbazine to MTIC depends on the action of CYP1A1 and CYP1A2 enzymes, with a smaller contribution by CYP2E1 (Fig. 42.11) (23,26). The $O^6$ and $N^7$ positions of guanine are the most vulnerable to triazene methylation.

### SPECIFIC DRUGS

***Procarbazine.*** This methyl radical generator is utilized predominantly in the treatment of Hodgkin's disease. It is administered as part of a multidrug regimen that also includes a nitrogen mustard (mechlorethamine), a mitosis inhibitor (vincristine), and prednisone. It is administered as capsules and is well absorbed after oral administration. Procarbazine is extensively metabolized in the liver, and 70% of an administered dose is excreted in the urine as N-isopropylterephthalamic acid (Fig. 42.10). In addition to



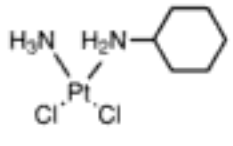


**Fig. 42.10.** Procarbazine metabolism and mechanism of action.

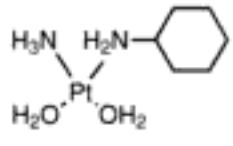
Copyrighted material



This distinct oxaliplatin conformation is believed to result from the steric impact of the (*R,R*)-DACH carrier, which orients the hydrogen atoms on the ammine ligands such that the *cis*-$NH_3$ can form a hydrogen bond with a guanine-$O^6$, a bond that the inactive (*S,S*)-isomer is unable to form (35). The conformation of the oxaliplatin-DNA adduct is much less likely to be recognized by MMR proteins, and the effectiveness of oxaliplatin in MMR-deficient cells is believed to be responsible for the lack of resistance that has plagued cisplatin and carboplatin (36,37). Oxaliplatin often retains activity in patients who are no longer responding to the "first-generation" organometallics and also is significantly less mutagenic, nephrotoxic, hematotoxic, and ototoxic than cisplatin. Excretion is via the kidney.

Oxaliplatin decomposes in alkaline media and should not be coadministered with drugs that will increase the pH of the IV solution. Oxaliplatin is used in the treatment of metastatic colon or rectal cancer, either alone or in combination with 5-fluorouracil. Pulmonary fibrosis and peripheral sensory neuropathies that can be life-threatening are known to occur. It has been proposed that the latter adverse effect is caused by oxalate-based chelation of intracellular $Ca^{2+}$, which inhibits voltage-gated sodium channels in sensory nerve cells (38). This hypothesis is supported by the observation that infusions of calcium or magnesium salts can significantly attenuate oxaliplatin-induced neuropathy without compromising therapeutic efficacy (39). In the future, exploitation of genetic differences in the expression of various repair proteins, growth factors, and metabolizing enzymes may allow the tailoring of oxaliplatin therapy based on an individual's pharmacogenetic profile (37).

***Satraplatin.*** This newest organometallic agent (Fig. 42.3) currently is in clinical trials as a second-line agent for the treatment of hormone-refractory prostate cancer (36). There is hope that it also will find value in ovarian cancer and small cell lung cancer. Satraplatin is a Pt(IV) complex. As with the Pt(II) complexes, the platinum has no net charge in the parent drug, because its original +4 charge has been "neutralized" by the donation of four electrons from the chloride and acetate ligands. Unlike the square-planar Pt(II) complexes currently on the market, it is active by the oral route. It is metabolized quickly in whole blood, producing up to six metabolites. The major metabolite is the desacetoxy analogue. As with other organoplatinum complexes, the diaquo form is active. At this early stage, the toxicity profile appears to be mild, with dose-related myelosuppression, particularly neutropenia and thrombocytopenia, being the major use-limiting side effect.

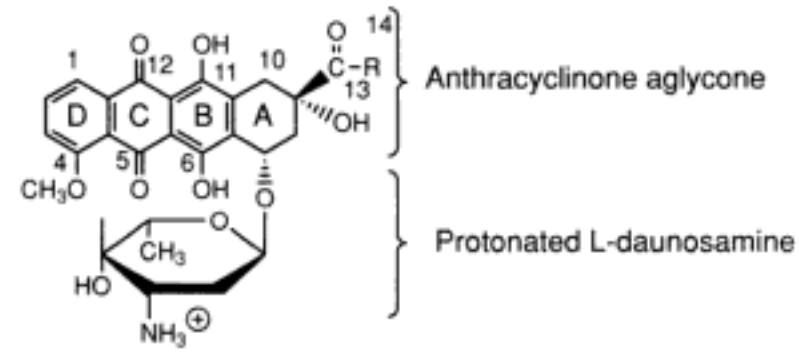
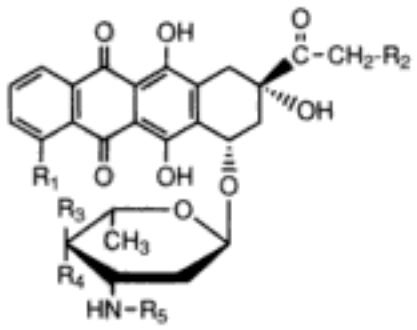
## Antibiotics



The antibiotic antineoplastics (Fig. 42.17) are a broad category of natural or semisynthetic compounds that block DNA transcription by nicking and/or inducing point mutations in the DNA strand and/or by inhibiting enzymes critical to the DNA replication process. Antibiotic antineoplastics that interact directly with DNA first intercalate the double-stranded helix by inserting between the base pairs and forming strong noncovalent interactions with DNA bases. The highly stabilized complex deforms and uncoils the DNA, prohibiting proper replication. To bulldoze its way between the bonded DNA strands, a segment of the antibiotic must have the trigonal coplanar geometry guaranteed by aromaticity.

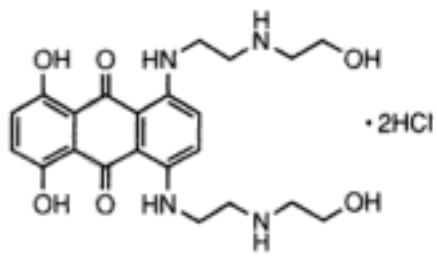
Many of the antineoplastic antibiotic compounds inhibit topoisomerase II, an enzyme responsible for maintaining proper DNA structure during replication and transcription to RNA. Topoisomerase II normally cleaves DNA during the replication phase but repairs its own damage after replication is complete. Topoisomerase II inhibitors act to stimulate the cleavage reaction but inhibit the DNA resealing activity of the enzyme, leaving the DNA irreversibly damaged and unable to replicate.

Yet another proposed mechanism of cytotoxic action is the generation of cytotoxic free radicals that cause single-strand breaks in DNA. One antibiotic (mitomycin) is capable of alkylating DNA, a mechanism more commonly associated with the nitrogen mustard antineoplastics but which is entirely predictable from the nucleophilic aziridine ring found within the structure of this anticancer agent.



### Anthracyclines and Anthracenediones

Anthracycline antineoplastic antibiotics are very closely related to the tetracycline antibacterials. Structurally, they are glycosides and contain a sugar portion (L-daunosamine) and a nonsugar organic portion. The nonsugar portion of glycosides is generically referred to as an aglycone. In anthracyclines, the aglycone moiety is specifically called anthracyclinone or anthroquinone.



**MECHANISM OF ACTION.** As previously mentioned, DNA intercalation initiates the antineoplastic action of the anthracyclines. The anthracyclinone portion of the structure, particularly rings B, C, and D, is large and predominantly aromatic. This flat ring system slides between the two DNA strands, orienting itself in a perpendicular fashion relative to the long axis of DNA. Once intercalated, the anthracycline-DNA complex is stabilized through van

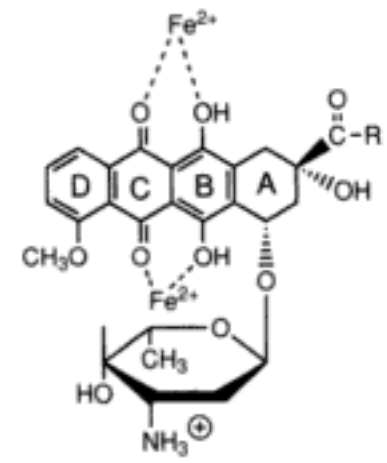
der Waals, hydrophobic, and hydrogen bonds. Binding is best in DNA regions that are rich in guanine and cytosine bases.

The protonated 3′-amino group on the daunosamine sugar has long been thought to stabilize the intercalated complex through interaction with an anionic DNA phosphate, but investigators recently have proposed that this substituent may link covalently to the $C_2$-$NH_2$ of guanine via a methylene bridging unit provided by formaldehyde (40). Regardless of the interaction, the daunosamine amino group is believed to play a crucial role in orchestrating the DNA sequence specificity of the intercalation process (41). The loss or epimerization of the 3′-amino moiety decreases, but does not destroy, DNA binding. In fact, the antitumor activity of these drugs is related more to the proper positioning and stabilization of the drug at its binding site than to the actual affinity of the drug for the DNA (41,42).

Even though DNA intercalation is required before the antineoplastic action of the anthracyclines can be realized, it alone does not kill the cell. Rather, the predominant cytotoxic effect is topoisomerase II inhibition. Anthracyclines bind to the DNA-enzyme complex in the area close to the DNA cleavage site. They stabilize a ternary cleavable complex that allows the DNA to be cut and covalently linked to topoisomerase Tyr residues but that does not permit the cleaved DNA to reseal. The aromatic portion of the anthracyclinone ring system and the daunosamine sugar bind to DNA, whereas the anthracyclinone A ring is believed to bind with the topoisomerase II enzyme (41). Removal of the 4-$OCH_3$ group found on all natural anthracycline anticancer products increases antitumor activity by facilitating the intercalation process and directing the binding of the dauosamine sugar in a way that stabilizes the ternary complex and promotes the cleavage (but not the resealing) of DNA (42). The daunosamine sugar is known to bind in the minor groove of DNA at the DNA-topoisomerase interface, but specific binding interactions between drug functional groups and topoisomerase residues have yet to be fully elucidated. Because a small



Copyrighted material

number of anthracycline-induced DNA breaks can result in a high level of cell death, it has been hypothesized that the site of DNA cleavage, which contains an essential T-A dinucleotide, is particularly lethal to the cell (43).

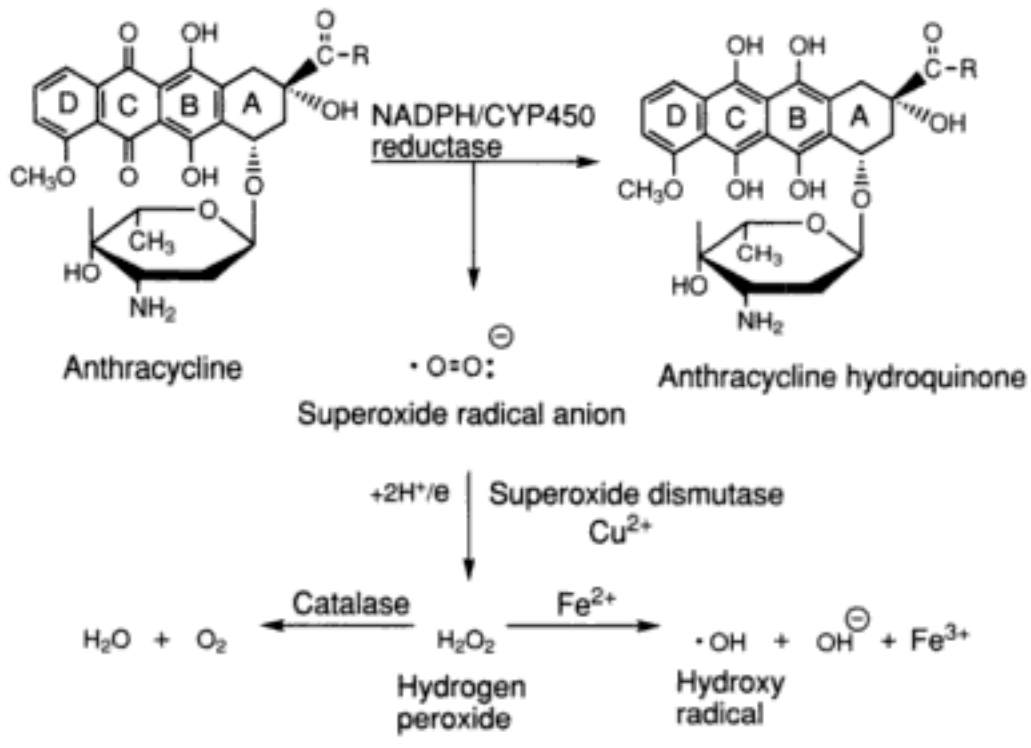
**MECHANISM OF CARDIOTOXICITY.** A very important mechanism of use-limiting anthracycline cardiotoxicity involves the formation of cytotoxic free radicals. A free radical is a highly reactive species with an unpaired electron. Of particular importance to the antineoplastic action of these drugs is the formation of the superoxide radical anion ($\cdot O_2^-$) and the hydroxyl radical ($\cdot OH$), both of which are formed via reduction of the anthracyclinone quinone (ring C) to hydroquinone by NADPH/CYP450 reductase. The mechanism by which cytotoxic free radicals are generated is shown in Figure 42.18.

When NADPH/CYP450 reductase reduces the quinone ring to a hydroquinone, superoxide radical anions ($\cdot O_2^-$) are generated. Superoxide radical anions react to generate hydrogen peroxide ($H_2O_2$), a reaction that requires protons and is catalyzed by the enzyme superoxide dismutase in a $Cu^{2+}$ mediated process. The fate of this hydrogen peroxide dictates the degree of cytotoxicity observed from the anthracycline.

In the presence of the enzyme catalase, hydrogen peroxide is rapidly converted to water and oxygen, which obviously are harmless chemicals as far as the body is concerned. In the presence of ferrous ion ($Fe^{2+}$), however, hydrogen peroxide is converted into the highly toxic hydroxyl radical through a process called the Fenton reaction. Hydroxyl radicals promote single-strand breaks in DNA, which is therapeutically desirable to treat the uncontrolled growth of cancer cells. Anthracycline anticancer agents also are known to interfere with normal ferritin-iron mobilization, resulting in iron accumulation (44). The anthracyclines chelate strongly with di- and trivalent cations, including intracellular $Fe^{2+}$, so the generation of cytotoxic hydroxyl radicals after the initial NADPH/CYP450 reductase reduction is essentially guaranteed. Hydroxide anion and ferric ion also are formed during the production of hydroxyl radicals.

Chelation of ferrous ion by anthracyclines

The generation of hydroxyl radicals inside the tumor cell might augment the antineoplastic effect of the anthracyclines, but such generation is uncommon at standard antineoplastic doses (43). These cytotoxic radicals are generated within the heart, however, leading to acute and often severe cardiotoxicity. Cardiac tissue is particularly vulnerable to free radical damage by the anthracyclines because it does not contain the catalase enzyme (45). When hydrogen peroxide forms in the myocardium, it has no choice but to go down the Fenton pathway. Cardiac toxicity is the major use-limiting side effect of anthracycline use, but coadministration of dexrazoxane (an antioxidant and iron chelator) has been shown to lower its incidence (46). A role for nitric oxide metabolism, particularly nitric oxide synthase, in anthracycline-mediated cardiotoxicity recently has been proposed (47). In the future, nitric oxide metabolic enzymes may be key targets for drugs that, when coadministered with anthracyclines, could lower the risk of cardiotoxicity.



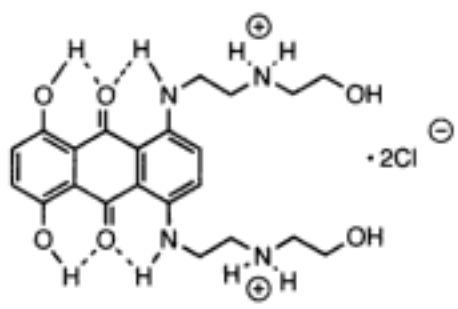


**Fig. 42.18.** Anthracycline-medicated free radical formation.

Copyrighted material

the blood 8 days after administration. Like other anthracyclines, excretion primarily is fecal, with a lesser dependence on renal elimination. Some authors have shown that idarubin is transported into cardiac tissue via a saturable transporter and that the coadministration of methylxanthines (e.g., caffeine) can increase both myocardial drug concentrations and the risk of idarubicin-induced cardiotoxicity (48).

***Mitoxantrone Hydrochloride.*** Chemically, mitoxantrone is classified as an anthracenedione (Fig. 42.17). The sugar moiety is missing, but the cationic side-chain amino nitrogens could bind to the anionic phosphate residue of the DNA backbone in the same fashion that the cationic L-daunosamine amino group of the true anthracyclines has been presumed to do. This molecule has the structural features needed to intercalate DNA and inhibit topoisomerase II, but the enhanced stability of the quinone ring (possibly through an increased potential for intramolecular hydrogen bonding) makes the ring highly resistant to NADPH/CYP450 reductase. This limits the formation of the superoxide radicals that are required for the generation of the highly toxic hydroxyl radical. In addition, there is no active cardiotoxic metabolite to induce chronic toxicity by disrupting the flow of myocardial cations. The chance of cardiovascular toxicity from mitoxantrone is significantly decreased, although patients who have been previously treated with anthracycline antineoplastics may still be at risk. It is thought that any observed myocardial toxicity may be operating through mechanisms other than the generation of cytotoxic radicals.

In addition, the risk of ulceration and necrosis on extravasation, as well as of nonmarrow-related toxicities such as nausea, vomiting, mucositis, and alopecia, is significantly less than observed with true anthracyclines. There is a significant risk of bone marrow suppression, however. The risk of myelosuppression increases with dose, but it can be observed even when low doses are used.

Mitoxantrone excretion primarily is biliary. Both the unchanged drug and inactive metabolites resulting from N-dealkylation, deamination, and oxidation of the resultant aldehyde to the carboxylic acid are observed. Both arms of the structure can be metabolized, leading to mono- or dicarboxylic acid metabolites (Fig. 42.20), which are excreted as the glucuronide conjugate. The conjugated metabolites are an intense, dark blue in color and will result in blue-green urine. The whites of the eyes and, in some cases, the skin also may take on a bluish cast.

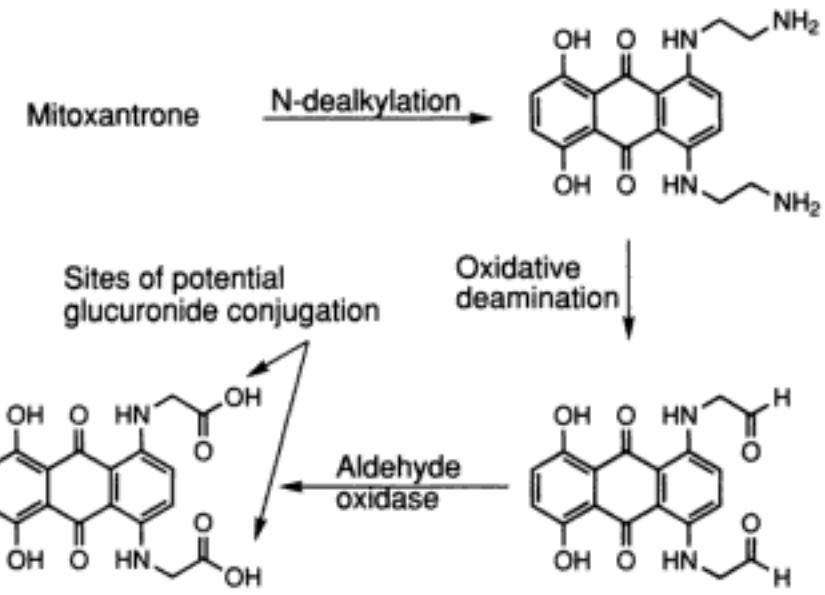

**Fig. 42.20.** Mitoxantrone metabolism.

Mitoxantrone is used in combination with other agents during the initial treatment of acute nonlymphocytic leukemia and hormone-refractory prostate cancer. Recent studies have shown that mitoxantrone also decreases the rate of relapse and disease progression in patients with multiple sclerosis (49). Although too toxic for use in patients with primary progressive disease, it is available for the treatment of chronic progressive, progressive relapsing, or deteriorating relapsing-remitting multiple sclerosis.

### Miscellaneous Antibiotics

**DACTINOMYCIN.** Dactinomycin (Fig. 42.17) has two pentapeptide lactones attached to an aromatic (and, therefore, flat) actinocin (or phenoxazinone) structure. It is capable of intercalating DNA and binds preferably between guanine and cytosine residues on a single DNA strand. This interaction results in DNA elongation and distortion, commonly referred to as a point mutation. When sliding between adjacent DNA base pairs, the actinocin orients itself perpendicular to the main DNA axis, allowing the pentapeptide lactone units to bind to residues in the minor groove of DNA through hydrophobic and hydrogen bonds. An affinity-enhancing bond between the threonine carbonyl oxygen and a protonated $C_2$-amino group of guanine also forms. Other hydrogen, hydrophobic, and van der Waals ($\pi$-stacking) interactions form between the lactone and DNA residues, particularly guanine and cytosine.

The binding of the actinocin and polypeptide lactone portions of dactinomycin to DNA is cooperative, meaning that the binding of one unit facilitates the binding of the other, most likely by promoting an optimal orientation. This significantly enhances drug-DNA affinity. The binding of dactinomycin to DNA, although noncovalent, is much stronger than that observed with the anthracyclines. Drug dissociation from DNA is slow, leading to a pseudoirreversible effect. As a result of very strong DNA binding interactions, topoisomerase II is inhibited, which results in nonrepairable double-strand breaks in DNA. Transcription and translation processes are blocked,

Copyrighted material

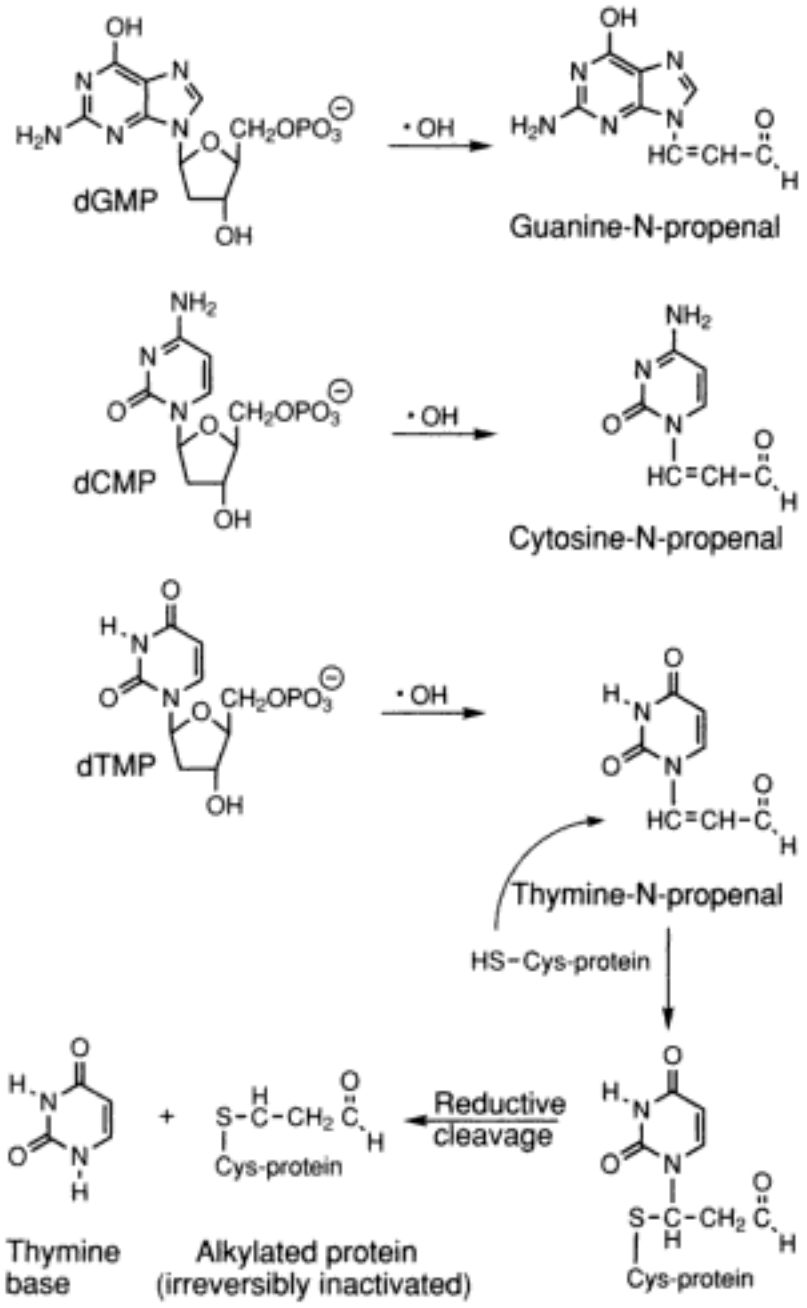

**Fig. 42.22.** Alkylation of Cys residues by hydroxyl radical–generated base propenals.

Bleomycin is a natural product isolated from *Streptomyces verticillus*. It normally is chelated with $Cu^{2+}$, which must be removed via catalytic reduction before marketing. This increases the cost of the drug, but it frees up the critical bleomycin functional groups for chelation with intracellular ferrous iron.

The action of bleomycin is terminated through the action of bleomycin hydrase, a cytosolic aminopeptidase that cleaves the terminal amide moiety to form the inactive carboxylate metabolite (Fig. 42.23). The metabolic replacement of the electron-withdrawing amide with an electron-donating carboxylate increases the $pK_a$ of the α-amino group, which normally interacts with DNA in the un-ionized conjugate form. After hydrolysis, the ratio of ionized to un-ionized forms of this critical amine increases approximately 126-fold, destroying DNA affinity and leading to the loss of therapeutic action. Drug destruction via the bleomycin hydrase pathway is rapid, and tumors will be resistant to bleomycin if they contain high concentrations of the enzyme. Conversely, tumors that are poor in bleomycin hydrase (e.g., squamous cell carcinoma) respond well to this agent.

Bleomycin hydrase is found in all tissues except skin and lung. Approximately 10% of patients who are administered bleomycin will experience potentially fatal pulmonary fibrosis, which can occur during therapy or several months following termination of therapy, often without warning. Some studies have shown that the copper-complexing agent tetrathiomolybdate can reduce the risk of bleomycin-induced fibrosis by inhibiting the action of copper-dependent inflammatory cytokines (53). Erythema and hypertrophic modifications in skin also are common side effects that manifest after 2 to 3 weeks of bleomycin therapy.

Bleomycin is used IV in the palliative treatment of squamous cell head and neck cancers, testicular and other genital carcinomas, and Hodgkin's and non-Hodgkin's lymphoma. It is excreted via the kidneys, and serum concentrations of active drug are increased in patients with renal disease. The elimination half-life can rise from 2 to 4 hours to more than 20 hours in renal failure, resulting in significant toxicity, especially pulmonary toxicity. Dosage adjustments are warranted. Unlike many antineoplastic agents, bleomycin does not suppress the bone marrow, and it often is given in combination with compounds that do, so that the dose of all

(leucovorin) must be initiated as soon as possible. Leucovorin generates the folate cofactors needed by DHFR and GAR transformylase to ensure the continued synthesis of pyrimidine and purine nucleotides in healthy cells. "Leucovorin rescue" therapy often is given as prophylaxis after high-dose methotrexate therapy.

5-Formyltetrahydrofolate
(Leucovorin)

***Pemetrexed.*** Pemetrexed (Fig. 42.25) is a novel multitarget antifolate used by the IV route for the treatment of advanced or metastatic nonsmall cell lung cancer and in combination with cisplatin in malignant pleural mesothelioma. Like methotrexate, it is actively transported into tumor cells through reduced folate carriers and, in polyglutamated form, inhibits the synthesis of pyrimidine and purine-based nucletotides by disrupting folate-dependent metabolic processes (63). In addition to DHFR, this pyrrolopyrimidine-based inhibitor binds tightly to thymidylate synthase and GAR transformylase (64,65). Patients on pemetrexed must take folate and vitamin $B_{12}$ supplements to reduce the risk of bone marrow suppression (neutropenia, thrombocytopenia, and anemia) and GI side effects. Pretreatment with corticosteroids can reduce the risk of drug-induced skin rash. Pemetrexed has a half-life of 3.5 hours and is excreted primarily unchanged via the kidneys. Significant cross-resistance has been noted between pemetrexed and other pyrimidine and folate antagonists (63).

### Purine Antagonists: Amidophosphoribosyl Transferase Inhibitors

**AMP AND GMP BIOSYNTHESIS.** The rate-limiting enzyme in the synthesis of purine nucleotides is amidophosphoribosyl transferase (also known as phosphoribosylpyrophosphate amido transferase), which is a major target for one of the two thiol-containing purine anticancer antimetabolites on the U.S. market.

The pathway outlining the normal synthesis of AMP and GMP is provided in Figure 42.31. It is important to recognize that the rate-limiting step is the first of the pathway; if that step is inhibited, no other step can proceed. Also, note that the rate-limiting transferase enzyme works on a phosphorylated ribose substrate. Because phosphorylated ribose is a component of every intermediate in the pathway, no enzyme in the sequence will function without its presence. Finally, note the reaction in the pathway catalyzed by GAR transformylase, which requires the methyl-donating 10-formyltetrahydrofolate. As previously mentioned, this step is inhibited by methotrexate.

**THIOPURINE METABOLISM.** The two currently marketed purine anticancer agents are both 6-thio analogues of the endogenous purine bases guanine and purine, also known as inosine (Fig. 42.25). They are prodrugs and must be converted to ribonucleotides by hypoxanthine guanine phosphoribosyl transferase (HGPRT) before they can exert their cytotoxic actions. Mercaptopurine, acting through a methylated ribonucleotide metabolite, inhibits the target amidophosphoribosyl transferase enzyme, leading to the true antimetabolic effect of lowered AMP and GMP biosynthesis (Fig. 42.32). A second mechanism of antineoplastic activity for mercaptopurine (and the predominant mechanism for thioguanine) involves the incorporation of di- and triphosphate deoxy- and ribonucleotides generated within the tumor cell into DNA and RNA, respectively (66). This illicit substitution further inhibits elongation of the strands and promotes apoptosis.

Thiopurines are metabolized by S-methylation via the polymorphic enzyme thiopurine methyl transferase (TPMT) with S-adenosylmethionine serving as cofactor. The methylated thiopurine bases cannot react with HGPRT and, therefore, cannot form the active false ribonucleotides. Drug manufacturers take this into account when establishing dosing regimens. The active false ribonucleotide 6-thioinosinic acid also is subject to extensive TPMT-catalyzed methylation. The S-methyl-6-thioinosinic acid metabolite is a potent inhibitor of the amidophosphoribosyl transferase enzyme and contributes to the cytotoxic action of the parent drug (Fig. 42.32). In contrast, little or no 6-methylthioguanylic acid is produced inside the cell (66,67).

Thiopurine methyl transferase is polymorphic in humans, and some individuals do not express this protein to any significant extent (68). Patients who are poor TPMT metabolizers (e.g., 10% of Caucasians, but also evident in other races) will not experience the activity-attenuating metabolic effect and will generate more active ribonucleotide per dose than patients with normal or excessive levels of the enzyme will. The TPMT genotype of patients should be assessed before initiating thiopurine therapy, because poor metabolizers are at a high risk of life-threatening myelosuppression from elevated levels of false ribonucleotides, even when standard doses are administered (67). In addition, the accumulation of mutagenic thiopurine-based ribonucleotides puts these patients at higher risk for secondary malignancies (66). Thiopurines can still be used in poor TPMT metabolizers, but the dose should be decreased significantly (e.g., 10- to 15-fold) and white blood cell counts monitored vigilantly.

Extensive TPMT metabolizers, who represent up to 90% of patients on thiopurine therapy, will form lower amounts of apoptotic 6-thiolated ribonucleotides. In the case of mercaptopurine, the molecules of ribonucleotide generated will be methylated very rapidly to the antimetabolic 6-methylthioinosinic acid, thus enhancing sensitivity to the drug (67). In contrast, extensive TPMT metabolizers show a decreased sensitivity to thioguanine,

Copyrighted material

deoxycytidine kinase, and cells with high levels of this enzyme should respond well to these agents. The $C_2$-halogen renders the molecules relatively resistant to the degradative action of adenosine deaminase, and a significant fraction of the dose is eliminated unchanged via the kidneys. Fludarabine, an arabinoside, actually is marketed as the monophosphate nucleotide to enhance water solubility for IV administration, but this group is cleaved rapidly in the bloodstream, allowing the free nucleoside to take advantage of the nucleoside-specific transporting proteins.

Cladribine is indicated in the treatment of hairy cell leukemia, whereas fludarabine phosphate is utilized in chronic lymphocytic leukemia. In addition to myelosuppression, fludarabine phosphate can induce hemolytic anemia, and severe CNS toxicity has been noted with high doses.

Clofarabine is used in acute lymphoblastic leukemia patients of 21 years or less who have failed with at least two previous regimens. In addition to inhibiting DNA chain elongation, this drug also inhibits ribonucleotide reductase and facilitates the release of proapoptotic proteins from mitochondria. The rapid attenuation of leukemia cells after administration of this agent can result in a condition known as tumor lysis syndrome, and respiratory and cardiac toxicities can occur secondary to cytokine release. Toxicity can progress to potentially fatal capillary leak syndrome and organ failure, and patients should receive IV fluids for the entire 5-day course of therapy to minimize risk of serious adverse events.

### Miscellaneous Antimetabolites

**PENTOSTATIN.** Pentostatin (Fig. 42.25) is a ring-expanded purine ribonucleoside that inhibits adenosine deaminase and is used in the treatment of hairy cell leukemia. The elevated levels of deoxyadenosine triphosphate that result from inhibition of this degradative enzyme inhibit the action of ribonucleotide reductase (the enzyme that converts ribose diphosphate to deoxyribose diphosphate), thus halting DNA synthesis within the tumor cell.

**HYDROXYUREA.** Hydroxyurea (Fig. 42.25) blocks the synthesis of DNA by trapping a tyrosyl free radical species at the catalytic site of ribonucleotide reductase, thereby inhibiting the enzyme that converts ribonucleotide diphosphates into their corresponding deoxyribonucleotides. It is used orally for the treatment of melanoma, metastatic or inoperable ovarian cancer, resistant chronic myelocytic leukemia, and as an adjunct to radiation in the treatment of squamous cell carcinoma and cancer of the head and neck. Hydroxyurea increases the effectiveness of radiation therapy through its selective toxicity to cells in the radiation-resistant S phase and by stalling the cell cycle in the $G_1$ stage, in which radiation therapy does the greatest damage. It addition, hydroxyurea thwarts the normal damage-repair mechanisms of surviving cells.

Hydroxyurea has excellent oral bioavailability (80–100%), and serum levels peak within 2 hours of consuming the capsules. If a positive response is noted within 6 weeks, toxicities generally are mild enough to permit long-term or indefinite therapy on either a daily or every-3-day basis. Leukopenia and, less commonly, thrombocytopenia and/or anemia are the most serious adverse effects. Excretion of the unchanged drug and the urea metabolite is via the kidneys. The carbon dioxide produced as a by-product of hydroxyurea metabolism is excreted in the expired air.

## Mitosis Inhibitors

The mitotic process depends on the structural and functional viability of microtubules (polymeric heterodimers consisting of isotypes of α- and β- tubulin proteins). These distinct but nearly identical 50-kDa proteins lie adjacent to one another within the tubule and "roll up" to form an open, pipe-like cylinder akin to a hollow peppermint candy stick. A γ-tubulin protein is found at the organizational center of the microtubule. The nature of the tubulin isotypes found in the microtubule are conserved throughout specific tissues within a given species and will impact the cell's sensitivity to mitosis inhibitors.

During cell division, tubulin undergoes intense, sporadic, and alternating periods of structural growth and erosion known as "dynamic instability." The proteins alternatively polymerize and depolymerize through guanosine triphosphate– and $Ca^{2+}$-dependent processes. Polymerization involves the addition of tubulin dimers to either end of the tubule, although the faster-growing (+)-end is more commonly involved. Polymerization results in tubular elongation, whereas depolymerization results in the shortening of the structure. The frenetic alteration in structure, facilitated by microtubule-associated proteins (MAPs), ultimately allows the formation of the mitotic spindle and the attachment to chromosomes that is a prerequisite to cell division. Inhibiting the essential hyperdynamic changes in microtubular structure results in mitotic arrest and apoptosis. Two classes of mitosis inhibitors currently are marketed for the treatment of cancer, taxanes, and vinca alkaloids.

### Taxanes

Anticancer taxanes initially were isolated from the bark of the Pacific yew (*Taxus brevifolia*) but are now produced semisynthetically from an inactive natural precursor found in the leaves of the European yew (*Taxus baccata*) a renewable resource. Taxanes bind to polymerized (elongated) β-tubulin at a specific receptor site located within the tubular lumen. At standard therapeutic doses (which should lead to intracellular concentrations of 1–20 μM), taxane-tubulin binding renders the microtubules resistant to depolymerization and prone to polymerization (69). This promotes the elongation phase of microtubule dynamic instability at the expense of the shortening phase, and it inhibits the disassembly of the tubule into the mitotic spindle. In turn, this interrupts the normal process of cell division. At these concentrations, extensive polymerization causes the formation of large and

Copyrighted material

mechanism. In addition to enhanced water solubility and a lack of P-glycoprotein affinity, epothilone is more efficiently produced through fermentation with the myxobacterium *Sorangium cellulosum* and has a higher antineoplastic potency (74,79,80).

### Specific drugs

***Paclitaxel.*** Paclitaxel (Fig. 42.35), which is claimed to be "the best-selling anticancer drug in history" (70), is indicated for IV use in combination with cisplatin as first-line therapy for advanced ovarian and nonsmall cell lung cancer. It also is used alone or in combination with the fluorouracil prodrug capecitabine in anthracycline-resistant metastatic breast cancer. Paxclitaxel's ability to upregulate thymidine phosphorylase, one of capecitabine's activating enzymes, is the rationale behind the combination therapy (81). Solution (Taxol, Onxol) and albumin-bound (Abraxane) formulations are available and cannot be used interchangeably. Abraxane also has been employed in various solid tumors of the GI and genitourinary tracts. Solution-based infusions generally are administered over 3 to 24 hours and can be passed through an in-line, 0.22-μm filter to reduce vehicle-related cloudiness. The albumin-bound form is given over 30 minutes and should be well-mixed (but not filtered) to ensure complete suspension of the protein–drug particles.

The major use-limiting adverse effect of paclitaxel is dose-dependent myelosuppression, particularly neutropenia, and first doses may need to be decreased in patients with hepatic dysfunction. Subsequent dose reductions, if any, should be tailored to individual response. The drug should not be given to patients who have baseline neutrophil counts below 1,500 cells/$mm^3$. The albumin-bound formulation also is associated with sensory neuropathy. As noted above, all patients receiving solution-based paclitaxel should be pretreated with antihistamines and a corticosteroid to minimize the risk of potentially fatal hypersensitivity reactions. Paclitaxel is a Category D teratogen and carries a high risk of fetal intrauterine mortality. Both male and female patients are advised not to attempt conception while on this drug. Due caution should be observed when coadministering paclitaxel with drugs that inhibit or compete for metabolizing enzymes, particularly CYP2C8 (e.g., 17α-ethinylestradiol and diazepam).

***Docetaxel.*** The indications for docetaxel (Fig. 42.35) generally mirror those of paclitaxel, although docetaxel is not used in ovarian cancer. It has greater water solubility than paclitaxel because of presence of the free $C_{10}$-OH group, and it is formulated with polysorbate 80 rather than with polyoxyethylated castor oil. Hypersensitivity reactions are still possible, and all patients should receive corticosteroid premedication. In addition to neutropenia and teratogenicity, this taxane can induce significant fluid retention, and 2-kg weight gains are not uncommon. Although rare, onycholysis also has been reported. Drug–drug interactions have been noted when docetaxel is coadministered with drugs that inhibit or compete for CYP3A4 enzymes (e.g., "azole" antifungals, erythromycin, and cyclosporine) (82).

### Vinca Alkaloids

Several alkaloids found naturally in *Catharanthus roseus* (periwinkle) have potent antimitotic activity. In opposition to the taxoids, vinca alkaloids halt cell division by inhibiting polymerization. They bind at the interface of two heterodimers within the inner tubular lumen at a single high-affinity site on the (+)-end of the tubules and attenuate the uptake of the guanosine triphosphate essential to tubule elongation (83). Simultaneous binding to α- and β-tubulin results in protein cross-linking, which promotes a stabilized protofilament structure (84). Inhibition of microtubule elongation occurs at "substoichiometric" concentrations, at which alkaloid occupation of only 1 to 2% of the total number of high-affinity sites can result in up to a 50% inhibition of microtubule assembly (85). At high concentrations, when alkaloid binding to high-affinity sites becomes stoichiometric and lower-affinity binding sites on the tubule wall also are occupied, microtubular depolymerization is stimulated, leading to the exposure of additional alkaloidal binding sites and resulting in dramatic changes in microtubular conformation. Spiral aggregates, protofilaments, and highly structured crystals form, and the mitotic spindle ultimately disintegrates (69,81). The loss of the directing mitotic spindle promotes chromosome "clumping" in unnatural shapes (balls and stars), leading to cell death (78). Other nonmitotic toxicities related to the microtubule-disrupting action of the vinca alkaloids include inhibition of axonal transport and secretory processes and disturbances in platelet structure and function (85).

**Chemistry.** The specific chemical nature of the vinca binding site remains elusive because of difficulties encountered in binding assay development and implementation as well as in data analysis. It is known that the active site is close to residue 339 and residue 390 on α- and β-tubulin, respectively (86). Of the three marketed vinca alkaloids (vincristine, vinblastine, and vinorelbine), vincristine binds most tightly, whereas vinblastine has the lowest affinity (85). Because vinca alkaloids enter cells by simple passive diffusion, unbound vinorelbine and vinblastine (being more lipophilic than vincristine) may be more extensively taken up into tissues. Vincristine, however, is cleared more slowly from the system and has the longest terminal half-life of the three agents, resulting in a more prolonged tumor cell exposure (69,85). Like the taxanes, tumor resistance to vinca alkaloids is mediated through P-glycoprotein.

The vinca alkaloids are complex structures composed of two polycyclic segments known as catharanthine (or velbanamine) and vindoline (Fig. 42.35), both of which are essential for high-affinity tubulin binding. The three commercially available anticancer alkaloids differ in the

Copyrighted material

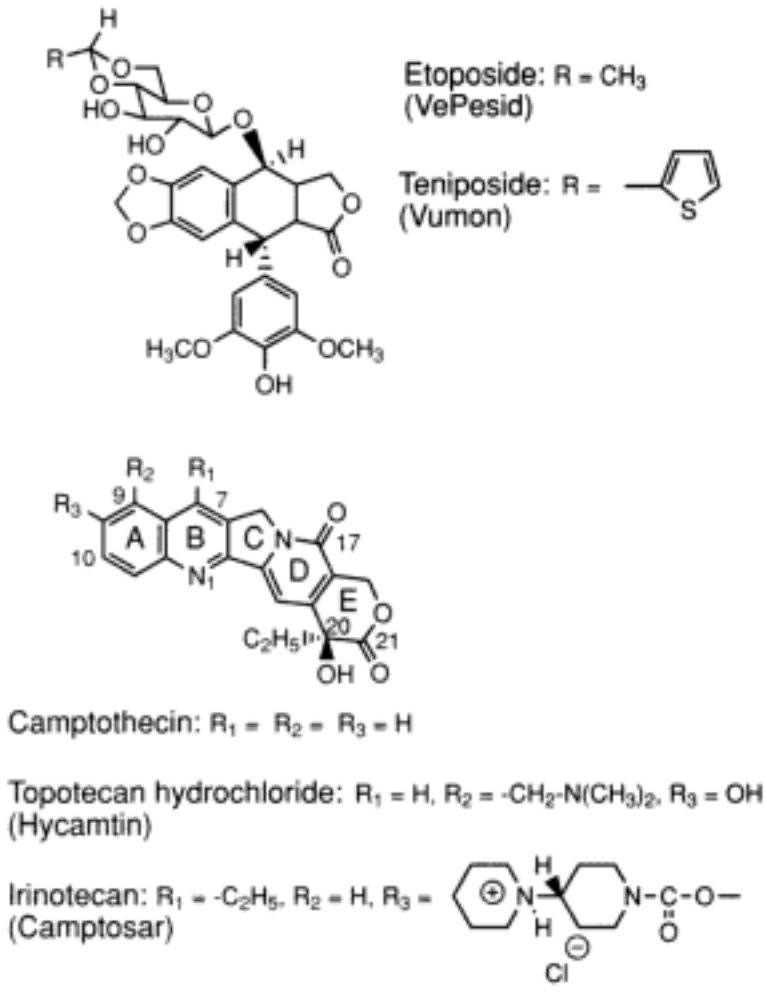

**Fig. 42.38.** Topoisomerase poisons.

with anthracyclines and dactinomycin (discussed with the antibiotic antineoplastics under *Antibiotics*). Topoisomerase IIα has two distinct DNA-independent binding sites for the epipodophyllotoxins, one within the catalytic domain and a second within the N-terminal ATP-binding domain (92). Once bound, the toxins stabilize the cleavable ternary drug-enzyme-DNA complex, stimulating DNA ligation but inhibiting resealing. The DNA-topoisomerase fragments accumulate in the cell, ultimately resulting in apoptosis. The RNA transcription processes also are disrupted by the interaction of epipodophyllotoxins with topoisomerase IIα (93).

Epipodophyllotoxins are cell-cycle specific and have their most devastating impact on cells in the S or early $G_2$ phase. For this reason, doses are divided and administered over several days. Resistance is multifaceted and involves down-regulation of topoisomerase IIα, attenuation of enzymatic activity levels, development of novel DNA repair mechanisms, and P-glycoprotein–mediated cellular efflux.

**CHEMISTRY.** Structurally, the two marketed epipodophyllotoxins, etoposide and teniposide, differ only in the nature of one β-D-glucopyranosyl substituent (methyl or thienyl, respectively). Both are highly water insoluble, but teniposide's higher lipophilicity facilitates cellular uptake and results in a 10-fold enhancement of potency (93). The need for solubility enhancers, such as polysorbate 80 (Tween, etoposide) or polyoxyethylated castor oil (Cremophor EL, teniposide), in IV formulations puts patients at risk for hypersensitivity reactions that can manifest as hypotension and thrombophlebitis. Epinephrine, antihistamines, and corticosteroids often are coadministered to minimize risk. A water-soluble phosphate ester analogue of etoposide can be administered in standard aqueous vehicles, permitting higher doses than the oil-modified formulations would allow. The phosphate ester is rapidly cleaved to the free alcohol in the blood.

**METABOLISM.** Epipodophyllotoxins are subject to metabolic transformation before renal and nonrenal elimination (Fig. 42.39). Etoposide is stable enough for oral administration, although a dose approximately twice that of the IV formulation must be administered. Teniposide is more extensively metabolized, presumably because of its enhanced ability to penetrate into hepatocytes, and no oral dosage form is marketed. Both drugs undergo lactone hydrolysis to generate the inactive hydroxy acid as the major metabolite, but the parent drugs also can be transformed by CYP3A4-catalyzed O-demethylation and Phase II glucuronide or sulfate conjugation. Phase II metabolism accounts for between 5 to 22% of the dose. Clinically significant interactions between epipodophyllotoxins and CYP3A4 inducers, such as phenytoin, phenobarbital, and St. John's wort, have been documented, and coadministration can enhance antineoplastic drug clearance by as much as

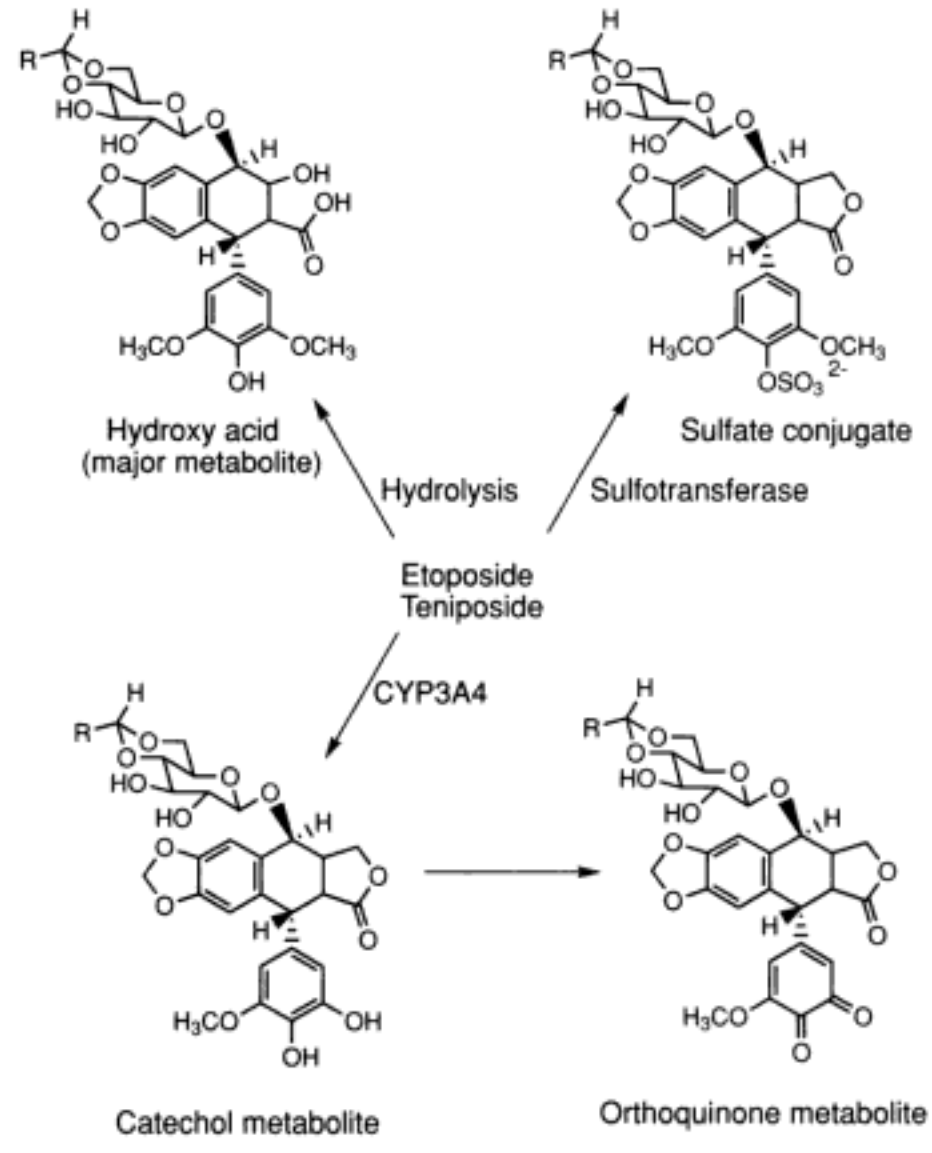

**Fig. 42.39.** Epipodophyllotoxin metabolism.

Copyrighted material

77%. Conversely, CYP3A4 inhibitors, such as cyclosporine or macrolide antibiotics, can decrease clearance, leading to unwanted toxicity.

The catechol metabolite can oxidize to a reactive orthoquinone, and both have been proposed to promote topoisomerase-mediated DNA cleavage, potentially enhancing the risk of the translocations that result in therapy-induced acute myeloid leukemia in children treated with these drugs. Epipodophyllotoxin-induced leukemia occurs in 2 to 12% of patients and is believed to result from translocation of the *MLL* gene at chromosome band 11q23. The mean latency period of 2 years is shorter than the 5- to 7-year latency for leukemia induced by DNA alkylators, and the drug-induced cancer often is resistant to standard treatment (including bone marrow transplantation) (94). Other serious adverse effects include dose-limiting mucositis and myelosuppression, particularly leukopenia. Alopecia is common, and nausea and vomiting, most noticeable with the oral dosage form, generally are mild.

#### SPECIFIC DRUGS

***Etoposide.*** Etoposide (Fig. 42.38) is utilized in the treatment of small cell lung cancer and in combination with other agents in refractory testicular cancer. Both IV and oral formulations are available. Oral bioavailability is concentration dependent and runs approximately 50% for the 50-mg capsule. Little first-pass metabolism is noted with the gelatin capsule dosage form. The drug is more than 96% protein bound, undergoes biphasic elimination, and has a terminal half-life of 4 to 11 hours. Approximately 35 to 45% of a dose is eliminated via the kidneys, with less than 6% excreted in feces. The drug should be used with caution in patients with renal or liver disease. Specifically, doses should be decreased in patients with creatinine clearance of less than 50 mL/min or bilirubin levels of greater than 1.5 mg/dL, and the drug should not be used in patients with bilirubin levels of greater than 3.1 mg/dL. Organoplatinum anticancer agents (e.g., cisplatin) decrease etoposide clearance, especially in children. If used in combination, administration must be separated by at least 2 days.

***Teniposide.*** Teniposide (Fig. 42.38) is used in combination with other agents for the treatment of refractory childhood acute lymphoblastic leukemia. Compared to etoposide, it is more tightly protein bound (>99%), more extensively metabolized, more slowly cleared (terminal half-life, 5–40 hours), and less dependent on renal elimination (10–21%). Exposure to heparin can cause teniposide to precipitate, so lines must be thoroughly flushed before and after teniposide administration. The drug also can spontaneously precipitate, particularly if solutions are overagitated, and patients receiving 24-hour infusions should be monitored for blockage of access catheters. Teniposide and etoposide are Category D teratogens and, if at all possible, should not be used in women of childbearing years.

### Camptothecins

**MECHANISM OF ACTION.** Camptothecins are chiral, extensively conjugated, amine-containing pentacyclic lactones (Fig. 42.38). The biological target of camptothecins is topoisomerase I (rather than the topoisomerase II enzyme that serves as the receptor for the anthracyclines, dactinomycin and epipodophyllotoxins), but the mechanism of antineoplastic action is qualitatively similar (stabilization of a cleavable ternary DNA-enzyme complex that does not permit the resealing of nicked DNA). Although the fragmented DNA is capable of resealing in the absence of drug, when DNA replication forks encounter the fragmented DNA, a double-stranded DNA break occurs, killing the cell.

The binding of camptothecins occurs in such a way as to stabilize a covalent DNA-topoisomerase bond at the point of single-strand breakage ($Tyr^{723}$ on the human enzyme). The binding pocket, located within the DNA strand, is revealed only after the normal DNA nicking has occurred, explaining why these poisons preferentially bind to the enzyme-DNA complex rather than to unoccupied DNA or enzyme. The flat camptothecin ring system intercalates DNA at the site of cleavage, mimicking a DNA base pair (95). The crystal structures of human ternary complexes involving the parent camptothecin alkaloid, camptothecin, and the semisynthetic analogue, topotecan (Fig. 42.38), have been solved, and important drug–protein interacting entities are noted in Table 42.8 (95,96). The bulky substituents at $C_7$, $C_9$, and $C_{10}$ of the marketed compounds, which project into the major groove of DNA, do not hinder binding.

Camptothecins are most potent in cells undergoing active DNA replication and cell division (e.g., they are S-phase specific). Mechanisms of resistance are similar to those discussed for other drugs and include down-regulation or mutation of the target enzyme, down-regulation of enzymes needed for drug activation, and cellular efflux. Breast cancer resistance protein and multidrug resistance (MDR)-associated proteins, such as MAP-2 and MAP-3, rather than P-glycoprotein, appear to mediate resistance to these agents (78,93).

**CHEMISTRY.** The parent camptothecin alkaloid, isolated from bark of *Camptotheca acuminate*, has antitumor activity, but its limited water solubility necessitated delivery as

Table 42.8. Topotecan–Topoisomerase I Interactions (95,96)

| Topotecan Functional Group | Topoisomerase I Residue |
|---|---|
| Pyridine $N_1$ | $Arg^{364}$ |
| $C_{10}$-OH | Enzyme associated water (H-bond) |
| $C_{17}$-pyridone carbonyl | $Asn^{722}$ |

| $C_{21}$-lactone carbonyl | $Tyr^{723}$-phosphate, $Lys^{532}$ |

Copyrighted material

the sodium salt of the significantly less active hydrolyzed lactone. Lactonization of the hydroxy acid in acidic urine was significant, and elevated levels of active intact alkaloid in the kidney accounted for the hemorrhagic cystitis induced by this compound. Currently marketed analogues have a basic side chain incorporated at either $C_9$ (tocotecan) or $C_{10}$ (irinotecan), allowing the formation of water-soluble salts of the intact semisynthetic alkaloid. At pH 7.4, the active lactone exists in equilibrium with the hydroxy acid hydrolysis product, with the direction dictated by the extent of binding to serum albumin. The preferential protein binding of the lactone, which occurs with irinotecan, shifts the equilibrium to favor the production of the more active lactone, thus enhancing potency.

### SPECIFIC DRUGS

***Irinotecan Hydrochloride.*** In combination with fluorouracil, this prodrug camptothecin (Fig. 42.38) analogue is considered to be first-line therapy in the treatment of metastatic colorectal cancer. It also has shown efficacy in small cell and nonsmall cell lung cancers when used in combination with cisplatin. Given IV, the drug is slowly bioactivated in the liver through hydrolysis of the $C_{10}$-carbamate ester. The catalyzing enzyme is a saturable carboxylesterase known as irinotecan-converting enzyme. Levels of active metabolite, known as SN-38 (Fig. 42.40), are 50- to 100-fold lower than the parent drug, but preferential protein binding of the lactone (95%) permits significant plasma levels of the optimally active SN-38 compared to the hydroxy acid metabolite. SN-38 has a terminal half-life of 11.5 hours (compared to 5.0–9.6 hours for the prodrug parent) and is glucuronidated at the $C_{10}$ phenol before elimination. CYP3A4 also cleaves the terminal piperidine ring through oxidation at the α-carbons, followed by hydrolysis of the resultant amides, producing inactive metabolites. Excretion of the parent drug and metabolites is renal (14–37%) and, to a lesser extent, biliary.

Delayed diarrhea induced by irinotecan is dose-limiting and potentially fatal, and vigorous loperamide therapy should be instituted at the first sign of symptoms. Acute diarrhea is attributed to the drug's ability to inhibit acetylcholinesterase and can be addressed through anticholinergic pretreatment. Pretreatment also helps patients to avoid "cholinergic syndrome," a collection of annoying side effects that include flushing, sweating, blurred vision, lacrimation, and less commonly, bradycardia. Camptothecins also are myelosuppressive, and neutropenia can be severe, particularly in patients with elevated bilirubin levels. Extensive biotransformation also demands cautious use of irinotecan in patients with hepatic dysfunction. Prophylactic antiemetic therapy should be given at least 30 minutes before the administration of irinotecan to minimize the nausea and vomiting associated with this anticancer agent.

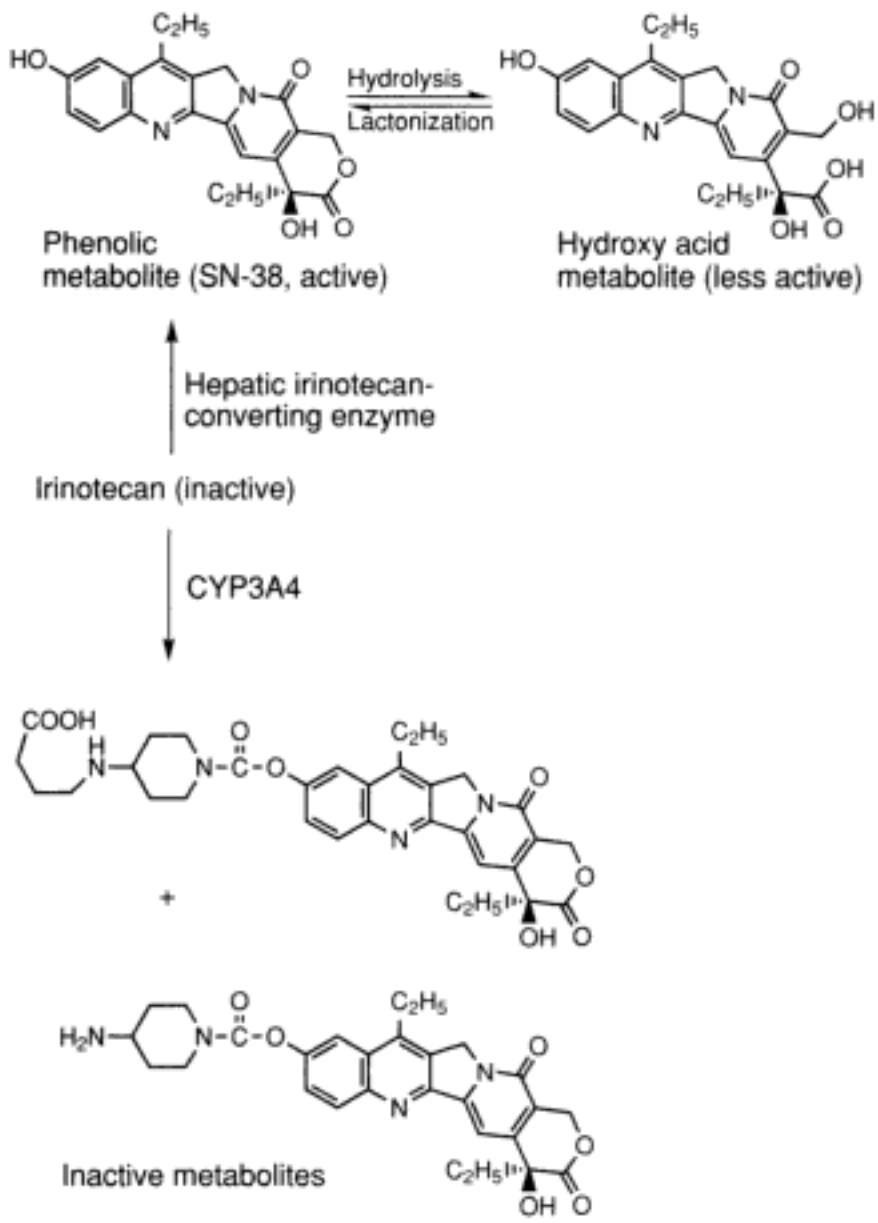

**Fig. 42.40.** Irinotecan metabolism.

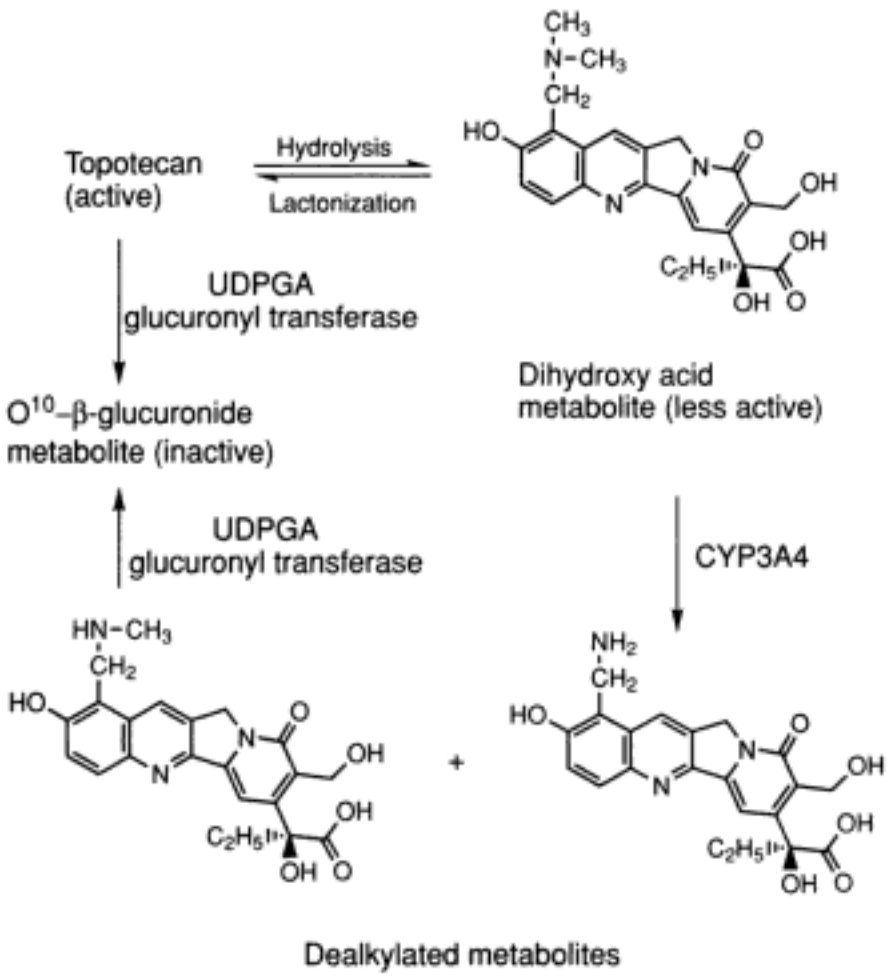
***Topotecan Hydrochloride.*** This active camptothecin analogue (Fig. 42.38) is used by the IV route in the treatment of ovarian and small cell lung cancer that has not responded to first-line therapy. Myelosuppression, particularly neutropenia, is use-limiting and has precluded combination therapy with other bone marrow-suppressing drugs. Thrombocytopenia and anemia occur in approximately one-third of treated patients. Schedules that call for daily (for 5 days) administration also can result in serious mucositis and diarrhea.

Topotecan elimination is biphasic, with a terminal half-life of 2.0 to 3.5 hours. Lactone hydrolysis is rapid, and binding to serum proteins is limited to between 25 and 40%. CYP3A4-mediated N-dealkylation to mono- and didealkylated metabolites occurs to a limited extent, and the O-glucuronides that form at multiple points along the metabolic path are excreted via the kidney (Fig. 42.41). Extensive renal clearance demands dosage adjustment in patients with kidney disease.

Because both topotecan and irinotecan are metabolized by CYP3A4, the potential for drug–drug interactions must be evaluated. Reduced clearance was noted when azole antifungal agents and cyclosporine were coadministered with irinotecan, and accelerated clearance

Copyrighted material



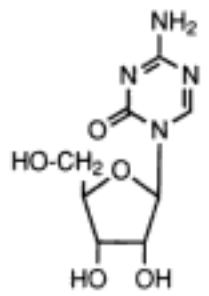


**Fig. 42.41.** Topotecan metabolism.

was observed when topotecan was coadministered with CYP3A4 inducers, such as phenobarbital and phenytoin.

## Miscellaneous Anticancer Agents: DNA Demethylators

Azacitidine
(Vidaza)

### Azacitidine

In contrast to the DNA alkylating agents discussed earlier in this chapter, one nucleic acid–based chemotherapeutic agent, azacitidine, blocks abnormal cellular proliferation by dealkylating (specifically demethylating) DNA residues on genes responsible for differentiation and growth. The hypomethylation effect sometimes can restore normal gene function while selectively killing cells that have stopped responding to the body's cellular proliferation control processes. Azacitidine is given subcutaneously for the treatment of myelodysplastic syndrome, and serum levels generally are maximized within 30 minutes. The parent drug and its metabolites are excreted in the urine. Azacitidine is carcinogenic and teratogenic in rodents, and leukopenia, thrombocytopenia, and neutropenia are the most common reasons for drug discontinuation or dosage reduction.

## Other Chemotherapeutic Approaches

### Hormone Therapy

Glucocorticoids (e.g., prednisone and methylprednisolone) commonly are administered with anticancer agents to suppress lymphocytic activity and to enhance the chance of success in the treatment of leukemias and lymphomas. In addition, some tumors, such as estrogen-dependent breast cancer, endometrial cancer, and metastatic cancer of the prostate, depend on the presence of sex hormones for viability. In these neoplastic diseases, the use of steroid receptor antagonists, synthesis inhibitors, or gonadotropin secretion inhibitors, either alone or in combination with other antineoplastic drugs, is a common approach to chemotherapeutic care. Antiestrogens (e.g., tamoxifen), antiandrogens (e.g., flutamide), progestins (e.g., megestrol acetate), aromatase inhibitors (e.g., exemestane), and luteinizing hormone–releasing hormone agonists (e.g., leuprolide acetate) are all available for use in managing hormone-dependent tumors and often are employed after surgery, radiation therapy, and/or other chemotherapy. (Readers are referred to Chapters 45 and 46 for a more detailed discussion of the hormone agonists and antagonists currently used in the treatment of cancer.)

### Enzyme Therapy

Exogenous asparagine is essential to the survival of malignant lymphocytic leukemia cells, because these cells lack asparagine synthetase enzymes. L-Asparaginase (also known as L-asparagine amidohydrolase) or its derivatives can be added to the chemotherapeutic regimen of patients with leukemia to deplete serum asparagine by hydrolysis to aspartate and ammonia. Being deprived of this avenue for asparagine acquisition, tumor cells die from an inability to synthesize essential proteins. Normal cells, which contain asparagine synthetase, are able to synthesize this essential nutrient and can withstand therapy.

### Biological Response Modifiers

Several human or recombinant antiproliferative proteins are currently in use for the treatment of cancer. Interleukin-2, interferons, BCG vaccine, tyrosine kinase, epidermal growth factor, proteasome inhibitors, and several monoclonal antibodies directed against tumor cell antigens now augment the cancer chemotherapeutic arsenal. (Readers are directed to Chapter 5 for a more in-depth discussion of the peptides and proteins available for the treatment of neoplastic disease.)

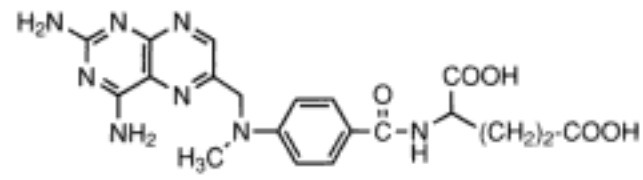
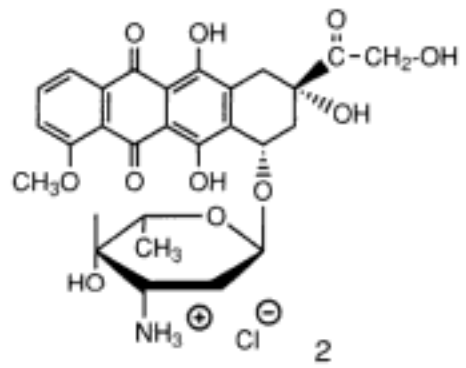
## CASE STUDY

***Victoria F. Roche and S. William Zito***



PR is a 37-year-old Portuguese man who survived Wilms' tumor during his childhood. Unfortunately, the chemotherapy used to treat his neoplasm induced a delayed and drug-resistant cardiomyopathy that ultimately resulted in a successful heart transplant when he was 25. Although he was managing fairly well, PR was recently dealt another health-related blow with a diagnosis of bladder cancer. The cancer was discovered last week and, although aggressive, appears to still be localized to the bladder. He is deemed not to be a candidate for surgery.

PR's current pharmacotherapy includes cyclosporine (an immunosuppressant that is metabolized predominantly by, and also inhibits, CYP3A4) and low-dose prednisone. In addition to the organoplatinum complex cisplatin, his oncologist wants to construct a chemotherapeutic regimen that combines an antimetabolite, a topoisomerase II inhibitor, and a mitosis inhibitor. Review the structure–activity relationships of the following five antineoplastic structures in preparation for your recommendation.



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient, and advise the physician.

  - Nelfinavar
  - Ritonavir
  - Saquinavir
  - Tipraqnavir

## INTRODUCTION

Viruses are the smallest of the human infectious agents, ranging in size from approximately by 20 to 300 nm in diameter (1,2). They contain one kind of nucleic acid, either RNA or DNA, as their entire genome, which codes for a variety of enzymes and other proteins used in replication and transmission of the organism. It can be argued that a virus does not qualify as a true life form, because it is nothing more than a nucleic acid strand with associated proteins and cannot move under its own power. When it attaches itself to a host cell, however, it internalizes itself and forces the host to make additional copies of the virus, demonstrating a clear reproductive plan. During replication, it utilizes host cellular biochemicals and processes and, thus, in a sense, takes in "nutrients" to survive and multiply. In some cases, viruses respond to external conditions and escape the immune response by integrating into the host DNA, demonstrating the ability to respond to external stimuli. Although viruses are simple organisms, they are a significant causative agent for numerous human diseases and, as such, represent one of the major challenges in the area of drug discovery. Agents that are used clinically for a variety of viral diseases act by targeting processes that are specific to the virus, such as a unique viral enzyme, or a necessary process, such as transcription. To date, however, no drug has been discovered that is truly curative for viral infection. In addition, because viruses have the ability to undergo mutations, resistance to existing therapies can develop. The discovery of new antiviral agents is thus an important ongoing effort in medicinal chemistry.

## VIRUS STRUCTURE AND CLASSIFICATION (1,2)

Numerous species of virus that infect bacteria, plants, and animals have been identified, and they exhibit a remarkable range of diversity. All viruses exist as obligate cellular parasites, and as such, they do not need to possess the complex biochemical machinery that is characteristic of higher organisms. They do, however, have a defined macromolecular structure that is designed to protect them from the environment and to facilitate their entry into cells. The basic subunit of a virus is its genome, which can be made up of either DNA or RNA. The nucleic acid portion of a virus can be single or double stranded and may be present in linear or circular form. Viral genomic DNA or RNA often is associated with basic nucleoproteins and may be surrounded by a symmetrical protein known as a capsid. The capsid is made up of repeating structural units known as protomers, which themselves are made up of nonidentical protein subunits. The combination of the nucleic acid core and the capsid is called the nucleocapsid, and in some cases, this comprises the entire virus. In other cases, the nucleocapsid structure is surrounded by a lipid-containing membrane that is derived during viral maturation, when the virus undergoes budding through the host cell membrane. The complete viral particle, with

## CLINICAL SIGNIFICANCE

Antiviral agents include diverse compounds with varied actions. A thorough clinical understanding about most of these compounds is dependent on a basic appreciation of biochemistry and medicinal chemistry. Viruses are mainly composed of either RNA or DNA nucleic acid strands. As such, one of the most ideal targets for treating viral pathogens has been the inhibition of viral replication. Successful viral replication is dependent on enzyme-mediated transcription of viral RNA or DNA. A significant number of antiviral agents, including HIV nucleoside reverse transcriptase inhibitors and a majority of antiherpes agents, are designed to be "false" substrates of viral transcription enzymes. It is through competitive inhibition that these agents are able to fulfill their intended effect. Their chemical structures are similar to naturally occurring substrate nucleoside purines (adenosine and guanosine) and pyrimidines (thymidine and cytidine). Their incorporation, however, will lead to termination of replication. These nucleoside antiviral agents typically require triphosphorylation to become active intracellularly. It is important to recognize that resistance to these antiviral medications can develop when genetic mutations alter the ability of viral enzymes to phosphorylate the drugs. Drugs like cidofovir and tenofovir are nucleotide analogues, which means they are already monophosphorylated. As a result, these agents can maintain activity against viruses that have developed resistance to other nucleoside agents through certain resistant mutations.

In clinical practice, HIV antiretroviral regimens usually require a pair of nucleoside reverse transcriptase inhibitors in the regimen. It is of paramount importance that combinations of "like" nucleosides analogues (i.e., two thymidines, two cytosines, etc.) are not used together, because they have displayed antagonism and reduced viral load suppression. Nonnucleoside reverse transcriptase inhibitors are not structurally related to nucleic purines and pyrimidines; therefore, they do not act as substrates of the target enzyme.

Protease inhibitors, which are the most potent antiretroviral agents currently available, were the end result of coordinated chemical design and structure-based computational analysis of the protease enzyme. With identification of the protease crystalline structure and identification of active binding sites, scientists were able to create compounds that would fit the protease enzyme with strong affinity and cause an inhibition of protease function. The clinical impact of these man-made drugs is regarded by many as being the greatest single advance in the treatment of HIV infection.

or without an envelope, is called the virion. Viral architecture can be grouped into three types based on the arrangement of morphologic subunits, and each virus exhibits cubic (icosahedral) symmetry, helical symmetry, or a complex structure. Icosahedral virions are symmetrical structures that contain 20 surfaces, each of which is an equilateral triangle. A sufficient number of capsid structural units must be employed in the icosahedron to make a capsid large enough to encapsulate the viral genome. Morphologic units called capsomeres are seen on the surface of icosahedral viral particles. These structures are clusters of polypeptides, but they do not necessarily correspond to the chemically defined structural units. Some viruses arrange their structural subunits into a standard helical formation. In viruses with helical symmetry, protein subunits systematically bind to the viral nucleic acid, ultimately forming a nucleocapsid helix. The filamentous nucleocapsid is then coiled inside a lipid-containing envelope. Unlike icosahedral virions, the regular, periodic interaction between capsid protein and viral nucleic acid prevents the formation of "empty" helical particles. Finally, some viral particles, such as the large and complex poxviruses, do not exhibit cubic or helical symmetry but, instead, form more complicated structures that can be spherical, brick-shaped, or ovoid. A subset of complex viruses are called pleomorphic viruses, in that they assume multiple, complex morphologies.

Viral taxonomy is complex, and viruses are classified according to a number of factors, including morphology, properties of the genome (i.e., DNA versus RNA, single strand versus double strand, linear or circular, and sense or antisense), physicochemical properties, structure of associated proteins, replication strategy, and so on. Viruses are separated into major groups called families, with names that end in the suffix -viridae, and then into genera that end in -virus. Thus, poxviruses are in the family Poxviridae and in the genus *Poxvirus*. A comparison of the genetic and structural features of viral families with members that can infect humans appears in Table 43.1.

## VIRAL REPLICATION, CELLULAR EFFECTS, AND PATHOGENESIS (2,3)

As mentioned above, all viruses exist as obligate intracellular parasites, and as such, they rely on the cellular machinery of the host for their growth, development, and replication. To synthesize the proteins needed for viral replication, the organism must be capable of producing usable mRNA in sufficient quantities to compete with host mRNA for protein synthesis. During viral replication, all of the macromolecules required by the virus are synthesized in a highly organized sequence. The replication cycle (Fig. 43.1) begins when the intact virion binds to a host cell through electrostatic adsorption to a specific "receptor"

## Table 43.1. Characteristics of Virus Families Containing Members that Infect Humans

| Family | Examples | Genome | Capsid Symmetry | Size ($nm^{-1}$) | Envelope | Diseases |
|---|---|---|---|---|---|---|
| Parvoviridae | Parvovirus B19 | ssDNA, sense or antisense | Icosa | 18–26 | No | Erythema infectiosum (fifth disease); polyarthralgia arthritis; aplastic crisis, anemia |
| Papillomaviridae | Human papilloma (wart)virus; polyoma virus; SV 40 | dsDNA, circular DNA | Icosa | 55 | No | Warts; salivary gland infection; multifocal leukoencephalopathy; tumors |
| Adenoviridae | Multiple types (40 adenoviruses/ mastadenovirus) | dsDNA | Icosa | 70–90 | No | Infections of the eye and respiratory tract; tumors |
| Hepadnaviridae | Hepadnavirus, hepatitis B virus | dsDNA, circular, one ss region | Icosa | 40–48 | Yes | Hepatitis B; tumors |
| Herpesviridae | Herpes simplex I and II; varicella-zoster; herpes zoster; cytomegalovirus; Epstein-Barr virus | dsDNA | Icosa | 150–200 | Yes | Eye, skin, and genital infection; chickenpox; shingles; mononucleosis; tumors |
| Poxviridae | Variola; vaccinia | dsDNA | Comp | 230–400 | Complex | Smallpox; cowpox; chickenpox; tumors |
| Picornaviridae | Hepatitis A virus; poliovirus; enterovirus; rhinovirus, coxsackie virus A and B | ssRNA, sense | Icosa | 28–30 | No | Respiratory diseases; gastrointestinal diseases; polio; aseptic meningitis |
| Astroviridae | Astrovirus | ssRNA, sense | Icosa | 28–30 | No | Diarrhea in infants and immunocompromised patients |
| Caliciviridae | Norwalk virus | ssRNA, sense | Icosa | 27–40 | No | Epidemic gastroenteritis |
| Togaviridae | Rubella virus; alphavirus, arbovirus | ssRNA, sense | Icosa | 50–70 | Yes | Measles (rubella) |
| Flaviviridae | Hepatitis C virus; arbovirus; yellow fever virus; dengue virus; West Nile virus | ssRNA, sense | Comp | 40–60 | Yes | Hepatitis C; yellow fever; dengue fever; encephalitis; tumors |
| Coronaviridae | Coronavirus | ssRNA, sense | Comp | 120–160 | Yes | Colds; gastroenteritis in infants; SARS |
| Retroviridae | HIV-I and -II; lentavirus; human T-cell lymphotropic viruses | ssRNA as dimer | Comp | 80–100 | Yes | AIDS; AIDS-related complex; breast cancer; human T-cell leukemia; nasopharyngeal carcinoma |
| Arenaviridae | Arenavirus | ssRNA, antisense | Comp | 50–300 | Yes | Lassa fever; hemorrhagic fever; choriomeningitis |
| Orthomyxoviridae | Influenza virus A, B, and C | ss RNA, antisense | Hel | 80–120 | Yes | Influenza |
| Bunyaviridae | Hantavirus | ssRNA, antisense | Hel | 80–120 | Yes | Hemorrhagic fever |
| Rhabdoviridae | Rhabdovirus; rabies virus; encephalitis virus | ssRNA, antisense | Hel | 75–180 | Yes | Rabies; encephalitis |
| Paramyxoviridae | Syncytial virus; parainfluenza virus | ssRNA, antisense | Hel | 150–300 | Yes | Mumps; measles (rubeola) |
| Filoviridae | Marburg virus; Ebola virus | ssRNA, antisense | Hel | 80–800 | Yes | Marburg viral fever; Ebola hemorrhagic fever |

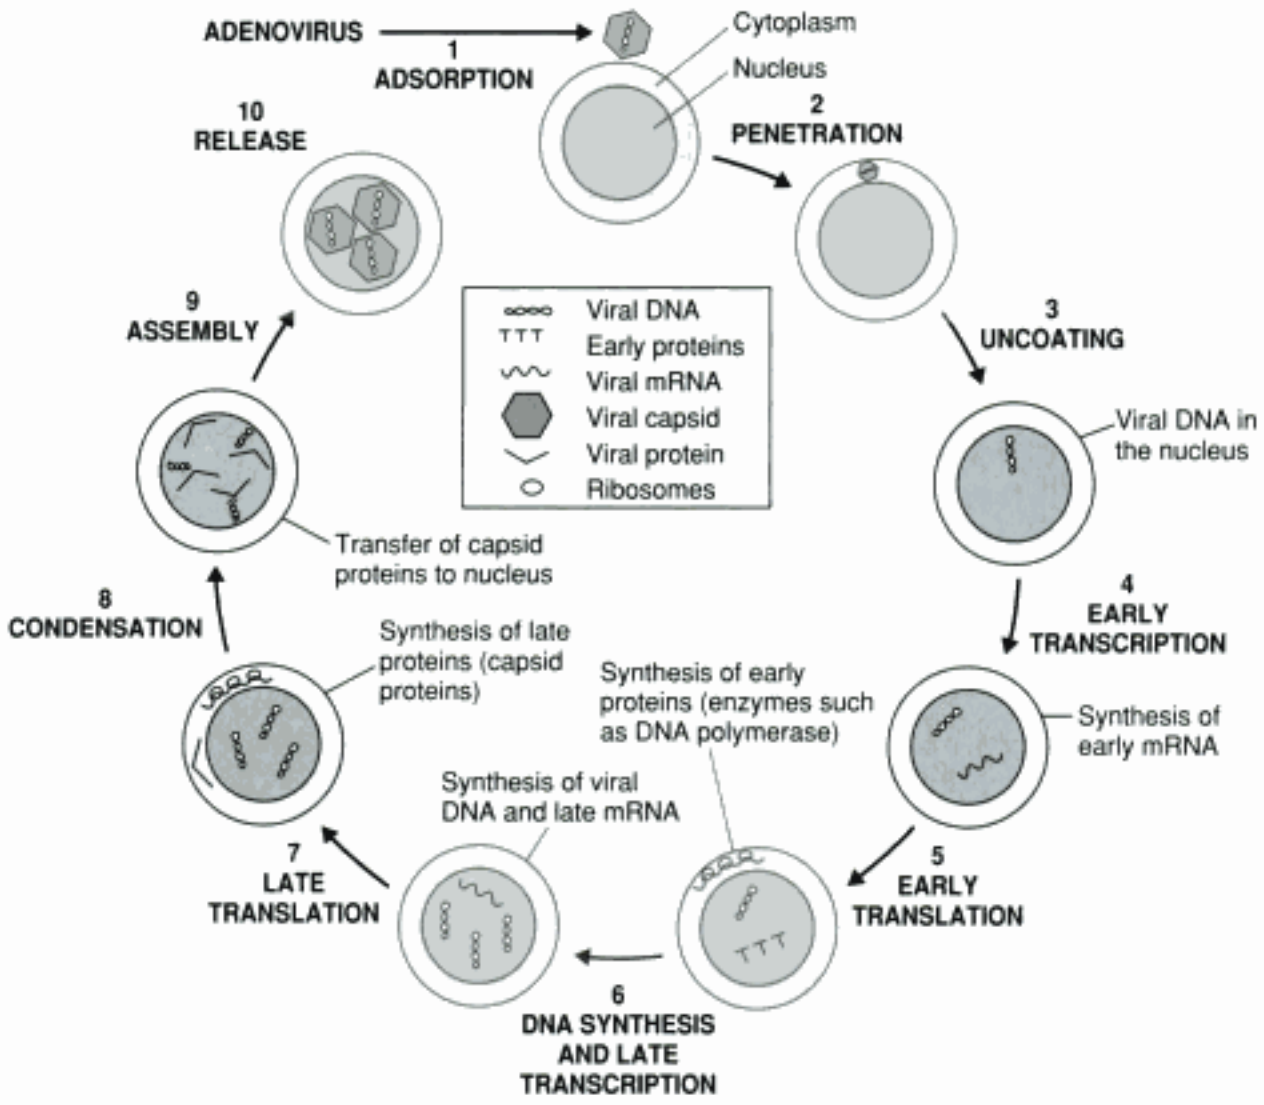

**Fig. 43.1.** Steps involved in the viral life cycle. (Adapted from Brooks GF, Butel JS, Morse SA, et al. Jawetz, Melnick, and Adelberg's Medical Microbiology. 23rd Ed. New York: McGraw-Hill, 2004; with permission. Copyright 2004 The McGraw-Hill Companies, Inc.)

site. This process is known as the attachment phase. Attachment is most likely a fortuitous event resulting from structural complementarity between the exterior structure of the virion and a normal cell surface structure on the host cell. For example, HIV binds to the CD4 receptor on cells of the immune system, rhinoviruses bind ICAM-1, and Epstein-Barr virus (EBV) recognizes the CD21 receptor on B cells. When attachment has been achieved, the virion enters the penetration phase, the process by which it gains entry into the host cell. Penetration may occur by receptor-mediated endocytosis, fusion of the viral envelope with the cell membrane, or in some cases, direct penetration of the membrane. Following penetration of the cell, viruses must be uncoated, resulting in either the naked nucleic acid or the nucleocapsid form, which usually contains polymerase enzymes. After they have been uncoated, viruses are no longer infectious.

Once the virus has penetrated the cell and uncoated, it enters a segment of its life cycle known as the eclipse period, the length of which varies with the type of virus. During this time, the virus utilizes host resources to replicate and produce necessary viral proteins. Cells that can support viral reproduction are called permissive. As a result, the infection is known as a productive infection, because it results in new viral particles. When new infectious viral particles are produced, host cellular metabolism may be completely directed toward the production of viral products, resulting in destruction of the cell. In other cases, host cell metabolism is not dramatically altered, and the infected cell can survive. During viral reproduction, up to 100,000 new virions can be produced, and the replication cycle can vary from a few hours to more than 3 days. Some cells types, called nonpermissive, are unable to support the reproduction of an infective virion, resulting in an abortive infection. Abortive infections also occur when the virus itself is defective. Either situation can lead to a latent infection, where the viral genome may persist in a surviving host cell. As will be described below, such an infection can lead to the transformation of a cell from normal to malignant.

### DNA Virus

The strategies used by various viruses to replicate vary widely, but all are characterized by the need to transcribe mRNA that is suitable for translation of viral proteins. Several pathways lead to the required mRNA, after which the host enzymes and raw materials are used to make viral proteins. Early viral proteins used in replication are synthesized immediately after infection, whereas late proteins used to produce the complete virion structure are synthesized after viral nucleic acid synthesis. Most DNA viruses contain double-stranded DNA as their genome and, thus, can replicate using host cell machinery to

Copyrighted material

produce mRNA directly. Papillomavirus, adenovirus, and herpesvirus are replicated in the host nucleus and, thus, use transcriptional enzymes of the host (i.e., DNA-dependent RNA polymerase) to synthesize mRNA. This mRNA is then translated to form proteins needed by the virus, including enzymes (e.g., DNA-dependent DNA polymerase) used to produce progeny DNA copies. These progeny DNA strands are infectious. By contrast, poxviruses replicate in the cytoplasm using a mechanism that is not well understood, wherein the genome initially is transcribed by a viral enzyme in the virion core. Parvoviruses contain a single-stranded DNA genome and must synthesize double-stranded DNA in the host nucleus before synthesis of mRNA and translation of proteins. This process may or may not require a helper virus, such as herpes simplex. The hepatitis B viral genome, comprised of double-stranded DNA, contains numerous gaps that must be repaired using a DNA polymerase packaged in the virion before transcription to form mRNA.

### RNA Virus

Compared to DNA viruses, those viruses with RNA-based genomes have evolved a wide variety of reproductive strategies. The single-stranded RNA viruses may be divided into three groups that differ in the method by which the RNA genome is utilized. In all three groups, the RNA genome must serve two functions: to be translated to form protein, and to be replicated to form progeny RNA strands. The first group is comprised of viruses such as picornaviruses, flaviviruses, and togaviruses that have an RNA genome that can be used directly as mRNA. Viral RNA that can be used as mRNA is by convention termed (+) or sense-strand RNA. In most cases (e.g. picornaviruses), this sense-strand RNA binds to the host ribosome shortly after entering the cell, where it is read and used to produce a single polypeptide called the polyprotein. The polyprotein is then processed by autocatalysis and various proteolytic enzymes to produce the required viral proteins. In some cases (e.g. togaviruses), only a portion of the RNA genome is available to be translated by the host ribosome. Following the initial translation of the sense strand, it serves a second function—namely, to serve as a template for the synthesis of a (−) or antisense strand via an RNA-dependent RNA polymerase. This antisense strand then can be used to produce additional sense-strand RNAs that are infectious and also can serve as mRNA. These progeny sense-strand RNAs are then packaged into an intact virion before transmission to another host cell.

The second group of single-stranded RNA viruses, including orthomyxoviruses, bunyaviruses, arenaviruses, paramyxoviruses, filoviruses, and rhabdoviruses, all contain an antisense RNA genome that can be used only for transcription of new RNA. All antisense RNA viruses contain an RNA transcriptase as part of their virion, because the host cell does not have this type of RNA-dependent RNA polymerase. During the first round of genome expression, a series of short sense-strand RNAs are made, which are then translated to form the required viral enzymes for replication. Ultimately, these enzymes are used to produce a full-length sense RNA strand, which is then used to make multiple copies of the antisense viral genome. The progeny antisense DNA strands by themselves are not infectious, because they have not yet been packaged with the required RNA transcriptase. When the progeny antisense RNA has been synthesized, it is packaged into an intact virion, in which form it becomes infectious before transmission to another cell.

The third group of RNA viruses are the retroviruses, in which single-stranded RNA exists as a dimer of a sense and an antisense strand. The genomic RNA strands can be base-paired, although the structure of this complex is not well understood, or the strands can be hydrogen-bonded to other macromolecules in the virion. Retroviral genomic RNA serves a single function—namely, to act as a template for the formation of double-stranded viral DNA. Host cells do not contain an enzyme that can form DNA from viral RNA; thus, the virion of a retrovirus must contain a reverse transcriptase (RT) enzyme as well as various host tRNA molecules. Transcription of the genome begins when a complex of RT and tRNA binds to the viral genome. A complimentary DNA strand is then synthesized using one of the host tRNAs as a primer, and the original RNA strand is digested by RNAse H and viral ribonuclease packaged in the virion. A complimentary DNA strand is then synthesized, and the resulting double-stranded DNA is translocated to the nucleus, where viral enzymes incorporate genome-length viral DNA into the host genome. In some cases, the viral portion of the genome can remain dormant for long periods, or it may be immediately used to make progeny viral RNA, a process that is catalyzed by host RNA polymerase II. Transcription produces both shortened segments that are used to make polyproteins and full-length progeny RNA. The polyproteins are processed to form various viral proteins, whereas the full length RNA is packaged into an infectious virion.

### Virus Protein

In addition to replication of the viral genome, a number of other structures associated with the complete virion also can be made. A number of viral proteins may be synthesized that have important functions in the structure, transmission, and survival of the virus. These proteins can protect the genetic material in the virus from destruction by nucleases, participate in the attachment process, and provide structure and symmetry to the virion. In addition, in certain cases where the virus requires an enzymatic process for which there is no host enzyme, a virion may include enzymes, such as RNA polymerases or a RT. Some viruses require a lipid envelope that contains transmembrane proteins specifically coded for by the virus and which envelopes the genetic material

Copyrighted material

a required step in the life cycle of the virus and ensures transmission of the virus to new hosts. Shedding usually occurs at the same site where the infection was initiated and can occur at various stages in the disease course.

## VIRAL DISEASES

### HIV (4,5)

The human immunodeficiency virus (HIV-1) was first identified in 1979 and was found to be the cause of acquired immune deficiency syndrome (AIDS) in 1981. Since that time, AIDS had become a serious worldwide epidemic that continues to expand. The Joint United Nations Program on HIV/AIDS estimated that by the end of 2005, a total of 40.3 million people worldwide were living with HIV/AIDS, the majority having been infected through heterosexual contact. It is estimated that in 2005, more than 3.1 million people died of AIDS, and 4.9 million new cases of HIV were diagnosed, including more than 700,000 children (6). The incidence of the disease varies by location, with sub-Saharan Africa having the highest incidence. Because it is sexually transmitted, a high percentage of infected individuals are young adult workers, and as such, the disease has a significant economic impact in some regions. In addition, infected mother-to-fetus transmission occurs between 13 and 40% of the time. Although a variety of drugs have been developed for treating patients with AIDS, none has proven to be successful in curing the disease. The basic difficulty experienced with this viral infection is the ability of virus to mutate, leading to rapid drug resistance.

The HIV-1 genome consists of two identical, 9.2-kb, single-stranded RNA molecules within the virion, each of which contains information for only nine genes. Following infection of the host cell, the persistent form of the HIV-1 genome is proviral double-stranded DNA. Mature HIV virions are spherical and consist of a lipid bilayer membrane surrounding a nucleocapsid that contains genomic RNA, a viral protease, RT, an integrase, and some other cellular factors. The HIV life cycle is depicted in Figure 43.2, and begins when the viral extracellular protein gp120 attaches to the CD4 receptor on T lymphocytes. Following attachment, the viral envelope and host cell membrane are fused, and the nucleocapsid is released into the cytoplasm. The nucleocapsid is uncoated, and the resulting RNA serves as a substrate for RT, producing a proviral double-stranded DNA that migrates to the nucleus and is incorporated into host DNA by integrase. This DNA is not expressed in resting T lymphocytes, but when the cell is activated, proviral DNA is transcribed by host RNA polymerase II. The viral RNA and proteins are transported to the cell membrane, where they assemble, form a viral bud, and are released from the lymphocyte membrane. This produces an immature virion, and processing of the viral surface proteins by HIV protease then affords the mature, infectious virus. Approximately 50% of HIV infections are asymptomatic, whereas the other 50% produce flu-like symptoms

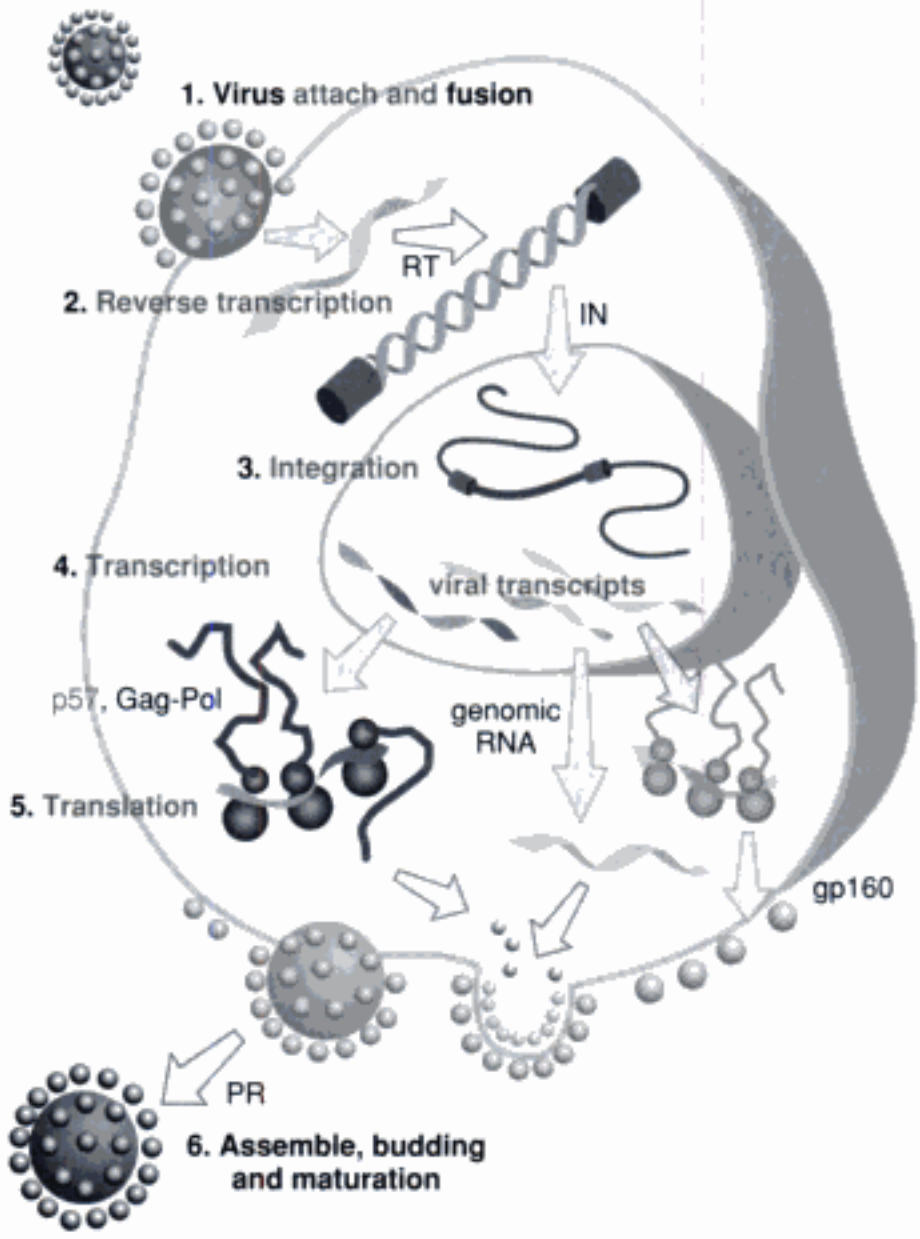

**Fig. 43.2.** Replicative cycle of HIV. (1) The virus gp120 protein binds to CD4 resulting in fusion of the viral envelope and the cellular membrane and the release of viral nucleocapsid into the cytoplasm. (2) The nucleocapsid is uncoated, and viral RNA is reverse transcribed by reverse transcriptase (RT). (3) The resulting double-stranded proviral DNA migrates into the cell nucleus and is integrated into the cellular DNA by integrase (IN). (4) Proviral DNA is transcribed by the cellular RNA polymerase II. (5) The mRNAs are translated by the cellular polysomes. (6) Viral proteins and genomic RNA are transported to the cellular membrane and assemble. Immature virions are released, and polypeptide precursors are processed by the viral protease (PR) to produce mature vital particles. (Adapted from Sierra S, Kupfer B, Kaiser R. Basics of the virology of HIV-1 and its replication. J Clin Virol 2005;34:233; with permission from Elsevier.)

within 4 weeks. During this initial phase, viral titers are very high but then decline as specific antibodies are formed. The latent period is mediated by factors that are not well understood and can last several years. During this time, viral replication continues, and the level of CD4-positive T lymphocytes steadily declines. Eventually, the patient's immune system becomes compromised, resulting in a variety of opportunistic infections. RT sometimes makes mistakes reading the viral RNA sequence, leading to mutations in the virus and changes in the structure of the surface proteins. Thus, vaccines, which induce the production of antibodies that recognize and bind to very specific viral surface molecules, are

Copyrighted material

morbidity and mortality caused by respiratory disease. Outbreaks of infection can occur in global epidemics that have resulted in millions of deaths worldwide. Genetic mutations often cause antigenic changes in the structure of viral surface glycoproteins, making influenza viruses extremely difficult to control. Three immunologic types of influenza viruses are known and are termed influenza A, B, and C. Antigenic changes are very common in influenza A, which is responsible for the majority of influenza epidemics. Influenza B undergoes more infrequent antigenic changes and is less often the cause of an influenza epidemic, whereas influenza C are antigenically stable and cause only mild illness in immunocompetent individuals. The viruses carry a single-stranded, negative-sense RNA genome that has eight segments in influenza A and B. Influenza C contains only seven segments of RNA and lack a neuraminidase gene (see below). The complete virion in each type contains nine different structural proteins. A nucleoprotein associates with viral RNA to form a ribonucleoprotein structure that makes up the viral nucleocapsid. Three other large proteins are bound to the viral ribonuclear protein and are responsible for RNA transcription and replication. A matrix protein also is included in the virion that forms a shell underneath the viral lipid envelope and comprises approximately 40% of all viral protein.

The influenza virion structure also includes a lipid envelope derived from the host cell. This envelope contains two viral surface glycoproteins called hemagglutinin and neuraminidase (NA). Mutations cause antigenic changes in the structure of these two surface glycoproteins; thus, they are the main determinants of antigenicity and host immunity. The ability of the virus to change the structure of hemagglutinin on the virus surface primarily is responsible for the continual evolution of new strains, sometimes leading to subsequent influenza epidemics. Neuraminidase is an enzyme that removes sialic acid from surface glycoproteins during viral maturation and is required to produce infectious particles and lower the viscosity of the mucin layer of the respiratory tract. Influenza virus spreads through airborne droplets or contact with contaminated hands or surfaces and has an incubation period that varies from 1 to 4 days. Transmission of the virus, however, begins to occur 24 hours before to the onset of symptoms. Interferon is detectable in respiratory secretions at the onset of symptoms, and the host response to interferon response contributes to recovery. Antibodies and other cell-mediated responses are seen 1 to 2 weeks after infection. It is well established that secondary infections from other viruses or bacteria can occur, and Reye's syndrome, an acute encephalopathy occurring in children and adolescents, is a rare complication of influenza B, influenza A, herpesvirus, and VZV infections. The chances of contracting Reye's syndrome are increased when salicylates are used in children suffering from influenza and related respiratory diseases.

### Tumor Viruses (2,8–12)

Viruses are etiologic factors in the development of several types of human tumors, most notably cervical cancer and liver cancer. At least 15% of all human tumors worldwide have a viral cause. Tumor viruses can be found in both the RNA and DNA virus kingdoms (13). The list of human viruses presently known to be involved in tumor development includes four DNA viruses (EBV, certain papilloma viruses, HBV, and the Kaposi's sarcoma–associated HHV-8), and two RNA viruses (adult T-cell leukemia virus [HTLV-1] and HCV). Tumor viruses alter cellular behavior through the use of a small amount of genetic information, employing two general strategies. The tumor virus either introduces a new "transforming gene" into the cell (direct-acting), or the virus alters the expression of a preexisting cellular gene or genes (indirect-acting). In both cases, normal regulation of cellular growth processes is lost. Viruses alone cannot act as carcinogens, and other events are necessary to disable regulatory pathways and checkpoints to produce transformed, malignant cells. The processes used in the transformation of host cells by human tumor viruses are very diverse.

Cellular transformation may be defined as a stable, heritable change in the growth control of cells that results in tumor formation. Transformation from a normal to a neoplastic cell generally requires the retention of viral genes in the host cell. In the majority of cases, this is accomplished by the integration of certain viral genes into the host cell genome. Retroviruses incorporate their proviral DNA, formed through the action of RT, into host cell DNA. By contrast, DNA tumor viruses integrate a portion of the DNA of the viral genome into the host cell chromosome.

All RNA tumor viruses are members of the retrovirus family and belong to one of two classes (9,10,12). Class I RNA viruses are direct-transforming and carry an oncogene obtained through accidental incorporation from the host cell. No class I RNA viruses are known to produce tumors in humans. Class II or chronic RNA tumor viruses are weakly transforming and do not carry host cell–derived oncogenes. The two known cancer-causing retroviruses in humans act indirectly. They often act by inserting their proviral DNA into the immediate neighborhood of a host cellular oncogene. HTLV-1 acts in this manner, thus increasing the number of preneoplastic cells and facilitating secondary cellular changes leading to transformation.

DNA tumor virus strains exist among the papilloma-, polyoma-, adeno-, herpes-, hepadna-, and poxvirus groups (11). DNA tumor viruses encode viral oncoproteins that are important for viral replication but also affect cellular growth control pathways. For example, inactivation of the retinoblastoma gene (*Rb*) and the p53 pathway by viral transforming proteins is a common strategy used by papovaviruses and adenoviruses. As mentioned above, all DNA tumor viruses kill their host cell when the infectious virion is released to infect other cells. Thus, transformation and tumorigenicity are entirely dependent on a host cell interaction with the virus that does not involve viral spread to other cells, and cells transformed by DNA tumor viruses depend on the continued expression of the virally encoded oncogene.

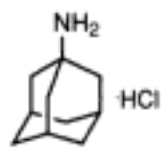
Table 43.2. Antiviral Agents Interfering with Cellular Penetration and Early Replication



| Generic Name | Trade Name | Spectrum of Activity | Dosage Form |
|---|---|---|---|
| Amantadine | Symmetrel | Influenza A | Capsule (100 mg), Syrup (50 mg/5 mL) |
| Rimantadine | Flumadine | Influenza A | Capsule (100 mg) |
| Interferon-$\alpha_{2a}$ | Roferon A, Alferon, Intron, Wellferon | Chronic hepatitis, CMV, HSV, papillomavirus, rhinovirus, and others | Injectable (3, 5, 10, 18, 25, and 50 million units/mL) |
| Interferon-$\alpha_{2b}$ | Interon A | Chronic hepatitis B and C, many other viruses | Injectable (3, 5, 10, 18, 25, and 50 million units/mL) |
| Interferon-$\gamma$ | Actimmune | | Injectable (100 μg/0.5 mL) |
| Zanamavir | Relenza | Influenza A and B | Inhaled powder (5 mg) |
| Oseltamivir | Tamiflu | Influenza A and B | Capsule (75 mg) |
| Enfurtizide | Fuzeon | HIV | Adult: 90 mg SQ b.i.d.<br>Children (6–16 years): 2 mg/kg SQ b.i.d. |

CMV, cytomegalovirus; HSV, herpes simplex virus, SQ, subcutaneous.

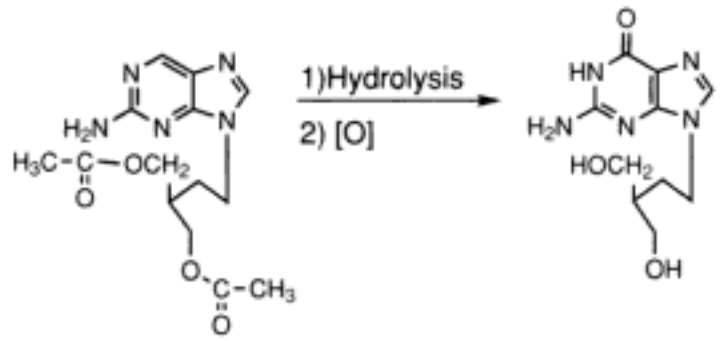
viral strains, and reach the target organ without interfering with normal cellular processes or the immune system of the host.

## Agents Inhibiting Virus Attachment, Penetration, Uncoating, and Early Viral Replication (Table 43.2)

### Amantadine

Amantadine

**Mechanism of action.** Amantadine hydrochloride (1-adamantanamine hydrochloride) is a symmetric, tricyclic, primary amine that inhibits penetration of RNA viral particles into the host cell (19). It also inhibits the early stages of viral replication by blocking the uncoating of the viral genome and the transfer of nucleic acid into the host cell.



**Clinical application.** Amantadine is clinically effective in preventing and treating all type A strains of influenza, particularly type A2 strains of Asian influenza virus, and to a lesser extent, German measles (rubella) or atoga virus. It also shows in vitro activity against influenza B, parainfluenza (paramyxovirus), respiratory syncytial virus (RSV), and some RNA viruses (murine, Rous, and Esh sarcoma viruses). Many prototype influenza A viruses of different human subtypes (H1N1; Fort Dix; H2N2, Asian type; and H3N2, Hong Kong type) also are inhibited by amantadine hydrochloride both in vitro and in animal model systems. If given within the first 48 hours of onset of symptoms, amantadine hydrochloride is effective in respiratory tract illness resulting from influenza A (but not influenza B), adenoviruses, and RSV.

**Pharmacokinetics.** Amantadine is well absorbed orally, and the usual dosage for oral administration is 100 mg twice daily. The drug has been approved as a capsule, tablet, and syrup for the treatment of keratoconjunctivitis caused by HSV infection. Amantadine hydrochloride oral solution should not be kept in a freezer but, rather, should be stored in a tight container at 15 to 30°C. Capsules and tablets should be protected from moisture and light. A 100 mg oral dose produces blood serum levels of 0.3 mg/mL within 1 to 8 hours. Maximum tissue concentration is reached in 48 hours when a 100 mg dose is given every 12 hours. In healthy adults receiving a 25, 100, or 150 mg dose of the drug twice daily, steady-state trough plasma concentrations were 110, 302, or 588 mg/mL, respectively. Usually, no neurotoxicity is observed if the plasma level of amantadine is no more than 1.00 mg/mL.

Amantadine crosses the blood-brain barrier and is distributed in saliva, nasal secretions, and breast milk (20). Approximately 90% of the drug is excreted unchanged by the kidney, primarily through glomerular filtration and tubular secretion, and there are no reports of metabolic products. Acidification of urine increases the rate of amantadine excretion. The half-life of the drug is 15 to 20 hours in patients with normal renal function.

**Side effects.** Generally, the drug has low toxicity at therapeutic levels but may cause severe CNS symptoms, such as nervousness, confusion, headache, drowsiness, insomnia, depression, and hallucinations. The GI side effects include nausea, diarrhea, constipation, and anorexia. Convulsions and coma occur with high doses and in patients with cerebral arteriosclerosis and convulsive disorders. Chronic toxicity with amantadine is unexpected, because few side effects have been experienced when the drug has been used in long-term therapy for Parkinson's disease. Some serious reactions, however, include depression, orthostatic hypotension, psychosis, urinary retention, and congestive heart failure. Amantadine hydrochloride should be used with caution in patients who have a history of epilepsy, severe arteriosclerosis, liver diseases, and eczematoid dermatitis. Because amantadine does not appear to interfere with the immunogenicity of inactivated influenza A vaccine, patients may continue the use of amantadine for 1 week after influenza A vaccination. A

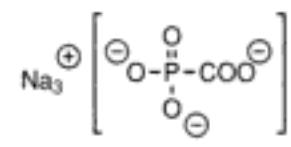
Famciclovir Penciclovir

**Fig. 43.7.** Metabolic activation of famciclovir.

the urine. The half-life of the drug in plasma is 3 to 5 hours. The toxic effects of cytarabine are chiefly on bone marrow, the GI tract, and the kidney. The drug is not given during the early months of pregnancy because of its teratogenic and carcinogenic effects in animals.

### Famciclovir

**MECHANISM OF ACTION.** Famciclovir (Fig. 43-7) is a synthetic purine nucleoside analogue related to guanine (45,46). It is the diacetyl 6-deoxy ester of penciclovir, which is structurally related to ganciclovir. Its pharmacological and microbiological activities are similar to those of acyclovir. Famciclovir is a prodrug of penciclovir, which is formed in vivo by hydrolysis of the acetyl groups and oxidation at the 6-position by mixed function oxidases. Penciclovir and its metabolite penciclovir triphosphate possess antiviral activity resulting from inhibition of viral DNA polymerase.



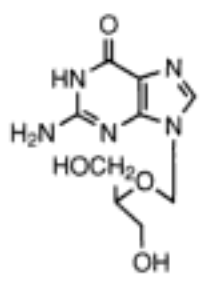
**CLINICAL APPLICATION.** Famciclovir is active against recurrent HSV (genital herpes and cold sores), VZV, and EBV but is less active against CMV (Table 43.3). It is used in the treatment of recurrent localized herpes zoster and genital herpes in immunocompetent adults, and it also is promising for the treatment of chronic HBV reinfection after liver transplantation.

**PHARMACOKINETICS.** Famciclovir can be given with or without food. The most common adverse effects are headache and GI disturbances. Concomitant use of famciclovir with probenecid results in increased plasma concentrations of penciclovir. The recommended dose of famciclovir is 500 mg every 8 hours for 7 days. The absolute bioavailability of famciclovir is 77%, and the area under plasma concentration–time curve (AUC) is 86 μg/mL. Famciclovir with digoxin increased plasma concentration of digoxin to 19% as compared to digoxin given alone.

### Fomivirsen

Fomivirsen sodium is used to treat CMV, which causes opportunistic retinitis in patients with AIDS. Such patients respond to fomivirsen but not to other treatment for CMV retinitis, which leads to blindness (47). Fomivirsen is the first antisense oligonucleotide agent that has been approved as an alternative medicine for patients with CMV retinitis for whom other agents did not work (see Chapter 8, Fomivirsen). It works by inhibiting the synthesis of proteins responsible for the regulation of viral gene expression that is involved in infection of CMV retinitis. Fomivirsen works only in the eye in which it is injected. It is not recommended if cidofovir is used within the last 2 to 4 weeks because of increased risk of eye inflammation. Fomivirsen is given in two induction doses, followed by monthly maintenance doses, each being 330 μg administered by intravitreal injection. It can cause increased pressure in the eye that requires treatment by an ophthalmologist. Fomivirsen also is used in the treatment of Crohn's disease and certain cancers. It causes eye inflammation, abnormal vision, cataract, eye pain, and retinal problems. In addition, it causes several other side effects, such as stomach pain, headache, fever, infection, rash, vomiting, and liver dysfunction.

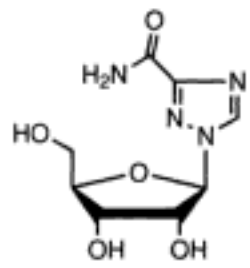
### Foscarnet



Foscarnet sodium

Foscarnet sodium is a trisodium phosphoformate hexahydrate that inhibits DNA polymerase of herpesviruses, including CMV and retroviral RT (48). It is not phosphorylated into an active form by viral host cell enzymes. Therefore, it has the advantage of not requiring an activation step before attacking the target viral enzyme.

**CLINICAL APPLICATION.** Foscarnet sodium was approved by the U.S. FDA for the treatment of CMV retinitis in patients with AIDS. In combination with ganciclovir, the results have been promising, even in progressive disease with ganciclovir-resistant strains. Foscarnet sodium also is effective in the treatment of mucocutaneous diseases caused by acyclovir-resistant strains of HSV and VZV in patients with AIDS. Foscarnet sodium is administered IV at 60 mg/kg three times a day for initial therapy and at 90 to 120 mg/kg daily for maintenance therapy (Table 43.3). The plasma-half life is 3 to 6 hours. Foscarnet sodium penetrates into the CSF and the eye. The drug is neurotoxic, and common adverse effects include phlebitis, anemia, nausea, vomiting, and seizures. Foscarnet sodium carries the risk of severe hypocalcemia, especially with concurrent use of IV pentamidine. Foscarnet sodium used with zidovudine (ZDV) has an additive effect against CMV and acts synergistically against HIV.

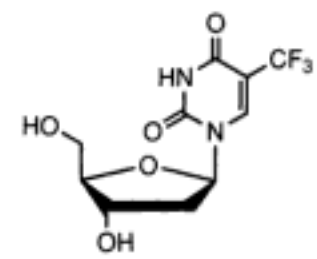


### Ganciclovir

Ganciclovir (DHPG)

Copyrighted material

### Ribavirin



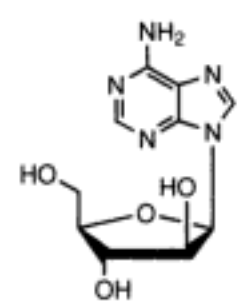
Ribavirin

**MECHANISM OF ACTION.** Ribavirin, a guanosine analogue, has broad-spectrum antiviral activity against both DNA and RNA viruses (52,53). It is phosphorylated by adenosine kinase to the triphosphate, resulting in the inhibition of viral specific RNA polymerase, disrupting messenger RNA and nucleic acid synthesis.

**CLINICAL APPLICATION.** Ribavirin is highly active against influenza A and B viruses and the parainfluenza group of viruses, genital herpes, herpes zoster, measles, and acute hepatitis types A, B, and C. Aerosolized ribavirin has been approved by the U.S. FDA for the treatment of lower respiratory tract infections (bronchiolitis and pneumonia) and serious RSV infections, but it can cause cardiopulmonary and immunologic disorders in children (Table 43.3). Ribavirin inhibits in vitro replication of HIV-1. Clinically, ribavirin has been shown to delay the onset of full-blown AIDS in patients with early symptoms of HIV infection. Some viruses are less susceptible, such as poliovirus, herpesviruses excluding varicella, vaccinia, mumps, reovirus, and rotavirus. A randomized, double-blind study of aerosolized ribavirin treatment of infants with RSV infections indicated significant improvement in the severity of infection, with a decrease in viral shedding (54).

**PHARMACOKINETICS.** Oral or IV forms of ribavirin are useful in the prevention and treatment of Lassa fever. The oral bioavailability is approximately 45%, and the serum half-life is 9 hours. Peak plasma level after 1 hour is 1 to 3 mg/mL. Intravenous administration of the drug has higher peak plasma levels. Aerosol preparation delivery of drug (0.8 mg/kg/hour) produced drug levels in respiratory secretions of 50 to 200 mg/mL (Table 43.3). The clinical benefits of this agent are yet to be confirmed. Its few side effects generally are limited to GI disturbances, such as nausea, vomiting, and diarrhea. The drug is contraindicated in patients with asthma because of deterioration of pulmonary function. Viral strains susceptible to ribavirin have not been found to develop drug resistance, as is the case with other antiviral agents, such as acyclovir, idoxuridine, and bromovinyldeoxyuridine.

### Trifluorothymidine



Trifluorothymidine (TFT, F3T)

**MECHANISM OF ACTION.** Trifluorothymidine is a fluorinated pyridine nucleoside structurally related to idoxuridine (55). It has been approved by the U.S. FDA and is a potent, specific inhibitor of replication of HSV-1 in vitro. Its mechanism of action is similar to that of idoxuridine. Like other antiherpes drugs, it is first phosphorylated by thymidine kinase to mono-, di-, and triphosphate forms, which are then incorporated into viral DNA in place of thymidine to stop the formation of late virus mRNA and subsequent synthesis of the virion proteins.

**CLINICAL APPLICATION.** Trifluorothymidine, because of its greater solubility in water, is active against HSV-1 and HSV-2. It also is useful in treating infections caused by human CMV and VZV infections (Table 43.3). The advantage of use of this agent over idoxuridine is its high topical efficacy in the cure of primary keratoconjunctivitis and recurrent epithelial keratitis. It also is useful for difficult cases of herpetic iritis and established stromal keratitis.

**PHARMACOKINETICS.** Trifluorothymidine is available as a 1% ophthalmic solution, which is effective in dendritic ulcers. Generally, a 1% eye solution of trifluorothymidine is well tolerated. Cross-hypersensitivity and cross-toxicity between trifluorothymidine, idoxuridine, and vidarabine are rare. The most frequent side effects are temporary burning, stinging, localized edema, and bone marrow toxicity. It is less toxic but more expensive than idoxuridine. Trifluorothymidine, when given IV, shows a plasma half-life of 18 minutes and is excreted in the urine either unchanged or as the inactive metabolite 5-carboxyuracil.

### Vidarabine

Vidarabine (ara-A)

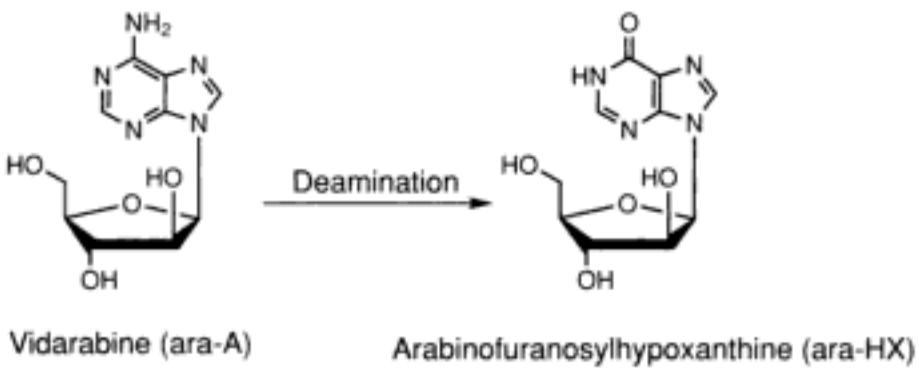
Copyrighted material

**MECHANISM OF ACTION.** Vidarabine is an adenosine nucleoside obtained from cultures of *Streptomyces antibioticus* (56). Cellular enzymes convert vidarabine to mono-, di-, and triphosphate derivatives that interfere with viral nucleic acid replication, specifically inhibiting the early steps in DNA synthesis. This agent was used originally as an antineoplastic drug. Its antiviral effect is, in some cases, superior to that of idoxuridine or cytarabine.

**CLINICAL APPLICATION.** Vidarabine is used mainly in human HSV-1 and HSV-2 encephalitis, decreasing the mortality rate from 70 to 30%. Whitley et al. (57) reported that early vidarabine therapy is helpful in controlling complications of localized or disseminated herpes zoster in immunocompromised patients. Vidarabine also is useful in neonatal herpes labialis or genitalis, vaccinia virus, adenovirus, RNA viruses, papovavirus, CMV, and smallpox virus infections. Given the efficacy of vidarabine in certain viral infections, the U.S. FDA approved a 3% ointment for the treatment of herpes simplex keratoconjunctivitis and recurrent epithelial keratitis, and a 2% IV injection for the treatment of herpes simplex encephalitis and herpes zoster infections (Table 43.3). A topical ophthalmic preparation of vidarabine is useful in herpes simplex keratitis but shows little promise in herpes simplex labialis or genitalis. The monophosphate esters of vidarabine are more water-soluble and can be used in smaller volumes and even intramuscularly. These esters are under clinical investigation for the treatment of hepatitis B, systemic and cutaneous herpes simplex, and herpes zoster virus infections in immunocompromised patients.

**PHARMACOKINETICS.** Vidarabine is deaminated rapidly by adenosine deaminase, which is present in serum and red blood cells. The enzyme converts vidarabine to its principal metabolite, arabinosyl hypoxanthine (ara-HX), which has weak antiviral activity (Fig. 43.8) (58). The half-life of vidarabine is approximately 1 hour, whereas ara-HX has a half-life of 3.5 hours. The drug is detected mostly in the kidney, liver, and spleen, because 50% of it is recovered in the urine as ara-HX. Levels of vidarabine in CSF fluid are 50% of those in the plasma.

The most common side effects of vidarabine are GI disturbances, such as anorexia, nausea, vomiting, and diarrhea. The CNS side effects include tremors, dizziness, pain syndromes, and seizures. Bone marrow suppression is reported at higher doses. Because vidarabine is reported to be mutagenic, carcinogenic, and teratogenic in animal studies, its use in pregnant women is to be avoided. Allopurinol and theophylline may interfere with the metabolism of vidarabine at higher doses because of the xanthine oxidase metabolism of vidarabine. Therefore, this agent should be avoided or given with caution to patients receiving these medications concurrently. Also, adjustment of the dose is necessary in patients with renal insufficiency.



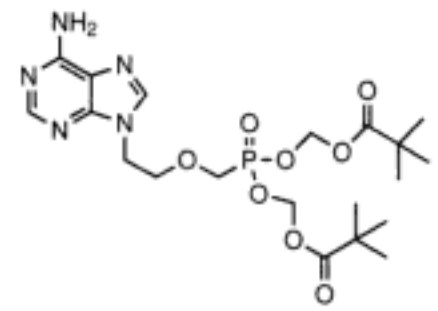


**Fig. 43.8.** Metabolism of vidarabine.

## Adefovir Dipivoxil (59)

**MECHANISM OF ACTION.** Adefovir dipivoxil is an orally active prodrug indicated for the treatment of chronic hepatitis B. The drug is hydrolyzed by extracellular esterases to produce adefovir, which in turn is phosphorylated by adenylate kinase to adefovir diphosphate, which inhibits HBV DNA polymerase. Incorporation of adefovir into viral DNA also leads to DNA chain termination. As shown in Figure 43.9, adefovir dipivoxyl is activated in two steps involving an esterase that exposes a free phosphate group (adefovir), followed by addition of a second phosphate by adenylate kinase to form adefovir diphosphate, the active form of the drug.

**PHARMACOKINETICS.** Adefovir is poorly absorbed orally, but the bioavailability of adefovir dipivoxil reaches approximately 59%. The drug is absorbed to an equal extent with or without the presence of food. Adefovir is excreted renally unchanged.

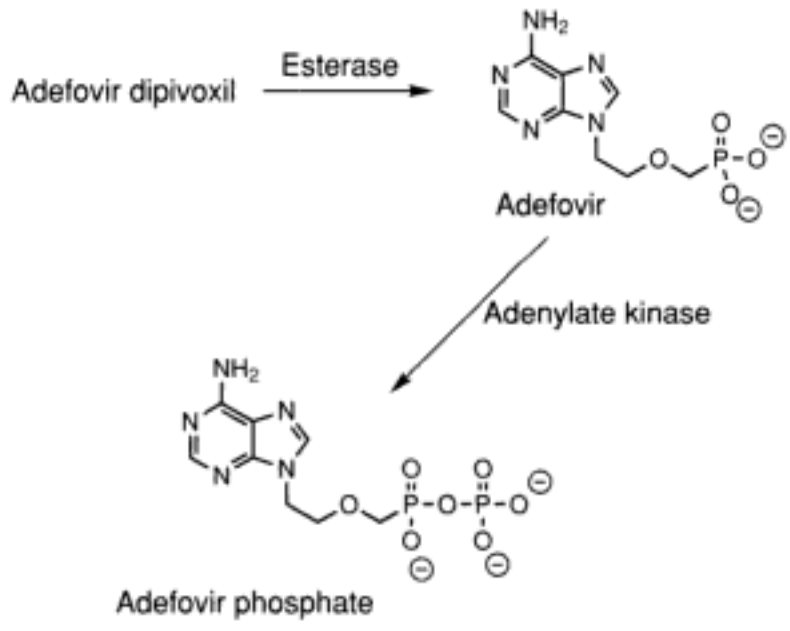

**Fig. 43.9.** Activation of the pro-drug adeflovir dipivoxyl by esterase and adenylate kinase.

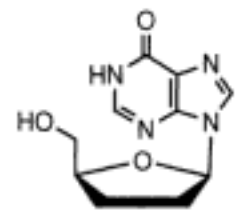

Copyrighted material

*Pneumocystis carinii* pneumonia and improves the condition of patients with advanced ARC by reducing the severity and frequency of opportunistic infections. Substantial benefits are obtained when the drug is given after the CD4 cell counts fall to less than 500/mm$^3$. Therefore, ZDV is used in early and advanced symptomatic treatment of patients with AIDS or ARC. Use with other RT inhibitors or in combination with PIs is more beneficial when resistance to ZDV occurs.

Human immunodeficiency virus attacks susceptible cells and interacts mainly with CD4 cell surface proteins of helper T cells. As discussed above, the viral glycoprotein gp120 forms a complex with CD4 receptor on host cells and enters the cells by endocytosis. The sequence of events is shown in Figure 43.2. Ultimately, the immune system of the host is altered, and symptoms of AIDS appear. Patients with AIDS have symptoms such as high fever, weight loss, lymphadenopathy, chronic diarrhea, myalgias, fatigue, and night sweats. Zidovudine is given in such conditions; however, the drug is toxic to the bone marrow and causes macrocytic anemia, neutropenia, and granulocytopenia. Other adverse reactions include headache, insomnia, nausea, vomiting, seizures, myalgias, and confusion.

***Pharmacokinetics.*** Zidovudine is available in various dosage forms for oral or IV administration (Table 43.4). For asymptomatic adults, the initial recommended dosage is 1,200 mg daily (200 mg every 4 hours), which is reduced to 600 mg daily (100 mg every 4 hours) for patients with advanced disease. The maintenance dose is 600 mg daily in symptomatic patients. Zidovudine is sensitive to heat and light because of its azide group and should be stored in colored bottles at 15 to 25°C. It is well absorbed through the GI tract, and it concentrates in the body tissues and fluids, including the CSF. The bioavailability of the drug was found to be approximately 65%. Its half-life is approximately 1 hour. Intravenous doses of 2.5 mg/kg or oral doses of 5 mg/kg yielded peak plasma concentrations of 5 mmol/L. Plasma protein binding was approximately 30%. Most of the drug is converted to its inactive glucuronide metabolite and is excreted unchanged through urine. Additionally, ZDV crosses the blood-brain barrier. Pentamidine, dapsone, amphotericin B, flucytosine, and doxorubicin may increase the toxic effects of ZDV. Probencid prolongs the plasma half-life of the drug.

### DIDANOSINE

Didanosine(ddI)

***Mechanism of Action.*** Didanosine (ddI) is a purine dideoxynucleoside, which is an analogue of inosine. Chemically, it is 2′,3′-dideoxyinosine, and it differs from inosine by having hydrogen atoms in place of the 2′- and 3′-hydroxyl groups on the ribose ring. Didanosine is a prodrug that is bioactivated by metabolism to dideoxyadenosine triphosphate, which is a competitive inhibitor of viral RT and is incorporated into the developing viral DNA in place of deoxyladenosine triphosphate. As such, this agent causes chain termination because of the absence of a 3′-hydroxyl group. Didanosine inhibits HIV RT and exerts a virustatic effect on the retroviruses. Combined with ZDV, antiretroviral activity of ddI is increased.

***Pharmacokinetics.*** Didanosine has a plasma half-life of 1.5 hours and is given in a 200 mg dose twice daily. Oral bioavailability of the drug is approximately 25% at doses of 7 mg/kg or less. Didanosine significantly decreased p24 antigen levels and increased CD4 cell counts. Viral resistance to ddI occurred after treatment for 1 year. Didanosine is less toxic than ZDV. The CSF fluid/plasma

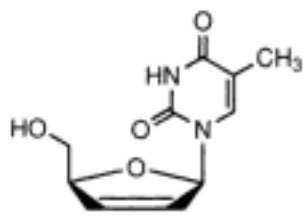

Table 43.4. HIV Reverse Transcriptase Inhibitors

| Generic Name | Common Name | Trade Name | Dosage Form |
|---|---|---|---|
| | | *Nucleoside Reverse Transcriptase Inhibitors* | |
| Zidovudine | AZT ZDV | Retrovir | Tablet (300 mg), Capsule (100 mg), syrup (50 mg/5 mL), injectable (10 mg/mL) |
| Didanosine | ddI | Videx | Tablet (25, 50, 100, 150, and 200 mg) |
| Dideoxyadenosine | ddA | | Powder for oral solution (100, 167, and 250 mg) |
| Zalcitabine | ddC | Hivid | Tablet (0.375 mg) |
| Stavudine | D4T | Zerit | Capsule (15, 20, 30, and 40 mg), powder for oral solution (1 mg/mL) |
| Lamivudine | 3TC | Epivir | Tablet (150 mg), solution (10 mg/mL) |
| | | Epivir HBV | Tablet (100 mg), solution (5 mg/mL) |
| Abacavir | ABC | Ziagen | Tablet (300 mg), solution (20 mg/mL) |

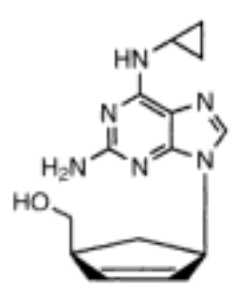
metabolites identified consist of the 3′-sulfoxide and the 2′-O-glucuronide. Emtricitabine is reported to be more active than lamivudine, with a low level of resistance developing when used in combination therapy with efavirenz and didanosine.

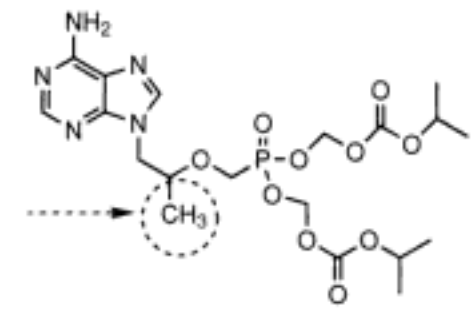
### STAVUDINE



Stavudine
(2',3'-Dideoxy-2',3'-didehydrothymidine, D4T)

Stavudine (D4T) is a pyrimidine nucleoside analogue that has significant activity against HIV-1 after intracellular conversion of the drug to a D4T-triphosphate. It differs in structure from thymidine by the replacement of the 3′-hydroxyl group with a hydrogen atom and a double bond in the 2′,3′-positions on the deoxyribose ring. It decreases p24 antigen and raised CD4 cell counts. D4T is beneficial for patients where CD4 cell counts do not decrease to less than 300 cells/mm$^3$ with ZDV and ddI. It is more effective than ZDV or ddC in treating patients by delaying the progression of HIV infection. It is recommended for patients with advanced HIV infection.

***Pharmacokinetics.*** D4T is rapidly absorbed, and absolute bioavailability in adults is 85% at an oral dose of 4 mg/kg (Table 43.4). A peak plasma concentration occurs in dose-dependent manner within 1 hour. It can be taken with food. The apparent volume distribution after oral dose is 66 L. The plasma half-life of D4T is approximately 1.5 hours, and the intracellular half-life of D4T-triphosphate is 3.5 hours. It is less toxic to bone marrow but causes peripheral neuropathic toxicity. The side effects include pain, tingling, and numbness in the hands and feet.



### ABACAVIR.

Abacavir (ABC)

Abacavir sulfate (ABC) was approved in 1998 as a nucleoside RT inhibitor to be used in combination with other drugs for the treatment of HIV and AIDS. The drug is extensively metabolized via stepwise phosphorylation to 5′-mono-, di-, and triphosphate. Abacavir is well absorbed (>75%) and penetrates the CNS. The drug can be taken without regard to meals. The drug does not show any clinically significant drug–drug interactions. Abacavir has been reported to produce life-threatening hypersensitivity reactions. The major use of abacavir appears to be in combination with other nucleoside RT inhibitors. A fixed-combination product has recently been approved by the U.S. FDA consisting of 300 mg of ABC, 150 mg of 3TC, and 300 mg of ZDV (Trizivar). The combination has been shown to be superior to other combinations in reducing viral load as well as to show improvement in CD4 cell count. The most common adverse effects reported with abacavir include headache, nausea, vomiting, malaise, and diarrhea.

### TENOFOVIR DISOPROXIL (86)

Tenofovir disoproxil

Tenofovir disoproxil is a prodrug in a manner similar to that of adefovir dipivoxil. In both cases, the phosphate esters are removed through the action of plasma esterase, leading in this case to tenofovir, which differs from adefovir by the presence of the indicated methyl group (Fig. 43.9). Tenofovir disoproxil exhibits good bioavailability (25%), which is improved in the presence of food (35%). The drug is approved for the treatment of HIV infections in adult patients. Tenofovir diphosphate is an HIV RT inhibitor. The active form of tenofovir is the tenofovir diphosphate, which competes with dATP for incorporation into viral DNA, and when incorporated, tenofovir diphosphate results in premature termination of DNA growth and inhibition of DNA polymerase. Tenofovir disoproxil is indicated for treatment-experienced patients with HIV-1. The drug also appears to be effective in treatment-naive patients, but initial approval is for treatment-experienced patients. The drug is administered as one tablet taken once daily (Table 43.4). It is recommended that the drug be combined with other RT inhibitors or HIV PIs, which results in additive or synergistic activity.

### Nonnucleoside RT Inhibitors

The U.S. FDA recently approved several nonnucleosides that inhibit RT activity. They are used with nucleoside drugs to obtain synergistic activity in decreasing the viral load and increasing the CD4 cell count. These drugs are primarily designed and synthesized by protein structure–based drug design methodologies. Their use as monotherapy may be limited because of rapid onset of resistance and hypersensitivity reactions. Interaction of nonnucleoside drugs, however, with other PIs, such as saquinavir, indinavir, and ritonavir, is being investigated. Also, interaction of these

Copyrighted material

The side effects of efavirenz include dizziness, insomnia, impaired concentration, abnormal dreams, and drowsiness. The most common adverse effect is a skin rash. Other side effects are diarrhea, headache, and dizziness. Efavirenz is recommended to be taken at bedtime with or without food. Patients on efavirenz should avoid driving or operating machinery and the intake of high fat meals. It should always be taken in combination with at least one other anti-HIV agent. Efavirenz is contraindicated with midazolam, triazolam, or ergot derivatives.

### HIV Protease Inhibitors (Table 43.5) (90)

The HIV protease is an enzyme that is essential for viral growth and that mediates the posttranslational modification of core proteins into structural proteins. The structural proteins p7, p9, p17, and p24, which play important roles in infectivity of HIV, are products of a *pol* gene. The HIV genome contains various regions designated as genes, such as the *gag* and *gag-pol* genes, that are translated as polyproteins and form immature viral particles. These precursor protein molecules are cleaved by a viral *pol*-encoded aspartic proteinase to form the desired structural proteins of the mature viral particle. The HIV protease also activates RT and plays an important role in the release of infectious viral particles. Thus, an area of considerable interest has been the development of drugs that act as inhibitors of protease and *pol* gene. Such inhibitors act on HIV protease and prevent posttranslational processing and budding of immature viral particles from the infected cells. This group of drugs represents a major breakthrough in the treatment of HIV when used in combination with RT inhibitors, and their development is one of the most significant advances in medicinal chemistry.

**Mechanism of action.** The HIV protease exists as a dimer in which each monomer contains one of two conserved aspartate residues at the active site. Drugs that inhibit HIV protease are designed as transition-state mimetics that align at the active site of HIV-1 protease, as defined by three-dimensional crystallographic analysis of the protein structure. A number of oligopeptide-like analogues have been synthesized that differentially inhibit viral and mammalian aspartic proteases, and the most useful of these are selective for the viral enzyme HIV-1 protease. Structurally, these agents are either peptidomimetic and nonpeptide compounds. Their effectiveness is related to their ability to inhibit the *gag-pol* gene, which processes p24, p55, and p160. Consequently, the infectivity of HIV-1 is diminished.

Although some compounds exhibit both in vitro and in vivo antiviral activities, optimization of their pharmacokinetic and pharmacodynamic properties has presented major problems. In view of the great demand for successful anti-AIDS drugs, the U.S. FDA has approved nine drugs as PIs under the accelerated approval process.

**Metabolism.** The PIs have a high potential for drug interactions, stemming from the fact that they are substrates for and inhibitors of the CYP3A4 enzyme system. As a result, concurrent use of PIs with other drugs metabolized by CYP3A4 may be contraindicated, and in some cases, the drug interactions can be life-threatening. The most potent cytochrome P450 (CYP450) inhibitor in this class is ritonavir (used to advantage in combination with lopinavir); followed by indinavir, nelfinavir, and amprenavir as moderate inhibitors; and by saquinavir as the least potent inhibitor. Drug interactions have been reported with bepridil, dihydroergotamine, and a number of benzodiazepines. Marked increase in activity of amiodarone, lidocaine (systemic), quinidine, the tricyclic antidepressants, and warfarin might be expected. Other interactions have been reported to include rifampin, rifabutin phenobarbital, phenytoin, dexamethasone, or carbazepine. Because the PIs are themselves metabolized by CYP450, their action may be altered by other agents that induce or inhibit this system. In the case of rifabutin, which inhibits CYP3A4 in the gut, relative bioavailability of the PIs is increased, and the dose of the PIs may need to be decreased.

**Resistance.** Resistance to the transition-state peptidomimetic PIs has already become problematic. Resistance is associated with point mutations among various amino acids within the peptide chain of the HIV protease. Single-amino-acid mutations reduce the activity of

Table 43.5. HIV Protease Inhibitors

| Generic Name | Common Name | Trade Name | Dosage Form(mg/unit) |
|---|---|---|---|
| Saquinavir | | Invirase | Capsule (200 mg) |
| | | Fortovase | Capsule (200 mg) |
| Ritonavir | RTV | Norvir | Capsule (200 mg) |

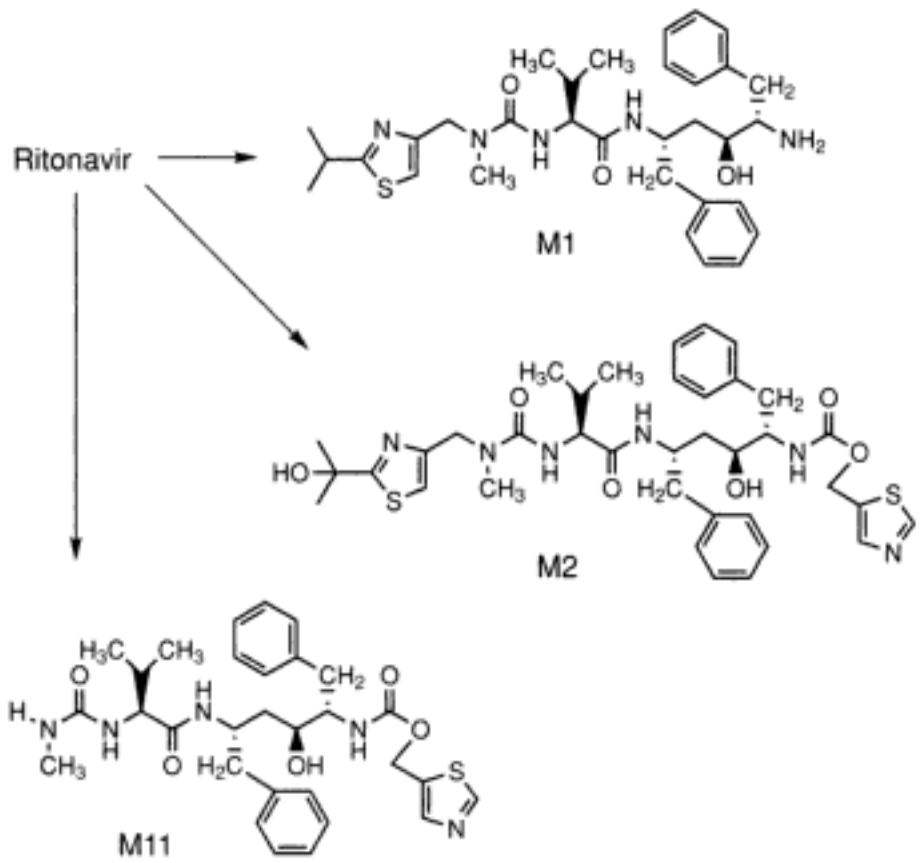

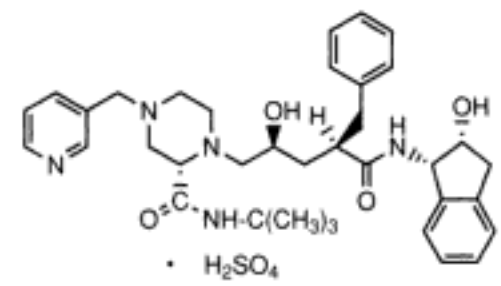

**Fig. 43.13.** Major metabolic products from CYP3A4 metabolism of ritonavir.

***Pharmacokinetics.*** After a 600 mg dose of an oral solution, peak concentrations of ritonavir were obtained in approximately 2 or 4 hours under fasting or nonfasting conditions, respectively. Under nonfasting conditions, peak ritonavir concentrations decreased 23%, and the extent of absorption decreased 7% relative to fasting conditions. In two separate studies, the capsule and oral solution indicated AUC values of 129.5 ± 47.1 and 129.0 ± 39.3 mg/h/mL, respectively, when a 600 mg dose was given under nonfasting conditions. Five ritonavir metabolites have been isolated from human urine and feces, the most significant of which are shown in Figure 43.13 (95). The isopropylthiazole oxidation product was the major active metabolite (M2).

As with saquinavir, ritonavir is metabolized by CYP3A4 and is an inhibitor of the CYP450 system. Ritonavir is contraindicated with various compounds, such as astemizole, cisapride, clarithromycin, desipramine, ethinyl estradiol, rifabutin, several of the statins, sulfamethoxazole, and trimethoprim, because of increased concentrations of these drugs in the plasma as a result of inhibited oxidative metabolism as well as the fact that several of these drugs are CYP450 inducers. Ritonavir is the most potent PI in its ability to inhibit CYP450 and the efflux pump P-glycoprotein; as a result, the potential for severe drug interactions is quite great. Ritonavir alone or in combination with 3TC, ZDV, saquinavir, or ddC increased CD4 cell counts and decreased HIV RNA particle levels. Cross-resistance between ritonavir and RT inhibitors is unlikely because of the different mode of action and enzyme involved. Common adverse reactions, such as nausea, diarrhea, vomiting, anorexia, abdominal pain, and neurologic disturbances, have been reported with the use of ritonavir alone or in combination with other nucleoside analogues. Ritonavir is used for the treatment of advanced HIV infection, including opportunistic infections. In combination with nucleoside drugs, ritonavir has reduced the risk of mortality and clinical progression.

Because of the strong CYP450-inhibiting effects of ritonavir, the drug has found value when used in fixed-dosage combinations with other PIs to block their metabolism and act as a booster for these drugs (lopinavir/ritonavir and tipranavir/ritonavir). In these cases, ritonavir is used in a subtherapeutic dose but boosts the effectiveness of the coadministered drug. The utilization of ritonavir in a therapeutic dose for treating HIV infections appears to be decreasing, but its utilization as a booster drug is finding favor.

***Indinavir***

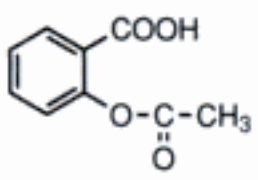
Indinavir sulfate, a pentanoic acid amide derivative, was approved by the U.S. FDA in March 1996 (96). The 95% inhibitory concentration against laboratory-adapted HIV variants, primary clinical isolates and clinically resistant virus to indinavir analogues, is 25 to 100 nM in drug combination studies with ZDV and ddI. In some patients, however, HIV has shown resistance to ritonavir. This resistance is caused by mutation of the virus that is correlated with the expression of amino acid substitutions in the viral protease. Cross-resistance to indinavir is observed with other PIs but not with the RT inhibitor. For this reason, indinavir is beneficial with ZDV and other nucleoside drugs.

***Pharmacokinetics.*** Indinavir is rapidly absorbed in fasting patients, and plasma peak concentration is observed in approximately 1 hour. At a dose of 800 mg every 8 hours, peak plasma concentration is approximately 300 nM. The drug is approximately 60% bound to human plasma proteins. Indinavir is metabolized via oxidation and glucuronide conjugation (M1 in Fig. 43.14). At least seven metabolites have been identified, with the conjugate being the major metabolite (97). These metabolites were recovered in feces and urine, with approximately 20% of the drug excreted in the urine. The half-life of indinavir is approximately 1.8 hours.

Because of indinavir's metabolism, a number of drug interactions are possible. Indinavir interacts with rifabutin or ketoconazole, leading to increased or decreased indinavir concentration, respectively, in the blood plasma. Administration of drug combinations of indinavir with antiviral nucleoside analogues, cimetidine, quinidine, trimethoprim/sulfamethoxazole, fluconazole, or isoniazid resulted in an increased activity of indinavir. Indinavir is

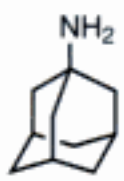
Copyrighted material

nucleotides in length are created from a parent double-stranded RNA molecule. These short interfering RNAs (siRNAs) direct the cell to cleave target mRNAs that share sequence identity with the siRNAs. Many research groups are attempting to develop RNAi therapies that induce the degradation of target mRNA involved in inherited or acquired disorders. This technology is especially well-suited to treating viral infections, and numerous examples now illustrate that a wide range of viruses can be inhibited with RNAi, both in vitro and in vivo. Antiviral RNAi therapies can be tailored to the biochemical characteristics of each pathogen and can be made more specific through choice of delivery vehicle, route of administration, selection of gene targets, and regulation of RNAi induction. As has been mentioned above, successful antiviral therapeutics possess the ability to discriminate virus from host. Because viruses rely extensively on host cell machinery for many functions and activities involved in viral replication, however, they offer a very limited number of therapeutic targets. Because RNAi specifically targets a short stretch of viral nucleic acids rather than a viral protein, even a small viral genome can provide a large number of potential targets.



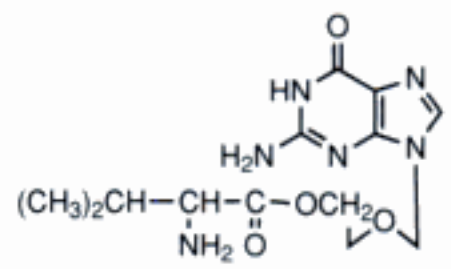
## CASE STUDY

***Victoria F. Roche and S. William Zito***



You are an Oregon pharmacist mentoring the American Pharmacist Association Academy of Student Pharmacists chapter of a local pharmacy school in its service outreach program with an area shelter for abused women. This shelter serves about 50 women and their children, assisting the women with work placements when needed and providing day care services and transportation to area schools for the kids. All residents have breakfast together at 6:30 AM, and dinner is offered at 6:00 PM. with about three-quarters of the families partaking on any given evening. Various community groups make sure the pantry is well stocked, and one has provided supplies of aspirin and other over-the-counter products for as-needed use by the shelter's clients. The corporate headquarters of Sea Mist, a company that markets products made from locally grown cranberries, has selected this shelter as the primary beneficiary of its community service commitment, and it provides the residents with essentially limitless quantities of its products, including cranberry juice (enjoyed often by most of those living at the shelter).

A recent outbreak of influenza A has struck your community, and although only a few residents of the shelter have become ill, you and the MD who also donates her services to the facility realize that all the residents (including the children) are at risk. Because of a nationwide shortage of vaccine, vaccination of the residents is not possible, but together, you are trying to secure sufficient quantities of an orally active, antiviral agent to treat and/or protect these patients. The Sea Mist employees have volunteered to cover the cost of any medication not donated by the manufacturer. Taking advantage of a "teachable moment" in clinical practice, you ask your ASP students who are currently taking medicinal chemistry to identify the best agent of the four structural choices shown below to meet the needs of this diverse population.



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patients.

**DRUGS COVERED IN THIS CHAPTER:**

$\beta_2$-ADRENERGIC AGONISTS
- Albuterol
- Bitolterol mesylate
- Epinephrine (Adrenalin)
- Fenoterol hydrobromide
- Formoterol fumarate
- Isoetharine hydrochloride
- Metaproterenol sulfate
- Salmeterol xinafoate
- Terbutaline sulfate

ANTIMUSCARINICS
- Ipratropium hydrobromide
- Tiotropium bromide

METHYLXANTHINES
- Dyphylline
- Theophylline

ADRENOCORTICOIDS
- Beclomethasone dipropionate
- Budesonide
- Flunisolide
- Fluticasone propionate
- Hydrocortisone
- Methylprednisolone
- Mometasone furoate
- Prednisolone
- Triamcinolone acetonide

MAST CELL DEGRANULATION INHIBITORS
- Cromolyn sodium
- Nedocromil sodium

LEUKOTRIENE MODIFERS
- Montelukast
- Zafirlukast
- Zileutin

MONOCLONAL ANTI-IgE ANTIBODY
- Omalizumab

## ASTHMA

### Epidemiology

Asthma is a Greek word that is derived from the verb "aasein," meaning to pant or exhale with open mouth. The earliest use of the term as a medical condition dates back to Ancient Greece, in Hippocrates' *Corpus Hippocraticum* (1). The incidence of asthma is greatest in the developed world, and there has been an increase in asthma over the last two decades in the United States (2). According to 2002 U.S. population data gathered by the National Center for Health Statistics, the number of people who were ever diagnosed with asthma by a health professional (lifetime prevalence) is 30.8 million (111 per 1,000). Of that number, it is estimated that 20 million people are currently under treatment and that as many as 12 million had an asthma attack in the 12 months before the survey. Children aged 0 to 17 years have the highest rate of asthma (83 per 1,000), but the rate decreases significantly in adults, indicating that many children "outgrow" the disease. Race and gender seem to play a role in the prevalence of asthma. Puerto Ricans, blacks, and Native Americans have an asthma prevalence much higher than in Caucasians. The high Puerto Rican incidence is masked when they are included among all Hispanics. Boys have a higher incidence of asthma than girls; however, this reverses in adulthood, when females show a 30% higher prevalence compared to males. Asthma causes a significant loss of schooldays and workdays and results in nearly 2 million visits to the emergency department each year. If asthma is not controlled, it can result in death: almost 5,000 people died from asthma in 2002. Blacks had an asthma death rate more than 200% higher than that in Caucausians, and women had a death rate 40% higher than males. These data reinforce the influence of race and gender on the morbidity and mortality of asthma and point out the fact that asthma is a significant public health burden in the United States (3).

### Etiology, Signs, and Symptoms

Asthma is a complex disorder involving biochemical, autonomic, immunologic, infectious, environmental, and psychological factors to varying degrees in different individuals. Patients with asthma demonstrate recurrent episodes of paroxysmal dyspnea, wheezing, and cough. Most asthmatic attacks are short-lived, with the patient being free from symptoms between exacerbations. Some patients may have persistent difficulty breathing that does not respond to any treatment and that is believed to be the result of airway remodeling (4). The National Institutes of Health (NIH) Expert Panel Report 2: Guidelines for the Diagnosis and Management of Asthma (EPR-2) simply defines asthma as a chronic inflammatory response of the airways (5).

The most common form of asthma is allergic asthma (atopic or extrinsic asthma), and it is associated with environmental allergens, such as plant pollens, house dust mites (*Dermatophagoides farinae*), domestic pet dander, molds, and foods. The less common form, intrinsic asthma, has no known allergic cause and usually occurs in adults older than 35 years. Intrinsic asthma may result from an autonomic dysfunction characterized by excess cholinergic and/or tachykinin activity, but this hypothesis has never been proven (6). Aside from environmental allergens, an asthmatic attack may be precipitated by

## CLINICAL SIGNIFICANCE

The therapeutic approach to the management of asthma and chronic obstructive pulmonary disease (COPD) has changed dramatically over the past several decades. Treatment guidelines have evolved based on a better understanding of these disease states as well as on the development of newer and more efficacious treatment modalities through the application of structure-activity relationships (SARs) of chemical lead compounds. Although both disease states are characterized by pulmonary obstruction and chronic inflammation, the nature of such pulmonary abnormalities differ between the two conditions. Traditional therapy had focused on the symptomatic relief of airflow obstruction through the use of bronchodilators, such as adrenergic agonists and anticholinergics. Today, however, greater emphasis is placed on managing the underlying inflammation and minimizing disease progression.

The current therapeutic approach to managing these diseases includes the use of rapidly acting drugs to relieve acute symptoms as well as maintenance medications to minimize inflammation and control long-term symptoms. Short-acting adrenergic agonists are the agents most commonly used to manage acute exacerbations of these disease states. Although effective, older agents, such as epinephrine and isoproterenol, were limited in their pharmacokinetic profile as well as in their lack of pulmonary selectivity. Modifying the chemical structure of these compounds, however, has resulted in the development of agents with significant clinical advantages in terms of duration of action and adverse effect profiles. Similarly, the application of SAR principles to the development of anti-inflammatory agents, such as corticosteroids, leukotriene antagonists, and mast-cell stabilizers, has lead to the availability of superior long-term controlling agents in terms of potency, pharmacokinetic profile, and safety.

In treating patients with asthma and COPD clinicians should be mindful of the SARs of those agents being employed. The application of these principles should be used to determine the most appropriate drug therapy in light of patient-specific needs and desired therapeutic outcomes. Additionally, clinicians can look forward to the availability of newer and more clinically appropriate agents for the management of asthma and COPD as research in medicinal chemistry results in the development of increasingly selective drug entities and improved receptor targeting modalities.

respiratory infection, exercise, polyps, drugs (e.g., aspirin and β-adrenergic antagonists), and environmental pollutants (e.g., sulfur dioxide, cigarette smoke, and occupational chemicals). In predisposed individuals, emotional stress and drugs or foods that contain tartrazine, sulfites, and preservatives also can precipitate an asthmatic onset (7).

Why has there been a marked increase in asthma in affluent industrialized countries? To answer this question, recent thought has focused on the "hygiene hypothesis," which implicates an imbalance of $TH_1$ and $TH_2$ lymphocytes as a major cause of the increased prevalence of asthma (8). The $TH_1$ lymphocytes are the type of CD4+ T lymphocyte associated with defense against bacterial infection, whereas the $TH_2$ type predominates in allergic inflammation. The hypothesis claims that because bacterial infections have significantly decreased in industrialized nations, there is an imbalance, in susceptible children, in favor of the $TH_2$-type lymphocytes, and this imbalance therefore favors allergic asthma (9).

Asthma frequently occurs in families, and studies have shown that this results, at least in part, from mutually shared genes (10,11). Asthma is a complex disorder and lacks a mendelian genetic pattern, so it is difficult to study. To date, however, genetic research indicates that what is inherited is the susceptibility to develop asthma. It is clear that genes alone are not responsible for the development of asthma, because environmental factors also play a major role. Numerous genes on various chromosomes have been linked to asthma. Table 44.1 shows several gene products that may influence the development of asthma (10–15). In reality, however, there is little correlation between gene expression and clinical symptoms. The one exception to this is the low-expression allele of macrophage migration inhibitory factor (MIF), which has been shown to have a strong association with patients that have mild asthma (16). Drug development of MIF inhibitors might lead to future treatments for asthma.

## Pathogenesis of Asthma

For a long time, asthmatic symptoms were thought to be the result of airway smooth muscle abnormalities, resulting in episodic bronchoconstriction. Today, however, it is clear that the constriction of bronchial smooth muscle is only one of many effects of chronic airway inflammation. Evidence of inflammation appears very soon after the onset of symptoms; therefore, treatment algorithms for asthma now emphasize quick relief of the bronchoconstriction and the amelioration of the underlying inflammation (17).

Inflammation in asthma is characterized by mucous plugging, epithelial shedding, basement membrane thickening, inflammatory cell infiltration, and smooth muscle hypertrophy and hyperplasia (Fig. 44.1). An acute extrinsic asthmatic attack begins when mast cells become activated. Activation of mast cells occurs when an antigen cross-links with immunoglobulin (Ig) Es on their surface. This IgE complex triggers mast cell degranulation, leading to the rapid release of inflammatory mediators, such as histamine, prostaglandins, leukotrienes, and cytokines (including tumor necrosis factor α and interleukins). The initial attack generally resolves within an hour; however, a second phase begins 4 to 6 hours after exposure and can last up to 24 hours. This late phase is a result of recruitment of additional inflammatory cells, primarily eosinophils, by the release of cytokines from macrophages and $TH_2$-type lymphocytes in the lower lung (18).

## Clinical Evaluation

Most patients with asthma are asymptomatic between acute exacerbations. The onset of symptoms can be sudden or gradual and frequently can occur during the night or early in the morning. Acute symptoms include shortness of breath, wheezing or whistling at the end of exhalation, cough, and chest tightness. Patients with chronic and poorly controlled asthma develop barrel chest and diminished diaphragm movement, both of which are evidence of chronic pulmonary hyperinflation.

Acute asthmatic attacks may be mild, moderate, or severe depending on the degree of airway obstruction. The determination of the degree of airflow obstruction is accomplished by pulmonary function testing. The most common pulmonary function test utilizes spirometry, which measures the rate at which the lung changes volume during forced breathing maneuvers. The most important spirometric measure is the forced vital capacity (FVC). This requires the patient to exhale as rapidly and as completely as possible after a maximal inhalation. Normal lungs generally can empty their volume in 6 seconds or less. When airflow is obstructed, however, the expiratory time may increase by as much as fivefold. In practice, the forced expiratory volume in the first second of expiration ($FEV_1$) is measured and compared to the FVC and then recorded as the ratio of $FEV_1$ to FVC ($FEV_1/FVC$) (Fig. 44.2) (measurement is done by means

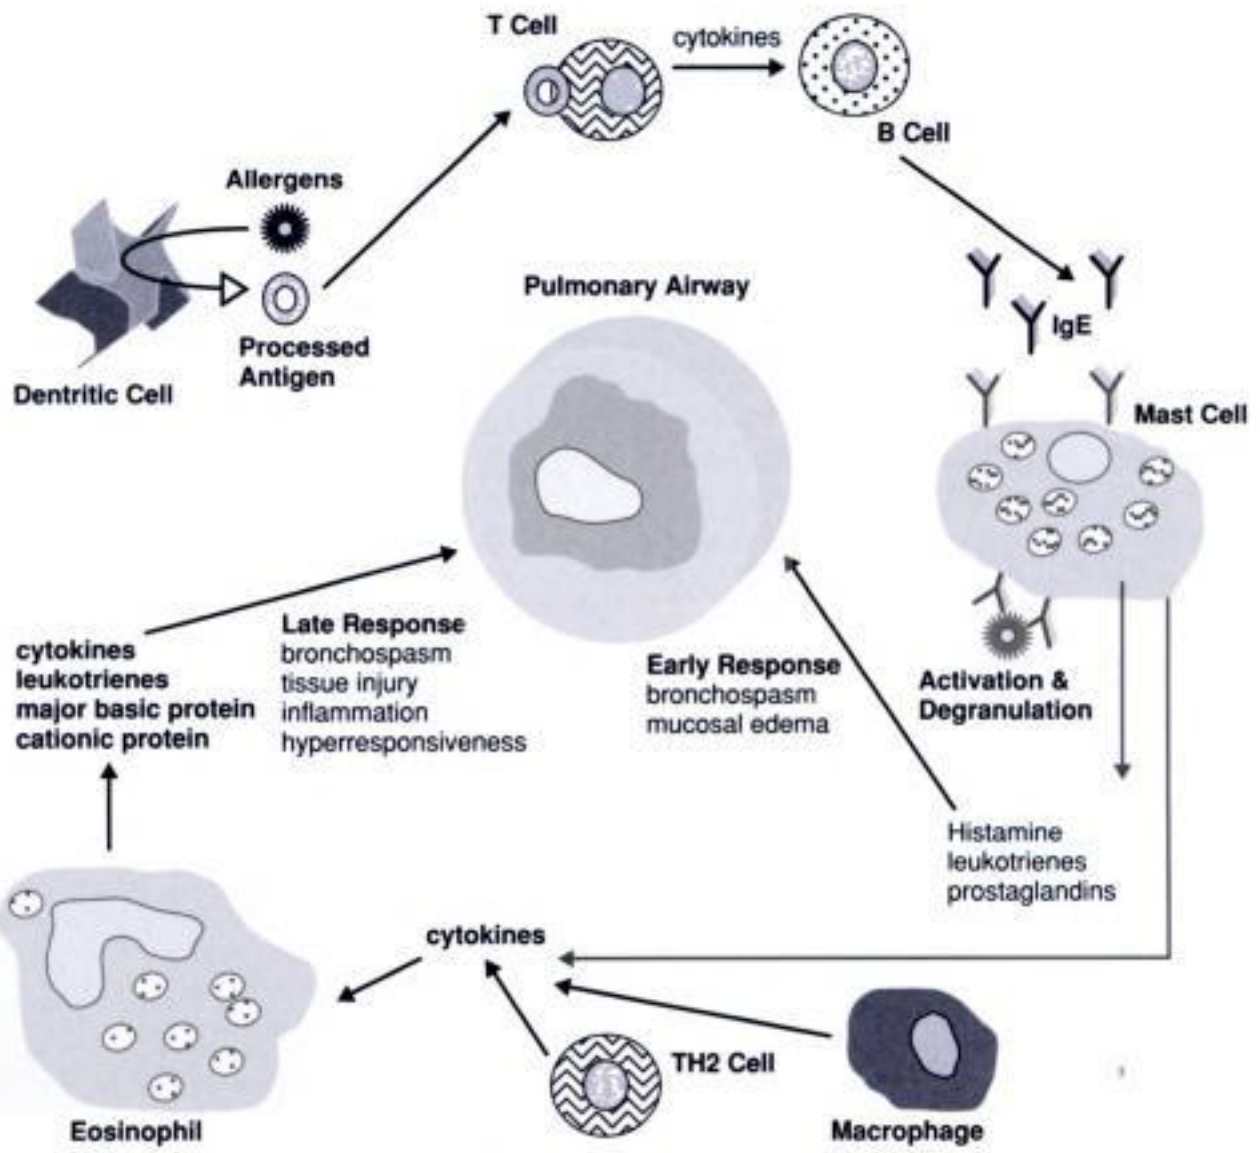

**Fig. 44.1.** Pictorial summary of asthma pathogenesis.

Copyrighted material

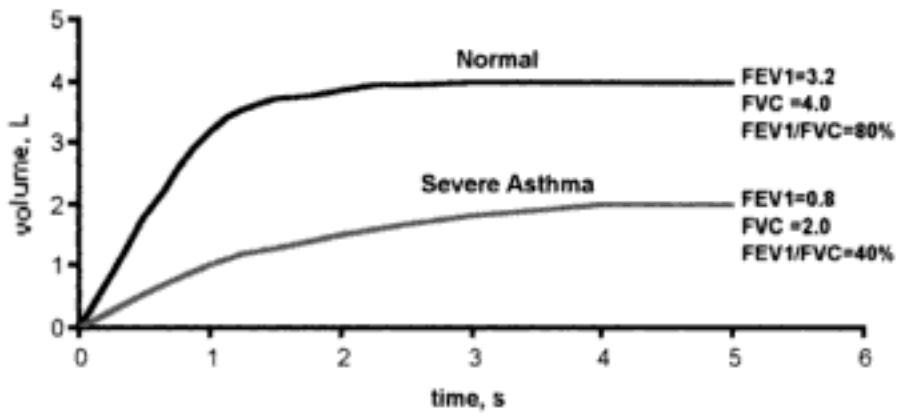

**Fig. 44.2.** Spirometric comparison of normal and severe asthma. $FEV_1$, forced expiratory volume in 1 second; FVC, forced vital capacity.

of a spirometer). Healthy persons normally can expel at least 75% of their FVC in the first second. Deceases in the $FEV_1$/FVC ratio indicate obstruction, and a decrease below 40% indicates severe asthma (17,18).

A more convenient way to measure airway obstruction is to determine the peak expiratory flow (PEF) rate. The PEF rate correlates well with the $FEV_1$; can be determined using inexpensive, handheld, peak flow meters; and is easily and simply measured at home. The PEF rate is the maximal rate of flow that is produced through forced expiration. Peak flow meters come with a chart that lists predicted PEF rates based on the patient's age, gender, and height. The patient or clinician can then compare the determined PEF rate with the predicted PEF rate and make an evaluation regarding the severity of an asthmatic attack. The PEF rate or the $FEV_1$, along with the frequency of daytime and nighttime symptoms, forms the basis for the classification of the severity of an asthmatic attack. Table 44.2 shows the severity classification of asthma established by the NIH Expert Panel Report 2: Guidelines for the Diagnosis and Management of Asthma (EPR-2) (5).

## GENERAL THERAPEUTIC APPROACHES TO THE TREATMENT AND MANAGEMENT OF ASTHMA

Asthma symptoms are caused by bronchoconstriction and inflammation, and approaches to treatment are directed at both these physiological problems. Therefore, drugs that affect adrenergic/cholinergic bronchial smooth muscle tone and drugs that inhibit the inflammatory process are used to treat and control asthma symptoms. In the normal lung, bronchiole smooth muscle tone results from the balance between the bronchoconstrictive effects of the cholinergic system and the bronchodilating effects of the adrenergic system on the smooth muscles of the bronchioles. Pharmacological treatment of asthmatic bronchoconstriction consists of either increasing adrenergic tone with an adrenergic agonist or inhibiting cholinergic tone with an anticholinergic agent.

The inflammatory effects seen in asthma result from the release of physiologically active chemicals from a variety of inflammatory cells. Pharmacological treatment, therefore, uses anti-inflammatory drugs (corticosteroids), mast cell stabilizers, leukotriene modifiers, and IgE monoclonal antibodies. Figure 44.3 depicts the overall approach to the pharmacological treatment of asthma.

Therapeutic management of asthma requires the use of quickly acting drugs to relieve an acute attack as well as drugs that control symptoms over the long-term. The current approach to asthma management utilizes a stepwise approach (5). The quick-reliever medication is almost always an inhaled short-acting $\beta_2$-adrenergic agonist, whereas controller drugs are inhaled corticosteroids, long-acting $\beta_2$-agonists, leukotriene modifiers, cromolyn sodium, and/or methylxanthines. The dose, route of administration, and number of controller drugs depends on the severity of the patient's disease. Table 44.3 shows the stepwise approach to asthma management based on disease severity.

## THERAPEUTIC CLASSES OF DRUGS USED TO TREAT ASTHMA AND CHRONIC OBSTRUCTIVE PULMONARY DISEASE

### $\beta_2$-Adrenergic Agonists

#### Introduction

What structural features make a drug an adrenergic agonist? What features make it a selective $\beta_2$-agonist? The answers to these questions lie in the structural relationship

Table 44.2. Classification of Asthma Severity (5)

| | Step 1 (Mild Intermittent) | Step 2 (Mild Persistent) | Step 3 (Moderate Persistent) | Step 4 (Severe Persistent) |
|---|---|---|---|---|
| Frequency of symptoms | | | | |
| Days | ≤2/week | 3–6/week | Daily | Continual |
| Nights | ≤2/month | 3–4/month | ≥5/month | Frequent |
| PEF or $FEV_1$ | ≥80% | ≥80% | >60%<br><80% | ≤60% |
| PEF or $FEV_1$ variability | <20% | 20–30% | >30% | >30% |

of a drug to that of norepinephrine (NE), the physiological neurotransmitter of the sympathetic branch of the autonomic nervous system. Drugs that act on postsynaptic sympathetic receptors in the same way as NE are called sympathomimetics or, more commonly, adrenergic agonists. The related natural agonist epinephrine (EPI; adrenalin) is the predominant adrenergic hormone produced in the chromaffin cells of the adrenal medulla. Epinephrine interacts just like NE at all adrenergic receptors.

### Chemistry and Biochemistry of Norepinephrine and Epinephrine

Chemically, NE is classified as a catecholamine. A catechol is a 1,2-dihydroxybenzene, and NE is a β-hydroxyethylaminodihydroxybenzene. Epinephrine is the N-methyl derivative of NE, and they both have acidic and basic functional groups. Physiologically, however, they behave as a base, being more than 90% protonated at pH 7.4 ($pK_a$ = 9.6) and functioning as an ionized acid.

Norepinephrine R = H
Epinephrine R = $CH_3$

Norepinephrine is biosynthesized in the neurons of both the central nervous system and the autonomic nervous system, whereas EPI is formed in the chromaffin cells of the adrenal medulla. Both NE and EPI are derived from L-tyrosine by a series of enzyme-catalyzed reactions (Fig. 44.4 depicts the overall pathway). L-Tyrosine hydroxylase hydroxylates the meta position of L-tyrosine, producing L-dihydroxyphenylalanine (L-DOPA) and is the rate-limiting step. The L-DOPA is then decarboxylated by L-aromatic amino acid decarboxylase to form dopamine, which is converted to NE by the action of dopamine β-hydroxylase. Dopamine β-hydroxylase occurs in storage vesicles of the nerve ending, and the NE formed is stored there until it is released into the synaptic cleft. In the chromaffin cells, the formed NE is converted to EPI by N-methylation catalyzed by phenylethanolamine N-methyltransferase.

### Termination of Neurotransmission

Stimulated adrenergic neurons release NE into the synaptic cleft, which then binds reversibly with receptors to produce a characteristic adrenergic response. Termination of the adrenergic response occurs primarily by reuptake (uptake-1) into the presynaptic neuron; however, diffusion away from the receptors and extracellular metabolism also occurs to a limited extent. The NE that is taken back up into the presynaptic neuron is

Copyrighted material

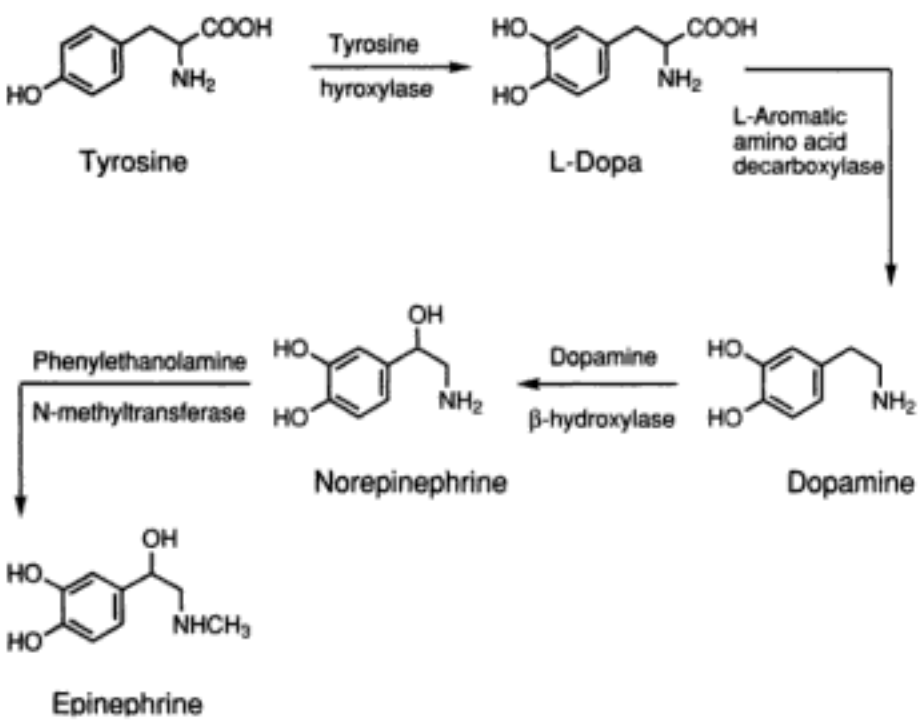

**Fig. 44.4.** The biosynthesis of norepinephrine and epinephrine from tyrosine.

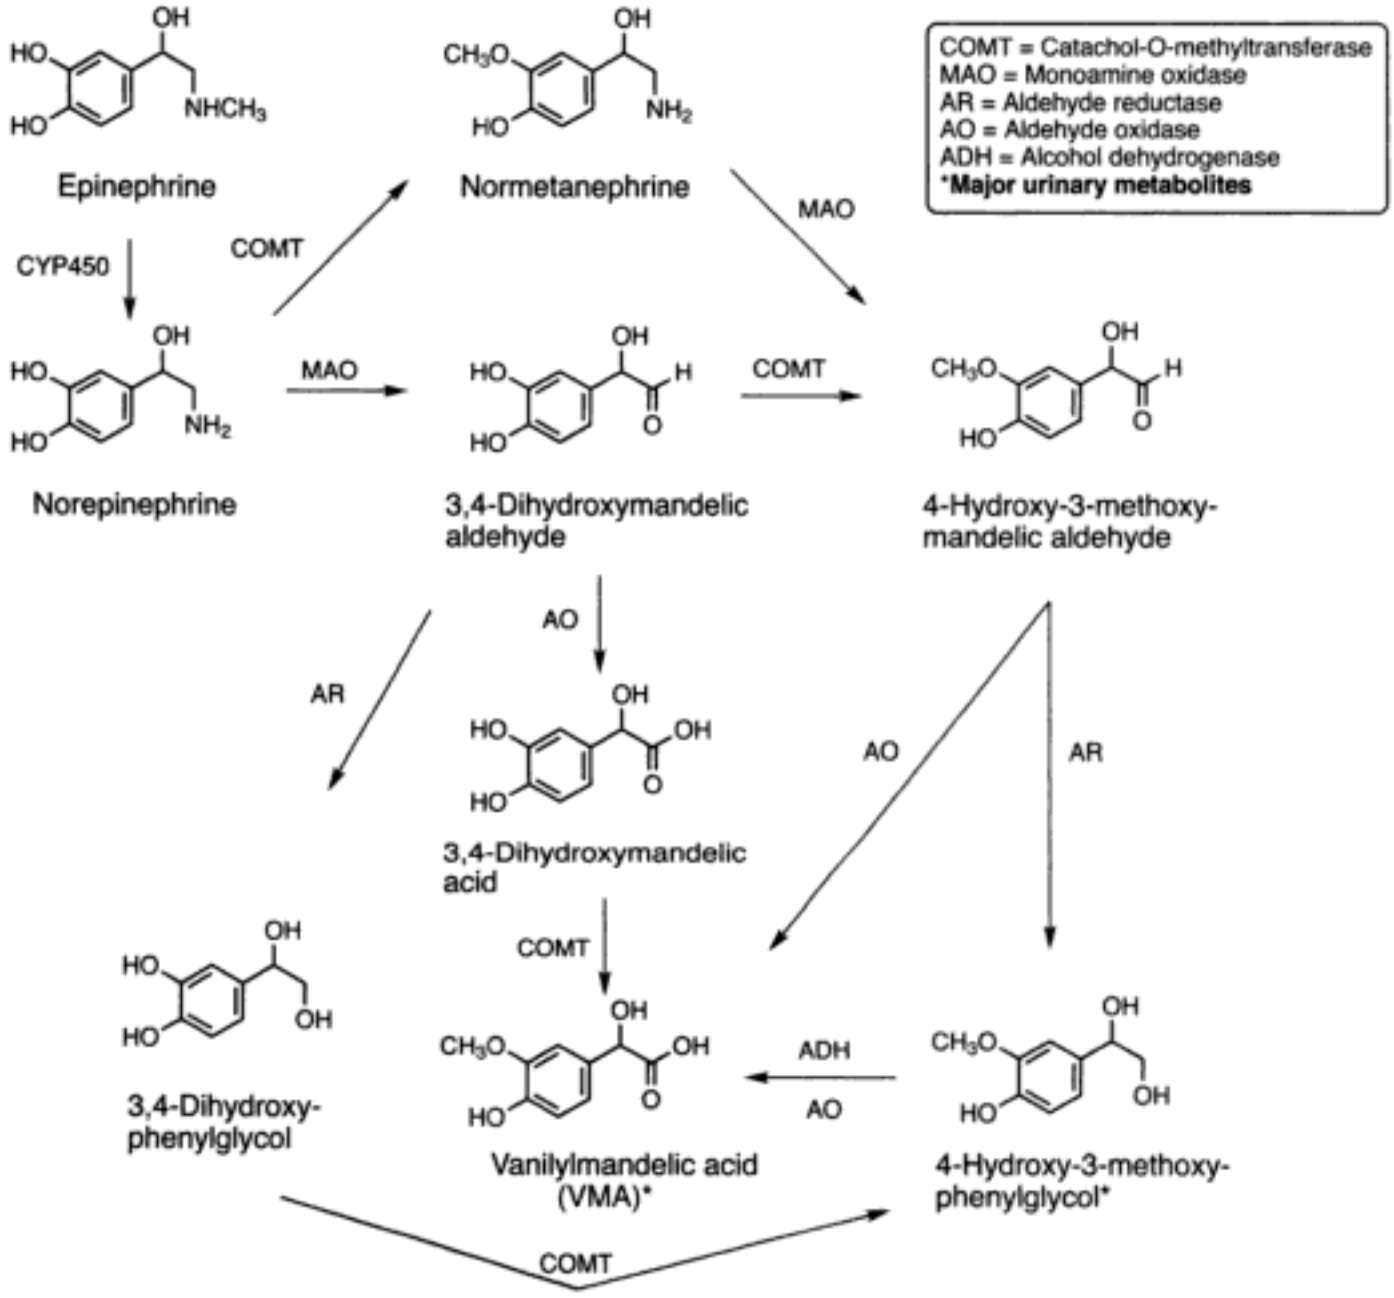
either used again as a neurotransmitter or is metabolized by mitochondrial monoamine oxidase (MAO). The extraneuronal NE that diffuses away from the neurons is either metabolized by catechol O-methyl transferase (COMT) in situ or reaches the circulatory system and is metabolized by COMT and MAO in various tissues, most importantly the liver, gastrointestinal (GI) tract, and the lungs. Figure 44.5 depicts the possible metabolic pathways for both NE and EPI. It is important to note that agonists that are resistant to MAO and/or COMT have greater oral availability and longer duration of action.

## Adrenergic Receptors

The adrenergic receptors have long been pharmacologically classified as α or β based on their interaction with NE, EPI, and the adrenergic prototype, isoproterenol (19).



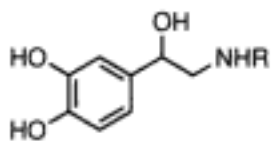


**Fig. 44.5.** Metabolic pathways for norepinephrine and epinephrine.

Copyrighted material

Norepinephrine (NE) R = H

Epinephrine (EPI) R = $CH_3$

Isoproterenol (ISO) R = $HC(CH_3)_2$

As mentioned above, NE and EPI are nonselective and interact with all adrenergic receptors, but isoproterenol selectively interacts only with the β-receptors. The adrenergic receptors have been further divided into three groups, $\alpha_1$, $\alpha_2$ and β, each of which has been further divided into three receptor subtypes based on their organ distribution and physiologic activities (20). Therefore, there are now a total of nine adrenergic receptor subtypes, but the most important in relation to the treatment of asthma and chronic obstructive pulmonary disease (COPD) are the $\beta_1$ and $\beta_2$ subtypes that are found primarily in the heart and the lung, respectively. As may be deduced from Table 44.4, adrenergic agonists that are selective for the $\beta_2$ subtype will cause bronchial dilation and might be expected to relieve the bronchospasm of an asthmatic attack. Nonselective β-agonists, however, will have stimulatory cardiac effects and, therefore, would have limited use in cardiac patients with asthma.

### Adrenergic Receptor Structure and Agonist Interactions

The adrenergic receptors are a member of the guanine nucleotide binding regulatory protein–coupled receptor family more commonly referred to as G protein–coupled receptors. They affect biological activity by releasing secondary messenger molecules inside the cell after they bind an extracellular agonist. This process usually is referred to as signal transduction and is common to hormone and neurotransmitter receptors found in the muscarinic, serotonergic, dopaminergic, and adrenergic systems. All the G protein–coupled receptors are structurally similar, being comprised of seven transmembrane

Table 44.4. Physiological Response in Relationship to β-receptor Subtype and Organ Site

| Receptor Subtype | Organ Location | Response |
|---|---|---|
| $\beta_1$ | Heart | Increased rate and force<br>Increased conduction velocity |
| $\beta_2$ | Bronchiole smooth muscle | Dilation |
| | Intestine | Decreased motility |
| | Liver | Increased gluconeogenesis<br>Increased glycogenolysis |
| | Uterus | Contraction |
| | Lungs | Bronchial dilation |

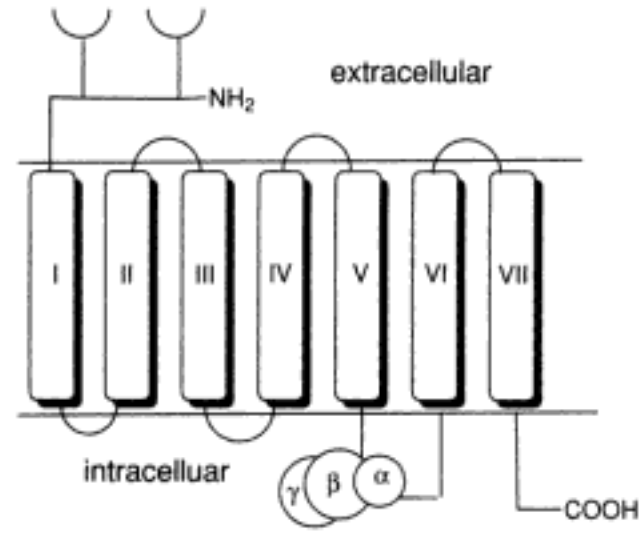

**Fig. 44.6.** Representation of the G protein–coupled receptor.

α-helix bundles. The helices are connected by short stretches of hydrophilic residues, which form multiple loops in the intracellular and extracellular domains. The G proteins generally are bound to the third intracellular loop and imbedded in the inner membrane (Fig. 44.6).

All the β-adrenergic receptors are coupled to adenylate cyclase via specific G stimulatory proteins (Gs). When agonist binds to the β-adrenergic receptors, the α-subunit migrates through the membrane and stimulates adenylate cyclase to form cyclic adenosine monophosphate (cAMP) from adenosine triphosphate. Once formed in the cell, cAMP activates protein kinase A, which catalyzes the phosphorylation of numerous proteins, thereby regulating their activity and leading to characteristic cellular responses. The intracellular enzyme phosphodiesterase (PDE) hydrolyzes cAMP to form AMP and terminates its action (Fig. 44.7).

A great deal of research has been done to identify the binding residues of the adrenergic receptors. Molecular modeling methods have been used to construct three-dimensional models for agonist complexes with the β-adrenergic receptors. The picture that has emerged is that NE binds ionically via its protonated amine to Asp-113 in helix 3 and hydrogen bonds to both hydroxyls of the catechol ring with Ser-204 and Ser-207 in helix 5. That binding limits configurational and rotational freedoms, which allows reinforcing van der Waals interactions between the aromatic ring with residues Phe-290 in helix 6 and Val-114 in helix 3. The N-alkyl substituents are believed to fit into a

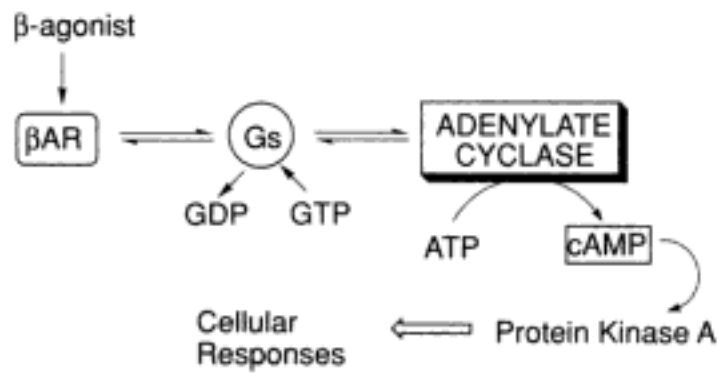

**Fig. 44.7.** β-Adrenergic receptor G protein coupling to adenylate cyclase.

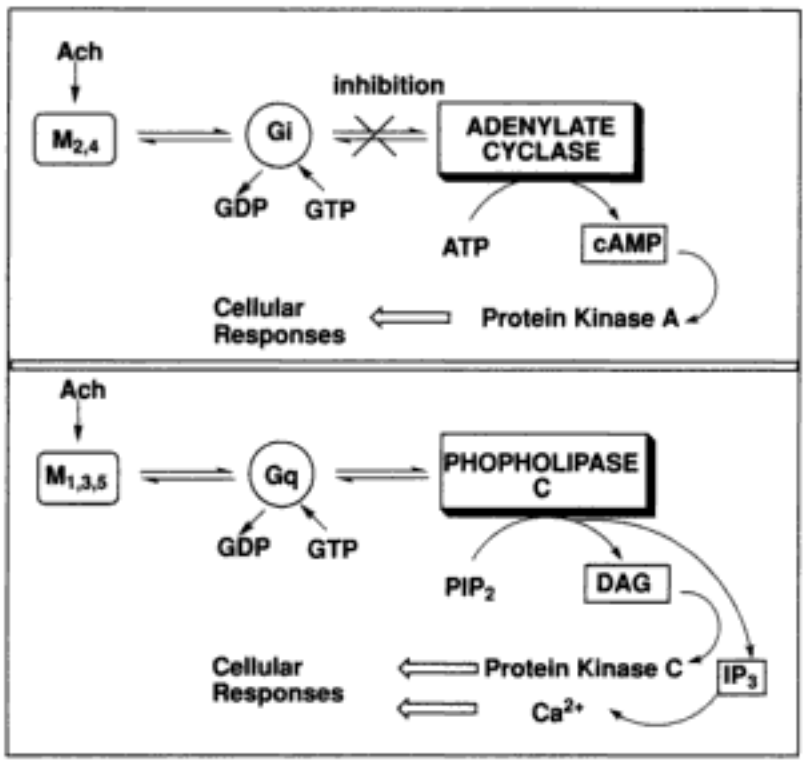

**Fig. 44.14.** Comparison of the role of G protein in odd- and even-numbered muscarinic receptors.

adrenergic bronchiole dilation to help overcome the pulmonary constriction associated with an asthmatic attack.

Affinity labeling and mutagenic studies have established that acetylcholine binds to its receptor in a narrow region of the circular arrangement of the seven transmembrane helices approximately 10 to 15 angstroms away from the membrane surface. The cationic nitrogen of acetylcholine binds to the anionic carboxylate of an Asp located in helix 3 (26). As depicted in Figure 44.15, the ionic interaction is stabilized by hydrogen-bonding with a Tyr in helix 5 and a Thr in helix 5. It is postulated that muscarinic antagonists (see *Structure–Activity Relationships of Antimuscarinic Agents* below) bind to the Asp and contain hydrophobic substituents that bind to a hydrophobic pocket in the receptor, which does not allow the change in conformation needed to transfer the agonist signal to the coupled G protein (27).

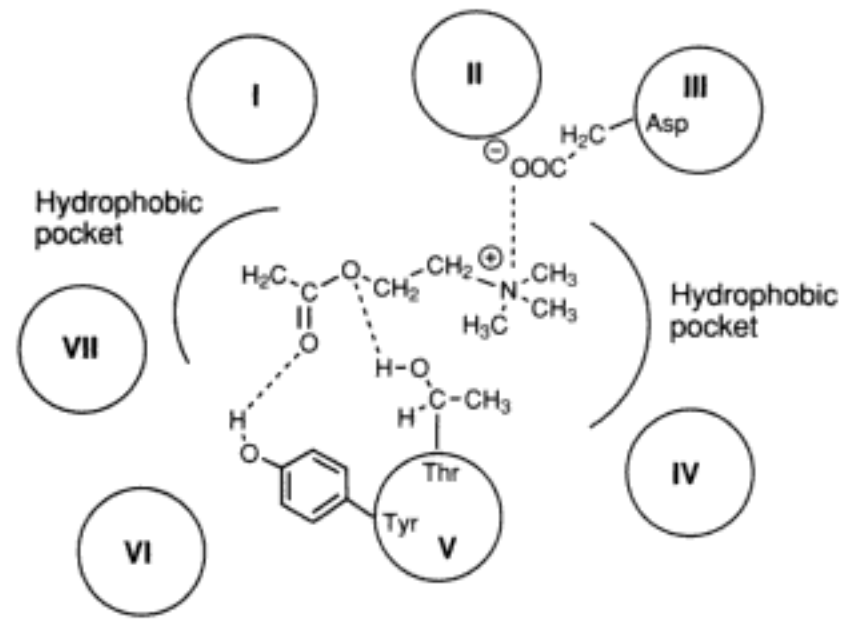

**Fig. 44.15.** Acetylcholine binding to residues in the muscarinic receptor.

### Structure–Activity Relationships of Antimuscarinic Agents

The structural pharmacophore for all antimuscarinic drugs is an acetylcholine analogue in which the acetyl methyl group is substituted with at least one phenyl ring. This pharmacophore generally is classified as an amino alcohol ester. The ester function can be replaced with different moieties to produce different classes of antimuscarinic drugs. When the ester function is replaced by an ether function, the amino alcohol ether class is produced. When the ester function is replaced by a saturated carbon, the amino alcohols are obtained when $R_1$ is a hydroxyl group, and the amino amides are obtained when $R_1$ is an amido group (Fig. 44.16).

The classic chemical prototype for the antimuscarinics is atropine, an alkaloid from *Atropa belladonna*. Buried within its structure is the amino alcohol ester pharmacophore, where $R_1$ is a hydroxymethyl group, $R_2$ is a hydrogen, and the nitrogen is part of a bicyclic ring system called tropine (Fig. 44.17).

**Table 44.6. Physiological Action Associated with the $M_3$ Muscarinic Receptors**

| Organ | $M_3$-Receptor Effect |
|---|---|

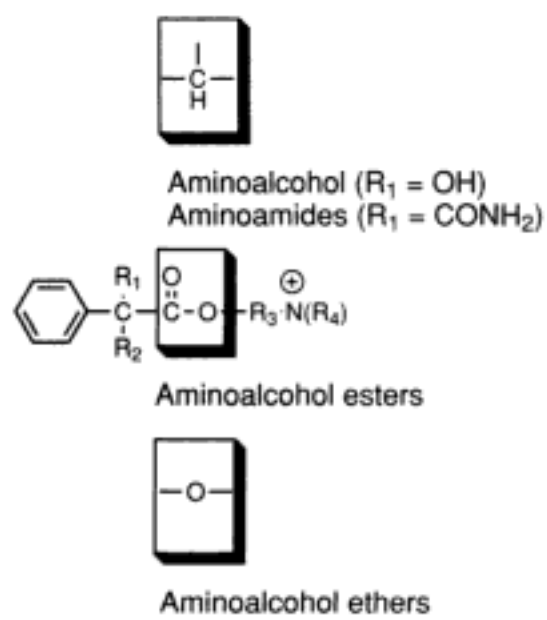

**Fig. 44.16.** The pharmacophore for all classes of antimuscarinic agents.

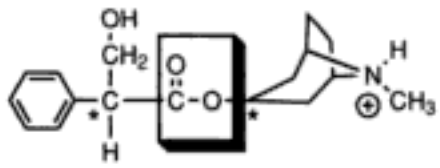
Copyrighted material



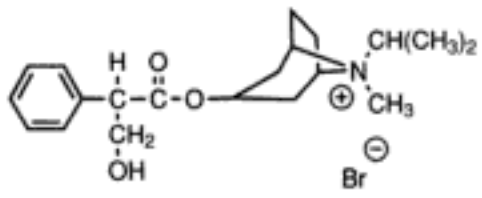


**Fig. 44.17.** Atropine is an example of the amino alcohol ester class of antimuscarinic agents.

Although atropine does not have a quaternary nitrogen, the nitrogen is protonated at physiologic pH; therefore, it can bind to the anionic Asp residue in the muscarinic receptor. The nitrogen is not absolutely necessary for activity and can be replaced with a carbon atom. This leads to a substantial lose of binding affinity, however, and there are no marketed drugs with this configuration. The nitrogen can be substituted with alkyl groups, and methyl is the optimal size. When the nitrogen is made quaternary, the molecule loses its oral availability but leads to compounds that can be administered effectively by inhalation. The asterisks in atropine (Fig. 49.17) refer to chiral carbons. When stereochemistry is present in the amino alcohol moiety (tropine), there is little difference between the activities of the *R*- and *S*-configurations. When stereochemistry is found in the acid moiety, however, the *R* configuration is approximately 100-fold more active than the *S*-isomer. This indicates the importance of the binding role for the phenyl ring in causing the uncoupling of the G protein, which leads to receptor inhibition (28).

## Specific Antimuscarinic Drugs Used to Treat Asthma

For a more detailed discussion of the chemistry of cholinergic agents, see Chapter 12.

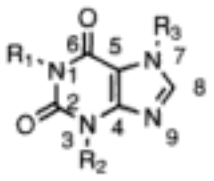
Ipratropium hydrobromide
(Atrovent)

Ipratropium is the N-isopropyl analogue of atropine. Its quaternary cationic nature makes it highly hydrophilic and poorly absorbed from the lungs after inhalation via solution or aerosol. Much of an inhaled dose is swallowed. There is no significant absorption, however, and the bronchodilation effect can be considered to be a local, site-specific effect. Ipratropium is indicated primarily for the relief of bronchospasms associated with COPD (chronic obstructive pulmonary disease) and has seen little application for the treatment of asthma. It also is administered by nasal spray for the relief of rhinorrhea associated with the common cold and perennial rhinitis. Inhaled ipratropium has a 15-minute onset of action and a rather short duration of action (<4 hours); therefore, it is dosed four times a day. Other drugs, including adrenergic agonists, methylxanthines, steroids, and cromolyn sodium, can be coadministered with ipratropium without adverse drug reactions. The little ipratropium that reaches the circulation is minimally protein bound and is partially metabolized to inactive esterase products. Most adverse effects from ipratropium are common to antimuscarinics and include blurred vision, dry mouth, tachycardia, urinary difficulty, and headache. Patients should be careful not to spray ipratropium into their eyes, because its dilation effects can precipitate or exacerbate narrow-angle glaucoma.

### Tiotropium Bromide

Tiotropium bromide
(Spiriva)

Scopolamine



Tiotropium is the dithienyl derivative of N-methyl scopolamine, a quaternary analogue of naturally occurring scopolamine in *Atropa belladonna*. It is indicated primarily for the relief of bronchospasms associated with COPD and can be considered to be a site-specific, local medication to the lung. Tiotropium is administered as a dry powder via inhalation using a HandiHaler, in which is placed the drug, contained in a green capsule. Patients should be cautioned not to be confused and take the medication orally. Systemic distribution following oral inhalation is minimal, essentially because of its hydrophilic character. If swallowed, only approximately 14% of the dose is eliminated in the urine, with the remainder being found in the feces. Inhaled tiotropium has a 30-minute onset of action but a much longer duration of action than ipratropium (24 versus <4 hours, respectively). Tiotropium is metabolized by both CYP3A4 and CYP2D6, followed by glutathione conjugation to a variety of metabolites. Only a very small amount is nonenzymatically hydrolyzed to inactive products. Tiotropium has an adverse reaction profile similar to that of ipratropium, with dry mouth being the most common adverse effect; however, blurred vision, tachycardia, urinary difficulty, headache precipitation, and exacerbation of narrow-angle glaucoma have been reported.

## Methylxanthines

### Introduction

The methylxanthines naturally occur in coffee (*Coffea arabica*), cacao (*Theobroma cacao*), and tea (*Camellia sinensis*) (29). The major methylxanthines are caffeine, theophylline, and theobromine, and they differ by the

Copyrighted material

| | $R_1$ | $R_2$ | $R_3$ |
|---|---|---|---|
| Caffeine | $CH_3$ | $CH_3$ | $CH_3$ |
| Theophylline | $CH_3$ | $CH_3$ | H |
| Theobromine | H | $CH_3$ | $CH_3$ |

**Fig. 44.18.** Structural differences between the methylxanthines.

position and number of methyl groups on their xanthine ring system (Fig. 44.18).

The most common source of these xanthines is in the beverages coffee, tea, and cocoa, which are universally consumed mainly for their stimulant properties. A cup of coffee or tea contains between 60 and 85 mg of caffeine, and a cup of cocoa can have as much as 250 mg of theobromine. Caffeine frequently is added to cola drinks as well as to over-the-counter analgesics and stimulants. Theophylline is used for its bronchodilating effects in the treatment of asthma. Its importance has declined greatly since the development of the inhaled $\beta_2$-adrenergic agonists and inhaled steroids and because its narrow therapeutic window requires close patient monitoring and periodic blood level determination to avoid serious side effects.

### Theophylline

In spite of a great deal of investigation, just how theophylline causes bronchodilation is not clearly understood. Inhibition of the enzyme PDE, which is responsible for the hydrolysis of cAMP and cyclic guanosine monophosphate (cGMP), generally is put forth as the mechanism of action; however, theophylline also is an adenosine antagonist and has been implicated in stimulation of the release of catecholamines. It has been clearly shown that theophylline does inhibit PDEs in vitro, and x-ray crystallographic studies have identified the binding residues that interact with the methylxanthines (Fig. 44.19).

Theophylline binds to a subpocket of the active site and appears to be sandwiched between a phenylalanine and a valine via hydrophobic bonds. Its binding affinity is reinforced by hydrogen-bonding between a tyrosine and

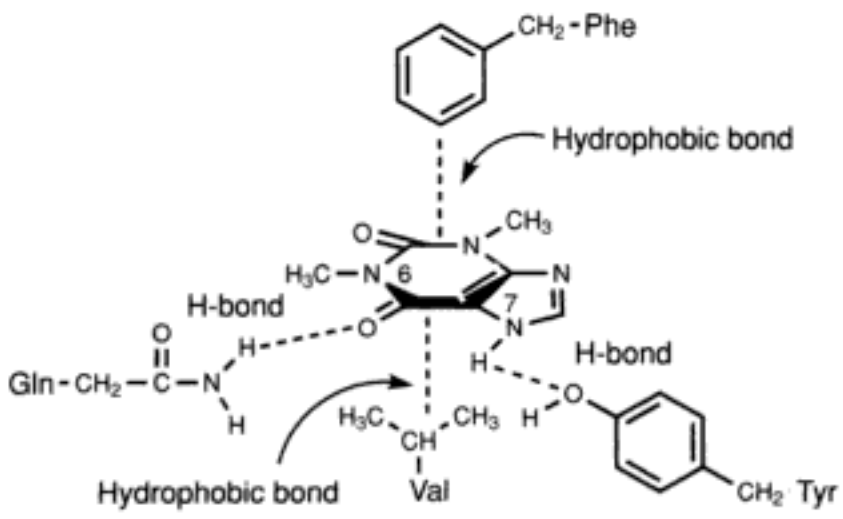


**Fig. 44.19.** Methylxanthine binding interactions in the catalytic pocket of phosphodiesterase.

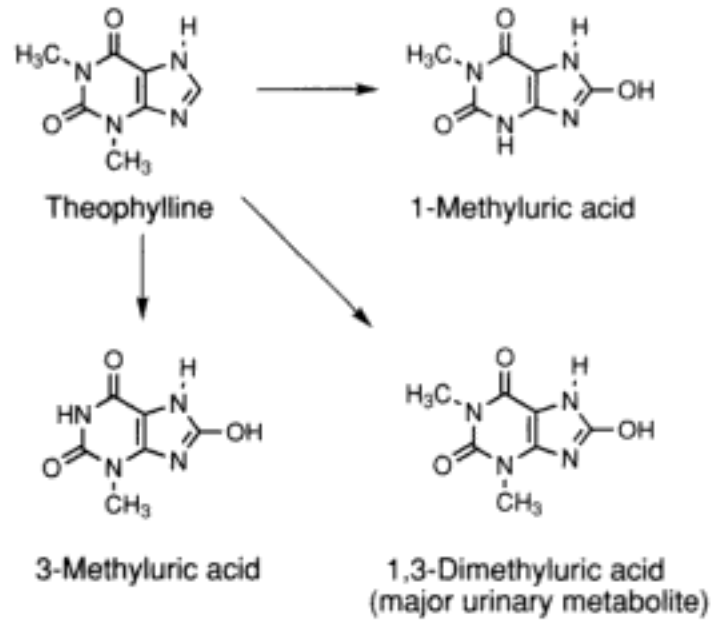

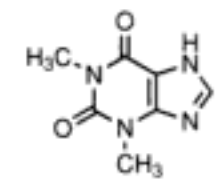

**Fig. 44.20.** Metabolism of theophylline.

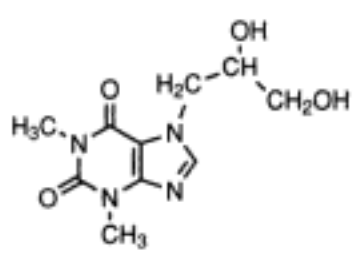
N-7 and a glutamine and O-6 of the xanthine ring system. There are more than 11 families of PDEs, and studies have shown that theophylline binds in a similar manner to both the PDE4 and PDE5 family isoforms (30). (For a more detailed description of PDE subtypes and their inhibitors, see Chapter 17.)

Chemically, theophylline is 1,3-dimethylxanthine and contains both an acidic and a basic nitrogen (N-7 and N-9, respectively). Physiologically, it behaves as an acid ($pK_a$ = 8.6), and its poor aqueous solubility can be enhanced by salt formation with organic bases. Theophylline is metabolized by a combination of C-8 oxidation and N-demethylation to yield methyluric acid metabolites (Fig. 44.20). The major urinary metabolite is 1,3-dimethyl uric acid, which is the product of the action of xanthine oxidase. Because none of the metabolites is uric acid itself, theophylline can be safely given to patients who suffer from gout.

## Methylxanthine Drugs Used to Treat Asthma

### Theophylline



Theophylline
(Elixophylline, Bronkodyl,
various others)

The primary indication for theophylline is as a controller medication for the treatment of bronchospasm of asthma and COPD. In addition to bronchodilation effects, theophylline dilates pulmonary blood vessels, acts centrally to stimulate respiration, acts as a diuretic, increases gastric acid secretion, and inhibits uterine contractions. Dosing requires the determination of plasma levels with 10 to 20 μg/mL being associated with the least incidence of side effects. Overdose of theophylline can result in a quick onset of ventricular arrhythmias, convulsions, or even death

Copyrighted material

without any previous warning. Many drugs increase the plasma concentration of theophylline, including quinolone and macrolide antibiotics, nonselective β-blockers, ephedrine, calcium channel blockers, cimetidine, and oral contraceptives. Theophylline is available in tablet, capsule, liquid, and parenteral dosage preparations. There also are combination products with guaifenesin and ephedrine available as tablet and liquid dosage forms. There are two products that are theophylline salts. Aminophylline is theophylline ethylenediamine, which contains 70% theophylline and is available in tablets, liquid, parenteral, and suppository dosage forms. Oxytriphylline is the choline salt of theophylline, and it contains 64% theophylline in tablets and liquid dosage forms. Care must be taken to correctly calculate the equivalent dose when switching a patient from theophylline to one of its salts.

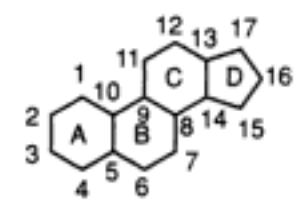
### Dyphylline (Dihydroxypropyl Theophylline)

Dyphylline

Dyphylline is the N-7 dihydroxypropyl derivative of theophylline and is not a theophylline salt. Dyphylline does not get metabolized to theophylline in vivo, and even though it contains 70% theophylline by molecular weight ratio, the equivalent amount to theophylline is not known. Dosing must be accomplished independently by monitoring dyphylline blood levels. Dyphylline has a diminished bronchodilator effect compared to theophylline, but it may have lower and less serious side effects. Dosage forms available are an elixir and tablets.

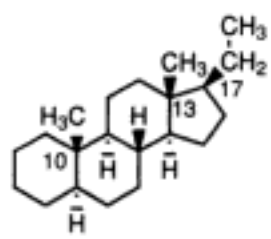
## Adrenocorticoids Used to Treat Asthma and COPD

### Introduction



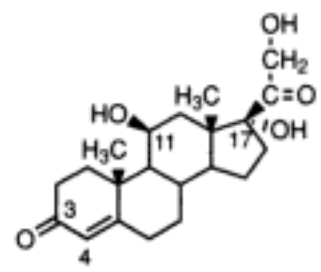
Steroids are a large class of tetracyclic terpene compounds that are widely distributed in plants and animals. Many synthetic analogues have been made to take advantages of their various pharmacological activities. There are four major classes of steroids: the adrenocorticoids, the sex hormones, the bile acids, and the vitamins. The adrenocorticoids are formed in the adrenal cortex and are subdivided into the glucocorticoids and mineralocorticoids. The glucocorticoids are so named because they affect glucose homeostasis, but they also have significant anti-inflammatory activity. The mineralocorticoids affect sodium and water retention. The reproductive organs in both the male and female produce steroid hormones that are responsible for the differentiation of the sex characteristics and the development of muscle and hair. The bile acids are derived from cholesterol and are an essential aid to the action of lipase in the digestion of fats, and vitamin D and its derivatives are associated with calcium homeostasis. We will limit our discussion to the glucocorticoids, because their anti-inflammatory activity makes them useful for the treatment of asthma and COPD. Of note, because the major role of the glucocorticoids is to provide the body with levels of glucose that are compatible with life, they should be used with caution in patients with diabetes. Similarly, because the major role of the mineralocorticoids is to maintain blood volume and regulate electrolyte balance, their use in patients with hypertension should be monitored carefully. (For more detail regarding the adrenal corticosteroids, see Chapter 33.)

### Steroid Nomenclature



The basic structure of a steroid is a tetracyclic cyclopentanoperhydrophenanthrene, referred to as the sterid nucleus, as depicted in Figure 44.21. The addition of methyl groups at C-10 and C-13 and of an ethyl group at C-17 to the sterid nucleus gives a 21-carbon base structure called pregnane. All glucocorticoids are substituted pregnanes. Rings A, B, and C are in the chair conformation, All ring junctions are *trans,* giving the glucocorticoids a rigid backbone with α and β faces. The glucocorticoids bind to their receptor via the β face. All glucocorticoids have at least one double bond in ring A and hydroxyl groups at C-11, C-17, and C-21 as well as 3- and 20-keto groups. For example, hydrocortisone is $\Delta^4$-11β,17α,21-trihydroxy-3,20-pregnenedione. A more complete discussion of steroid nomenclature and stereochemistry has been published elsewhere (31).

### Steroid Biosynthesis and Secretion



Steroids are biosynthesized from cholesterol. Cholesterol is obtained through our diet (~0.3 g/day), but the majority is biosynthesized from acetate in the liver (~1 g/day). The complete pathway can be seen in Figure 44.22. Of note is the central branching role played by pregnenolone, leading to both classes of the adrenocorticoids.

significant mineralocorticoid activity. These include triamcinolone, methylprednisolone, fluticasone, beclomethasone, budesonide, and mometasone.

### Glucocorticoid Metabolism

If one or more of the essential functional groups on the glucocorticoid skeleton are modified by metabolism, glucocorticoid activity will be lost. There are three major metabolic reactions that will eliminate the glucocorticoid activity. They are ring A reductions, C-17 oxidation, and C-11 keto-enol isomerization. Reduction of the ring A 3-keto to a 3α-hydroxy by 3α-hydroxysteroid dehydrogenase, and the reduction of the 4,5-double bond by 5β-reductase to produce the A/B *cis*-fused ring, gives rise to inactive metabolites (Fig. 44.29). Oxidation of the C-17 side chain to produce a 17-keto steroid requires both the C-17 hydroxyl group and a free C-21 hydroxyl group. Esterification of one or both will inhibit this metabolism and prolong the duration of action. The rapid in vivo equilibrium that exists between cortisone (11-keto) and hydrocortisone (11-β-hydroxy) is catalyzed by 11β-hydroxysteroid dehydrogenase, produces the keto form that is inactive but also the hydroxy form that is highly glucocorticoid enhancing and found on all glucocorticoids. Figure 44.29 summarizes the metabolism of hydrocortisone.

### Synthetic Steroid Esters

The glucocorticoids are lipophilic in spite of having at least three hydroxyl groups. The hydroxyl groups can be esterified with an appropriate acid that will either enhance or decrease that lipophilicity. The C-21

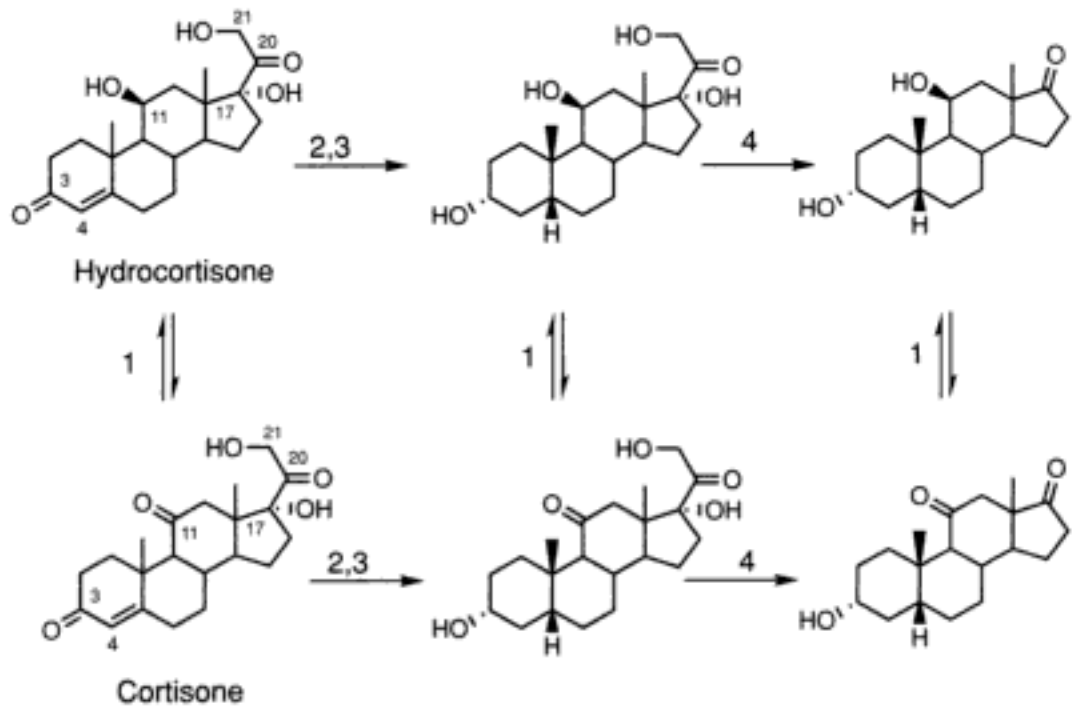

**Fig. 44.29.** Metabolic pathways for hydrocortisone.

Copyrighted material

hydroxyl group is the most accessible and, therefore, is the easiest to esterify. The C-17 hydroxyl group also is easily esterified, but because it is slightly hindered by the C-17 side chain, it will react more slowly. The C-11 hydroxyl group is highly hindered by the C-10 and C-13 methyl groups and will not react with acids to form esters. In addition, esterification has an effect on both receptor affinity and glucocorticoid metabolism. Because the C-21 must be free to hydrogen bond to the Arg-564 in the glucocorticoid receptor, C-21 esters are prodrugs requiring hydrolysis to become active. Also, the C-17 hydroxyl group needs to be free to be metabolically oxidized; therefore, esterification of the C-17 hydroxyl group inhibits oxidation to the C-17 keto group, thus prolonging duration of action. Duration also is prolonged because of the fact that the lipophilic glucocorticoid esters do not concentrate in the urine (i.e., they undergo tubular reabsorption following glomerular filtration).

The lipophilicity of a glucocorticoid can be enhanced by esterification with lipophilic acids. Doing so results in a number of effects, including increasing the log P, which provides local activity with less systemic absorption and decreased side effects. The fact that C-21 lipophilic esters are prodrugs means that they have a longer duration of action. They also have a slower onset, because the lipophilic esters generally are bulky and retard hydrolytic enzymes.

These lipophilic prodrugs can be administered orally to treat a variety of conditions, by inhalation to treat asthma and COPD, and topically to treat various types of dermatitis. When administered orally, their longer duration of action means that they can be given less frequently, which often results in better compliance. Figure 44.30 shows the structures of the most common C-21 lipophilic esters found on commercially available glucocorticoids.

Diesters and ketals provide a further enhancement of log P (i.e., increased lipophilicity) and an increased duration of action, because they are slow to metabolize. It should be noted that diesters and hexacatonides (Fig. 44.31) are prodrugs, whereas plain ketals are not (i.e., they already have a free C-21 hydroxyl group). Diesters are formed at C-21 and at either the C-17 or, if present, the C-16 hydroxyl groups. The diesters are prodrugs; however, the esters at C-17 or C-16 are active intact. The most common diesters are either the diacetate or dipropionate.

A ketal is a cyclic derivative formed between hydroxyl groups on adjacent carbons and a carbonyl carbon of a ketone. The most common ketal found in glucocorticoids is called an acetonide and is the condensation product formed between the C-16 and C-17 hydroxyl groups and the carbonyl carbon of acetone ($CH_3COCH_3$) (Fig. 44.31). If the acetonide is found along with a C-21-*t*-butylacetate ester, it is named a hexacetonide; the "hex" refers to the total number of carbons found in the butylacetate group. The hexacetonides are prodrugs and must hydrolyze to become active. The buteprate (i.e., probutate) is a diester consisting of a propionate at C-21 and a butyrate at C-17 (Fig. 44.31). It also is a prodrug, and the C-21 ester must be hydrolyzed to yield the active form.

Esterification also can be used to increase the hydrophilicity of the glucocorticoids, making them water-soluble prodrugs. The synthetic approach here is to use either a dicarboxylic acid or phosphoric acid to condense with the C-21 hydoxyl group (Fig. 44.31). This

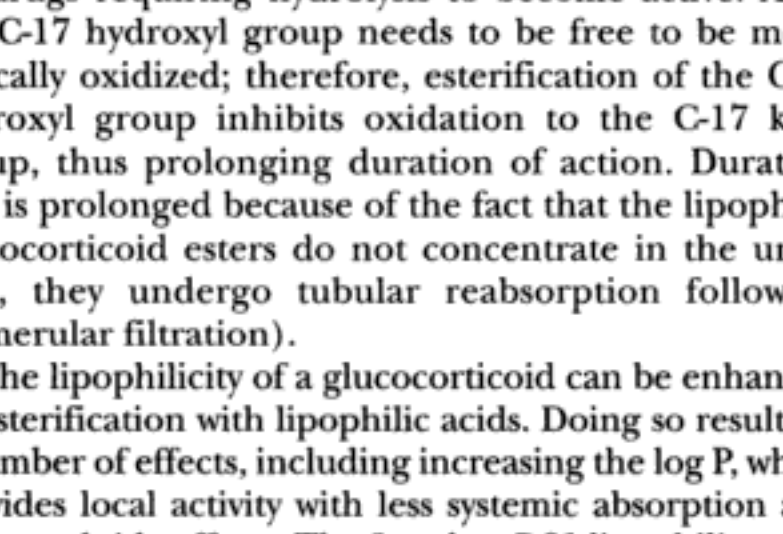

**Fig. 44.30.** Common lipophilic esters of glucocorticoids.

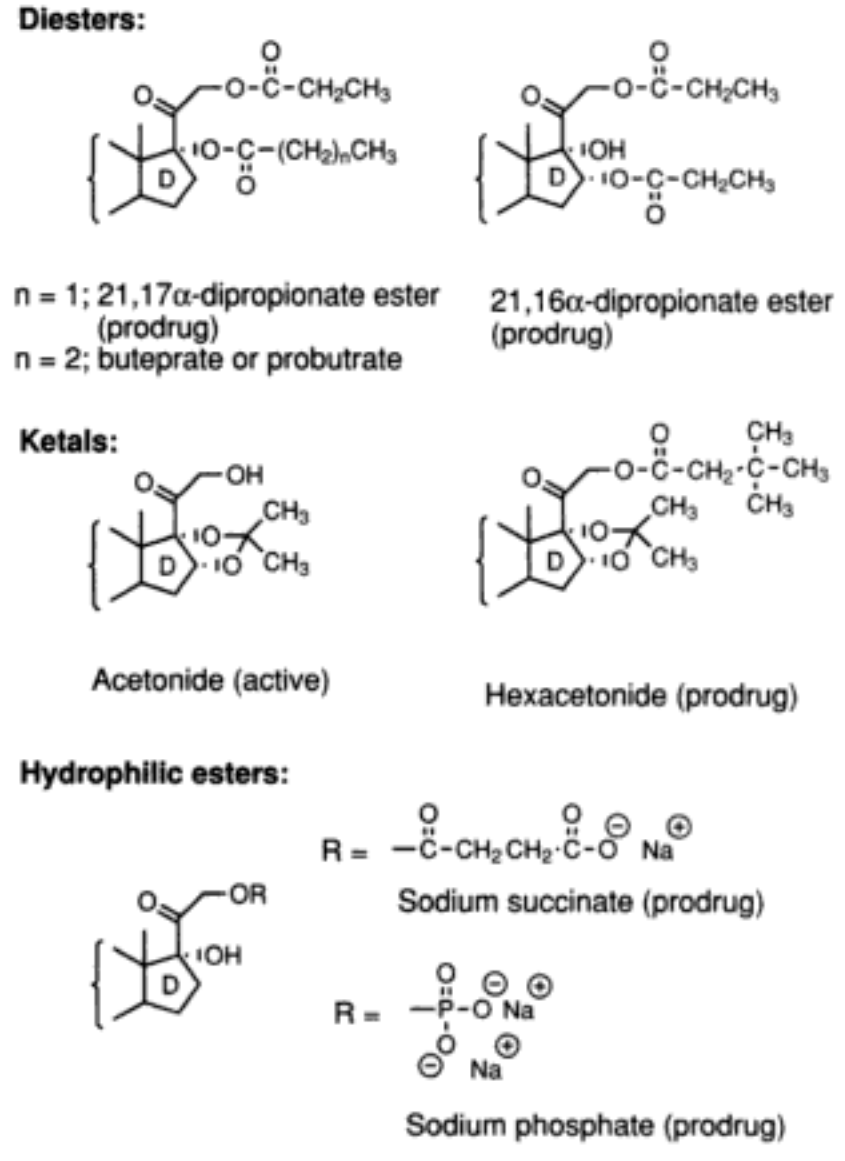

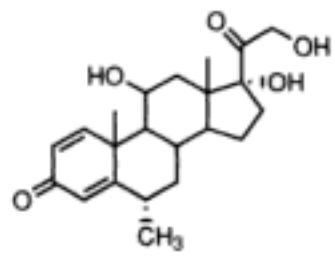

**Fig. 44.31.** Examples of glucocorticoid lipophilic diesters and ketals and hydrophilic esters.

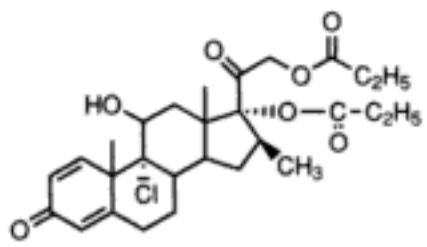
Copyrighted material

nisolone and must be converted in vivo to the active 11β-hydroxy compound, which is necessary to hydrogen bond to Asn-564 in the glucocorticoid receptor. Prednisone should not be used in patients with hepatic dysfunction, because their ability to reduce the 11-keto group with 11β-hydroxysteroid dehydrogenase to the active metabolite may be impaired.

#### METHYLPREDNISOLONE



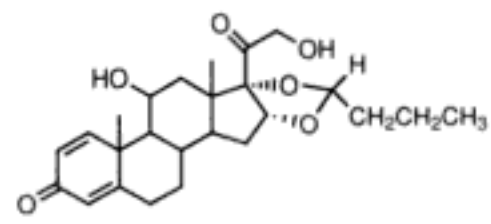
6-Methylprednisolone
(Medrol)

$\Delta^{1,4}$-6α-methyl-11α,17α,21-trihydroxy-pregnadiene-3,20-dione

Adding a 6α-methyl group to prednisolone increases the glucocorticoid activity and effectively abolishes mineralocorticoid action. It has fivefold the glucocorticoid activity of hydrocortisone (prednisolone has fourfold the glucocorticoid activity) and none of its mineralocorticoid properties. It is used almost exclusively as a systemic product and is available as the free alcohol for oral administration and as various esters (Table 44.7).

### Glucocorticoids for Inhalation

#### BECLOMETHASONE DIPROPIONATE

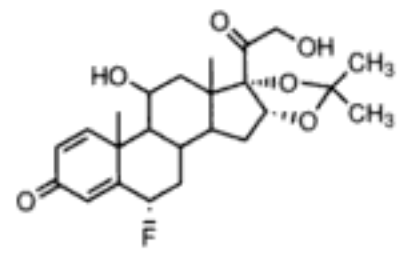


Beclomethasone dipropionate
(QVAR, Vanceril)

9α-Chloro-16β-methyl-11β,17α,21-trihydroxypregna-1,4-diene-3,20-dione 17,21-dipropionate

Beclomethasone dipropionate is a lipophilic prodrug that, when inhaled, shows a systemic bioavailability of approximately 20% of the administered dose. The 16β-methyl group decreases mineralocorticoid activity, and the 9α-chloro group increases both the glucocorticoid and mineralocorticoid activity, resulting in potent anti-inflammatory activity with little or no salt-retaining effects. The main adverse effects are headache, sinusitis, and pain. Beclomethasone dipropionate is metabolized to the more active 17α-monopropionate derivative during absorption from the lungs and then further metabolized to the free alcohol in the liver. The dipropionate also is metabolized to the inactive 21-monopropionate in the liver. Beclomethasone dipropionate and its metabolites are mainly excreted in the feces, with less than 10% excreted in the urine.

#### BUDESONIDE



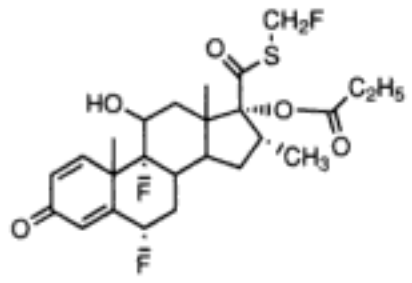
Budesonide
(Pulmacort tubuhaler, Respules)

16α,17–[(*R,S*-butylidenebis(oxy)]-11β,21-dihydroxypregna-1,4-diene-3,20-dione

Budesonide is an acetal formed between the 16α,17α-dihydroxyl groups and butanal. It is a nonhalogenated glucocorticoid with a 16,17-acetal that decreases the mineralocorticoid activity. In receptor affinity studies, the *R*-epimer was twofold more active than the *S*-epimer. Because the C-21 hydroxy is free, budesonide is not a prodrug and is active as administered. Only 34% of the metered dose of inhaled budesonide reaches the lung. Systemically absorbed budesonide is highly protein bound and metabolized to 16α-hydroxyprednisolone and 6β-hydroxybudesonide in the liver. Both metabolites have less than 1% of the glucocorticoid activity of the parent compound. Inhaled budesonide is excreted mainly as metabolites via both the feces (15%) and the urine (32%). Budesonide is available as a powder delivered through an aerosol or as a suspension for inhalation.

#### FLUNISOLIDE

Flunisolide
(Aerobid)



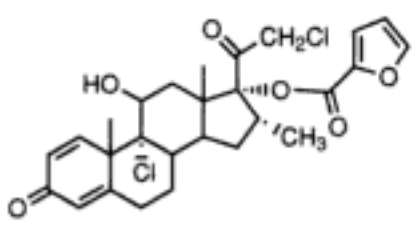
6α–Fluoro-11β,21-dihydroxy-16α,17-[(1-methyl-ethylidene)bis(oxy)]pregna-1,4-diene-3,20-dione

Flunisolide is an acetone ketal (acetonide) with a 6α-fluoro group and a free C-21 hydroxyl group. The acetonide decreases mineralocorticoid activity, and the 6α-fluoro group increases glucocorticoid activity. It is not a prodrug, because it has the free hydroxyl group at C-21. Flunisolide has approximately 20% of the receptor affinity as budesonide, and approximately 40% of the inhaled dose is systemically bioavailable. Flunisolide is quickly metabolized by CYP3A4 to the 6β-hydroxy metabolite, which has less than 1% of the activity of the parent compound. This, along with the rapid elimination of both flunisolide and its metabolite as glucuronides, greatly

Copyrighted material

limits any systemic adverse effects. Flunisolide is available as a microcrystalline powder aerosol.

### FLUTICASONE PROPIONATE

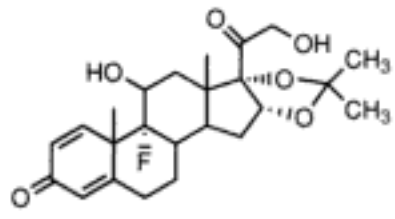


Fluticasone (Flovent, Flonase)

6α,9α-Difluoro-S-fluoromethyl-11β-hydroxy-16α-methyl-3-oxo-17α-propionyloxyandrosta-1, 4-diene-17α-carbothioate

Fluticasone propionate has a unique C-20 thioflouromethyl group, and that, in combination with the 17α-propionate ester, gives it 36-fold the glucocorticoid receptor affinity as compared to beclomethasone dipropionate and twofold the affinity as compared to budesonide. The 9α-flouro group increases both glucocorticoid and mineralocorticoid activities, and the 6α-flouro group enhances only the glucocorticoid action. Studies have determined that the effectiveness of inhaled fluticasone propionate results from a local rather than a systemic effect. Interestingly, less than 1% of the swallowed dose is bioavailable, in contrast to the fact that the majority of the inhaled dose is systemically available and highly protein bound. Fluticasone propionate is not a prodrug and is extensively metabolized by the liver. The only detectable metabolite is the 17β-carboxylic acid derived from CYP3A4 oxidation. This metabolite has 2,000-fold less affinity for the glucocorticoid receptor than the parent drug. Elimination is through both the feces and the urine, with the relative amounts determined by the route of administration. Fluticasone propionate is available in aerosol and powder inhalation formulations.

### MOMETASONE FUROATE



Mometasone furoate (Asmanex twisthaler)

9α,21-dichloro-17α–[(2-furanylcarbonyl)oxy]-11β-hydroxy-16α-methylpregna-1,4-diene-3,20-dione

Mometasone furoate is the most recent glucocorticoid to be developed and commercialized. It has a number of unique functional groups that confer enhanced glucocorticoid activity as well as pharmacokinetic advantages. The combination of the C-21 chloro and the furoic acid ester at C-17 results in the highest glucocorticoid receptor affinity of any topical corticosteroid. The 16α- methyl decreases the mineralocorticoid effects, and the 9α-chloro group increases both glucocorticoid and mineralocorticoid activities. Inhaled mometasone furoate acts locally as an anti-inflammatory treatment for asthma and has the least systemic bioavailability of all the inhaled glucocorticoids (<1%). It is extensively metabolized, with 6β-hydroxymometasone and 21-hydroxymometasone being found among the metabolites. Inhaled mometasone furoate in mainly excreted in the feces (~74%) as metabolites and only minimally excreted in the urine (~8%). It has a relatively long half-life in the lung and is administered once daily, usually in the evening.

### TRIAMCINOLONE ACETONIDE

Triamcinolone acetonide (Azmacort)

9α–Fluoro-11β,17α,21-trihydroxypregna-1,4-diene-3,20-dione-16α,17-acetonide

Triamcinolone acetonide has the acetonide function, which greatly decreases its mineralocorticoid activity. The 9α-flouro group increases both the glucocorticoid and the mineralocorticoid activities. Triamcinolone acetonide has a receptor affinity that is 10-fold that of beclomethasone dipropionate but sixfold less that of mometasone furoate. After oral inhalation, as much of 25% of triamcinolone acetonide can be detected systemically; a good proportion of that is assumed to be from swallowing and absorbed from the GI tract unchanged. It is metabolized in the liver to a number of metabolites, including 6β-hydroxytriamcinolone acetonide and the C-21 carboxy-6β-hydroxytriamcinolone acetonide, both of which are readily excreted via the kidneys. The acetonide remains intact during metabolic reactions and, therefore, is highly resistant to hydrolytic cleavage. Triamcinolone acetonide is excreted mainly as metabolites in the urine (40%) and in the feces (60%), with less than 1% being excreted unchanged.

## Mast Cell Degranulation Inhibitors

### Introduction

The discovery that a Middle Eastern herb, *Ammi visnaga* (Khella, Bishop's weed), had mild bronchodilation effects led to the isolation of a benzopyrone (a chromone), khellin. Khellin had only weak bronchodilator effects, so synthetic analogues were prepared in an attempt to enhance the bronchodilation. All analogues

Copyrighted material

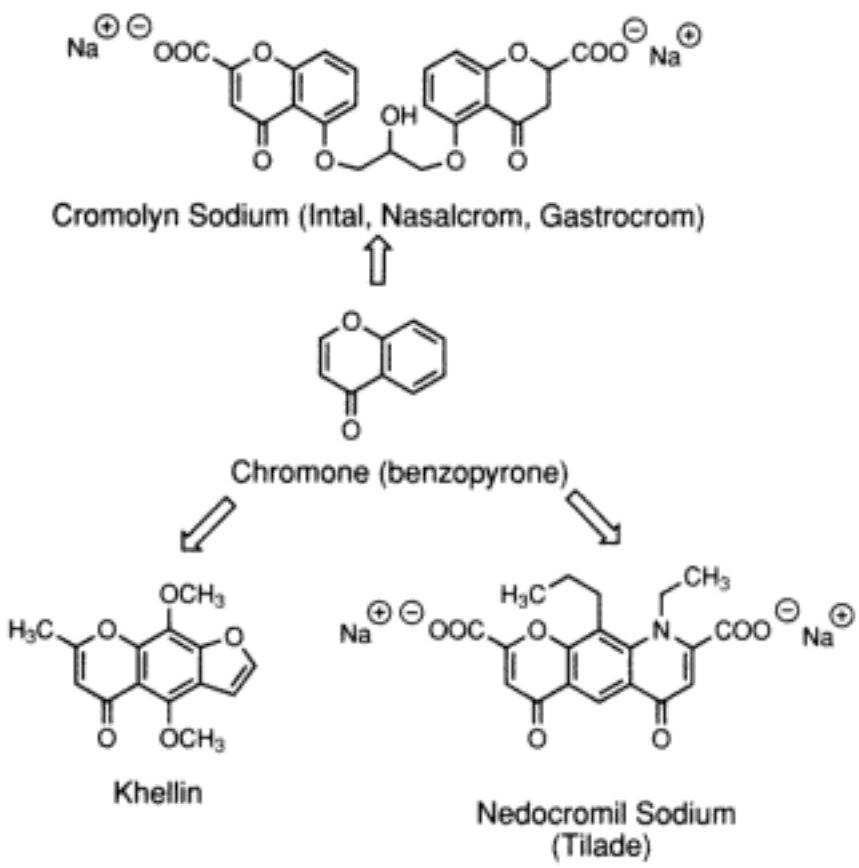


**Fig. 44.32.** Structures of several chromone mast cell stabilizers.

were less active; however, it was noted by Dr. Roger Altounyans, who was experimenting on himself with these analogues, that one of them, if inhaled before an asthmatic attack, gave excellent protection against the attack's severity (36). The active compound was identified as a bischromone and named cromolyn sodium in the United States and sodium cromoglycate in Europe (Fig. 44.32).

This class of mast cell degranulation inhibitors prevents the release of histamine, leukotrienes, prostaglandins, and other inflammatory autocoids by interaction with the sensitized mast cell before antigenic challenge and does not inhibit the binding of IgE to the mast cell or the antigen to IgE. The exact mechanism of action is still not completely understood; however, it is clear that inhibition of the role of calcium in the degranulation process is involved. A number of membrane and cellular proteins that bind cromolyn sodium are known to regulate intracellular calcium levels and include basophilic membrane protein, nucleoside diphosphate kinase, calgranulins B and C, and annexins I through V (37,38). Mast cell degranulation inhibitors also are used topically in the eye to treat allergic reactions; in addition to cromolyn sodium, they include nedocromil sodium, lodoxamide tromethamine, and pemirolast potassium. (For additional details about this class of compounds, see Chapter 37.)

## Mast Cell Stabilizers Used to Treat Asthma

### Cromolyn sodium

Cromolyn sodium is a bischromone that contains the fundamental benzopyrone moiety of khellin (Fig. 44.32). The two chromone rings are necessary for activity and must be coplanar, with a linking chain of no longer than six carbons. If one changes the linking chain to positions 8 and 8′, coplanarity cannot be maintained, and the compound loses all activity. Cromolyn sodium is poorly absorbed from the lungs (~8%), insignificantly from the eye (~0.07%), and by approximately 1% from the GI tract. What little that finds its way into systemic circulation is eliminated intact in the urine and the bile. For the treatment of asthma, cromolyn sodium is available as a solution for both intranasal and inhalation administration. There also is an oral concentrate (100 mg/5 mL), which is administered as a 200-mg dose given four times a day.

### Nedocromil Sodium

Nedocromil sodium was developed by changing the furan ring of khellin to a piperidinone ring (Fig. 44.32). In vitro, nedocromil sodium inhibits the release of inflammatory response mediators from a variety of cells, including neutrophils, mast cells, macrophages, and platelets. Inhaled nedocromil sodium is poorly absorbed into the systemic circulation, with approximately 3% of an inhaled dose excreted in the urine during the first 6 hours after administration. Only 2% of orally dosed nedocromil sodium is bioavailable, 89% of which is protein bound. When administered IV, nedocromil sodium is not metabolized and is excreted unchanged in the bile and the urine. Nedocromil sodium is available in aerosol canisters for oral inhalation via a mouthpiece.

## Leukotriene Modifiers

### Introduction

It has been known for more than 40 years that a substance called SRS-A (slow-reacting substance of anaphylaxis) produced a slowly developing, long-lasting contraction of isolated guinea pig ileum and that this same substance was associated with the pathophysiology of asthma. Subsequently, it was determined that SRS-A actually was a mixture of triene-containing lipids, designated as cysteine-leukotrienes: $LTC_4$, $LTD_4$, and $LTE_4$. Determination of the chemical structure of these biologically active compounds led to the development of biosynthesis inhibitors as well as receptor antagonists that are useful in the treatment of asthma (39).

### Biosynthesis of leukotrienes

The leukotrienes occur in a variety of inflammatory cells that are abundant in asthma, including eosinophils, mast cells, and macrophages. They are derived from arachidonic acid via a branch of the common pathway to the prostacyclins and thromboxanes. Arachidonic acid itself is produced by the action of phospholipase $A_2$ on cell walls. Unlike the prostacyclins and thromboxanes, excess arachidonic acid does not activate the pathway. Instead, the first step in the conversion of arachidonic acid to produce the leukotrienes is controlled by an activating protein, 5-lipoxygenase–activating protein, which

Copyrighted material

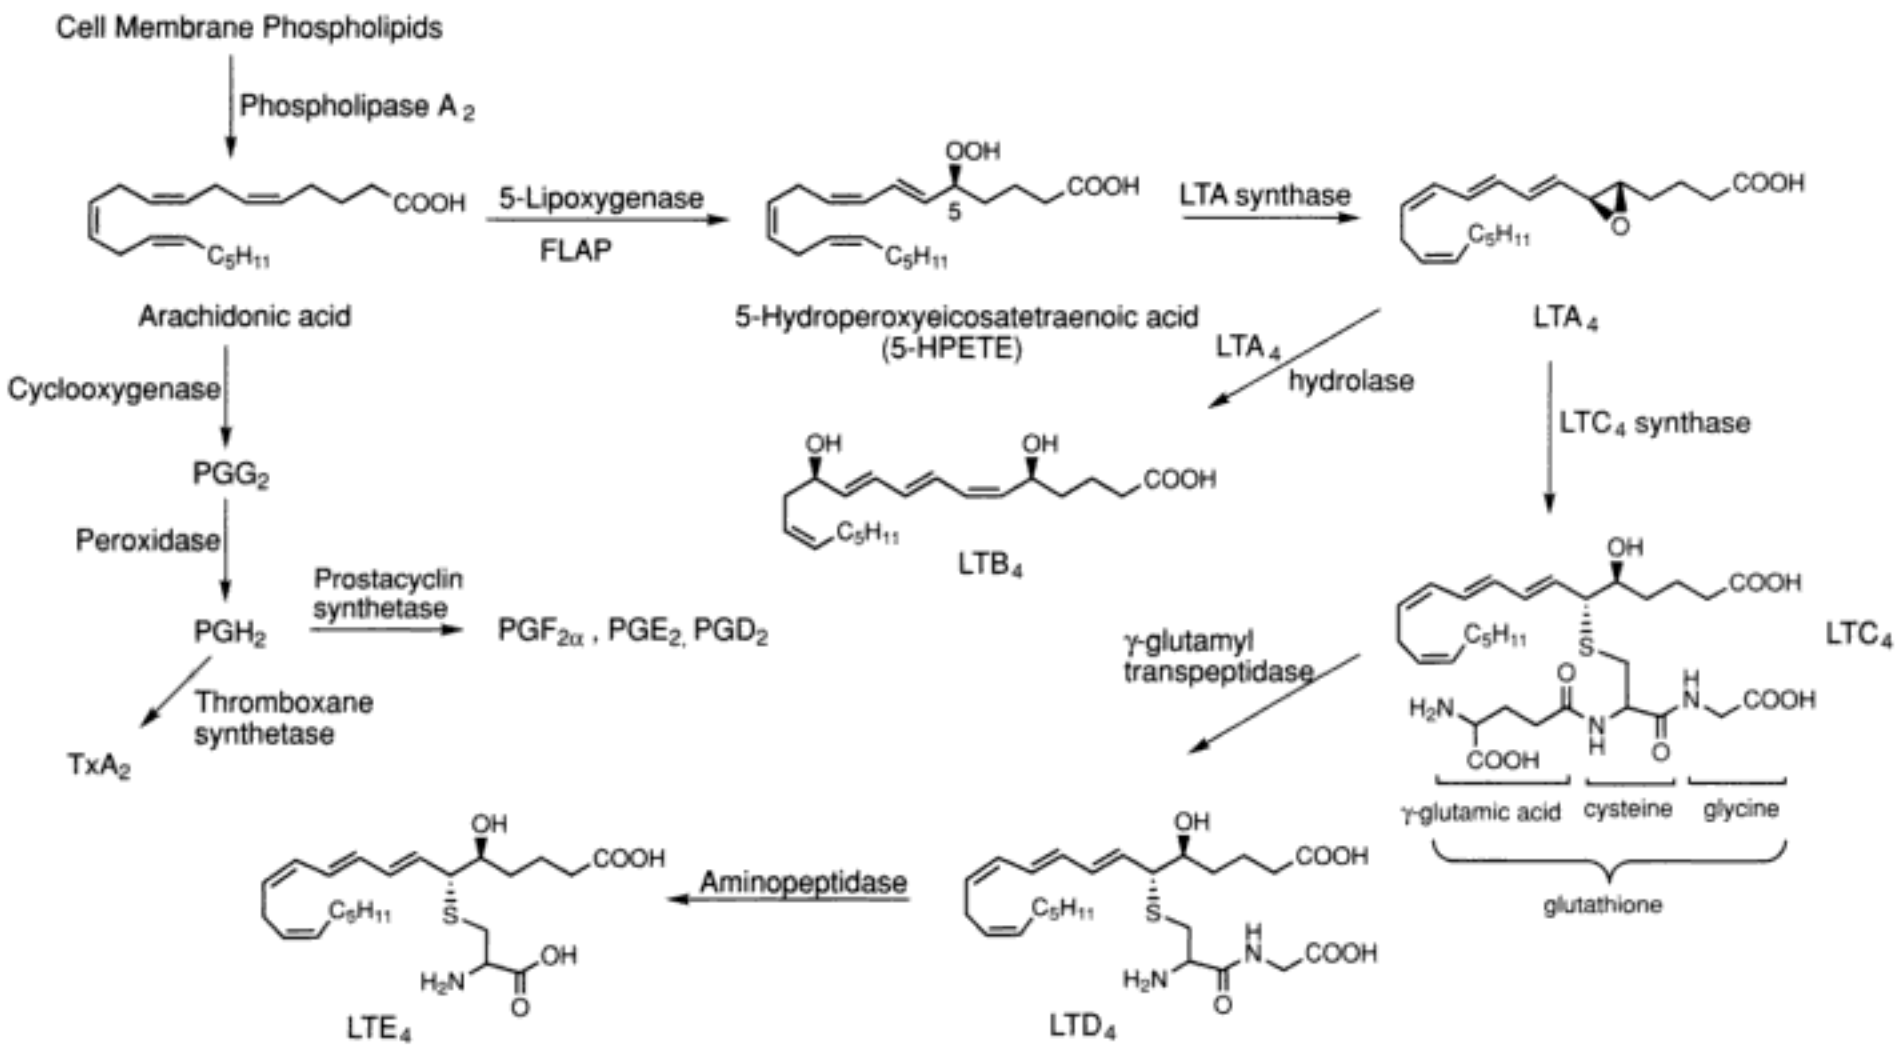

**Fig. 44.33.** Biochemical pathways leading to the leukotrienes.

regulates the interaction of 5-lipoxygenase with its substrate. Figure 44.33 depicts the biosynthetic pathway and shows that 5-lipoxygenase oxidizes arachidonic acid to the unstable peroxide intermediate, 5-hydroperoxyeicosatetraenoic acid, which is quickly dehydrated to $LTA_4$, which in turn is further metabolized by $LTA_4$ hydrolase to $LTB_4$ and by $LTA_4$ synthase to the glutathione adduct, $LTC_4$. Cleavage of γ-glutamic acid by γ-glutamyl transpeptidase converts $LTC_4$ to $LTD_4$, which in turn is converted to $LTE_4$ by the removal of glycine under the action of dipeptidase. The three leukotrienes produced from $LTA_4$ have strong bronchoconstrictive activity: $LTD_4$ is the most potent bronchoconstrictor, with the fastest onset of action; however, $LTB_4$ has no bronchoconstrictive activity but is a potent neutrophil chemotactic agent.

### Leukotriene Receptors

The cysteinyl leukotriene (cysLT) receptors are of the rhodopsin family of the G protein–coupled receptor family. As such, they consist of seven transmembrane-spanning helices that activate intracellular signaling pathways in response to their endogenous ligands ($LTC_4$, $LTD_4$, and $LTE_4$). Studies have identified two distinct cysLT receptors, and molecular biologists have cloned the human genes for both the $cysLT_1$ receptor and the $cysLT_2$ receptor (40). Pharmacology studies distinguished between the two cysLT receptors by evaluating their interaction with known antagonists, showing that the $cysLT_1$ receptor is competitively inhibited from binding $LTD_4$ whereas the $cysLT_2$ receptor was not. In addition, there is a slight difference in ligand-binding affinities between the two receptors. The $cysLT_1$ receptors have an affinity profile of $LTD_4 > LTC_4 = LTE_4$, whereas the $cysLT_2$ receptors show an affinity profile of $LTC_4 = LTD_4 > LTE_4$. Both receptor types occur in the lungs and spleen. The $cysLT_1$ receptor is found only in the placenta and small intestines, whereas the $cysLT_2$ receptor occurs only in the heart, lymph nodes, and brain. The incomplete overlap of tissue distribution along with their distinct ligand-binding properties suggests the $cysLT_1$ receptors and the $cysLT_2$ receptors might serve different functions in vivo (41), and because the $cysLT_1$ receptors are inhibited by selective antagonists, they have importance in the treatment of leukotriene related bronchoconstriction in asthma.

### Leukotriene Modifier Drugs

Two approaches to the development of leukotriene modifiers have been taken. The first approach was to block their biosynthesis by looking for compounds that inhibit one or more of the enzymes involved in the biochemical pathway. The second approach was to identify antagonists with selective affinity for the $cysLT_1$ receptors.

liver by CYP3A4 and CYP2C9 to oxidated products. CYP3A4 oxidizes the sulfur and the C-21 benzylic carbon, whereas CYP2C9 is selectively responsible for the methyl hydroxylation. Figure 44.35 shows the primary metabolic pathway for montelukast in humans (45). More than 86% of an oral dose is eliminated as metabolites through the bile. Montelukast did not demonstrate any significant adverse effects greater than placebo in clinical trials; however, because it is metabolized by the cytochrome P450 (CYP450) enzymes, its plasma levels should be monitored when coadministered with CYP450-inducing drugs, such as phenobarbital, rifampin, and phenytoin. Montelukast is available in tablet, chewable tablet, and granules for administration mixed with food.

### ZAFIRLUKAST

Zafirlukast (Accolate)

Zafirlukast is an indole derivative with a sulfonamide group that fulfills the need for an ionizable moiety on the pharmacophore. A large number of analogues have been prepared; however, they all resulted in a decrease in antagonist activity. Zafirlukast, like montelukast, is a selective antagonist for the cysLT$_1$ receptor and antagonizes the bronchoconstrictive effects of all leukotrienes ($LTC_4$, $LTD_4$, and $LTE_4$). Zafirlukast is well absorbed orally; however, food will decrease its absorption by as much as 40%. Zafirlukast is primarily metabolized in the liver by CYP2C9 and CYP3A4 to hydroxylated metabolites (46). Zafirlukast also has been shown to undergo carbamate hydrolysis, followed by N-acetylation. Additionally, zafirlukast in known to produce an idiosyncratic hepatotoxicity in susceptible patients. This is appears to result from the formation of an electrophilic α,β-unsaturated iminium intermediate evidenced by the formation of a glutathione adduct on the methylene carbon bridging the indole ring to the methoxybenzene moiety of the molecule (47).

Figure 44.36 summarizes the metabolism of zafirlukast. More than 90% if its metabolites are excreted in the feces, with the remaining found in the urine. Zafirlukast inhibits CYP3A4 and CYP2C9 in concentrations equivalent to clinical plasma levels and, therefore, should be used with caution in patients taking drugs metabolized by these enzymes. Specifically, coadministration with warfarin results in a significant increase in prothrombin time. Other drugs metabolized by CYP2C9 are phenytoin and carbamazepine. In addi-

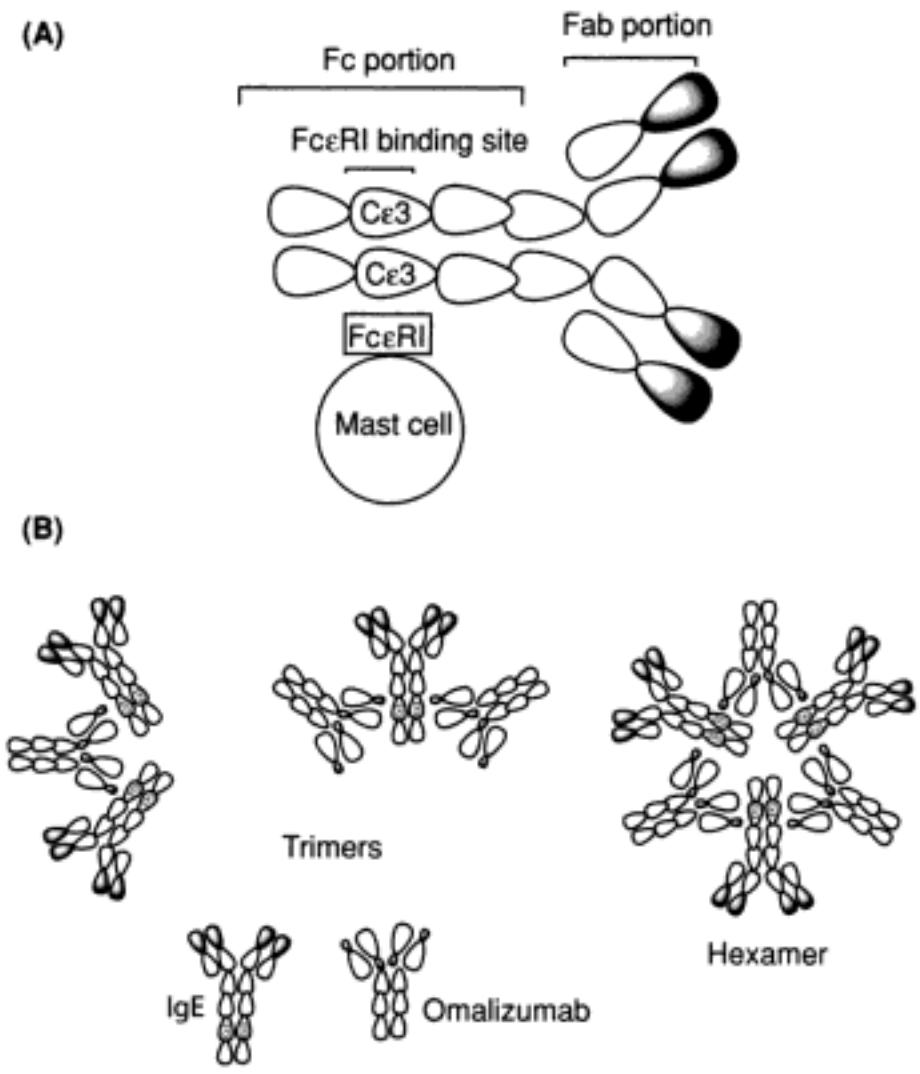

**Fig. 44.37.** (A) Graphic representation of IgE binding to the FCεRI on a mast cell. (B) Graphic representation of immune complexes formed between omalizumab. Hexamers predominate when components are in a 1:1 ratio, and the trimers predominate when one of the components is in excess.

### Omalizumab (Xolaire)

The clinical role for omalizumab is in the treatment of allergic asthma. It is approved for the treatment of adults and adolescents 12 years of age and older whose symptoms are not controlled with inhaled glucocorticoids and who have a positive skin test for airborne allergens. The bioavailability after subcutaneous administration is 62%, with slow absorption resulting in peak serum levels in 7 to 8 days from a single dose. Steady-state plasma concentration is reached in 14 to 29 days with multiple dosing regimens. The elimination of omalizumab is not clearly understood; however, studies have determined that intact IgE is excreted via the bile and that omalizumab:IgE complexes are cleared faster than uncomplexed omalizumab and slower than free IgE. This means that over time, total IgE concentrations (free and complexed IgE) increase, because the complex is cleared more slowly. The metabolism of omalizumab is not known, and the clearance of the complex is similar to the liver elimination of another immunoglobulin, IgG. The reticuloendothelial system degrades IgG, and it is believed that the same process occurs for the omalizumab:IgE complex. Omalizumab is available as a lyophilized powder for injection in single-use, 5-mL vials.

## CHRONIC OBSTRUCTIVE LUNG DISEASE

### Definition and Epidemiology

Chromic obstructive lung disease is characterized by persistent breathing difficulty that is not completely reversible and is progressive over time. It usually is the result of an abnormal inflammatory response to airborne toxic chemicals. Thus, COPD is a general term and most commonly refers to chronic bronchitis and emphysema. Asthma is considered to be a disease entity unto itself and is not included in the definition of COPD. Both COPD and asthma are both considered to be inflammatory diseases; however, the nature of the inflammation is different. Asthma is associated with the release of inflammatory mediators from mast cells and eosinophils, whereas chronic bronchitis is primarily associated with neutrophils and emphysema with alveoli damage. In addition, asthma is more often than not allergenic, whereas chronic bronchitis and emphysema have no allergic component. Finally, it is uncommon for asthma to be associated with smoking, whereas there is a very high incidence of both chronic bronchitis and emphysema in smokers.

Patients with COPD display a variety of symptoms, ranging from chronic productive cough to severe dyspnea requiring hospitalization. Other chronic illnesses, including cardiac, endocrine, and renal disease, often occur along with COPD in many patients. In the United States, COPD is the fourth leading cause of death, being responsible for more than 100,000 deaths per year (49). It has been estimated that between 16 and 24 million people in the United States have COPD and that those with chronic bronchitis outnumber those with emphysema. Rates of COPD-related death among women have tripled over the last 30 years, and this is being attributed to their increase in smoking. Chronic obstructive pulmonary disease is recognized as a global health problem, and in 2001, the NIH and the World Health Organization developed the Global Initiative for Chronic Lung Disease (GOLD) guidelines, which present only evidence-based recommendations for the treatment of COPD (50,51).

### Pathogenesis

The single most important risk factor for the development of COPD is smoking. It is estimated that 85% of COPD cases are attributable to cigarette smoking. Not all people who smoke, however, develop the disease, which means other factors are involved. It seems that genetics, environmental pollutants, and infection along with bronchial hyperreactivity all play an important role.

Cigarette smoke attracts inflammatory cells into the lungs and stimulates the release of the proteolytic enzyme elastase. Elastase breaks down elastin, which is a needed structural component of lung tissue. Normally, the lung is protected from elastase by an inhibitor, $\alpha_1$-antitrypsin (ATT). Cigarette smoke, however, causes an abnormal amount of elastase to be produced that ATT

Copyrighted material

cannot counter, leading to lung damage. Smokers with an inherited deficiency of ATT have a greatly increased risk of developing emphysema, especially at an early age. Patients with COPD show an accelerated decline in lung function (50–90 mL $FEV_1$/year) as compared to nonsmokers (20–30 mL/year) (see earlier discussion of FEV under *General Therapeutic Approaches to the Treatment and Management of Asthma*). Patients with COPD who stop smoking slow down the progression of the disease. Unfortunately, however, they do not improve, because the symptoms are an indication of irreparable lung tissue damage.

The role of other risk factors for developing COPD is not clear. Air pollution and occupational exposure to gases and particulates from the incomplete combustion of coal, diesel, and gasoline are related to the development of cough and sputum, but development of COPD seems to occur only in susceptible individuals. Passive cigarette smoke comes from the burning end of the cigarette and actually is higher in toxic substances compared with exhaled smoke. It has been established that respiratory infections as well as cough and sputum production are more common in children who live in households where one or both parents smoke. Chinese and Afro-Caribbean races have a reduced incidence of COPD, whereas COPD in American blacks is on the rise (49).

Permanent destructive enlargement of the airspaces distal to the terminal bronchioles without obvious fibrosis is the pathological characteristic of emphysema. On the other hand, chronic bronchitis is characterized by hypersecretion of mucus, most of which is produced by the trachea and first branches of the bronchi. The smaller bronchi and terminal bronchioles, however, are the site of the increased airway resistance in chronic bronchitis. In the early stages of chronic bronchitis, the mucus and inflammation contribute to "smoker's cough," with little effect on airway obstruction. As inflammation continues, cell wall edema and the production of large amounts of mucus contribute to airway narrowing and the difficulty in breathing associated with COPD. Even though bronchospasm may seem to be involved in COPD, there is little related pathogenesis. Chronic obstructive pulmonary disease is a disease of the small airways and their adjacent alveoli. In chronic bronchitis, there are structural changes in the small airways as a result of persistent inflammatory irritation, which leads to airway narrowing. Emphysema on the other hand is the result of loss of lung elastic recoil because of inflammation and alveolar wall destruction. Both diseases often occur together, with one predominate over the other. An important clinical manifestation between chronic bronchitis and emphysema is that there is significant hypoxia and carbon dioxide retention with chronic bronchitis, which does not happen with emphysema. Because of this, emphysema patients are referred to as "pink puffers," whereas patients with chronic bronchitis are called "blue bloaters" (52).

### Pharmacotherapy

All the medications used to treat COPD have already been covered in the previous section on asthma. The GOLD guidelines base their treatment protocols on a classification of disease severity divided into five stages (50,51). Stages O and I are defined as "at risk" (O) and mild COPD (I). In stage O, the patient has normal lung function, with chronic cough and sputum production. Treatment at this stage is to counsel the patient to reduce risks and, especially, to stop smoking. In stage I, there is minor airway limitation, characterized as $FEV_1/FVC < 70\%$ but $FEV_1 \geq 80\%$ of the predicted value. Stage I treatment is to use a short-acting bronchodilator, usually as needed, but regular use is effective in patients with concurrent asthma. The most frequently used short-acting bronchodilator is the $\beta_2$-agonist albuterol, although pirbuterol and the anticholinergic ipratropium can be just as effective, but with a slightly longer onset of action. The patient also should take precautions to avoid bacterial or viral infections by receiving vaccinations against influenza and pneumococcal pneumonia.

Stage II COPD is a moderate disease condition in which the patient demonstrates shortness of breath on exertion and spirometry reveals $FEV_1/FVC < 70\%$ and $FEV_1$ between 50 and 80% of the predicted value. Stage II drug treatment requires the addition of a long-acting bronchodilator along with the short-acting bronchodilator. Salmeterol and formoterol are long-acting $\beta_2$-agonists, and tiotropium is the long-acting anticholinergic most often used. Alternatively, the addition of ipratropium along with the short-acting $\beta_2$-agonist also can be effective at this stage. Extended- release theophylline is an option for patients who do not receive adequate relief of symptoms or who cannot tolerate other bronchodilators.

Stage III is a severe form of COPD, with $FEV_1/FVC < 70\%$ and $FEV_1$ between 30 and 50% of the predicted value. The patient experiences increasing dyspnea that affects his or her ability to perform routine tasks (i.e., climbing stairs). A course of oral glucocorticoids (i.e., prednisone) may be used to control a severe attack. The role of inhaled glucocorticoids is not clearly established, and no evidence suggests that an inhaled glucocorticoid has any advantage in patients who can maintain their $FEV_1$ with bronchodilators. As of this writing, no inhaled glucocorticoids are approved for the treatment of COPD; however, there is one combination formulation of fluticasone propionate and salmeterol dosage (250 μg/50 μg) approved for twice-daily administration.

Stage IV is the most severe form of COPD, with airflow restriction of $FEV_1/FVC < 70\%$ and $FEV_1 < 30\%$ of the predicted value along with chronic respiratory failure. At this stage, the patient is experiencing debilitating exacerbations that are not controlled by medication and requires

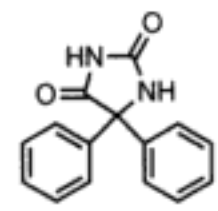
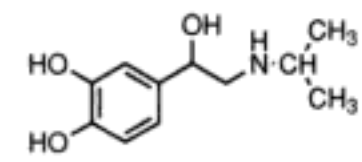
## CASE STUDY

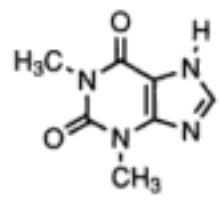


***Victoria F. Roche and S. William Zito***

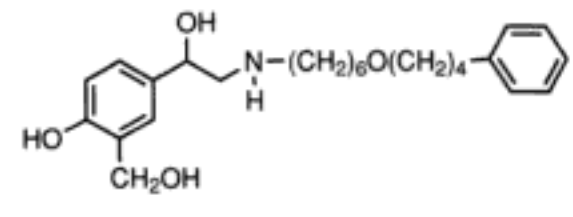
BJ is a Las Vegas blackjack dealer. He is a 38-year-old Caucasian man who has mild intermittent asthma treated with inhaled albuterol for occasional exacerbations. He works nights and sleeps during the day. He shows up at the emergency room early one morning complaining that he is not sleeping well lately. He says he wakes up about once a week gasping for breath. In addition, he has been having increased episodes of acute asthma during his job, which have caused him to use his inhaler at least once a night. He finds that his clients are disturbed by his wheezing and audible gurgling, and he fears he will lose his job unless something is done about it. On further inquiry, you determine that BJ is taking phenytoin (100 mg t.i.d.) to control the epilepsy he has had since he was an adolescent. The attending physician determines that BJ's asthma has progressed to the mild persistent stage and wants to prescribe an appropriate medication. Evaluate the following choices for use in this case.



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure-activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the SAR findings against the patient specific factors and desired therapeutic outcomes and make a therapeutic decision.
5. Counsel your patient.



Albuterol



phenytoin

**DRUGS COVERED IN THIS CHAPTER:**

TESTOSTERONE PRODUCTS
- Oral testosterone
  - Methyltestosterone
  - Fluoxymesterone
- Testosterone esters
- Transdermal patches
- Transdermal gels
- Buccal

ANABOLIC AGENTS
- Nandrolone
- Oxandrolone
- Oxymetholone
- Stanozolol
- Testolactone

$\alpha_1$-ADRENERGIC ANTAGONISTS
- Alfuzosin
- Doxazosin
- Tamsulosin
- Terazosin

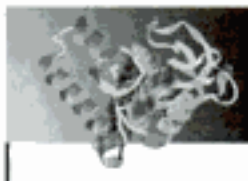
ANTIANDROGENS
- Bicalutamide
- Flutamide
- Nilutamide

INHIBITORS OF ANDROGEN BIOSYNTHESIS
- 5α-Reductase inhibitors
  - Finasteride
  - Dutasteride
- 17α-Hydroxylase/17,20-lyase inhibitors

- Luteinizing hormone–releasing hormone agonists
  - Buserelin
  - Goserelin
  - Leuprolide

DRUGS FOR TREATMENT OF ERECTILE DYSFUNCTION
- Phosphodiesterase-5 inhibitors
  - Sildenafil
  - Vardenafil
  - Tadalafil
- OTHER DRUGS
  - Prostaglandin $E_1$
  - Papaverine
  - Phentolamine

## INTRODUCTION



This chapter focuses on the physiology, pharmacology, metabolism, and structure–activity relationships for therapeutic and emerging classes of drugs that are used almost exclusively in men. Major differences in endocrine hormones and the anatomy and physiology of the reproductive system and genitourinary tract between males and females make men uniquely susceptible to a variety of disorders, including aging-related androgen insufficiency (hypogonadism and andropause), prostate and testicular cancer, benign prostatic hyperplasia (BPH), and erectile dysfunction (ED). The majority of these disorders and their treatments are associated with the male sex hormones (i.e., androgens), their pharmacological target (i.e., the androgen receptor [AR]), and the tissues that rely on the androgens.

Prostate problems are common in older men, particularly those aged 50 years and older. A man may have prostate problems for a number of reasons, including an infection of the prostate (prostatitis), a noncancerous enlargement of the prostate (BPH), or prostate cancer, the second most common cancer in men. Risk of prostate cancer increases with age; approximately 70 percent of all cases of the disease are diagnosed in men aged 65 years and older. Prostate problems often are discovered by men themselves. The signs of prostate problems include frequent urge to urinate, blood in the urine, painful or burning urination, difficulty urinating, or inability to urinate.

Aging-related androgen insufficiency (male hypogonadism) is a physiological condition characterized by the inability of the testes to produce sufficient testosterone to maintain sexual function, muscle strength, bone mineral density, and fertility (spermatogenesis). One in five men older than 50 years will exhibit symptoms of this condition. Symptoms of aging-related androgen insufficiency may include lethargy or decreased energy, decreased libido or interest in sex, ED (with loss of erections), muscle weakness and aches, inability to sleep, hot flashes, night sweats, depression, infertility, thinning of bones or bone loss, and cardiovascular disease. By the time that men are between the ages of 40 and 55 years, some may experience a phenomenon similar to the female menopause, called andropause. Whether andropause is more common than hypogonadism in the aging male is a matter for debate. The decline in testosterone occurs very gradually in men over several decades and may be accompanied by loss of bone mass (osteoporosis), loss of muscle mass and strength, and changes in fat distribution, cholesterol levels, spermatogenesis, sexual performance, quality of life, and impotence (i.e., ED). Studies show that a decline in testosterone actually can put men at risk for other health problems, such as heart disease and weak bones. Psychological stress, alcohol abuse, injuries or surgery, medications, obesity and infections, tobacco, and drugs, such as decongestants, antihypertensives, tranquilizers, statins, or antiseizure agents, can contribute to the onset of these conditions. There is no way of predicting who will experience the symptoms of androgen insufficiency that are of sufficient severity to seek medical help; neither is it predictable at what age the symptoms of aging-related androgen insufficiency will occur in a particular individual. Each man's symptoms also may be different. Because all this happens at a time of life when many men begin to question their values, accomplishments, and direction in life, it often is difficult to realize that the changes occurring are related to more than just external conditions.

## CLINICAL SIGNIFICANCE

Significant research is currently underway in the area of men's health. In less than a decade, we have gone from having minimally effective pharmacological agents for erectile dysfunction (ED) to having several options. The widespread use of these phosphodiesterase (PDE5) inhibitors is acknowledged by the fact that Viagra (sildenafil) was one of the Top 200 drugs dispensed in 2004.

There are advantages and disadvantages to each of these PDE5 inhibitors. Some can be taken with food and other cannot. Some have optimal durations of action, and others are much shorter. All, however, have been known to have adverse effects and drug interactions in common. Some of these adverse effects can be rather severe, and the drug interactions with nitrates can be fatal.

The development of newer, more effective, and less deleterious agents is essential for ED. Agents that are more selective for PDE5 and avoid other PDEs are critical to this endeavor. By studying the structure–activity relationships between the PDEs and the inhibitors, this can be achieved. Minor changes to the side chains or functional groups of the currently available PDE inhibitors can potentially eliminate the adverse effects and drug interactions that limit the use of these agents. As new agents become available, clinicians continually compare and contrast these new agents to the ones that are currently available in an effort to improve patient care. This is an ongoing, joint effort by chemists and clinicians alike to optimize patient care either indirectly or directly by continually making adjustments to either chemical structures or therapeutic treatment plans for the patient.

**Catherine L. Hatfield, Pharm.D.**

*University of Houston*
*College of Pharmacy*

Now that men are living longer, there is heightened interest in aging-related androgen insufficiency, its risks for other health problems, and its treatment.

Testicular cancer is the most common form of cancer among males aged 15 to 44 years and is approximately four times more common in white men than in African–American men. After motor vehicle accidents and suicide, cancer is the leading cause of death in this age group, followed by homicide, heart disease, and HIV. Testicular cancer is known as "young man's cancer." Early detection is the key to survival. Testicular cancer is androgen-dependent, with a very fast onset. because the tumors can be very aggressive. When the cancer is confined to the testicles, there often is no pain, but by the time pain develops, it often is a sign that the cancer has already spread. Survival rates increase significantly if treatment has begun before the cancer has a chance to metastasize. Testicular cancer most often is discovered by men. Therefore, all men should conduct testicular self-examinations at least monthly and, preferably, every time they shower for any changes or lumps and to see a doctor immediately if any changes noted. The diagnosis is noninvasive and involves using ultrasound to look at the density, size, and shape of the testicles and other masses in the scrotum.

Men who experience any of these symptoms associated with the prostate, aging-related androgen insufficiency, and testicular cancer should see a doctor to find out the cause of the problem and to talk about possible treatment.

The discovery and clinical development of selective estrogen receptor modulators transformed the therapeutic use of estrogens (1). Similarly, nonsteroidal selective AR modulators (SARMs), with the ability to selectively stimulate or maintain muscle and bone mass or to reduce prostate mass in BPH without the androgenic effects of testosterone and 5α-dihydrotestosterone (DHT), now are leading a similar revolution in the therapeutic use of androgens. The discovery of SARMs not only provides a potentially significant therapeutic advance for androgen replacement therapy but also provides model compounds to further study the molecular mechanism of action of the AR (2). Results from in vitro and in vivo animal studies suggest that the therapeutic promise of SARMs as a treatment of muscle wasting, osteoporosis, hormonal male contraception, and BPH may be soon realized.

Testosterone and its metabolite, DHT, are the primary endogenous androgens and play crucial physiological roles in establishing and maintaining the male phenotype (3). Their actions are essential for the differentiation and growth of male reproductive organs, initiation and regulation of spermatogenesis, and control of male sexual behavior. In addition, androgens are important for the development of male characteristics in certain extragenital structures, such as muscle, bone, hair, larynx, skin, lipid tissue, and kidney (4). In females, the precise physiological roles of androgens are not completely understood, but the aging-related decline in circulating androgen levels has been linked to symptoms such as decreased libido and sexuality, lack of vigor, diminished well-being, and loss of bone mineral density in postmenopausal women (5–7).

## THE SEX HORMONES

The sex steroid hormones are steroid molecules that are necessary for reproduction in females and males and that affect the development of secondary sex characteristics in both sexes. The sex steroids are comprised of three

Copyrighted material

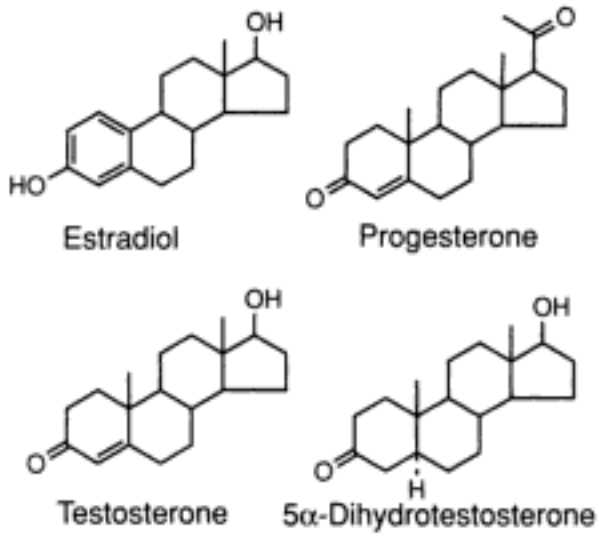

**Fig. 45.1.** The sex hormones.

classes: estrogens, progestins, and androgens (Fig. 45.1). The two principal classes of female sex steroid hormones are estrogens and progestins (for further discussion, see Chapter 46). Chemically, the naturally occurring estrogens are C-18 steroids and have in common a planar unsaturated A ring with a 3-phenolic group that aids in separation and purification from nonphenolic substances. The most potent endogenous estrogen is estradiol (Fig. 45.1). The naturally occurring progestins are $C_{21}$ steroids and have in common a 3-keto-4-ene structure in the A ring and a ketone at the C-21 position. The most potent endogenous progestin is progesterone (Fig. 45.1). The principal class of the male sex steroid hormone is the androgens. The naturally occurring androgens are C-19 steroids and have in common oxygen atoms (as either hydroxyl or ketone groups) at both the C-3 and C-17 positions. The potent androgen found in the blood is testosterone (Fig. 45.1), with the more potent metabolite formed in certain androgen target tissues being DHT (Fig. 45.1). All three classes of endogenous steroids are present in both males and females. The production and circulating plasma levels of estrogens and progestins are higher in females, however, and the production and circulating plasma levels of androgens are higher in males.

## DISCOVERY OF ANDROGENS

One of the early and unusual experiments with testicular extracts was carried out in 1889 by the French physiologist Brown-Séquard. He administered such an extract to himself and reported that he felt an increased vigor and capacity for work (8). In 1911, Pézard showed that extracts of testicular tissue increase comb growth in capons (9). Early attempts to isolate pure male hormones from the testes failed, because only small amounts are present in this tissue.

The earliest report of an isolated androgen was presented by Butenandt (10) in 1931. He isolated 15 mg of crystalline androsterone from 15,000 L of human male urine. A second crystalline compound, dehydroepiandrosterone, which has weak androgenic activity, was isolated by Butenandt and Dannenberg (11) in 1934. During the following year, testosterone was isolated from bull testes by David et al. (12). This hormone was shown to be 6 to 10 times as active as androsterone.

Shortly after testosterone was isolated, Butenandt and Hanisch (13) reported its synthesis. In that same year, extracts of urine from males were shown to cause nitrogen retention as well as the expected androgenic effects (14). Many steroids with androgenic activity have subsequently been synthesized. Steroid hormones may have many potent effects on various tissues, and slight chemical alterations of androgenic steroids may increase some of these effects without altering others.

Testosterone was the first androgen to be used clinically for its anabolic activity. New sources of the hormone were needed, however, because only 270 mg could be isolated from a ton of bull testes (15). Commercially, testosterone is prepared from various steroids, including sarsasapogenin, diosgenin, and certain androgens found in stallion urine. Because of its androgenic action, testosterone is limited in its use in humans as an anabolic steroid. Many steroids were synthesized in an attempt to separate the androgenic and the anabolic actions. Because testosterone had to be given parenterally, it also was desirable to find orally active agents.

In the United States, most of the androgens and anabolic steroid products are subject to control by the U.S. Federal Control Substances Act as amended by the Anabolic Steroid Control Act of 1990 as Schedule III drugs.

## ANDROGEN PHYSIOLOGY

The overall physiological effects of endogenous androgens are contributed by testosterone and its active metabolites, DHT and estradiol. Testosterone and DHT execute their actions predominantly through the AR, which belongs to the nuclear receptor superfamily and functions as a ligand-dependent transcription factor. Circulating testosterone is essential for the differentiation and growth of male accessory reproductive organs (e.g., prostate and seminal vesicles), control of male sexual behavior, and the development and maintenance of male secondary characteristics that involve muscle, bone, larynx, and hair. Healthy young adult men produce approximately 3 to 10 mg of testosterone per day, with circulating plasma levels ranging from approximately 500 to 1,000 ng/dL in eugonadal (normal) men. Circulating testosterone participates in the feedback regulation of androgen production by the hypothalamus-pituitary-testis axis, as shown in Figure 45.2. Testosterone, luteinizing hormone (LH), and LH-releasing hormone (LHRH; a.k.a. gonadotropin-releasing hormone) constitute the elements of a negative feedback control mechanism, whereby testosterone controls its own release. Low circulating testosterone levels increase the hypothalamic secretion of LHRH, which leads to increased production of LH and, consequently, increased testosterone production by the Leydig cells. More than 95% of circulating testosterone is synthesized and secreted by the Leydig

Copyrighted material

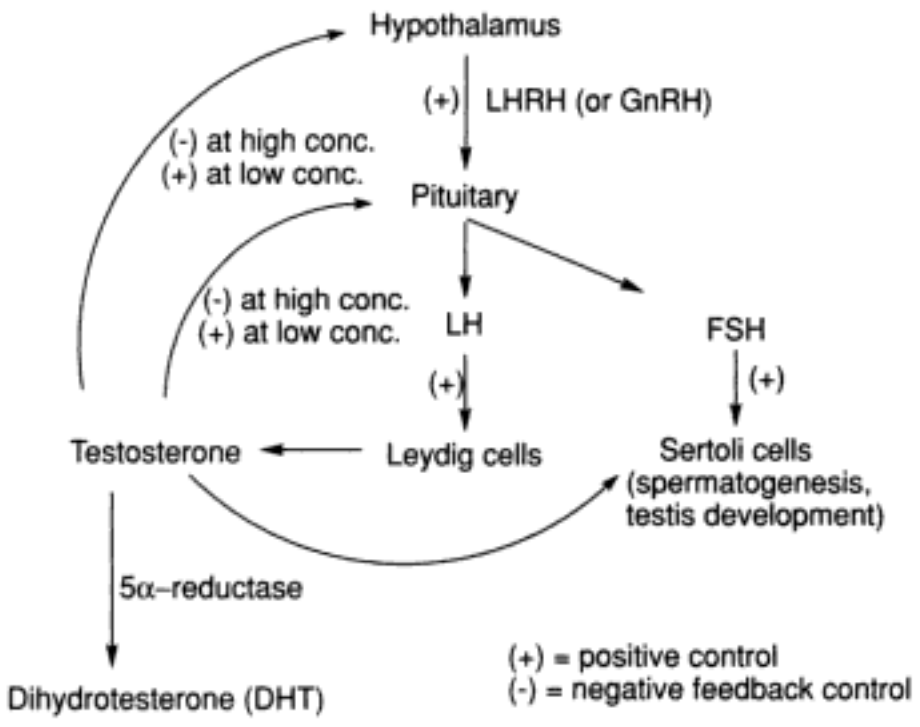

**Fig. 45.2.** Hypothalamus-pituitary-testicular axis. (+), positive control; (−), negative feedback control.

cells in the testes. High testosterone levels, on the other hand, inhibit LHRH release, thus suppressing both LH secretion and testosterone secretion. The LHRH is released from the hypothalamus in short, intermittent pulses every 2 hours and at greater magnitude in the morning, which in turn stimulates the pulsatile secretion of LH and follicle-stimulating hormone (FSH) from the pituitary. Follicle-stimulating hormone stimulates the Sertoli cells controlling spermatogenesis and development of the testis. Thus, testosterone secretion likewise is pulsatile and diurnal, with the highest concentration occurring at approximately 8:00 AM and the lowest at approximately 8:00 PM. In older men, especially those older than 60 years, the body does not produce enough testosterone that is needed to do all the intended work, and the testosterone levels remain relatively constant, without the morning pulses observed in young adult men. Average plasma testosterone concentrations in older men peak in the morning, with daily ranges of approximately 300 to 550 ng/dL by 70 years of age. The diurnal cycling is blunted as men age (16). In women, testosterone levels range from 15 to 100 ng/dL. Starting at approximately 40 years of age, testosterone levels drop by approximately 10 percent every decade. In the normal functioning of the male hormonal system, 97 to 98% of plasma testosterone is bound to sex hormone binding globulin, making it unavailable to the body's tissues. The remaining 2 to 3% is known as "bioavailable" or free testosterone. Furthermore, the receptor sites where testosterone must bind to be effective also can be occupied by estradiol, an estrogen also found in men that increases with age and body weight.

In the testis, FSH directly interacts with FSH receptors expressed in Sertoli cells and stimulates spermatogenesis, whereas LH indirectly stimulates spermatogenesis through testosterone synthesized by Leydig cells. Testosterone and its aromatized metabolite (estradiol) negatively regulate circulating levels of testosterone in the hypothalamus and pituitary. Activin and inhibin produced by Sertoli cells stimulate or inhibit, respectively, the secretion of FSH from the pituitary (17). High concentrations of intratesticular testosterone are essential for the initiation and maintenance of spermatogenesis, as evidenced by the infertility of hypogonadal men. Results from both animal models and humans, however, support the idea that both FSH and testosterone are required to achieve quantitative and qualitative spermatogenesis.

Androgens also are needed for the development of secondary sex characteristics. The male voice deepens because of thickening of the laryngeal mucosa and lengthening of the vocal cords. In both men and women, they play a role first in stimulating the growth of hair on the face, arms, legs, and pubic areas and later in the recession of the male hairline. The fructose content of human semen and both the size and the secretory capacity of the sebaceous glands also depend on the levels of testosterone.

Testosterone causes nitrogen retention by increasing the rate of protein synthesis and muscle mass while decreasing the rate of protein catabolism. The positive nitrogen balance therefore results from both decreased catabolism and increased anabolism of proteins that are used in male sex accessory apparatus and muscle. The actions of androgen in the reproductive tissues, including prostate, seminal vesicle, testis, and accessory structures, are known as the androgenic effects, whereas the nitrogen-retaining effects of androgen in muscle and bone are known as the anabolic effects. Although the precise mechanism of androgen action on muscle remains unknown, the common hypothesis is that androgens promote muscle protein synthesis. Evidence supports the idea that testosterone supplementation increases muscle protein synthesis in elderly men (18) and young hypogonadal men (19). Also, androgen-induced increases in muscle mass appear to arise from muscle fiber hypertrophy rather than hyperplasia (i.e., cellular enlargement rather than cellular proliferation) (20).

The thickness and linear growth of bones are stimulated and, later, limited by testosterone because of closure of the epiphyses. Androgens affect bone mineral density by changing overall osteoblast (bone-forming cell) activity and osteoclast (bone-resorbing cell) activity, resulting from changes in the total number of each cell type and individual cell functional capacity (21,22). Androgens seem to have the ability to decelerate the bone remodeling cycle and tilt the focal balance of that cycle toward bone formation. The loss of androgens is thought to increase the rate of bone remodeling by removing the restraining effects on osteoblastogenesis and osteoclastogenesis.

## ANDROGEN BIOSYNTHESIS

The major pathways for the biosynthesis of the sex steroid hormones are summarized in Figure 45.3. Cholesterol is

Copyrighted material

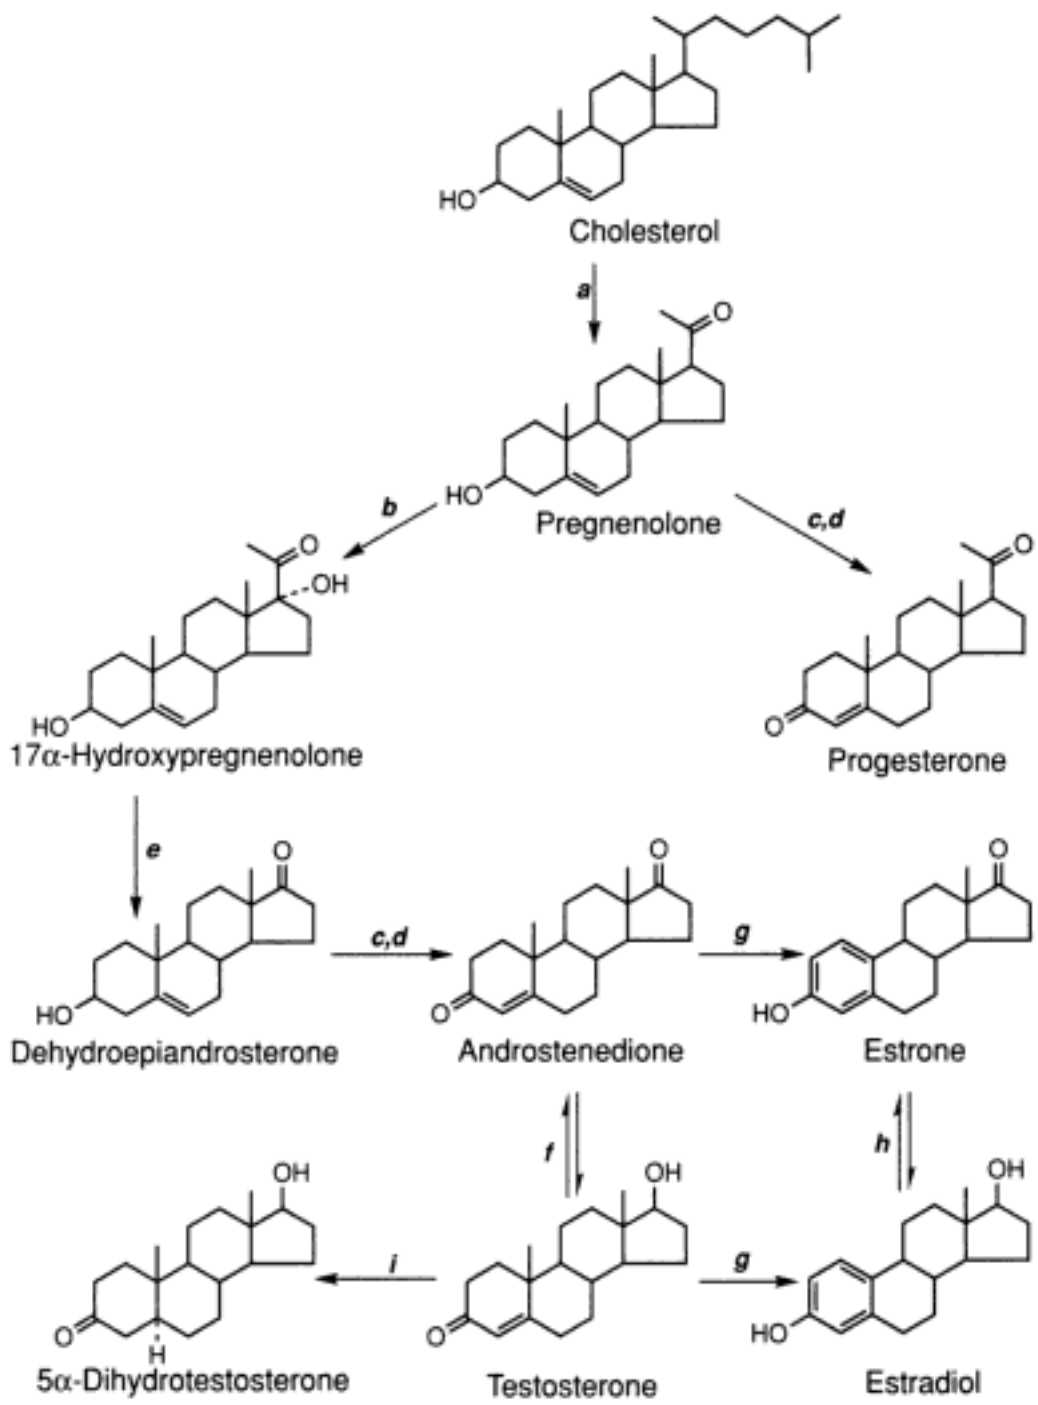

**Fig. 45.3.** Biosynthesis of androgens and other sex steroid hormones. The enzymes involved in this biosynthesis are (a) side-chain cleavage, (b) 17α-hydroxylase (c) 5-ene-3β-hydroxysteroid dehydrogenase, (d) 3-oxo-steroid-4,5-isomerase, (e) 17,20-lyase, (f) 17β-hydroxysteroid dehydrogenase, (g) aromatase, (h) estradiol dehydrogenase, and (i) 5α-reductase.

stored in endocrine tissues and is converted to androgen, estrogen, or progesterone when the tissue is stimulated by a gonadotropic hormone. Androgens (male sex hormones) primarily are synthesized from cholesterol in the testes, whereas estrogens are biosynthesized chiefly in the ovary in mature, premenopausal women. This is not surprising, because androgens are intermediates in the biosynthesis of estrogens. In the liver, androgens are formed from C-21 steroids. During pregnancy, the placenta is the main source of estrogen biosynthesis and pathways for production change (23,24). Small amounts of these hormones also are synthesized by the adrenal cortex, the hypothalamus, and the anterior pituitary in both sexes. The major source of estrogens in both postmenopausal women and men is adipose tissue (25).

Luteinizing hormone binds to its receptor on the surface of the Leydig cells to initiate testosterone biosynthesis. As in other endocrine cells, the binding of gonadotropin activates the $G_S$ signal transduction pathway, increasing intracellular cyclic adenosine monophosphate (cAMP) levels via activation of adenylate cyclase. One of the processes influenced by elevated cAMP levels is the activation of cholesterol esterase, which cleaves cholesterol esters and liberates free cholesterol. The free cholesterol is then converted in mitochondria to pregnenolone via the side-chain cleavage reaction (Fig. 45.3). Pregnenolone is converted by 17α-hydroxylase to 17α-hydroxypregnenolone and then to dehydroepiandrosterone (DHEA; a C-19 steroid) via 17-20 lyase, which involves cleavage of the C-17 to C-20 carbon–carbon bond and loss of the 17β-acetyl side chain (26). The 17α-hydroxylase is found in the endoplasmic reticulum membrane and is comprised of the cytochrome $P450_{17\alpha}$ protein and the ubiquitous NADPH-cytochrome P450 reductase. Cytochrome $P450_{17\alpha}$ is expressed by the *CYP17* gene found on chromosome 10 in humans. Alternatively, progesterone can be formed from pregnenolone via the action of 5-ene-3β-hydroxysteroid dehydrogenase and

Copyrighted material

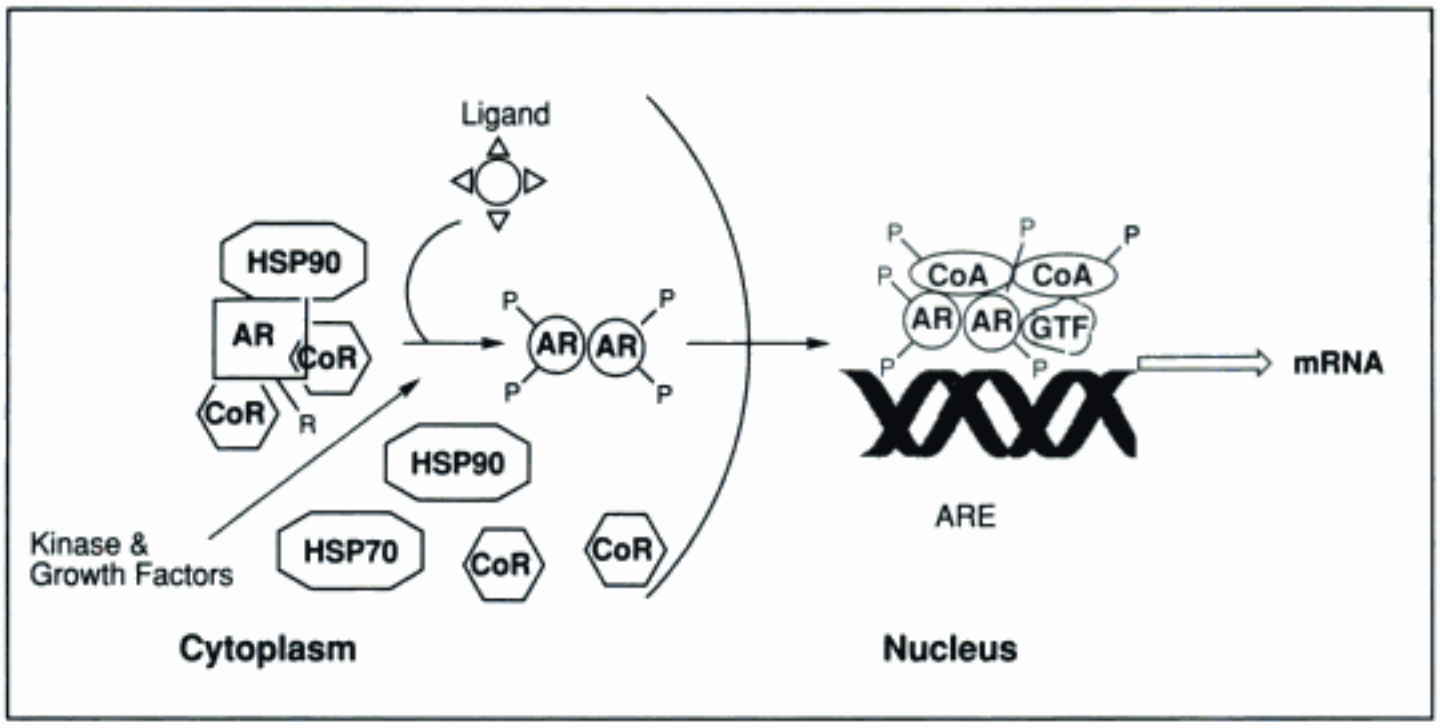

**Fig. 45.8.** Mechanism of androgen action. The androgen receptor (AR) is maintained in an inactive complex by heat shock protein (HSP) 70, HSP 90, and corepressors (CoR). On ligand binding, it homodimerizes and enters the nucleus. The receptor is basally phosphorylated (P) in the absence of hormone, and hormone binding increases the phosphorylation status of the receptor. The AR binds to the androgen-response element (ARE) on the promoter of androgen responsive genes, leading to the recruitment of coactivators (CoA) and general transcription factors (GTF), leading to gene transcription.

related to the ligand-induced conformational change of the LBD or, indirectly, the N-terminal domain. Functionally, the nongenomic action of androgen involves either rapid activation of kinase-signaling cascades or modulation of intracellular calcium levels, which could be related to stimulation of gap junction communication, neuronal plasticity, and aortic relaxation (64). Separation of the genomic and nongenomic functions of steroid receptors using specific ligands also was proposed as a new strategy to achieve tissue selectivity (63,65).

## DRUGS USED IN THE TREATMENT OF AGING-RELATED ANDROGEN INSUFFICIENCIES

### Male Hypogonadism

Male hypogonadism (testosterone deficiency) is the inability of the testes to produce sufficient testosterone to maintain sexual function, muscle strength, bone mineral density, and fertility (spermatogenesis). In men, there is a gradual decline of approximately 1% per year in the production of testosterone beginning around 40 years of age. For most men, testosterone levels naturally decline with advancing age but still remain within the physiological range throughout their lifetimes, causing no significant problems. Approximately 20% of men older than age 60 years and 30 to 40% of men older than 80 years have plasma testosterone levels indicative of hypogonadism (<325 ng/dL). Male hypogonadism is most commonly primary hypogonadism (testicular failure to produce testosterone for various reasons), secondary hypogonadism (hypothalamic-pituitary failure to stimulate testicles to produce testosterone), or a combination of both.

Testosterone and structurally related steroidal androgens have been used for decades to treat male hypogonadism, Klinefelter's syndrome (a chromosomal abnormality resulting in testicular dysfunction), anemia secondary to chronic renal failure, aplastic anemia, protein wasting diseases associated with cancer, burns, traumas, AIDS, short stature, breast cancer (as an antiestrogen), or hereditary angioedema (46). However, these agents have been demoted to the therapy of final resort because of serious hepatotoxicity and the recent development of more effective therapies (e.g., erythropoietin, aromatase inhibitors, and taxanes). Although severe hypogonadism is uncommon, aging-related androgen insufficiency is much more frequent. Low endogenous testosterone concentrations are associated with sarcopenia and frailty arising from decreased fat-free mass, lessened muscle strength, and reduced bone mineral density (osteoporosis). Low testosterone concentrations also are associated with decreased sexual libido and ED. More than 30 million men older than 40 years in the United States are estimated to suffer from ED. Although androgens are not essential for erection (66), transdermal and intramuscular (IM) testosterone replacement therapy often is employed in hypogonadal men with ED (67). Furthermore, selective phosphodiesterase (PDE5) inhibitors that increase penile blood flow are considered to be the treatment of choice for men with ED. Hormone replacement therapy with testosterone in aging men also improves body composition, bone and cartilage metabolism, and memory and cognition, and it even decreases cardiovascular risk (68).

Copyrighted material

emerging class of drugs known as SARMs may soon transform the therapeutic landscape of androgen use by selectively stimulating anabolic targets and avoiding steroid-related side effects. Because of the long-term effects of TRT in otherwise healthy men remain unclear, the Institute of Medicine recommends that TRT not be used to prevent or to relieve the physical or psychological effects of aging (71).

Clearly, TRT is beneficial for hypogonadal men with androgen insufficiency to restore sexual function and muscle strength, to prevent bone loss, and to protect against heart disease (atherosclerosis) (70). Increasing testosterone levels with TRT, however, may pose problems by stimulating the growth of the prostate. Long-term TRT could cause prostate gland enlargement, which might fuel the growth of prostate cancer that is already present and could cause breast enlargement in men (gynecomastia). This is especially worrisome, because prostate cancer is common in older men and many men may have prostate cancer that is undiagnosed.

In elderly men, testosterone effects on muscle mass and strength have not been consistent or impressive, possibly because of the low dosages used in clinical trials. The high correlation between the dose (and plasma concentration) and the anabolic actions of androgen in muscle suggests that androgen administration of higher doses in elderly men may significantly increase muscle mass and strength, but high doses might increase the adverse effects and the aromatization of testosterone to estrogen.

### Types of Testosterone Replacement Therapy

Several types of TRT exist. Choosing a specific therapy depends on the patient's preference of a particular delivery system, the side effects, and the cost. Types include injection, transdermal, buccal mucosal, and oral (Table 45.2).

**INJECTION.** Because orally administered testosterone is ineffective in the treatment of male androgen insufficiency syndromes as a result of extensive presystemic first-pass metabolism, IM injections bypass the problems of first-pass metabolism. Intramuscular testosterone injections are depot esters that undergo differing rates of in vivo ester hydrolysis to release free testosterone over an extended period of time. Typically, the depot esters are administered IM into a large muscle once every 2 to 4 weeks depending on the depot ester used (Table 45.2). They are safe, effective, and the least expensive androgen preparations available. The major disadvantage with the IM route for the depot esters is that testosterone plasma concentrations exhibit a saw-toothed pattern, with supraphysiological levels within 2 to 4 days following the IM injection and subphysiological levels before the next injection. A more satisfactory physiological replacement therapy without the fluctuations in free testosterone plasma levels would be to IM administer a lower dose (i.e., 100 mg) on a weekly or biweekly schedule. Because IM injection of testosterone or its esters causes local irritation, the rate of absorption may be erratic.

Among the esters of testosterone available for IM administration include the 17β-propionate, 17β-enanthate, and the cypionate (17β-cyclopentylpropionate) (Fig. 45.9). Testosterone enanthate and cypionate are the depot esters commonly used with comparable pharmacokinetics. Testosterone enanthate (Delasteryl) is formed by esterification of the 17β-hydroxy group of testosterone with heptanoic acid and testosterone cypionate with cyclopentanepropionic acid. Sterile solutions of these esters are available in a suitable vegetable oil, such as cottonseed oil. Unlike oral testosterone, with a half-life of 10 to 100 minutes, IM testosterone administration avoids first-pass metabolism. Generally, the amount of sex hormone binding globulin in plasma determines the distribution of testosterone between free and bound forms, and free testosterone concentrations determine the drug's half-life. The bulky cypionate and enanthate esters of testosterone have a duration of action of up to 2 to 4 weeks, whereas the shorter propionate ester has a shorter duration of action of 1 to 2 weeks. Doses may be adjusted by aiming for midphysiological (400–600 ng/dL) testosterone values after 1 week or at the low end (300–400 ng/dL) just before the next injection is due.

**TRANSDERMAL.** Transdermal TRT systems are, perhaps, the most commonly used systems for delivering testosterone to bypass the rapid first-pass metabolism associated with oral testosterone. Clinical studies have shown that these formulations are effective forms of testosterone replacement, with peak response within 3 to 6 months. Discontinue use of the transdermal formulation if the desired response is not reached within this time period. Skin irritation is more common with the transdermal formulations, with more than 50% experiencing some form of skin irritation at some point during the treatment. Pretreatment with corticosteroid creams (not with the ointment) has been shown to reduce the severity and incidence of skin irritation without significantly affecting testosterone absorption from the formulation. With the transdermal formulations, testosterone levels were maintained within physiological values, and a beneficial effect was observed on general mood and sexual functioning. A plasma concentration in the midphysiological range (400–600 ng/dL) is the goal.

***Matrix-Type Transdermal Systems.*** This type of patch (scrotal patch; Testoderm®) must be applied to dry, clean (shaven) scrotal skin, which is 5 to 30 times more permeable to testosterone than other skin sites, every 24 hours to produce an adequate testosterone plasma concentration. The matrix system is described as a "drug-in-adhesive film," in which the drug is located on the adhesive layer of the film; thus, it is thinner and less bulky than the reservoir system. The advantage of the matrix system is that it produces supraphysiological levels of DHT

Copyrighted material

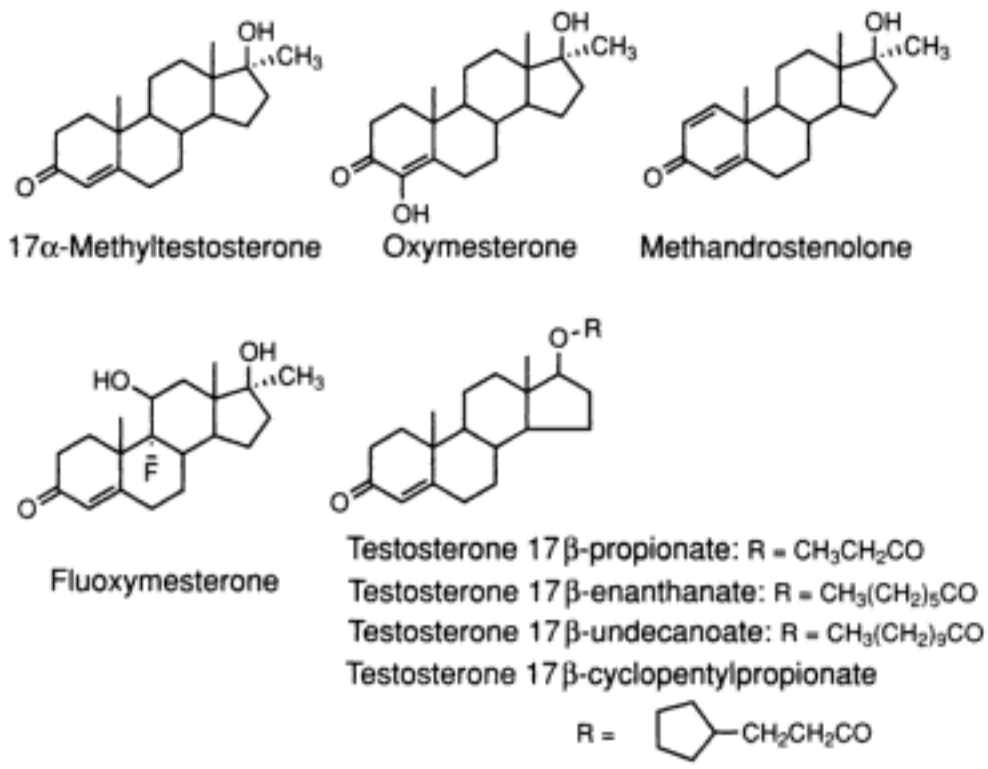

**Fig. 45.9.** Testosterone esters and synthetic testosterone derivatives.

because of the high 5α-reductase enzyme activity of the scrotal tissue. The patches have an occlusive backing that prevents sex partners from coming in contact with the active drug. A matrix transdermal system will not produce adequate plasma testosterone concentrations if applied to nonscrotal skin. Plasma testosterone concentrations are reached in approximately 2 to 4 hours. Although testosterone is absorbed throughout a 24-hour period, concentrations do not simulate the circadian rhythm of endogenous testosterone in normal (eugonadal) males. Within 24 hours after application of the matrix system, plasma testosterone concentration gradually falls to 60 to 80% of the peak plasma concentration, and when the system is removed, testosterone plasma concentration declines to baseline within 2 hours. Inadequate scrotal size and adherence problems are limitations. Skin irritation does occur in those with sensitive scrotal skins.

***Reservoir-Type Transdermal Systems.*** The reservoir-type patch (nonscrotal patch; Androderm, Testoderm TTS) is not applied to scrotal skin but, rather, to the abdomen, back, thighs, or upper arms every 24 hours (see Table 45.4 for dosage strength). This type of patch is membrane-controlled for the drug to diffuse continuously over 24 hours from the reservoir into the skin. Thus, this type of patch is thicker than the matrix (scrotal) patch. The patches have an occlusive backing that prevents sex partners from coming in contact with the active drug. The site of the application is rotated at 7-day intervals between applications to lessen skin reactions at the same application site. The advantage of the reservoir transdermal system is that it achieves normal testosterone circadian rhythm as seen in younger men, peaking in the morning and decreasing throughout the rest of the day. The reservoir-type patch, when applied to nonscrotal skin, produced physiological DHT and estradiol plasma concentrations. Steady-state plasma concentrations of testosterone, which are approximately 10 times baseline values, are reached in about 6 hours (range, 4–10 hours depending on application patch location), which then fall to 60 to 80% of the peak plasma concentration within 24 hours after application of the transdermal system. Thus, physiological plasma testosterone concentrations are maintained over 24 hours with this type of patch. Drug accumulation does not occur with repeated applications. When the system is removed, testosterone plasma concentrations decline to baseline within 2 hours. A usual dose for the reservoir-type transdermal results in the systemic absorption of 2 to 10 mg daily in hypogonadal men.

***Gel.*** Testosterone gel (AndroGel, Testim) is a 1% testosterone hydroalcoholic gel that provides continuous transdermal delivery of testosterone for 24 hours once the gel is rubbed into the skin on the lower abdomen, upper arm, or shoulder; do not apply to scrotal tissue (Table 45.2). Because there is a continuous release of testosterone over 24 hours, the normal circadian rhythm is not observed. As the gel dries, approximately 10% of the testosterone is absorbed through the skin. Gel application of TRT appears to cause fewer skin reactions than occur with the patches. Avoid showering or bathing for several hours after an application to ensure adequate absorption. A potential side effect of the gel is the possibility of transferring the medication to your partner; skin-to-skin contact should be avoided either until the gel is completely dry or by covering the area after an application. Following the application of 5 g of gel, which will deliver 50 mg of testosterone, the mean peak testosterone concentrations are reached in approximately 2 hours, which are about two to three times baseline values. For optimum results, the gel is best applied in the evening to allow

Copyrighted material

maximum concentration to occur early in the morning hours. Doses of the gel may be adjusted by aiming for midphysiological (400–600 ng/dL) testosterone values after 1 week. When the gel treatment is discontinued, plasma testosterone levels remain in the physiological range for 24 to 48 hours, then return to their pretreatment levels within 5 days following the last application. An increase in plasma testosterone can be observed within 30 minutes of application. Plasma concentrations approximate the steady-state level by the end of the first 24 hours and are at steady state by the second or third day of dosing.

***Buccal Mucosal.*** Striant is a gel-like substance that adheres to the gumline, which softens to deliver physiological amounts of testosterone to the systemic circulation, thereby producing circulating testosterone concentrations in hypogonadal males that approximate physiological levels seen in healthy young men (400–700 ng/dL). One buccal system (30 mg) is applied to the gum region twice daily, morning and evening, approximately 12 hours apart. Because there is a continuous release of testosterone over 24 hours, the normal circadian rhythm is not observed. Peak plasma testosterone concentrations are reached within 10 to 12 hours and are stable within a few days of the buccal preparation. The buccal preparation is difficult for patients to get used to, because the side effects may include gum irritation or pain, bitter taste, or headache. A study found that this form of TRT delivers a steadier dose of testosterone throughout the day without significant adverse effects, comparable to the gel.

**ORAL.** Orally administered testosterone is ineffective in the treatment of male androgen deficiency syndromes because of extensive presystemic first-pass metabolism, primarily to inactive 17-ketosteroid, etiocholanolone and androsterone, and androstanediol metabolites in the gastrointestinal mucosa during absorption and in the liver (Fig. 45.5). Oral administration results in supraphysiological elevations of testosterone and undesirable variability of plasma concentrations. The plasma half-life of testosterone is less than 30 minutes. Generally, the amount of sex hormone binding globulin in plasma determines the distribution of testosterone between free and bound forms, and free testosterone concentrations determine the drug's half-life. Approximately 90% of a dose of testosterone is metabolized, and its metabolites are excreted in the urine primarily as glucuronide conjugates, with approximately 6% of a dose being excreted in the feces as unmetabolized testosterone. Comparative dosage ranges for testosterone and its synthetic preparations are shown in Table 45.2. Taking testosterone orally (Android, Testred) is not recommended for long-term replacement. Oral testosterone may cause an unfavorable cholesterol profile and increase your risk of blood clots and heart and liver problems.

The androgenic activity of lipophilic long-chain ester testosterone 17β-undecanoate (Android Testocaps is not approved for use in the United States) (Fig. 45.9) has been attributed to formation of testosterone via systemic ester hydrolysis of lymphatically transported testosterone undecanoate (72). Its oral bioavailability was approximately 3%. Lymphatically transported testosterone undecanoate accounted for between 90 and 100% of the systemically available ester and that 83 and 85% of the systemically available testosterone resulted from systemic hydrolysis of lymphatically transported testosterone undecanoate. These data demonstrate that intestinal lymphatic transport of testosterone undecanoate produces increased systemic exposure of testosterone by avoiding the extensive first-pass hepatic metabolism responsible for the inactivation of testosterone after oral administration.

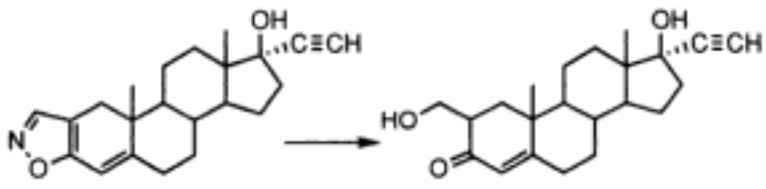
Testosterone also has been compressed into 75- or 200-mg testosterone pellets, which release 1 to 3 mg of testosterone/day. One to two pellets are implanted under the skin, typically in the buttocks or abdomen, through a special needle under local anesthesia. They usually are replaced every 3 to 4 months. Although the pellets have been used experimentally for approximately 15 years, the use of testosterone pellets is not approved by the U.S. Food and Drug Administration. Reportedly, the pellets offer the advantage of very consistent testosterone blood levels. Some users have reported problems with the pellets working their way out from under the skin.

### Synthetic Derivatives of Testosterone

Some of the early studies with androgens included structural modifications of the naturally occurring hormones to avoid first-pass metabolism. Blocking the metabolism of the 17β-hydroxy group with substituents in the 17α-position resulted in androgens with an increased bioavailability and duration of action when given orally. The synthetic androgens include methyltestosterone and fluoxymesterone (Fig. 45.9). The long-term use of oral androgens has been related to liver cancer.

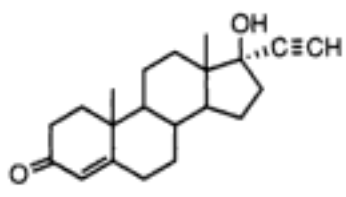
**17α-METHYLTESTOSTERONE.** The synthesis of 17α-methyltestosterone made available a compound that was orally active (73) in daily doses between 10 and 50 mg, which is equivalent to a 400 mg oral dose of testosterone. The presence of a 17α alkyl group reduces susceptibility to hepatic oxidative metabolism, thereby increasing oral bioavailability by slowing metabolism. Following oral administration, methyltestosterone is well absorbed from the gastrointestinal tract, with a half-life of approximately 3 hours. This drug has the androgenic and anabolic activities of testosterone. Although orally active, it is more effective when administered sublingually. The alkylated oral androgens should be viewed as potentially hepatotoxic and should not be used.

Copyrighted material



***Fluoxymesterone.*** By substituting a 9α-fluoro group onto an analog of 17α-methyltestosterone, fluoxymesterone has 20 times the anabolic and 10 times the androgenic activity of 17α-methyltestosterone (Fig. 45.9) (73). It has a mean half-life of 9 hours, and less than 5% of the drug is excreted unchanged. An adverse effect of fluoxymesterone is sodium and water retention that could lead to edema.

### Structure–Activity Relationships of Steroidal Androgens



For a substance to have androgenic activity, it must contain a steroid skeleton (74). Oxygen functional groups normally occurring at positions 3 and 17 are not essential, because the basic nucleus, 5α-androstane, has androgenic activity (Fig. 45.1). This appears to be the minimal structural requirement for hormonal activity. For derivatives of etiocholane, in which the hydrogen is in the 5β-position, thereby affording a *cis* A/B ring juncture, no active androgens and anabolic agents are known (74). Generally, both ring expansion (to form homo derivatives by inserting a methylene group into one of the rings in the steroid nucleus) or ring contraction (by removing a methylene group) significantly reduces or destroys the androgenic and anabolic activities.

Introduction of a 3-ketone function or a 3α-OH group enhances androgenic activity. A hydroxyl group in the 17α-position of androstane contributes no androgenic or anabolic activity; no known substituent can approach the effectiveness of a 17β-OH group. Evidence indicates that the longer-acting esters of the 17β-OH compounds are hydrolyzed in vivo to the free alcohol, which is the active species. It is thought that the 17β-oxygen atom is important for attachment to the receptor site and that 17α-alkyl groups are important for preventing metabolic changes at this position (73). Such 17α-substituents render the compounds orally active.

Increasing the length of the alkyl side chain at the 17α-position, however, resulted in decreased activity, and the incorporation of other substituents, such as the 17α-ethynyl group, produced compounds with useful progestational activity (progestins) (see Chapter 46), such as ethisterone. Attaching an isoxazole ring to ethisterone produced danazol (Danatrol, Danocrine), which exhibited potent antigonadotropic properties, weak androgen and anabolic properties, and no estrogen or progestin activity. As a gonadotropin inhibitor, danazol suppresses the surge of LH and FSH from the pituitary, thus suppressing ovarian steroidogenesis. For this reason, it is used in the treatment of endometriosis. Previous treatment of endometriosis had been surgical or medical, with progestins or a combination of estrogen and progestin. Danazol is metabolized by CYP3A4 to its inactive metabolite, 2-hydroxymethylethisterone.

Danazol — 2-Hydroxymethylethisterone (Danazol metabolite)

Ethisterone

Several modifications of 17α-methyltestosterone lead to potent, orally active anabolic agents. Two hydroxylated analogs include oxymesterone (Fig. 45.9) and oxymetholone (Fig. 45.10). These drugs have at least three times the anabolic and half the androgenic activity of testosterone (73).

Halogen substitution produces compounds with decreased activity except when inserted into positions 4 or 9 (e.g., fluoxymesterone). Replacement of a carbon atom in position 2 by oxygen has produced the only clinically successful heterocyclic steroid among a number of azasteroids and oxasteroids. Some of the 2-oxasteroids are potent anabolic agents.

Introduction of a $sp^2$ hybridized carbon atom into the A ring renders the ring more planar, and in turn, this may be responsible for greater anabolic activity. The 19-norsteroids are of interest, because these agents seem to produce a more favorable ratio of anabolic to androgenic activity. Vida (73) has extensively reviewed the replacement of various hydrogens on the androgen steroid skeleton by other functional groups. It appears that certain substitutions at positions 1, 2, 7, 17, and 18 may result in compounds with favorable activities that will be of clinical importance.

**ADVERSE EFFECTS.** Testosterone replacement therapy can have undesirable side effects depending on the type of delivery system used. The adverse effects from oral testosterone include stomach upset, headache, acne, increased hair growth on the face or body, jaundice (liver toxicity), anxiety, change in sex drive, sleeplessness, increased urination, depression, enlargement of breasts, and increased frequency and duration of erections (46). Breast enlargement can develop because testosterone can be converted to estradiol via aromatase. Other adverse effects include water retention, liver toxicity, cardiovascular disease, sleep apnea, and prostate enlargement. These risks are relatively uncommon when the dosage is closely monitored to maintain physiological plasma testosterone concentrations. Testosterone replacement therapy is contraindicated in men with carcinoma of the breast or with known or suspected carcinoma of the prostate. Therefore, pretreatment screening for any prostate dysfunction is mandatory before starting TRT.

## Anabolic Agents

Because complete dissociation of anabolic and androgenic effects is not possible, many of the actions of anabolic

Copyrighted material

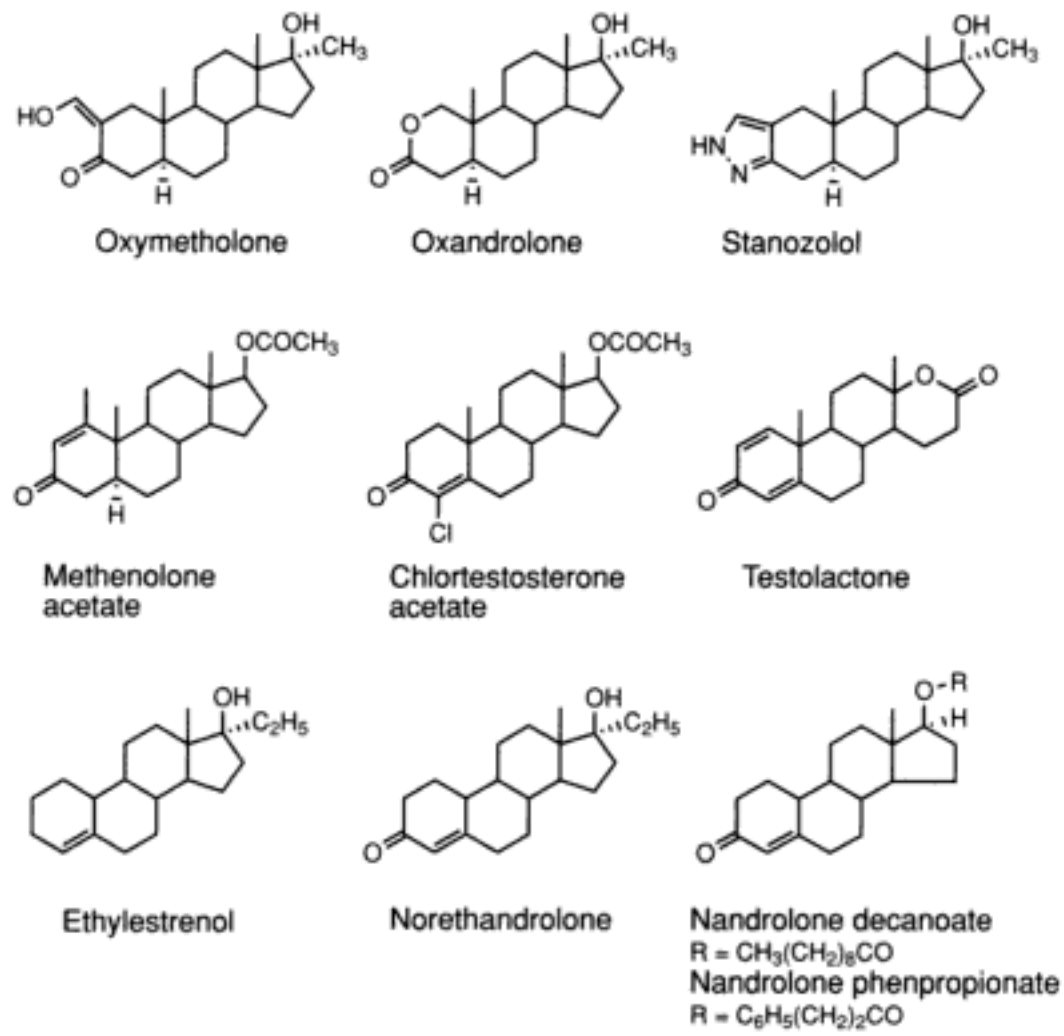


**Fig. 45.10.** Anabolic steroids.

steroids are similar to those of androgens. Comparative dosage ranges for the anabolic steroids are shown in Table 45.2.

Selenium dioxide dehydrogenation of 17α-methyltestosterone yields the 1,4-diene analogue, methandrostenolone, as shown in Fig. 45.10, which has several-fold the anabolic activity of the starting material. It has low androgenic activity but, apparently, can produce mammogenic effects in men. These effects are thought to result from estrogenic metabolites.

The 17α-alkylated anabolic steroids in clinical use are oxandrolone (Anavar, Oxandrin), oxymetholone (Anadrol-50), stanozolol (Winstrol), nandrolone decanoate (Deca-Durabolin, Hybolin), and phenpropionate, as shown in Figure 45.10.

A 2-oxasteroid analogue of 17α-methyltestosterone is oxandrolone, which contains a lactone in the A ring (oxygen bio-isostere of ring A) and, therefore, is susceptible to in vivo hydrolysis. It has three times the anabolic activity of 17α-methyltestosterone but exhibits slight androgenic activity (75). A pyrazole heterocyclic compound used for its anabolic effects is stanozolol (75).

The anabolic steroid oxymetholone is used primarily to stimulate production of erythropoietin in the treatment of anemias resulting from bone marrow failure.

Testolactone (Teslac), a 18-oxasteroid, is a D-homo-oxoandrostandienedione analogue, with ring D being a 6-membered lactone ring. Although testolactone possesses some anabolic activity with weak androgenic effects, it is used primarily in the treatment of breast cancer as a non-competitive irreversible inhibitor of aromatase to suppress the formation of estrogens that would stimulate the growth of breast tissue (46). It is primarily excreted in the urine unchanged, but it is metabolized in the liver by partial reduction of the 4-ene double bond in ring A to the 5β-metabolite (*cis* A/B ring juncture). Testolactone is available in both parenteral and oral forms.

Alkylation in the 1, 2, 7, and 18 positions of the androstane molecule generally increases anabolic activity (73). One of these derivatives, methenolone acetate, is an example of a potent anabolic agent that does not have an alkyl substituent at the 17α-position. A halogenated anabolic agent used in about the same dosage is chlortestosterone acetate.

Androgens, having no methyl group in position 10 of the steroid nucleus, are an important class of anabolic agents often referred to as the 19-norandrogens, as shown in Fig. 45.10. The removal of the 19-$CH_3$ group of the androgen results in reduction of its androgenic properties but retention of its anabolic, tissue-building properties. These steroids can be synthesized by the Birch reduction of the aromatic A ring of a 3-methoxy estrogen to a 2,5(10)-estradiene. Cleavage of the enol ether with HCl results in the 19-nortestosterone derivative. In animal assays, 19-nortestosterone has about the same anabolic activity as the propionate ester of testosterone, but its androgenic activity is much lower. Because 19-nortestosterone showed some separation of anabolic and androgenic activities, related analogues were synthesized and biologically investigated. Two of the more potent members of the series are norethandrolone and ethylestrenol, are shown in Figure 45.10. Norethandrolone has a better ratio of anabolic to

Copyrighted material

androgenic activity than either 19-nortestosterone or 17α-methyl-19-nortestosterone does (46). Both androgenic and progestational side effects have been observed with this agent. Ethylestrenol is more potent than norethandrolone as an anabolic agent and is used in a dosage of 4 mg per day orally.

Nandrolone phenpropionate and nandrolone decanoate are esters of 19-nortestosterone, as shown in Figure 45.10, that when administered IM, slow in vivo hydrolysis of the ester occurs releasing free 19-nortestosterone over a prolonged period. Nandrolone decanoate is the longer-acting ester intended for deep IM injection, preferably into the gluteal muscle, in the treatment of anemia associated with renal insufficiency. Nandrolone phenpropionate has a shorter duration of action than the decanoate and is used in the treatment of metastatic breast cancer in women.

### Abuse of Steroidal Anabolic Agents to Enhance Athletic Performance

Performance-enhancing substances are now a point of major interest for athletes, government, and news media. These substances are having a major impact on sports and the public in general. It appears that we are headed for much greater antidoping efforts in sports. A great deal of interest has recently been shown in "designer" anabolic steroids for their high-muscle-building effects, as shown in Fig. 45.11. Tetrahydrogestrinone and desoxymethyltestosterone (DMT), as shown in Figure 45.11, brought a great deal of interest to the performance-enhancing area, because their use was very difficult to detect (77,78). Tetrahydrogestrinone is thought to have been derived from gestrinone, a substance that has been used for the treatment of a variety of gynecological disorders. Tetrahydrogestrinone also is related to trenbolone, which has been used by body builders and by ranchers to build up cattle before marketing. Before tetrahydrogestrinone, both gestrinone and trenbolone had been on the banned anabolic steroid list of the International Olympic Committee. Tetrahydrogestrinone was very difficult to trace, however, because it was unstable under the normal conditions of testing for anabolic steroids. Once a suitable assay was developed, it was possible to go back and test samples of athletes around the world, and several were found to have taken tetrahydrogestrinone.

## Nonsteroidal Androgens

### Selective Androgen Receptor Modulators

In the past several years, the successful marketing and clinical application of selective estrogen receptor modulators (see Chapter 46) has raised the possibility of developing selective ligands for other members of the nuclear receptor superfamily. The concept of SARMs (2,78,79) also emerged—namely, a compound that is an antagonist or weak agonist in the prostate but agonist in the bone and muscle and is orally available with low hepatotoxicity. For an ideal SARM, the antagonist or weak agonist activity in the prostate will reduce concern for the potential to stimulate nascent or undetected prostate cancer; whereas the strong agonist activity in the muscle and bone can be used to treat muscle-wasting conditions, hypogonadism, and/or aging-related frailty. Currently, research on SARMs is in its early stages—namely, preclinical discovery and the early phase of clinical development. Phase II studies planned for the next 2 to 3 years, however, should reveal the true promise of this exciting new therapeutic class of drugs.

The SARM pharmacophores can be classified into four categories: N-arylpropionamide (81,82), bicyclic hydantoin (83), tricyclic quinolines (84), and tetrahydroquinoline (85) analogs, as shown in Figure 45.12. These nonsteroidal AR ligands are not substrates for aromatase or 5α-reductase but exhibit affinity as full AR agonists in anabolic organs (e.g., muscle and bone) or as partial AR agonists in androgenic tissues (e.g., prostate and seminal vesicles).

**STRUCTURE–ACTIVITY RELATIONSHIPS FOR THE N-ARYLPROPIONAMIDES.** The majority of published preclinical research has focused on a series of N-arylpropionamide analogues as AR agonists or partial agonists, utilizing the key structural elements of bicalutamide, an androgen antagonist (see below for a comparison of both structures) (2,81,82). A

Copyrighted material

compromise the quality of life for men. The enlarging prostate increases the adrenergic tone of the prostate in patients with BPH, which results in further tightening of the urethra. When partial obstruction is present, urinary retention also can be brought on by alcohol, cold temperatures, a long period of immobility, or the ingestion of over-the-counter cold or allergy medicines that contain a sympathomimetic decongestant drug or anticholinergics.

Severe BPH can cause serious problems over time, including urinary retention and strain on the bladder, which can lead to urinary tract infections, bladder or kidney damage, bladder stones, and incontinence.

Before and during adulthood, DHT plays a critical role in determining prostate size, and multiple lines of evidence suggest the importance of DHT in the development of BPH (95,96). For instance, BPH does not develop in males with certain type 2 5α-reductase mutations or in males with very low levels of androgen because of prepubertal castration or hypopituitarism-related hypogonadism. Moreover, clinical treatment of BPH either by chemical or surgical castration or by type 2 5α-reductase inhibitor (e.g., finasteride) induces apoptosis of epithelial cells, which in turn significantly decreases the volume of the prostate (96). Recently, the role of age-dependent changes in the intraprostatic hormonal environment in the development of BPH was evaluated (90). Despite the aging-related decrease in testosterone and intraprostatic DHT production, an increased estradiol/DHT ratio was observed in the aging human prostate, which can be relevant to the development of BPH. Furthermore, estradiol is capable of inducing precancerous lesions and prostate cancer in aging dogs (97). Therefore, TRT in older men raises concern regarding acceleration of BPH and/or prostate cancer.

Surgical procedures often are used to reduce a large prostate mass, but there are early pharmacological treatments of BPH with an $\alpha_1$-adrenergic blocker, a 5α-reductase inhibitor, and phytotherapy.

The $\alpha_1$-adrenergic antagonists treat the increased adrenergic tone of the sympathetic nervous system by relaxing the muscles at the neck of the bladder and in the prostate, thereby reducing the pressure on the urethra and increasing the flow of urine (91). They do not cure BPH but, rather, help to alleviate some of the symptoms. Approximately 60% of men find that symptoms improve significantly within the first 2 to 3 weeks of treatment with an $\alpha_1$-antagonist. In addition to alfuzosin and tamsulosin, which are the first-line $\alpha_1$-adrenergic antagonists, other $\alpha_1$-antagonists include doxazosin and terazosin, which also have been used to treat high blood pressure. Tamsulosin and alfuzosin are uroseletive $\alpha_1$-adrenergic antagonists developed specifically to treat BPH.

The 5α-reductase inhibitors work by suppressing the production of intraprostatic DHT, thereby reducing the size of the prostate (90). Finasteride and dutasteride are the most commonly used drugs for this purpose. Unlike $\alpha_1$-antagonists, 5α-reductase inhibitors are able to reverse BPH to some extent and so may delay the need for surgery. Several months of treatment may be needed before the benefit is noticed.

### $\alpha_1$-Adrenergic Antagonists

**MECHANISM OF ACTION.** $\alpha_1$-Adrenoceptors are widely distributed in the human body and play important

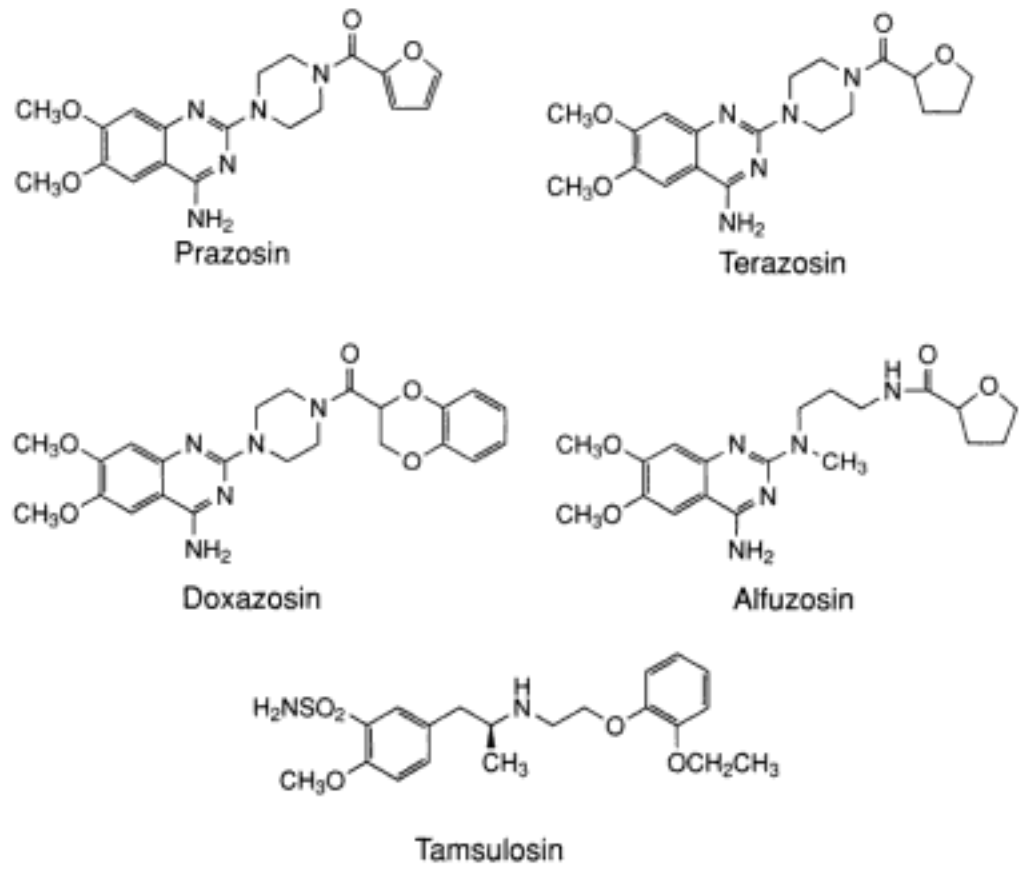

**Fig. 45.13.** $\alpha_1$-Adrenergic antagonists for treatment of benign prostatic hyperplasia.

Copyrighted material

an increase in fecal excretion of metabolites. Caution should be used during administration to patients with liver function abnormalities, because finasteride is metabolized extensively in the liver.

**DUTASTERIDE.** Similar to finasteride, dutasteride is a competitive and mechanism-based inhibitor not only of type 2 but also of type 1 5α-reductase isoenzymes, with which stable enzyme-NADP adduct complexes are formed, inhibiting the conversion of testosterone to DHT (106). The suppression of both type 1 and type 2 isoforms results in greater and more consistent reduction of plasma DHT than that observed for finasteride (107–109). The more effective dual inhibition of type 1 and type 2 5α-reductase isoforms lowers circulating DHT to a greater extent than with finasteride and shows advantages in treating BPH and other disease states (e.g., prostate cancer) that are DHT-dependent.

The maximum effect of 0.5 mg daily doses of dutasteride on the suppression of DHT is dose-dependent and is observed within 1 to 2 weeks. After 2 weeks of 0.5 mg daily dosing, median plasma DHT concentrations were reduced by 90%, and after 1 year, the median decrease in plasma DHT was 94% (108,109). The median increase in plasma testosterone was 19% but remained within the physiological range. The drug also reduced serum prostatic specific antigen by approximately 50% at 6 months and total prostate volume by 25% at 2 years. Dutasteride produced improvements in quality of life and peak urinary flow rate and reduction of acute urinary retention without the need for surgery. The main side effects are ED, decreased libido, gynecomastia, and ejaculation disorders. Long-term use (>4 years), however, did not reveal increased onset of sexual side effects. In addition, the combination of dutasteride and tamsulosin is well-tolerated and has the added advantage of rapid symptomatic relief.

***Pharmacokinetics.*** Following oral administration, peak plasma concentrations of dutasteride occurs in approximately 2 to 3 hours, with a bioavailability of approximately 60% (Table 45.4), and no meaningful reduction in absorption with occurs with food (107). Dutasteride is highly bound to plasma proteins 99%. The concentrations of dutasteride in semen averaged approximately 3 ng/mL, with no significant effects of on DHT plasma levels of sex partners. Dutasteride is extensively metabolized in humans by CYP3A4 to three major metabolites: 4′-hydroxydutasteride and 1,2-dihydrodutasteride, which are less potent than parent drug, and 6′-hydroxydutasteride, which is comparable to the parent drug as an inhibitor of both Type 1 and Type 2 5α-reductases. Dutasteride and its metabolites were excreted mainly (40%) in feces as dutasteride-related metabolites. The terminal elimination half-life of dutasteride is approximately 5 weeks. Because of its long half-life, plasma concentrations remain detectable for up to 4 to 6 months after discontinuation of treatment. No dose adjustment is necessary in elderly patients, even though its half-life increased with age from approximately 170 hours in men between 20 and 49 years to 300 hours in men older than 70 years (102). No adjustment in dosage is necessary for patients with renal impairment.

### Phytotherapy

A number of plant extracts are popularly used to alleviate BPH, although formal evidence that they are effective is often scanty (110). Extracts of the saw palmetto berry (*Serenoa repens*) are widely used for the treatment of BPH, often as an alternative to pharmaceutical agents. In a national survey conducted in 2002, 1.1% of the adult male population in the United States, or approximately 2.5 million males, reported using saw palmetto. The herb is widely used in Europe, where half of the German urologists prefer prescribing plant-based extracts rather than synthetic drugs. The most common nonstandardized preparation used is either the hexane-extract (Permixon®) or the ethanol or carbon dioxide extraction of the dried ripe fruit from the American dwarf saw palmetto plant (*Serenoa repens*), which is rich in fatty acids and plant sterols. The plant sterols appear to be the primary active constituents. The U.S. Pharmacopeia states that the liposterolic extract product should contain 70 to 95% fatty acids and 0.2 to 0.5% sterols. Other substances in the extracts include polyprenic compounds and flavonoids. The usual therapeutic dose of the extracts is 320 mg daily.

*Serenoa repens* had been popular in the United States during the 19th century as a treatment for a variety of urogenital disorders and had been mentioned as a treatment for prostate problems as early as 1899. Research into the effects of *S. repens* in many European countries appeared to confirm a positive action on BPH. The mechanism of action for the saw palmetto is not clearly established, but the sterols may have, as one mechanism of action, the inhibition of 5α-reductase and a decrease in DHT production. Therapeutic results should be expected in 6 to 8 weeks, but clinical efficacy is observed with BPH for 6 months or longer. The liposterolic extract is largely devoid of the side effects noted for prescription BPH drugs.

Although most previous randomized trials of saw palmetto have reported small improvements in the symptoms of BPH or in urinary flow rates, these studies were limited by the small numbers of subjects enrolled, their short duration, failure to use standardized products, their failure to use standard outcome measures, and the lack of information from participants concerning how effectively the placebo was blinded. Using widely accepted outcome measures from the American Urological Association (AUA) and a matched placebo capsule, a randomized, 1-year, double-blind saw palmetto trial (funded by the National Institutes of Health National Institute on Complementary and Alternative Medicine) was performed to determine the efficacy of saw palmetto for the treatment of BPH (111) A total of 225 men aged

Copyrighted material

50 years and older with documented disease received 160 mg of a standardized saw palmetto extract twice a day or a matching-placebo capsule. Over the course of a year, the men made eight office visits and were evaluated for assessment of AUA standardized changes which induced maximal urine flow, postvoid residual urine volume, prostate size, and other health-related outcomes. In contrast to most previous studies, this study reported no significant benefit of saw palmetto on urinary symptoms in terms of objective measures of BPH over a 1-year period.

Despite the differences between these studies, the weight of evidence suggests that saw palmetto may induce mild to moderate improvements in urinary symptoms and flow measures.

Other Western herbs that have been investigated for the treatment of BPH include pumpkin seeds (*Cucurbita pepo*), nettle root (*Urtica dioica* or *Urtica urens*), bee pollen (particularly that from the rye plant), African potato (tubers of *Hypoxis rooperi*), and the African tree *Pygeum africanum*, also known as *Prunus africanum*. In most cases, but particularly with pumpkin seeds and African potato, the main active components are sterols, such as β-sitosterol, which also has been used for BPH. Triterpenoids in *Pygeum* sp. also have been proposed to be active components, potentially having the action of reducing prostate swelling. Among the Chinese herbs recommended for BPH, the iridoid glycosides may be the active components from plantago seed, catalpol from rehmannia, and morroniside from cornus (an ingredient in the rehmannia formulas). Iridoids have not been found in the Western herbal therapies for BPH and represent a potential new area for future investigation. Iridoids are the recognized active constituents of the Western herb chaste tree berry (*Vitex agnus costus*), which has been shown to reduce prolactin levels in women; elevated prolactin may be a risk factor for prostate enlargement in men. Triterpenoids found in vaccaria and alisma (an ingredient in rehmannia formulas) could contribute to their therapeutic effects in a manner similar to that suggested for pygeum.

## Prostatic Cancer

Prostate cancer is the second leading cause of death in the United States and is the most commonly diagnosed cancer in American males (92). Prostate cancer is more common in African-American males, in whom it tends to be more aggressive and progressive, leading to advanced disease. The incidence of prostate cancer increases with age. Traditional treatments for prostate cancer include surgery (radical prostatectomy), radiotherapy, hormonal therapy, chemotherapy, cryosurgery (tissue is frozen to kill cancer cells), or watchful waiting.

Ever since Huggins and Hodges won the 1966 Nobel Prize for describing the relationship between testosterone and prostate cancer, androgen deprivation has become an important component in the treatment of prostate cancer by providing what amounts to chemical castration, reducing the need for testicular surgery. Testicular surgery (bilateral orchiectomy) to prevent testosterone production was once the standard treatment for advanced prostate cancer. Although this surgery is not a cure, it may delay the advance of the disease. Refinements in the therapy have occurred since this time, including androgen deprivation with antiandrogens, 5α-reductase inhibitor combinations, intravenous bisphosphonate infusions, and chemotherapy for advanced cases. If the cancer is no longer responding to hormonal treatment, chemotherapy may be tried for advanced disease.

Because prostate cancer typically grows slowly and causes no symptoms, the prostate-specific antigen (PSA) test is most often used as a screening test for prostate cancer, although it also may be used to evaluate and manage other prostate problems. Screening tests are able to detect prostate cancer at an early stage, but it is not clear whether this earlier detection and consequent earlier treatment leads to any change in the natural history and outcome of prostate cancer. The PSA screening test cannot tell the difference between prostate cancer and other prostate problems. The PSA is a protein made by the prostate tissue. Men with prostate cancer often have elevated PSA levels, because the cancer cells make excessive amounts of this protein.

### Antiandrogens (Androgen Antagonists)

Treatment for advanced prostate cancer involves the use of hormone-blocking drugs called antiandrogens. The goal of antiandrogen therapy is to block the effects of testosterone and DHT on ARs. Antiandrogens, however, are not a cure for prostate cancer. Nonsteroidal antiandrogens (Fig. 45.16), such as flutamide, nilutamide, and bicalutamide, are referred to as pure antiandrogens, because they bind exclusively to AR and, thus, are devoid of antigonadotropic, antiestrogenic, and progestational effects (112). These agents have advantages over steroidal antiandrogens, such as megesterol acetate or cyproterone acetate (Fig. 45.17), in terms of specificity, selectivity, and pharmacokinetic properties.

Antiandrogens block the binding of DHT at the AR and, when administered with an androgen, blocks or diminishes the effectiveness of androgens in androgen-sensitive tissues. Such compounds have shown potential therapeutic use in the treatment of acne, virilization in women, and hyperplasia and neoplasia of the prostate (113). Several steroidal and nonsteroidal agents have demonstrated antiandrogenic activity. Cyproterone acetate suppresses gonadotropin release and binds with high affinity to the AR (114,115). Oxendolone also acts by competing for the receptor binding sites (116). A novel AR antagonist, WIN 49,596, has been described (117) which contains a fused pyrazole ring at carbons 2 and 3 of the steroid nucleus. A potent nonsteroidal antiandrogen, flutamide, has been shown to compete with DHT for the AR (118). Its hydroxylated metabolite is a more powerful antiandrogen in vivo, and it has a higher affinity for the receptor than the parent compound (119).

Copyrighted material

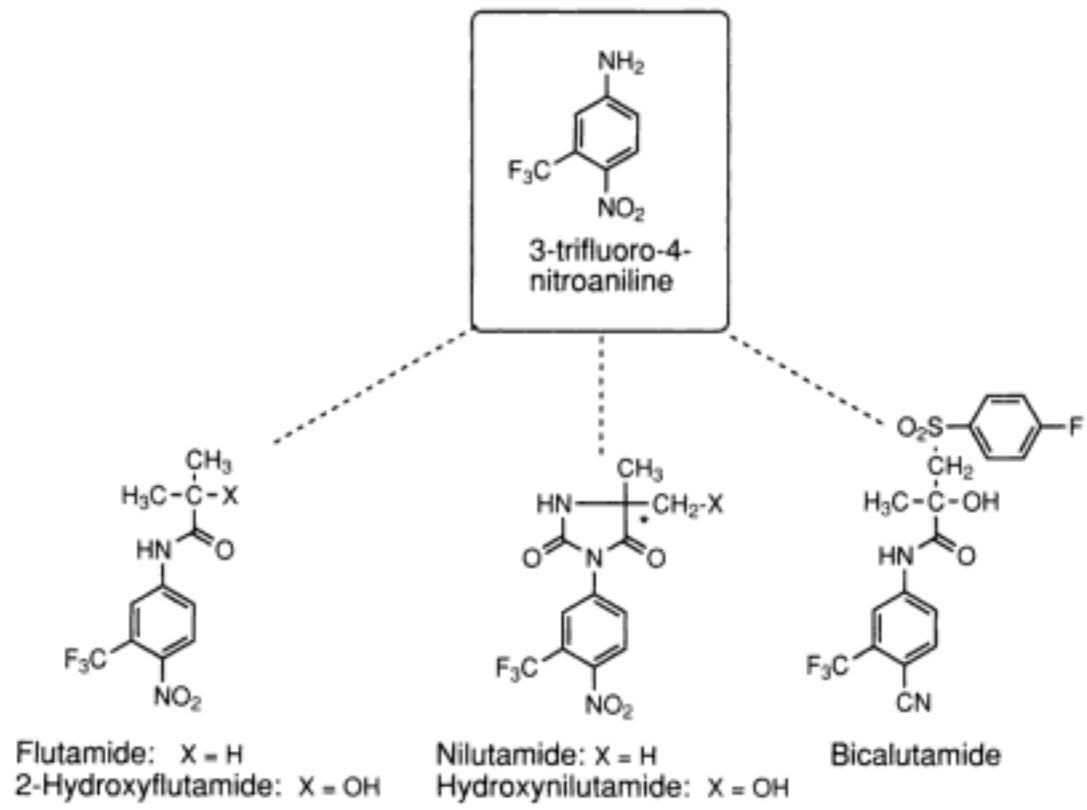

**Fig. 45.16.** Nonsteroidal antiandrogens.

Antiandrogens are particularly useful for the treatment of prostate cancer during its early stages. Often, however, prostate cancer advances to a "hormone-refractory" state, in which the disease progresses in the presence of continued androgen ablation or antiandrogen therapy, suggesting the development of androgen-independent prostate cancer cells or the ability of adrenal androgens to support tumor growth (as discussed above). Instances of antiandrogen withdrawal syndrome also have been reported after prolonged treatment with antiandrogens. Antiandrogen withdrawal syndrome is commonly observed clinically and is defined in terms of the tumor regression or symptomatic relief observed on cessation of antiandrogen therapy. The AR mutations that result in receptor promiscuity and the ability of these antiandrogens to exhibit agonist activity may account, at least in part, for this phenomenon. For example, hydroxyflutamide and bicalutamide act as AR agonists in AR mutants with an alanine residue at position 877 or leucine residue at position 741 (as opposed to threonine or tryptophan residues, respectively, that are present at these positions in the wild-type AR) (120,121).

The search for nonsteroidal antiandrogens lead to the development of the substituted toluidides, flutamide and bicalutamide, and nilutamide, a hydantoin that is structurally related to the toluidides (Fig. 45.16). These compounds are pure antiandrogens and compete with DHT for the human prostate AR. They are used in combination with other drugs in the treatment of metastatic prostate cancer. Although these compounds possess no intrinsic hormonal activity, their antiandrogenic mechanism of action is via competitive blockade of ARs for DHT in the hormone-sensitive tumor cells of the prostate (122). As a result of this antagonism, androgen-dependent DNA and protein synthesis is inhibited, causing arrest or regression of the prostatic tumor. Because these nonsteroidal antiandrogens are metabolized extensively in the liver, they should be used with caution in patients who have liver function abnormalities.

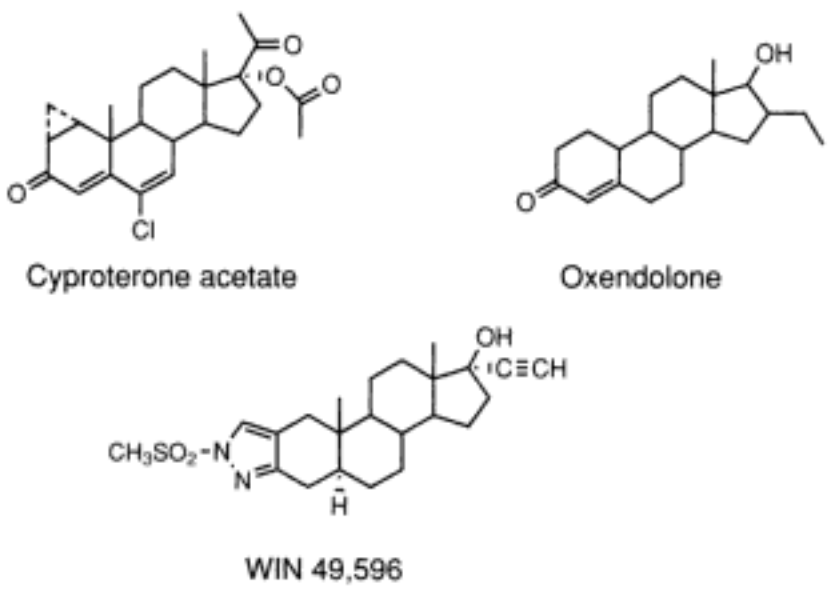

**Fig. 45.17.** Steroidal antiandrogens.

### SPECIFIC DRUGS

***Bicalutamide.*** Bicalutamide is a nonsteroidal pure antiandrogen given at a dosage of 150 mg once daily as monotherapy for the treatment of early (localized or locally advanced) nonmetastatic prostate cancer (123). It also can be used at a lower dosage in combination with a LHRH analogue or surgical castration for the treatment of advanced prostate cancer. Bicalutamide is a racemate and its antiandrogenic activity resides almost exclusively in the (*R*)-enantiomer, which has an approximately four-fold higher affinity for the prostate AR than hydroxyflutamide does. The (*S*)-enantiomer has no antiandrogenic activity. (*R*)-Bicalutamide is slowly absorbed, but absorption is unaffected by food (124). It has a long plasma elimination half-life of 1 week and accumulates approximately 10 times in plasma during daily administration

Copyrighted material

Table 45.5. Some Properties and Pharmacokinetics of the Antiandrogens

| Drugs | Bicalutamide | Flutamide | Nilutamide |
|---|---|---|---|

[b]Time for significant improvement in prostate-specific antigen or other biomarkers.

(Table 45.5). (*S*)-Bicalutamide is much more rapidly absorbed and cleared from plasma. At steady state, the plasma levels of (*R*)-bicalutamide are 100 times higher than those of (*S*)-bicalutamide. Although mild to moderate hepatic impairment does not affect pharmacokinetics, evidence suggests slower elimination of (*R*)-bicalutamide in subjects with severe hepatic impairment (124). Bicalutamide metabolites are excreted almost equally in urine and feces, with little or no unchanged drug excreted in urine. Unmetabolized drug predominates in the plasma. Following oral administration, the racemate displays stereoselective oxidative metabolism of its (*R*)-enantiomer, with an elimination half-life of approximately 6 days. (*R*)-Bicalutamide is cleared almost exclusively by CYP3A4-mediated metabolism, but glucuronidation is the predominant metabolic route for (*S*)-bicalutamide. No evidence indicates CYP3A4 induction in humans.

***Flutamide.*** Following oral administration, flutamide is completely absorbed from the gastrointestinal tract and undergoes extensive first-pass metabolism by CYP1A2 to its major metabolite, 2-hydroxyflutamide, and its hydrolysis product, 3-trifluoromethyl-4-nitroaniline (Fig. 45.16) (119). 2-Hydroxyflutamide is a more powerful antiandrogen in vivo, with higher affinity for the receptor than that of flutamide (123). 2-Hydroxyflutamide has an elimination half-life of approximately 8 hours. These studies show the principal role of CYP1A2 in the metabolism of flutamide to 2-hydroxyflutamide, with minor contribution from CYP3A4. 2-Hydroxyflutamide inhibits the metabolism of flutamide and both 2- and 4-hydroxylation of estradiol. Flutamide is a pure antagonist, whereas 2-hydroxyflutamide is a more potent AR antagonist but also can activate the androgenic receptor at higher concentrations (125). These findings raise the possibility that increased conversion of flutamide to 2-hydroxyflutamide or accumulation of 2-hydroxyflutamide in cells may contribute to the anomalous responses to flutamide that are observed in some advanced prostate cancers.

***Nilutamide.*** Nilutamide is a hepatotoxic nitroaromatic antiandrogen used for the treatment of metastatic prostate carcinoma in men (114). It is a competitive antagonist of the AR. Nilutamide is a nitroaromatic hydantoin analog of flutamide, as shown in Figure 45.16, that is completely absorbed after oral administration, with a mean elimination half-life of approximately 50 hours (Table 45.5) (124). One of the methyl groups attached to the hydantoin ring is stereoselectively hydroxylated to a chiral metabolite, which subsequently is oxidized to its carboxylic acid metabolite. Less than 2% of nilutamide is excreted unchanged in the urine. In vitro, the nitro group of nilutamide was reduced to the amine and hydroxylamine moieties by nitric oxide (NO) synthases, a flavin monooxygenase (FMO) system (126). The therapeutic effects of nilutamide are overshadowed, however, by the occurrence of several adverse reactions mediated by toxic mechanisms, which are poorly investigated. The reduction of nilutamide is catalyzed by NO synthases via the formation of either or both a nitro anion free radical or its reduction to its hydroxylamino derivative could explain some of the toxic effects of this drug (127). Nitric oxide synthases also are involved in the formation of reactive NO and oxygen species and in the interactions with some xenobiotic compounds.

### Inhibitors of Androgen Biosynthesis

The association between lifetime exposure to testosterone and DHT and the risk of developing prostate cancer suggests chemoprevention with specific inhibitors of key enzymes associated with androgen biosynthesis (127). Two key enzymes considered for inhibition are

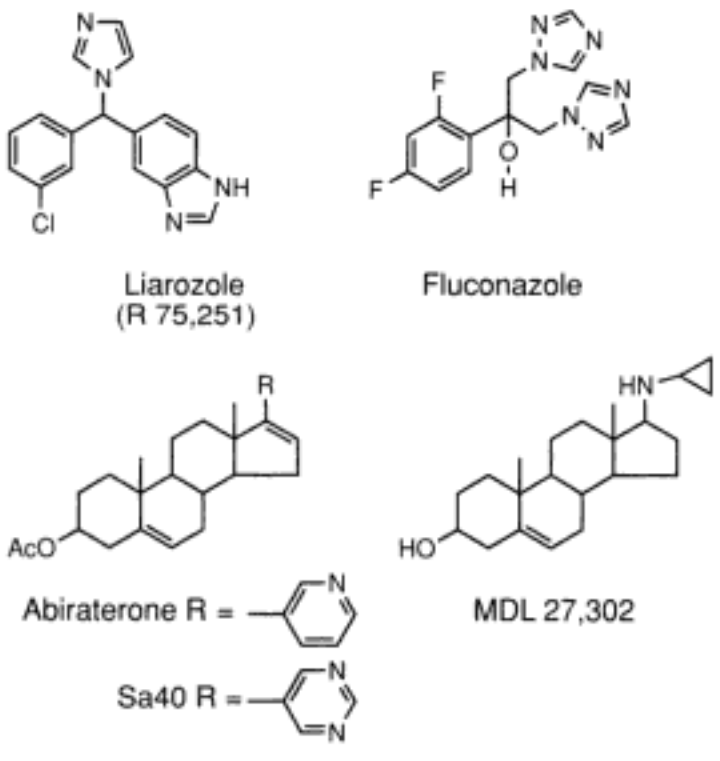
Copyrighted material

5α-reductase, which inhibits the formation of DHT and 17α-hydroxylase/17,20-lyase, which inhibits testosterone biosynthesis (Fig. 45.3).

**5α-Reductase inhibitors.** The 5α-reductase inhibitors have been discussed previously (see *Benign Prostatic Hyperplasia*). The results of the Prostate Cancer Prevention Trial (128) for finasteride showed a 25% relative risk reduction in prostate cancer in men aged 55 years or older, albeit at an increased risk of invasive tumors (129). The risk of invasive tumors may outweigh the benefit of these agents. The 5α-reductase inhibitors have not been proven to be effective as chemoprevention against clinically significant prostate cancer.

**17α-Hydroxylase/17,20-lyase inhibitors.** A second enzyme system targeted for androgen inhibition is 17α-hydroxylase/17,20-lyase, which is the key enzyme that converts pregnenolone to DHA and, subsequently, to testosterone (Fig. 45.3). Because testosterone has androgenic activity, inhibition of its biosynthesis would be useful in treating androgen-dependent diseases, such as prostate cancer (130). Inhibitors of 17α-hydroxylase/17,20-lyase inhibitors could prevent androgen biosynthesis from both testes and adrenals and may provide effective treatment of patients with prostate cancer.

The antifungal agent ketoconazole (Fig. 45.18) is an effective inhibitor of 17α-hydroxylase ($IC_{50}$, 76 nM), which has demonstrated the promise of 17α-hydroxylase inhibitors for the treatment of metastatic prostate cancer patients (131). The nonsteroidal imidazole agent R 75251 (Liarozole) (Fig. 45.18) (132), is under development as a potentially more selective inhibitor of 17α-hydroxylase/17,20-lyase. The steroidal compounds MDL 27302 (133) as well as abiraterone (CB7598) and Sa 40 (134) (Fig. 45.18), were designed as mechanism-based inhibitors of 17α-hydroxylase/17,20-lyase. For MDL 27302, inhibition is specific to the cyclopropylamino compound, because the isopropylamino- or the cyclobutylamino-analogs were not inhibitory. Enzymatic specificity of MDL 27,302 of 17α-hydroxylase/17,20-lyase was demonstrated by its failure to inhibit steroid 21-hydroxylase and the cholesterol side-chain cleavage enzyme (CYP450scc). Both the 17α-hydroxylase and 17/20-lyase activities of human testicular microsomes were inhibited by MDL 27,302. Abiraterone and Sa 40 are heterocyclic analogues of MDL 27,302 and potent irreversible inhibitors of 17α-hydroxylase (IC50s, 4 and 24 nM, respectively) (134). Inhibition studies show that the 16,17-double bond is necessary for irreversible binding of these 17-pyridyl and 17-pyrimidyl steroids to 17α-hydroxylase. Oxidation to an epoxide probably is not involved, however, because the epoxide was a weak inhibitor (IC50, 260 nM).



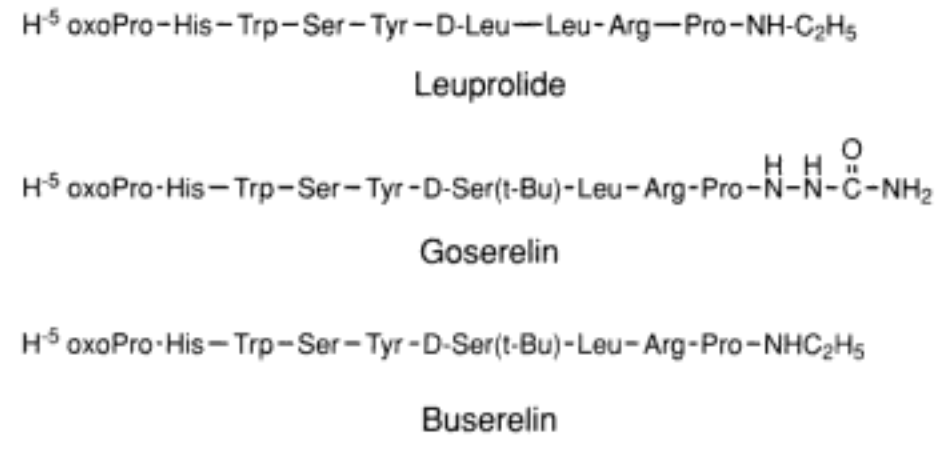


**Fig. 45.18.** 17-Hydroxylase/lyase inhibitors for prostate cancer.

**Luteinizing hormone–releasing hormone agonists.** The goal of LHRH therapy for prostate cancer is to suppress the production of testosterone in the testis and/or block its effects at its tissue receptors. Androgen deprivation using LHRH agonists (Fig. 45.19), such as leuprolide acetate (Lupron Depot), goserelin (Zoladex), and buserelin (Suprefact), suppresses the secretion of LH and, consequently, testosterone synthesis to castration levels (i.e., chemical castration) (135). The LHRH agonists significantly suppress the synthesis of intraprostatic DHT from testosterone and the size of the prostate (see the hypothalamus-pituitary-testis axis in Fig. 45.2). This effect is not immediate, however, and occurs 2 to 4 weeks after initiation of therapy. LHRH therapy slows the spread of cancerous cells and helps to alleviate or ease the symptoms associated with advanced prostate cancer. However, LHRH agonists are not cures for prostate cancer. The most common side effects associated with LHRH therapy are hot flashes, but impotence and loss of libido may also occur. Long-term use of LHRH therapy is associated with osteoporosis, decreased cognitive abilities, fatigue, and vascular stiffness. Symptoms may worsen over the first few weeks of treatment. Periodic monitoring of PSA and plasma testosterone levels is recommended. Tumor flare reactions may occur transiently but can be prevented by antiandrogens or by short-term estrogens at low dose for several weeks.

[Note: H-5 oxoPro = pGlu (PyroGlu)]

### Chemotherapy

Chemotherapy usually is reserved for patients whose prostate cancer has spread outside of the prostate gland and are no longer responsive to hormonal therapy. Chemotherapeutic drugs that can be used for prostate cancer include a combination regimen of mitoxantrone/ corticosteroids or estramustane/docetaxel (Taxotere) (see Chapter 42).

### Bone-Protecting Treatments

The most common site for the spread of prostate cancer is bone. Most symptoms of advanced prostate cancer are caused by the presence of disease in the bone. These symptoms can be mitigated with a drug called zoledronic acid (Zometa), a bisphosphonic acid administered by intravenous infusion that inhibits osteoclastic bone resorption, which can slow the spread of disease, reducing the development of bone pain and inhibiting bone fractures. Zoledronic acid is most commonly given to patients whose cancer is no longer responding to hormones, but it also may be given to prevent the bone thinning and weakening that results from hormonal treatments.

Zoledronic acid

## Treatment of Prostatitis

Prostatitis is a broad term used to identify inflammation of the prostate gland associated with lower urinary tract symptoms in men (136). Prostatitis rarely occurs in males younger than 30 years; however, it is a common problem in older males, being described as acute bacterial prostatitis, chronic bacterial prostatitis, or nonbacterial prostatitis. Because antimicrobial drug penetration generally is poor into the prostate gland, with poor efficacy of the antimicrobial agents and long duration of treatment; a 30 to 40% failure rate occurs with common treatment modalities. Three major factors determine the diffusion and concentration of antimicrobial agents in prostatic fluid and tissue: the lipid solubility of the antimicrobial agent, its dissociation constant ($pK_a$), and the percentage plasma protein binding. The physiological pH of human prostatic fluid is 6.5 to 6.7, but it increases in chronic prostatitis, ranging from 7.0 to 8.3 (136). A greater concentration of antimicrobial agents in the prostatic fluid occurs in the presence of a pH gradient across the membrane separating plasma from prostatic fluid. Of the available antimicrobial agents, β-lactam drugs have a low $pK_a$ and poor lipid solubility and, thus, penetrate poorly into prostatic fluid, except for some cephalosporins. Good to excellent penetration into prostatic fluid and tissue has been demonstrated with many antimicrobial agents, including tobramycin, tetracyclines, macrolides, fluoroquinolones, sulfonamides, and nitrofurantoin. The diagnosis and therapy of prostatitis remains a challenge. Because prostatitis usually requires prolonged therapy, patients must understand the importance of compliance, and physicians should screen for drug interactions that may decrease compliance and efficacy.

Acute bacterial prostatitis is the least common of the prostate infections and, usually, is accompanied by a urinary tract infection with positive cultures. The symptoms include sudden onset of fever, chills, and low back pain, as well as complaints of urinary obstruction (e.g., dysuria, nocturia, urgency, frequency, and burning) and urinary irritation (e.g., hesitancy, straining, dribbling, weak stream, and incomplete emptying). The most commonly prescribed antimicrobials for acute bacterial prostatitis are trimethoprim–sulfamethoxazole, doxycline, and the fluoroquinolones, ciprofloxacin, ofloxacin, and norfloxacin (see Chapter 38). The concentrations of these antimicrobial agents in the prostatic fluid are two to three times that in plasma, thus achieving adequate concentrations in prostatic tissues to eradicate the most common causative pathogens. The recommended duration of treatment for acute bacterial prostatitis is 4 to 6 weeks. A short-course therapy is not recommended because of the risk of relapse or progression to chronic bacterial prostatitis.

Chronic bacterial prostatitis occurs when acute bacterial prostatitis has been inadequately treated because of pathogen resistance, relapse, or short-course therapy or because of blocked drainage of secretions from the prostate. Most men with chronic prostatitis will have had a previous bout of acute prostatitis. The most common clinical feature of chronic prostatitis is recurrent urinary tract infections and the symptoms and complaints of acute bacterial prostatitis. Fluoroquinolones, trimethoprim–sulfamethoxazole, doxycycline, and nitrofurantoin are used in the management of chronic prostatitis. Chronic prostatitis warrants at least 10 to 12 weeks of therapy. Poor clinical outcomes, however, have been observed because of poor diffusion of antimicrobials into the prostate.

Nonbacterial prostatitis is the most common type of prostatitis. It occurs more frequently than bacterial prostatitis, with the same signs and symptoms as bacterial prostatitis except that prostatic fluid cultures are negative for presence of bacteria. Inflammation is evident on prostate gland examination. Treatment includes minocycline, doxycycline, or erythromycin. Treatment duration is approximately 2 to 4 weeks.

# DRUGS USED FOR ERECTILE DYSFUNCTION

## Phosphodiesterase Inhibitors

The currently available first- and second-generation oral PDE5 inhibitors, sildenafil, tadalafil, and vardenafil, have emerged as the first-line treatment for ED because of patient convenience, safety, and clinical efficacy and have markedly improved the quality of life in men with ED of various etiologies. As defined by the National Institutes of Health Consensus Development Panel on Impotence in

$IC_{50}$, median inhibitory concentration; PDE, phosphodiesterase.

and 7.4 for sildenafil (Table 45.6). The low PDE5/PDE6 selectivity ratio suggests that at therapeutic doses, sildenafil is only approximately 10 times as potent for PDE5 as for PDE6, which is a retinal enzyme found in the photoreceptors of the human retina. This lower PDE5/PDE6 selectivity ratio toward PDE6 for sildenafil indicates it is more likely to inhibit PDE6, which is presumed to be the cause for color vision abnormalities observed with high doses or plasma levels of sildenafil.

### Pharmacokinetics

Sildenafil, vardenafil and tadalafil have only limited oral bioavailability because of extensive presystemic metabolism in the intestine and hepatic first-pass metabolism via CYP3A isoform family (Table 45.6) (141). The three drugs are rapidly absorbed after oral administration and reach peak plasma concentrations within 30 to 60 minutes. Rapid absorption and lipophilicity are considered to be a prerequisite for their rapid onset of efficacy and sexual satisfaction. Sildenafil and vardenafil are both rapidly absorbed, but with a significant difference in their mean bioavailability of approximately 15% for vadenafil and 40% for sildenafil. The administration of a high-fat meal had no significant effect on the rate and extent of absorption of tadalafil but did decrease the rate of absorption for sildenafil and vardenafil, which is consistent with their calculated lipophilicity (Table 45.6). It remains unclear whether food has any effect on their absorption and therapeutic efficacy. They are all highly protein bound, with free plasma concentration fractions of only 4 to 6%. Although the bioavailability for tadalafil has not been reported, pharmacokinetic studies and its long duration of action suggest that it is predominately metabolized by hepatic CYP3A4 to catechol metabolites, with minimal presystemic metabolism.

The major route of elimination for the three PDE5 inhibitors is hepatic metabolism, with renal excretion of unmetabolized drug accounting for 1% or less of the elimination pathways (141). CYP3A is the major drug-metabolizing enzymes for the three PDE5 inhibitors. CYP2C9, CYP2C19, and CYP2D6, however, also contribute to the metabolism of sildenafil, and CYP2C9 contributes to the metabolism of vardenafil. Both sildenafil and vardenafil have active metabolites that reach plasma concentrations high enough to contribute to the overall efficacy and safety profile of their parent-drug molecules. Grapefruit juice increases the bioavailability of sildenafil and vardenafil as well as delays their absorption. The pharmacokinetics of sildenafil and vardenafil may become less predictable in patients who also drink grapefruit juice. Although patients usually will not be endangered by concomitant use of grapefruit juice, it seems advisable to avoid this combination, which can cause systemic vasodilatation.

The larger differences in their volumes of distribution, together with the substantial differences in their systemic clearance, result in distinct differences in their elimination half-lives: 3 to 5 hours for sildenafil and vardenafil, compared with approximately 18 hours for tadalafil.

Hepatic CYP3A and CYP2C activity has been described as being age-dependent, with reduced activity being exhibited in elderly compared to young individuals. This decrease in metabolic activity is reflected by a corresponding increase in plasma concentrations of all three PDE5 inhibitors, warranting dose reductions for sildenafil and

Copyrighted material

vardenafil in elderly patients. Similarly, ethnicity-dependent differences in the pharmacokinetics of all three PDE5 inhibitors may be expected based on known ethnic differences in CYP3A4/5 activity. Gender differences in pharmacokinetics have not been described for any of the three PDE5 inhibitors, which seems to be in agreement with the literature. Severe renal impairment resulted in an increase in plasma concentrations for all the drugs, and this warrants dose reductions for sildenafil and tadalafil in the affected patient population.

### Drug Interactions

None of the three PDE5 inhibitors has been identified as CYP inhibitors, including CYP3A or CYP2C substrates. Because metabolism via CYP3A is the major elimination pathway for all three drugs (sildenafil, vardenafil, and tadalafil), all inducers and inhibitors of CYP3A activity have the potential to interfere with the elimination of these drugs. This interaction potential has been verified clinically for inducers of CYP3A activity only for rifampicin and tadalafil (141). The strong inhibitors of CYP3A4 (ritonavir, indinavir, saquinavir, erythromycin, and ketoconazole) increased the plasma levels for sildenafil, vardenafil, and tadalafil. Grapefruit juice, a selective inhibitor of CYP3A intestinal metabolism, also increased the plasma concentrations of sildenafil and vardenafil but not of tadalafil. Ritonavir, as an inhibitor of CYP3A4 and CYP2C9, increased the plasma levels for vardenafil by 50 to 300 times, most likely as a consequence of the simultaneous inhibition of both CYP3A4 and CYP2C9, the major metabolism pathways for vardenafil. The effect of ritonavir on sildenafil was much less pronounced (11 times), because other compensatory CYP-mediated metabolism pathways were still available. Ritonavir increased the plasma levels for tadalafil (CYP3A4) by approximately three times.

### Adverse Effects

A number of side effects have been reported with these drugs, including nausea, cutaneous flushing, headache, and retinal effects, including a bluish haze and increased light sensitivity, and indigestion. It has been suggested that some of these side effects result from the inhibition of other PDEs, including the isoform PDE6 (141,142). The search is on for even more selective ED agents to see if additional side effects can be eliminated. If one is taking α-adrenergic blockers for high blood pressure, one should consult a physician before using the agents together (141). Other vasodilators associated with regulating the intracellular levels of cGMP, such as nitroglycerin, should not be used in combination with the PDE5 inhibitors.

### Therapeutic Effects

The first line of treatment of ED is PDE5 inhibition, because the three drugs can be given orally. If the PDE5 inhibitors are not effective, then the cause may be low libido, and men should have their testosterone blood levels checked (in some instances, TRT may help to resolve ED). Other alternative drugs currently available for the treatment of ED include prostaglandin $E_1$, which is given by injection at the base of the penis or by suppository into the tip of the penis, as well as the $\alpha_1$-adrenergic blocker and the nonselective PDE inhibitor papaverine. Apomorphine is a dopamine agonist that can be used for treating ED but, in humans, has the undesirable emetic side effect. Some selective dopamine $D_4$ agents are now being investigated for treatment of ED. Vacuum devices and penile implants are also available.

### Specific Drugs for Erectile Dysfunction

**SILDENAFIL.** In 1998, sildenafil was the first selective PDE inhibitor to be approved and found to be effective in treating ED (137). Sildenafil has approximately one-tenth the selectivity for PDE5 as for PDE6, which is found in the photoreceptors of the human retina. In vitro metabolism studies for sildenafil have shown that the primary metabolite, N-desmethylsildenafil, and the minor metabolite, oxidative opening of the piperazine ring, are mediated by CYP3A4, CYP2C9, CYP2C19, and CYP2D6. The estimated relative contributions to clearance were 79% for CYP3A4, 20% for CYP2C9, and less than 2% for CYP2C19 and CYP2D6. These results demonstrate that CYP3A4 is the primary cytochrome mediating N-demethylation and that drugs inhibiting CYP3A4 likely impair sildenafil biotransformation and clearance. The pharmacokinetics of radiolabeled sildenafil were consistent with rapid absorption, first-pass metabolism, and primarily fecal elimination of N-demethylated metabolites. The absorption of sildenafil following oral administration was rapid (~92%), whereas the oral bioavailability was approximately 38% as a result of first-pass metabolism.

**VARDENAFIL.** Vardenafil was the second agent to be marketed and had the advantage that its onset time was not reduced by taking the medication on a full stomach (Table 45.6) (141,143). It is 30 times more potent as an inhibitor of PDE5 (mean $IC_{50}$, 3.9 nM) than sildenafil and 10 times more potent than tadalafil, with a greater selectivity (>1,000 times) for human PDE5 than for human PDE2, PDE3, and PDE4 and moderate selectivity (>80 times) for PDE1 (140,144) (Table 45.6). The PDE inhibitory selectivity and both the in vitro and in vivo potency of the new PDE5 inhibitor vardenafil. Vardenafil specifically inhibited the hydrolysis of cGMP by PDE5, with an IC50 of 0.7 nM (sildenafil 6..6 nM). The $IC_{50}$ of vardenafil for PDE1 was 180 nM, for PDE6 11 nM, and for PDE2, PDE3 and PDE4 more than 1,000 nM.

**TADALAFIL.** Tadalafil was the last agent to be released and can be taken on a full stomach without slowing the onset (Table 45.6) (141). It has a much longer duration of action, lasting up to 48 hours, compared with sildenafil and vardenafil, which last for approximately 4 hours. The

Copyrighted material

blood flow into the corpus cavernosa as well as swelling and elongation of the penis. Venous outflow also is reduced, possibly as a result of increased venous resistance. Phentolamine is slowly released into venous circulation with minimal, if any, systemic effects. Time to peak effect is within 10 minutes, and duration of action when used with papaverine is 1 to 6 hours.

### Testicular Cancer

Testicular cancer develops in the testicles and, according to the National Cancer Institute (NCI), accounts only for approximately 1% of all cancers in men. Compared with prostate cancer, testicular cancer is relatively rare. It is most common among males between 15 and 40 years of age and is approximately fourfold more common in white men than in black men.

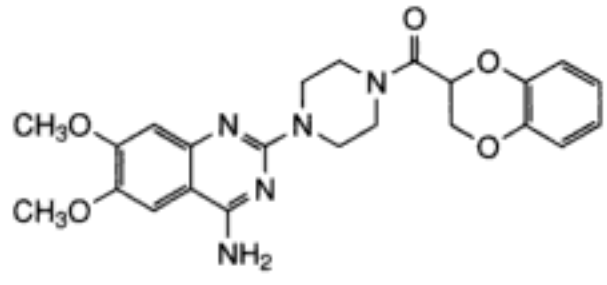
Nearly all testicular tumors originate from germ cells, the specialized sperm-forming cells within the testicles. These tumors fall into one of two types, seminomas or nonseminomas (149). Seminomas account for approximately 40 percent of all testicular cancer and are made up of immature germ cells. Seminomas are slow-growing and tend to stay localized in the testicle for long periods. Nonseminomas arise from more mature, specialized germ cells and tend to be more aggressive than seminomas. According to the American Cancer Society, 60 to 70% of patients with nonseminomas have cancer that has spread to the lymph nodes. α-Fetoprotein is a tumor-associated marker in blood for testicular cancer. Its measurement can help to show how well the chemotherapeutic drugs are working. Because seminomas are slow-growing, they tend to stay localized and usually are diagnosed at stage 1 (confined to testicle) or stage 2 (spread to lymph nodes). Treatment might be a combination of testicle removal, radiation, or chemotherapy. Most nonseminomas are not diagnosed at stage 1. Advanced testicular cancer (stage 3, metastasized to other tissues) seminomas as well as stage 2 and stage 3 nonseminomas usually are treated with multidrug chemotherapy. The majority of cases are stage 1 when first identified; stage 3 cases are relatively rare.

Chemotherapy is the standard treatment, with or without radiation, when the cancer has spread to other parts of the body. The drugs approved to treat testicular cancer, including ifosfamide, etoposide, vinblastine, bleomycin, and cisplatin. Cisplatin usually is given in combination with bleomycin and etoposide or other chemotherapy drugs following surgery or radiation therapy. Testicular cancer has one of the highest cure rates of all cancers, essentially 100% at stage 1. Approximately 90% of men with advanced testicular cancer can be cured, according to the NCI. Because testicular cancer is curable when detected early, the NCI recommends regular monthly testicular self-examination after a hot shower, when the scrotum is looser, feeling for lumps or enlargement.

### Male Osteoporosis

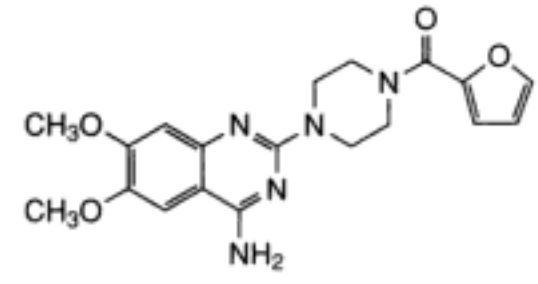
Osteoporosis is a common condition in men that usually develops after the age of 70 years and affects approximately 2 million men in the United States (150). Osteoporosis occurs less frequently in men because of greater skeletal bone mass during growth (i.e., greater bone size). Approximately 20 to 25% of all hip fractures occur in men, however, and the age-adjusted prevalence of vertebral deformities appears to be similar in men and in women. Currently, bisphosphonates (alendronate and risedronate) (see Chapter 35) are the therapy of choice for increasing bone mineral density to decrease the risk of fracture in the treatment of male osteoporosis, and a short course of parathyroid hormone (1-34; teriparatide) may be indicated for men with very low bone mineral density or for those in whom bisphosphonate therapy is unsuccessful. Antiandrogen therapy for the treatment of prostate cancer, hypogonadism, and diabetes are some of the risk factors for osteoporosis and fracture. Vitamin D and calcium have been shown to help improve bone mineral density. Testosterone replacement therapy is controversial except in men who clearly have hypogonadism and low levels of testosterone; in those men, treatment with testosterone appears to increase bone density.

## CASE STUDY



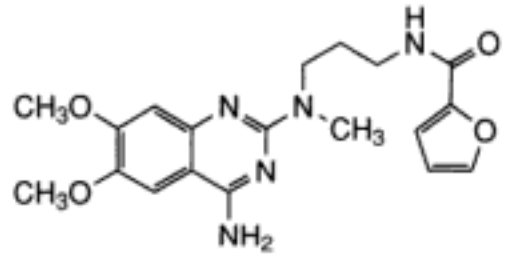
***Victoria F. Roche and S. William Zito***

BD is a 84-year-old white man who is spry for his age and lives with his 72-year-old wife in a small house in the rural countryside of New York State. They have several cats, and BD is allergic to cat dander and takes Dytan (diphenhydramine tannate; 50 mg every 12 hours) to control his symptoms. He reports to the ambulatory care clinic that he has had a recent onset of urinary hesitancy, a weak stream, intermittent flow, and postmicturation dribble. In addition, he complains that he has to urinate more frequently, especially during the night. BD reports that when he has to get up to urinate at night, he feels dizzy and wobbly in his rush to get to the bathroom. On further questioning, BD states that he gets dizzy every time he rises quickly from a sitting position. After examination and elimination of other conditions that could cause his symptoms (urinary tract infections, bladder cancer, or bladder stones), a diagnosis of benign prostatic hyperplasia (BPH) is made, and the physician wants to treat BD with medication. Evaluate the following choices for use in this case:



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.

Copyrighted material



3. Conduct a thorough and mechanistically oriented structure-activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure-activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

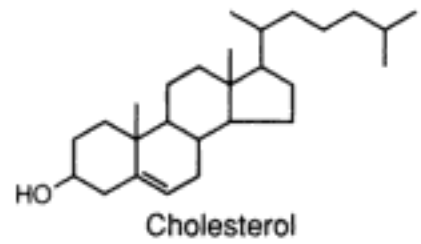
form of estriol, a very weak estrogen. Estrone was the first estrogen to be isolated in crystalline form from the urine of pregnant women. The two other $C_{18}$ estrogen steroids, 17β-estradiol and estriol, were isolated and characterized later.

Estrone



Estriol

### Biosynthesis

Estrogens are biosynthesized in the maturing dominant follicle and in the corpus luteum in premenopausal women. During pregnancy, the placenta becomes the primary location of estrogen biosynthesis (5,6). Approximately 50% of estrone production occurs in the ovaries. The remaining estrone is biosynthesized from estradiol as well as from the conversion of estrone sulfate to estrone in the adrenal gland and the aromatization of androstenedione. In contrast to premenopausal women, in whom the natural estrone to estradiol ratio is 1:2, postmenopausal women have an estrone to estradiol ratio of 2:1, which reflects the loss of ovarian function.

In endocrine tissues, cholesterol is the steroid that is stored and converted to estrogen, progesterone, or androgen when the tissue is stimulated by a gonadotropic hormone. The major pathways for the biosynthesis of sex steroid hormones are summarized in Figure 46.3. In the ovary, FSH acts on the preovulatory follicle to stimulate the biosynthesis of estrogens. The thecal cells of the preovulatory follicle convert cholesterol into androgens, whereas the granulosa cells convert androgens to estrogens.

Cleavage of the side chain of cholesterol produces pregnenolone (step a in Fig. 46.3), which can then be transformed into progesterone or, via several biosynthetic

Cholesterol

The enzymes involved in this biosynthesis are (a) side-chain cleavage, (b) 17α-hydroxylase, (c) 5-ene-3β-hydroxysteroid dehydrogenase, (d) 3-oxosteroid-4,5-isomerase, (e) 17,20-lyase, (f) 17β-hydroxysteroid dehydrogenase, (g) aromatase, (h) estradiol dehydrogenase, and (i) 5α-reductase.

Copyrighted material

steps, to the aromatic A ring system found in estrogens (7). Pregnenolone is converted by 17α-hydroxylase to 17α-hydroxypregnenolone (step b), which then proceeds on to the intermediate dehydroepiandrosterone (DHEA) via 17,20-lyase reaction (step e) (8). DHEA is converted by 5-ene-3β-hydroxysteroid dehydrogenase and 3-oxosteroid-4,5-isomerase to the 17-ketosteroid, androstenedione (steps c and d), which is interconvertible with testosterone via 17β-hydroxysteroid dehydrogenase (step f). The final step in the biosynthesis is the conversion of the $C_{19}$ androgens to the $C_{18}$ estrogens via the loss of the $C_{19}$ angular methyl group and aromatization of ring A to form 17β-estradiol or estrone (step g) catalyzed by aromatase. The interconversion of 17β-estradiol and estrone is catalyzed by estradiol dehydrogenase (step h), a member of the 17β-hydroxysteroid dehydrogenase family.

### Metabolism

Metabolism of the estrogens to their water-soluble glucuronide and sulfate conjugates occurs mainly in the liver. Creation of a reservoir of estrogen occurs as a result of enterohepatic recycling, a process by which estrogens undergo desulfation followed by resulfation.

Approximately 50% of an exogenous dose of 17β-estradiol undergoes hepatic first-pass metabolism to metabolites that are readily excreted via the kidney, and the remaining 50% is found in bile fluid (9). Much of the material found in bile subsequently enters the intestine, where it is reabsorbed and returned to the liver. Only 10% of an administered dose is found in the feces (5). Both 17β-estradiol and estrone are converted by 16α-hydroxylase to yield estriol (Fig. 46.4A), which is found in the urine as the glucuronide conjugate.

SHBG, Sex hormone binding glovulin

Estrogens are metabolized by estrogen 2/4-hydroxylase (CYP3A4) at positions ortho to the 3-phenolic group to form the 2-hydroxyestrogens and the 4-hydroxyestrogens (Fig. 46.4B). The resulting catechol estrogens bind to estrogen receptors (ERs) and produce weak to moderate estrogenic effects. These metabolites are unstable in vivo, however, and are rapidly converted to their 2-methoxy and 4-methoxyestrogen metabolites as well as to their glucuronide, sulfate, and glutathione conjugates. These metabolites are found in comparatively large amounts in the urine (9,10).

Estradiol is 37% bound to sex hormone binding globulin (SHBG) and 61% bound to albumin, leaving only 2% free in circulation (Table 46.3) (11,12). The affinity of estrone and of the sulfated esters of estrone and estradiol for SHBG is less than that that of estradiol; however, they are more tightly bound to albumin than estradiol is. These proteins are vital to the transport, distribution, and metabolic clearance rate of estrogens (13). In addition, estradiol is capable of inducing the synthesis of SHBG.

### Mechanism of Estrogenic Action

**Molecular interactions.** Estradiol plays a key role in several physiological processes, including the development of secondary sex characteristics during puberty, stimulation of the mammary glands during pregnancy, and thermoregulatory capacity. Estradiol facilitates these processes via its biological target, the ER, of which there are two subtypes (ER-α and ER-β). The two receptors differ in size: ER-α is composed of 595 amino acids, and ER-β is composed of 485 amino acids. The expression and distribution of these subtypes is inconsistent between the various tissues and organs, which may explain the wide response that is observed (11). The predominant ER in the female reproductive tract and mammary glands is ER-α, whereas ER-β is found primarily in vascular endothelial cells, bone, and male prostate tissues. Expression of both ER-α and ER-β can be regulated hormonally via estradiol. Estradiol has similar affinities for both ER-α and ER-β (Table 46.4), which is not the case for certain nonsteroidal estrogenic compounds and antiestrogens (14).

Within each target cell are two receptor locations, one within the nucleus, where a genomic mechanism predominates, and a second within the cell membrane, where a nongenomic mechanism prevails. Unlike the nuclear receptors, the cell membrane receptors are coupled to G proteins that are linked to a cascade of intracellular signals. Nuclear ER-α and ER-β are virtually identical in their DNA binding sites but are only ~60% homologous in the C-terminal ligand binding domain (11,13).

When estradiol binds either ER-α or ER-β, the receptor protein is phosphorylated and undergoes a conformational change to produce either homo- or heterodimers (ER-α/ER-α, ER-β/ER-β, or ER-α/ER-β) (15). The dimeric ER complex then migrates from the cytosol to the cell nucleus, where it teams up with specific estrogen-response elements (ERE) found within an adaptor protein, typically a promoter, which aids in binding of the complex to estrogen activated genes (11,13). This complex also enlists a coactivator (CoA) complex to this promoter, which regulates DNA transcription (Fig. 46.5). Because the ER can interact with other nuclear receptors as well as with transcription factors, it is not easy to tease out all the factors that control estrogen-mediated biological responses.

**Physiological effects.** One of the principal actions of the estrogens is to promote the development of female secondary sex characteristics. These feminizing attributes include hair growth, skin softening, breast growth, and accumulation of fat in the thighs, hips, and buttocks. Estrogen also stimulates the growth and development of the female reproductive tract, including the uterine oviduct, cervix, and vagina.

Estrogens play a significant role in breast tissue as well. Considerable research has focused on understanding

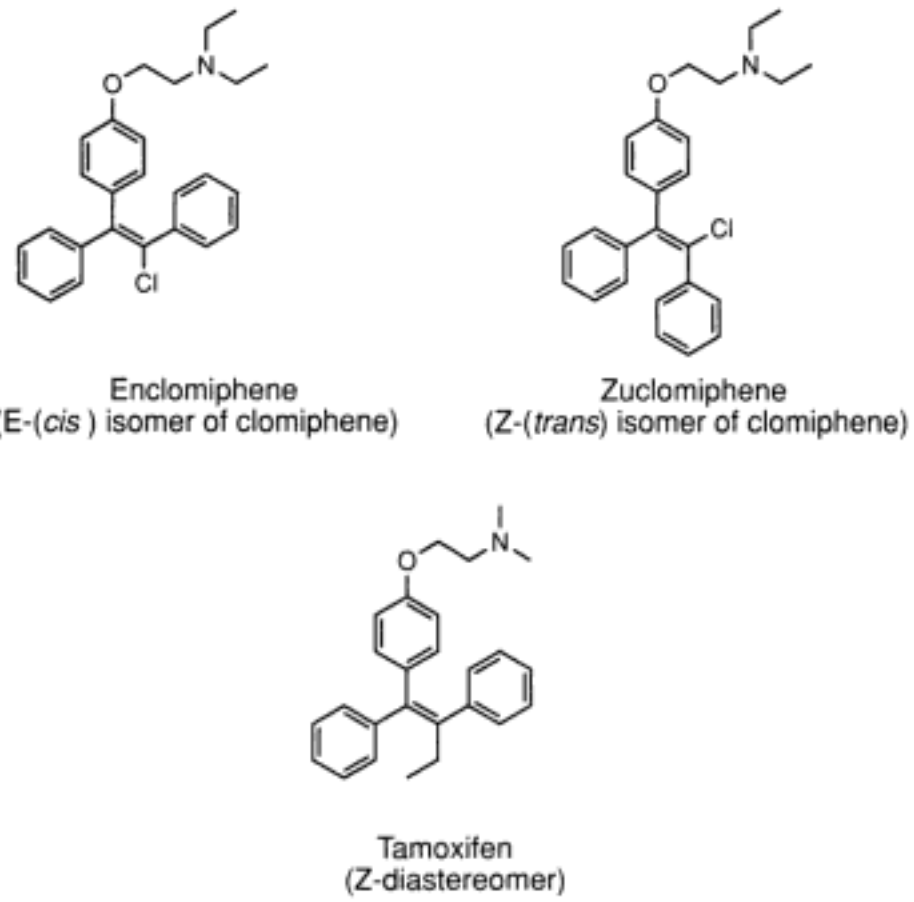

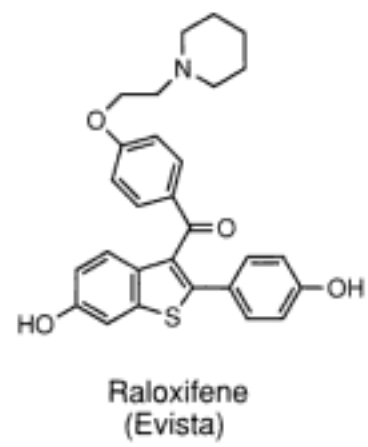

**Fig. 46.9.** Antiestrogens—triphenylethylene analogues.

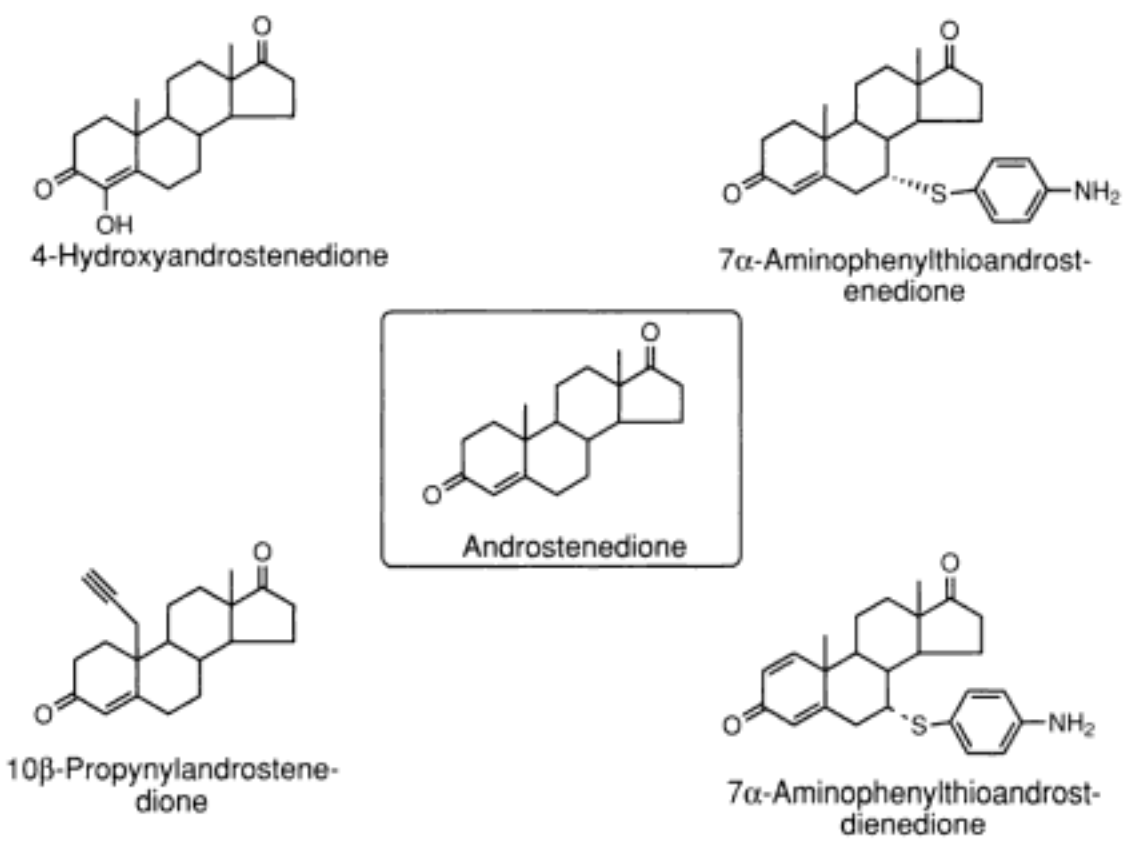
**IMPEDED ESTROGENS.** The impeded estrogens (e.g., estriol) interact with the ER in target tissues but dissociate from the receptor too rapidly to produce a significant estrogenic effect. If, however, the impeded estrogens are present in a high enough local concentration, they will compete with or impede estradiol access to its receptor site, thereby reducing the effect of estradiol on the cell (5,28).

**ANTIESTROGENS—TRIPHENYLETHYLENE ANALOGUES.** The triphenylethylene antiestrogens (Fig. 46.9) are structurally related to the stilbene family of estrogens and exhibit high affinity for the ER. They prevent translocation of the estrogen–receptor complex into the nucleus of target cells and interfere with the binding of the receptor–hormone complex to the acceptor site of the chromatin (29,30).

Advances in the molecular pharmacology of estrogen and ERs have led to the development of SERMs. These agents exhibit tissue-specific estrogen agonist or antagonist activity (31). The 3,4-dihydronaphthalene- and benzothiophene-containing SERMs are rigid analogues of the triphenylethylenes. The first SERM to be marketed for the treatment of osteoporosis was the benzothiophene raloxifene, an estrogen agonist at the bone (see Chapter 34). Discussion about the SERMs used in the treatment of breast cancer can be found later in this chapter.

**AROMATASE INHIBITORS**

***Androstenedione Derivatives.*** Inhibitors of aromatase block the conversion of androgens to estrogens and, therefore, have the therapeutic potential to control reproductive functions and aid in the treatment of estrogen-dependent cancers, such as breast cancer. These steroidal agents compete with androstenedione for the active site of the aromatase enzyme. The structure–activity relationships for steroidal aromatase inhibitors indicate that the best agents are substrate analogues, with only small structural changes to the A ring and at $C_{19}$ permitted (Fig. 46.10). Analogues



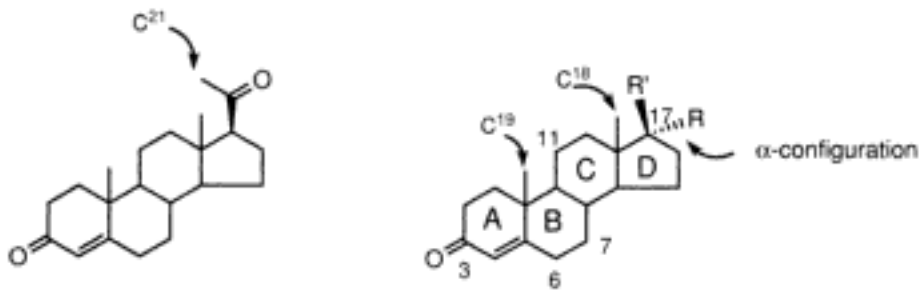


**Fig. 46.10.** Androstenedione aromatase inhibitors.

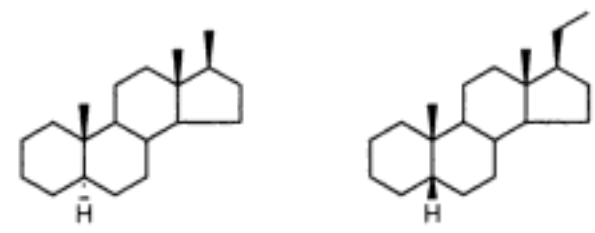
Copyrighted material

the first androstane found to be effective, has only about one-third the activity of progesterone when delivered subcutaneously, but is 15-fold more active than progesterone when administered orally. Closely related to testosterone, this progestin has significant androgenic activity. Removal of the $CH_3$ group at position 19 leads to norethindrone (norethisterone) (Fig. 46.14), which has 5- to 10-fold more progestin activity. The activity of norethindrone is increased further by the addition of a chlorine substituent at position 21 (blocks metabolic hydroxylation) or by the addition of a methyl group at carbon 18 (norgestrel) (see Fig. 46.15). Ethynodiol acetate is an extremely potent oral progestin. It is more active when administered orally than parenterally and, when combined with an estrogen, is effective as an OC.

Progesterone



Further unsaturation of the B or C ring of 19-androstane derivatives usually enhances progestin activity. Introduction of a halogen or methyl substituent in the 6α or 7α positions generally increases hormonal activity. Acetylation of the 17β-OH of norethindrone increases the duration of action of the drug. Removal of the 3-keto function of norethindrone allows retention of potent progestin activity and no androgenic effects.

Activity of the 17α-hydroxyprogesterones is enhanced by unsaturation at $C_6$ and $C_7$ and by substitution of a methyl group or a halogen at $C_6$. This activity may be further increased by introducing a $CH_3$ group at $C_{11}$. These substitutions prevent metabolic reduction of the two carbonyl groups and metabolic oxidation at $C_6$. Substitution of a fluoro group at $C_{21}$ prevents metabolic hydroxylation and enhances oral effectiveness.

Because glucocorticoid receptor activity is not desirable yet is innate to those derivatives that bind with high affinity to the progesterone receptor, structural alterations have been investigated to pare out this biological activity. Small B-ring substituents serve to decrease glucocorticoid action, as do substituents at the $C_{17}$ position.

### Synthetic Progestins

Early generations of the progestins were utilized primarily for contraceptive purposes, so antigonadotropic activity was considered to be desirable. Unfortunately, many of these agents were plagued by androgenic activity and the corresponding adverse effects (Table 46.7) (11). Development of newer progestins is now focused on analogues with improved progesterone receptor selectivity (Table 46.8) and little or no effect on the androgen, estrogen, or glucocorticoid receptors (43). From a structural perspective, these synthetic progestins contain either a pregnane or androstane steroid nucleus.

Androstane Pregnane

Not only can the progestins be classified structurally, they also can be organized by generation. The first-generation agents include 17-hydroxyprogesterone analogues (Fig. 46.13) as well as norethynodrel, norethindrone, and their derivatives (Fig. 46.14). Norgestrel and levonorgestrel are two of the predominant agents in the second-generation (Fig. 46.15). The levonorgestrel derivatives desogestrel, gestodene, and norgestimate compose the third generation (Fig. 46.16), and the new,

The number in parentheses indicates the generation of progestogen.

fourth-generation 19-norprogesterones include NES, nomegestrol acetate, and trimegestone (Fig. 46.17). In addition, there is one nonethynylated estrane, dienogest, and one spironolactone derivative, drospirenone, to round out the fourth generation (43). The antiandrogenic activity associated with several fourth-generation agents (e.g., trimegestone, drospirenone, and dienogest) makes this group of progestins unique (Table 46.7) (11). Trimegestone and elcometrine are the most potent progestins, with the third-generation levonorgestrel and etonogestrel (3-ketodesogestrel) being slightly less potent (Table 46.8).

### Progesterone and Its Derivatives

Progesterone has a significant role in priming the uterine endometrium for implantation of a potential blastocyst. It also is involved in formation of the placenta postimplantation, the development of mammary glands, and by preventing contraction of the uterine musculature, pregnancy maintenance. Progesterone also has inhibitory roles, including ovulation prevention via an antigonadotropic effect and inhibition of the conversion of testosterone to dihydrotestosterone, an active metabolite, by virtue of its ability to be a substrate for 5α-reductase (43). Interestingly, progesterone reduces nuclear estradiol receptor levels and induces 17-hydroxysteroid dehydrogenase, the enzyme that catalyzes the conversion of estradiol to the less potent estrone (50).

There are some limitations as to how progesterone can be administered, because it has relatively low bioavailability when administered orally. The pharmacokinetics for progesterone and its derivatives are listed in Table 46.6. To achieve consistent therapeutic benefit, progesterone must be administered either by injection or intravaginally. Progesterone may need to be administered over a relatively long period of time to maintain a

Copyrighted material

of ethisterone have improved progestogenic action, including introduction of methyl groups in the $C_{6\alpha}$ and $C_{21}$ positions (e.g., dimethisterone) (Fig. 46.14) (39).

A second breakthrough was made in 1944, when Ehrenstein (54) discovered that the $C_{19}$ methyl group is not necessary for progestogenic activity. In fact, this work showed that loss of the $C_{19}$ methyl results in analogues with activity equal to or greater than that of parenterally administered progesterone. In 1953, Djerassi et al. (55) synthesized 19-norprogesterone (Fig. 46.14). This drug differed from the natural hormone only in replacement of the $C_{19}$ angular methyl group with a hydrogen atom. When administered parenterally, this analogue was eightfold more active than progesterone and, at the time, was the most potent progestin known.

**NORETHINDRONE (NORETHISTERONE) AND NORETHYNODREL.** Research on 19-norsteroids as potential progestins culminated in the synthesis of two potent, orally active progestins, norethindrone and norethynodrel (Fig. 46.14) (46). These two substances were among the first 19-norsteroids to be used clinically for progesterone-related disorders. When combined with estrogens, such as EE or mestranol, these agents were effective contraceptives. Because the progestogenic action of norethynodrel is approximately one-tenth that of norethindrone, it is no longer utilized in OC formulations. Although norethindrone is a weak androgen, it does not exhibit any glucocorticoid or antimineralocorticoid activity (Table 46.7).

Following oral administration, norethindrone acetate is completely and rapidly deacetylated by hepatic and intestinal first-pass metabolism to norethindrone, with an oral bioavailability of approximately 64%. Subsequent metabolism of norethindrone includes reduction of the $\Delta^4$ double bond to both the 5α- and 5β-dihydronorethindrone products as well as reduction of the ketone. The pharmacokinetics for norethindrone acetate are indistinguishable from that of orally administered norethindrone. Roughly 36% of norethindrone is bound to SHBG, and 61% is bound to albumin (11).

Norethindrone acetate also can be administered transdermally along with estradiol when formulated as a patch. This combination of hormones can be utilized as part of either a continuous or a cyclic hormone replacement regimen.

**NORGESTREL AND LEVONORGESTREL.** Norgestrel is formulated as a racemic mixture despite the fact that only its levo isomer, levonorgestrel, is pharmacologically active (Fig. 46.15). Levonorgestrel exhibits some androgenic activity but no glucocorticoid or antimineralocorticoid action. Levonorgestrel can be administered orally, transdermally (combined with estradiol and formulated as a 7-day patch), and for prolonged, continuous use, via an intrauterine device (IUD). The oral bioavailability of levonorgestrel is approximately 95% (11). From a protein binding perspective, 48% of an oral dose is bound to SHBG, and 50% is bound to albumin. Levonorgestrel undergoes metabolic reduction of its ketone and is hydroxylated.

**NORGESTIMATE AND DESOGESTREL.** Norgestimate (Fig. 46.16) is considered to be a pro-progestin (prodrug), because it rapidly undergoes a two-step metabolic transformation to form two active products, norelgestromine (levonorgestrel 3-oxime) and levonorgestrel (Fig. 46.15). Deacetylation occurs in the intestine and liver, whereas conversion of the 3-oxime to the corresponding ketone occurs primarily in the liver. Unlike the other progestins mentioned, norgestimate and its metabolites are not bound to SHBG.

Norgestimate exhibits high selectivity for the progesterone receptor and low androgenic activity as a result of a large drug-induced increase in the production of SHBG. As a component of both mono- and triphasic OC formulations, this progestin exhibits fewer androgenic side effects, including less of a detrimental effect on the patient's lipid profile and lack of significant weight gain (56). Rates of breakthrough bleeding were lower with a triphasic regimen including norgestimate compared to a monophasic regimen containing norethindrone acetate. Norgestimate is metabolized to norelgestromin, the primary active metabolite and the active progestin found in the contraceptive patch (Ortho Evra).

Desogestrel also is a prodrug and is rapidly metabolized in the intestinal mucosa and on first pass through the liver to its active metabolite, etonogestrel (3-ketodesogestrel) (Fig. 46.16). Following oral administration, the relative bioavailability for desogestrel is approximately 84%. Desogestrel also exhibits high selectivity for the progesterone receptor and low androgenic activity, and it does not diminish the beneficial effects of estrogen on the lipid profile. The rates of breakthrough bleeding are low with the monophasic desogestrel/EE formulation, which has improved therapy discontinuation percentages. Unfortunately, there is conflicting evidence regarding the risk of venous thromboembolism with these preparations, with some studies suggesting a twofold increase in risk (56).

**GESTODENE.** Unlike the other members of the third generation of progestins, gestodene is not a prodrug (Fig. 46.16). It exhibits nearly 100% oral bioavailability and excellent receptor binding affinity for the progesterone receptor. Because the SHBG level is considered to be a surrogate marker for venous thromboembolism (VTE) risk, it is important to note that an increase in SHBG levels is evident both in monophasic combination OC preparations (200–300% increase) and in triphasic preparations (150% increase) that contain gestodene (57). Both the monophasic and triphasic preparations also cause an increase in triglyceride and total cholesterol levels, although the increase is smaller in magnitude than those associated with desogestrel and norgestimate. An increase in high-density lipoprotein (HDL) levels was not observed (58). The effectiveness of a gestodene/ethynyl estradiol combination transdermal patch is currently under investigation.

Copyrighted material

**DIENOGEST, DROSPIRENONE, ELCOMDETRINE, NOMEGESTROL ACETATE, AND TRIMEGESTONE.** Classified as a testosterone-like, norethindrone-related progestin, dienogest is structurally unique in that it contains an estrane skeleton, a $C_{17}$ cyanomethyl group that replaces the $C_{17}$ ethynyl group, and $\Delta^9$ unsaturation (Fig. 46.17). An effective OC preparation results when dienogest is combined with EE. Similarly, correction of menopausal symptoms results when dienogest is combined with estradiol valerate. Limited evidence suggests that this combination has a positive impact on cognition, which is in direct opposition to the Women's Health Initiative (WHI) study data regarding the combination of medroxyprogesterone acetate and conjugated estrogens.

Derived from spironolactone, drospirenone (Fig. 46.17) is the only progestin with antimineralocorticoid activity. Its affinity for the mineralocorticoid receptor is fivefold greater than that of aldosterone. Drospirenone has progestogenic action, but only 10% that of levonorgestrel. Drospirenone also has antiandrogenic action, because it blocks testosterone from binding to androgenic receptors but does not exhibit estrogenic or glucocorticoid receptor activity.

This androstane-based progestin has several distinctive functional groups: two cyclopropyl groups, one that

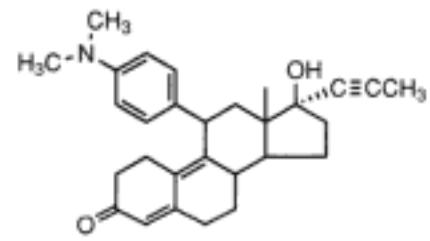
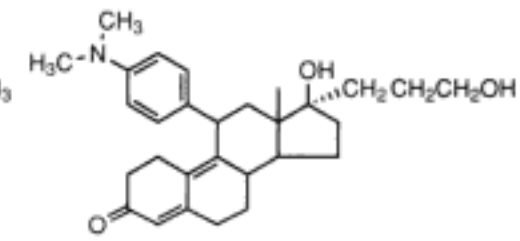
Copyrighted material

includes $C_6$ and $C_7$ and the other $C_{15}$ and $C_{16}$, and a $C_{17}$ lactone. When combined with EE, drospirenone is effective in a monophasic OC (Table 46.9). Additionally, drospirenone plus estradiol (Angeliq) is used in the treatment of various menopausal symptoms. The unique antimineralocorticoid activity of drospirenone effectively negates the side effects related to angiotensinogen production (causing an increase in sodium and water retention) associated with EE. Remarkably, within the first several cycles, women actually lost weight when utilizing this combination of hormones (43). Regrettably, this benefit was lost, and statistically significant weight gain occurred as the number of cycles approached 13 (56).



Elcometrine (Fig. 46.17) is a member of the 19-norprogesterone class of progestins. When administered subcutaneously (implant), intravaginally (vaginal ring), or transdermally, elcometrine is an exceptionally potent progestin. It is 100-fold more potent when administered subcutaneously than when delivered orally. Its oral bioavailability is only 10%, with a half life of just 1 to 2 hours because of rapid metabolism (11). The $C_{16}$ methylene functionality substantially increases its affinity for the progesterone receptor. Elcometrine does not bind to the androgenic receptor and, therefore, does not possess either androgenic or antiandrogenic activity (11). Unfortunately, like medroxyprogesterone acetate, elcometrine has affinity for the glucocorticoid receptor, although adverse effects were noted only at exceptionally high doses. Because of its antiestrogenic action, elcometrine also can be administered transdermally along with estradiol as a treatment for menopausal symptoms (43). From a protein binding perspective, elcometrine does not bind to SHBG but, rather, to albumin (11).

Nomogestrol acetate (Fig. 46.17) is structurally similar to megestrol acetate but lacks the angular $C_{19}$ methyl group. It has substantially better selectivity for the progesterone receptor and higher potency than medroxyprogesterone acetate. Nomogestrol acetate has potent antigonadotropic action and, therefore, is an appropriate progestin to use in an OC preparation. It exhibits no glucocorticoid, antimineralocorticoid, or androgenic activity; however, it does demonstrate significant antiandrogenic action (11). Like NES, this progestin is bound primarily to albumin. Like desogestrel, it does not diminish the beneficial effects of estrogen on the lipid profile (11).



Trimegestone, the most potent of the 19-norprogesterones, contains an unusual $C_{21}$ hydroxyl group (Fig. 46.17). It has very high affinity for the progesterone receptor but only weak affinity for the mineralocorticoid receptor. Trimegestone displays no glucocorticoid, androgenic, or antiandrogenic action. This progestin undergoes metabolic hydroxylation to produce metabolites with substantial progestogenic action. Either alone or in combination with estradiol, trimegestone has shown favorable results regarding bone loss and bone turnover (43). Given with estradiol, this hormone replacement therapy (HRT) combination is effective in the treatment of postmenopausal symptoms regardless of whether it is administered continuously or as part of cyclic therapy. Like desogestrel and nomogestrel acetate, this progestin does not diminish the beneficial effects of estrogen on the lipid profile (11).

### Progestin Antagonists

**MIFEPRISTONE.** An antiprogestin is a substance that competes with progesterone for its receptor and, ultimately, prevents progesterone from binding to and activating its receptor. Because progesterone is integral to the continuation of an early pregnancy, it is expected that antiprogestins will interfere with pregnancy maintenance. In 1982, the first antiprogestin, mifepristone (RU 486), was reported (59). Mifepristone was shown to interrupt early stages of implantation and pregnancy in humans (60). Following oral administration, mifepristone is rapidly absorbed, with a peak plasma concentration in approximately 90 minutes, an oral bioavailability of approximately 70%, and a terminal elimination half-life of 18 hours. It is 98% protein bound, primarily to albumin and $\alpha_1$-acid glycoprotein. Mifepristone is metabolized primarily via CYP3A4 pathways involving mono- and di-N-demethylation and terminal hydroxylation of the 17-propynyl chain. The fact that approximately 83% of the drug is recovered in the feces and 9% in the urine suggests a biliary route of elimination. Mifepristone also demonstrates antiglucocorticoid activity (61).

Mifepristone
(Mifeprex)

Onapristone

Additional antiprogestin analogues, such as onapristone (ZK 98,299), exhibit less antiglucocorticoid activity (62). These antiprogestins also have demonstrated therapeutic potential for the treatment of hormone-dependent breast cancer (63).

## THERAPEUTIC APPLICATIONS

A woman's reproductive life cycle spans nearly four decades. During this time her hormonal status and ability to reproduce vary considerably. The need for hormonal intervention during this time period varies from person to person and, typically, requires highly individualized medication regimens. The remainder of this chapter will focus on hormonal and selected nonhormonal therapies for the treatment and/or management of contraception, endometriosis, infertility, menopause, and breast cancer.

### Contraceptive Methods

Despite the availability of a wide variety of contraceptive methods and technologies, nearly half of all pregnancies in the United States are unplanned, and one-fourth are

Copyrighted material

terminated. You might expect that cost, adverse effects, and inconvenience would be some of the hurdles to achieving contraceptive efficacy, but one of the greatest barriers is ineffective patient education (64). Despite ease of use, nearly 50% of those patients who have chosen an OC regimen discontinue their therapy within a year (65). If information regarding potential side effects, dosing requirements, and how the therapy is able to prevent pregnancy is provided in an accessible fashion, however, there may be many fewer patients who discontinue their contraceptive therapy (64,66,67).

### Behavioral and Barrier Methods

Behavioral methods, such as natural family planning, fertility awareness, coitus interruptus, and lactation infertility, typically result in the highest pregnancy rates of all of the contraceptive methods. To be effective, these methods require disciplined effort on the part of the patient and her partner and somewhat detailed patient training. Barrier methods, such as male and female condoms, diaphragms, sponge (including nonoxynol-9 spermicide), and cervical caps, still require a very conscientious and often preplanned effort on the part of the patient as well as fairly detailed patient training. Unplanned pregnancy rates with these barrier methods are approximately 12 to 15%. Pharmacological contraception, including OCs, patches, vaginal rings, IUDs, and injectable medications, provides substantially lower pregnancy rates with diligent use, relatively limited patient effort, and patient education that is focused largely on adverse effects.

### Combination Oral Contraceptives

Available since the early 1960s, most OC pills contain both an estrogen and a progestin component. The estrogen component, either EE or mestranol, suppresses FSH release and, therefore, prevents the formation of a dominant follicle during the follicular phase of the menstrual cycle. The dominant follicle is responsible for producing estradiol, which sends a negative feedback signal to the hypothalamus to prevent the secretion of additional gonadotropins and, therefore, prevent maturation of additional follicles. The estrogen component also is responsible for maintaining the stability of the endometrial lining (68). The progestin component, of which there are many available, suppresses the LH surge and, therefore, blocks ovulation.

In the more than 40 year evolution of OCs, the estrogen dose has dropped to one-sixth, and the progestin dose to one-tenth, of the original levels. This makes the newer OC agents substantially safer but also subject to adverse effects, such as irregular and breakthrough bleeding. In addition to these dosage changes, the progestin components have become progressively more selective in their binding to the progesterone receptor, thereby limiting the androgenic side effects that were characteristic of the older progestins (56).

OC agents are either monophasic or multiphasic in their hormone composition (Table 46.9). The multiphasic formulations more closely mimic the natural changes in both hormone concentrations that occur throughout the menstrual cycle. Most of the OC formulations are administered for 21 days, followed by 7 drug-free days to allow monthly withdrawal bleeding. Recently approved extended-cycle products, which allow the patient to experience only 7 drug-free days every 3 months, have efficacies similar to that of the standard 28 day regimen (Seasonale and Seasonique) (Table 46.9). Another nonstandard combination OC consists of estrogen plus progestin for 21 days, followed by 2 hormone-free days and then 5 days of EE (Mircette) (Table 46.9) (66). In Spring 2007 the FDA approved the first continuous regimen of low-dose EE and levonorgestrel (hybrel) that completely eliminates the menstrual cycle.

Two triphasic formulations that use a low dose of estradiol (25 μg) are currently under development. These formulations aim to minimize the side effect profile (e.g., breast tenderness, bloating, and nausea) and to maximize cycle control (e.g., minimal breakthrough bleeding). The formulation includes estradiol and a triphasic stair-step dose of either norgestimate or desogestrel.

A low-dose formulation was approved by the U.S. Food and Drug Administration (FDA) in early spring of 2006 (YAZ) (Table 46.9). This preparation is monophasic and is comprised of estradiol and drospirenone. The dosing regimen for this OC is comprised of 24 days of drug therapy, followed by 4 drug-free days to allow withdrawal bleeding. The 3-mg drospireneone component of this preparation is equivalent to 25 mg of spironolactone in terms of diuretic potential. Because of the diuretic action of drospirenone, the drug has the potential to cause hyperkalemia. Diminished fluid-related weight gain is an obvious advantage to this OC formulation, but caution is advised in patients with renal or adrenal insufficiency, with hepatic dysfunction, or who are receiving chronic pharmacotherapy that may increase serum potassium levels (e.g., angiotensin-converting enzyme inhibitors and potassium-sparing diuretics). This product joins a previous OC formulation that contains drospirenone (Yasmin) (Table 46.9). It should be noted that intracyclic bleeding (spotting) is more prevalent with EE doses of less than 30 μg, as is the case with these OCs. Studies have shown that the incidence of this adverse effect was greatest during the first cycle of OC use and diminished to very low incidence within three cycles (69).

Although the adverse effects of OC therapy include an increased risk of stroke, acute myocardial infarction, and venous thromboembolic disease, the incidence of cardiovascular disease in this patient population (age, <35 years) is already low (66). In women older than 35 years, the natural incidence of cardiovascular disease increases, so these adverse effects become more important to consider. From a metabolic perspective, the primary adverse effect of the estrogen component is an increase in hepatic production of proteins, including those that enhance venous and arterial thromboembolism (70). In addition, the progestin component has an adverse effect

Copyrighted material

dosing regimens (67,75). This formulation is not without adverse effects, including decreased libido, nausea, vaginitis, and breast tenderness.

### Contraceptive Injectables

An intramuscular formulation that contains an aqueous suspension of medroxyprogesterone acetate and estradiol cypionate is available but is not currently marketed in the United States (Table 46.10). The 28- to 33-day dosing interval provides excellent contraceptive effectiveness. There are several advantages to this contraceptive method, including scheduled withdrawal bleeding and a quick return to a fertile state on discontinuation of therapy. The adverse effects are similar to those seen with other combination OC formulations, including headache, weight gain, decreased libido, and breast tenderness (67).

### Progestin-Only Injectables

The issue regarding timing of administration all but disappears when a progestin injection is administered every 3 months. In this formulation, medroxyprogesterone acetate is an aqueous microcrystalline suspension (Table 46.10). The mechanisms by which this progestin accomplishes contraceptive efficacy are the same as those discussed previously for other progestins. Despite the ease of use, the continuation rate after a year of injections is less than 30%, largely because of the adverse effects, including irregular and heavy bleeding, amenorrhea, and infertility that lasts for 9 to 21 months after the last injection (64). Improved patient education concerning the potential side effects may be a simple solution to discontinuation of therapy.

Several subdermal implants are available that provide contraceptive efficacy for 1 to 5 years depending on the formulation (Table 46.10). These implants consist of progestins contained within individual rods that are surgically implanted into the upper arm. As indicated in Table 46.10, varying durations of action can be expected depending on the number of rods implanted. Currently, Norplant is not available in the United States, and Implanon has only received "approval" status by the U.S. FDA. These formulation is subject to the same adverse effects as other progestin-only methods.

### Intrauterine Devices

There are two forms of IUDs: one that releases the progestin levonorgestrel (Table 46.10), and one that is copper-coated. Both devices are T-shaped and must be inserted into the uterus by a physician. These devices mechanically irritate the endometrium and create an inflammatory environment that is toxic to sperm and ova and is not conducive to embryo implantation (64), The copper coating further enhances this inflammatory response. The copper-based IUD can be used continuously for 10 years, whereas the progestin-containing device is only approved for 5 years of use (76). Although generally well tolerated, ectopic pregnancy and infection (related to device insertion or to the device itself) are two serious potential complications. Discontinuation of use often is a result of breakthrough and/or heavy withdrawal bleeding.

### Emergency Contraception

Emergency contraception is defined as any method that prevents pregnancy after intercourse. This type of therapy is available in either combination or single-agent formulations. The progestin only pills contain either levonorgestrel (Plan B) or norgestrel (Fig. 46.14). The two combination regimens include EE along with each of these progestins. Typically, these agents are administered as one dose within 72 hours of intercourse, with another dose taken 12 hours later. Nausea and vomiting are common side effects. If the patient is hormone adverse, then insertion of a copper IUD within 5 days of ovulation (the earliest estimated date) will prevent implantation (77).

Mifepristone (Mifeprex) is a 19-nortestosterone–based antiprogestogen that competes with the endogenous agonist for the progesterone receptor (see previous discussion). If administered within 5 days of unprotected intercourse, it also will prevent pregnancy. Despite the presence of the bulky 11β-diethylamino phenyl group, mifepristone has higher receptor affinity than progesterone itself. It is not completely understood how mifepristone inactivates the progesterone receptor. Of note is that mifepristone and progesterone do not interact similarly with the ligand binding domain, such that in the presence of mifepristone, the conformational change that occurs in this domain is unique from that produced by the natural agonist (42).

## Endometriosis

Endometriosis, a condition present in 1 of 10 menstruating women, is characterized by implantation of endometrial tissue outside the uterus, typically within the pelvic region (78,79). During a normal menstrual cycle, hormonal signals cause the endometrial tissues to thicken in anticipation of embryo implantation. If a pregnancy does not occur, then these tissues are shed, resulting in a monthly period. When endometrial tissues implant outside the uterus, they respond identically to those within the uterus, such that when hormones fall in response to a nonpregnant state, these tissues are shed—yet have no natural exit. This tissue may form cysts, which in turn may form scar tissue and/or adhesions. Typically, the presence of one or more of these elicits significant pain and discomfort, especially during menstruation. Because the resulting scars and/or adhesions can cause infertility (78), treatment should be sought if the patient wishes to have children.

The cause of endometriosis is not completely understood. Sampson's hypothesis in 1927 suggests that menstrual fluids flow back (retrograde) through the fallopian tubes, where the endometrial cells can then implant and grow. Another theory proposes that the bloodstream is responsible for transporting the endometrial cells to

| Therapeutic donor insemination | Women without partners<br>Severe male factor | Sperm donor |

FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; hMG, human menopausal gonadotropin; LH, luteinizing hormone; PCOS, polycystic ovarian syndrome.

zuclomiphene)-diastereomer displays estrogenic activity, and the E (*trans*, enclomiphene)-diastereomer exhibits antiestrogenic activity (Fig. 46.9). Its ability to stimulate ovulation stems from its action at the hypothalamic ERs, where it serves to block these receptors and interfere with natural feedback inhibition. When an estrogen deficiency is perceived by the hypothalamus, it responds by secreting GnRH. This peptide hormone signals the pituitary to release the gonadotropins FSH and LH. Elevated FSH levels promote follicular development, which in turn causes the maturing follicles to secrete estradiol. Clomiphene is administered orally (50 or 100 mg) for 5 consecutive days, typically on days 5 to 9 of the menstrual cycle. Approximately 7 days after the last clomiphene tablet is taken, the hypothalamus finally is able to detect that estradiol levels are elevated, and it then signals the pituitary to secrete LH. This surge in LH causes the dominant follicle to rupture and release an egg, a process known as ovulation.

The clomiphene citrate challenge test is a diagnostic tool utilized to evaluate ovarian reserve in women older than 35 years of age. The protocol involves measurement of FSH and estradiol levels on day 3 of the cycle, followed by administration of 100 mg of clomiphene citrate on days 5 to 9 and measurement of FSH and estradiol on day 10 of the cycle. Elevated estrogen levels on day 3 are a good predictor of a poor pregnancy prognosis. Any FSH measurement that is high (>10 mIU/mL), even if other levels measured within the same cycle are within the normal range, is interpreted to mean a significantly limited reproductive potential because of poor ovarian reserve (88,91,94).

The adverse effects associated with clomiphene include thickening of the cervical mucus, which creates a substantial barrier for motile sperm. A postcoital test can be performed to determine if this, in fact, represents an insurmountable hurdle. If so, an IUI is warranted to bypass this cervical challenge. Another adverse effect is endometrial thinning, which is not conducive to embryo implantation; if this is the case, additional pharmacological therapies are recommended to thicken the endometrial lining. Other adverse effects include hot flashes and mood swings (95).

Women with low estrogen levels or hypothalamic disorders that result in irregular or absent ovulation are not candidates for clomiphene therapy. There is a 10% chance of having twins and a slightly higher risk of miscarriage in women stimulated with clomiphene (95). Clomiphene-based ovulatory stimulation should only be considered for a maximum of six cycles.

Clomiphene is readily absorbed from the GI tract following oral administration, with a half-life of approximately 5 days. It is metabolized in the liver, and its metabolites are excreted principally in the feces via enterohepatic recirculation.

### Human Chorionic Gonadotropin (Pregnyl)

Human chorionic gonadotropin mimics LH both in structure and in function. It is produced by the placenta during pregnancy and is isolated from the urine of pregnant women. In the protocols for IUI or IVF, exogenous hCG must be administered to stimulate a scheduled ovulation. Between 36 and 72 hours after intramuscular administration, the dominant follicle ruptures and releases its egg. At that point, the scheduled IUI or IVF occurs. The hCG can be given in combination with clomiphene citrate to enhance ovulation (95). (For an in-depth discussion of hCG, see Chapter 7.)

### Human Menopausal Gonadotropin (Reprondex)

Human menopausal gonadotropin (menotropins) is composed of equal parts FSH and LH and is derived from the urine of menopausal women. This type of therapy is utilized after clomiphene-based therapy has failed or if a patient does not produce sufficient levels of FSH or LH and experiences amenorrhea. These hormones directly stimulate the ovaries to develop multiple follicles per reproductive cycle (95).

Human menopausal gonadotropin has a substantial role in several IVF protocols. It typically is administered

Copyrighted material

Two GnRH antagonists, ganirelix acetate (Antagon) and cetrorelix (Cetrotide), are administered by intramuscular injection (95). The primary advantage of the GnRH antagonists over the agonists is that they interact with and effectively block the GnRH receptor without causing an initial surge of FSH and LH. The primary role of both the antagonists and agonists is to prevent a premature LH surge.

In an IVF cycle, the GnRH antagonist is not administered until the dominant follicle reaches 14 mm in diameter, which is nearly a week after gonadotropin therapy is initiated. The GnRH antagonists suffer from low solubility and the tendency to form gels in aqueous solutions (96). Ganirelix acetate has a short half-life and must be administered daily until hCG is administered, whereas cetrorelix has a longer half-life and can be administered once every 3 to 4 days (93). (Discussion about structure–activity relationships can be found in Chapter 7.)

Women whose ovulatory cycle has been managed by gonadotropin therapy have a 25% risk of multiple pregnancies. Some evidence suggests a lower pregnancy rate in patients utilizing protocols that include a GnRH antagonist (96,97). Adverse effects include injection site pain and inflammation, abdominal bloating, mood swings, and menopausal symptoms, including hot flashes and vaginal dryness. The likelihood of developing OHSS is fairly small in protocols that include GnRH agonists or antagonists. In these regimens, the physician has control over the hCG injection necessary to trigger ovulation and can delay—or even withhold—this injection if estrogen levels are too high, a factor that predisposes the patient to develop OHSS (95). It should be noted that GnRH down-regulation caused by these agents may have an adverse effect on oocyte quality, which has a negative impact on an IVF cycle (92).

As part of an assisted reproductive technology protocol, the use of both a GnRH agonist or antagonist and exogenous gonadotropins provides significant benefits, including enhanced stimulation of follicular development, improved oocyte quality, and LH surge suppression, all of which lead to fewer cycle cancellations and improved reproductive capability (92).

### Lutropin alfa (Luveris)

Lutropin alfa is the first recombinant human form of LH approved by the U.S. FDA. This agent serves as LH replacement therapy for those women who are hypogonadotropic and hypogonadal with a substantial deficiency in LH (<1.2 IU/L). Lutropin alfa typically is utilized in combination with follitropin alfa to induce follicular growth and development. Both of these agents are administered subcutaneously.

The half-life of lutropin alfa is approximately 10 hours. Treatment should not exceed 14 days unless follicular development is clearly evident. Adverse effects include headache, breast and abdominal pain, and nausea. Lutropin alfa can contribute to the development of OHSS and should not be utilized in women primary ovarian failure or uncontrolled thyroid or adrenal dysfunction or who are pregnant.

## Menopause

Physiologically, menopause is described as the loss of ovarian follicle function, followed by the cessation of menses. Before menopause, the body typically is engaged in a 2- to 4-year preamble, complete with the signs and symptoms of menopause (e.g., hot flashes and night sweats). This stage is termed perimenopause and is characterized by a gradual decline in the secretion of estrogen and progesterone. When the ovary no longer prepares follicles for ovulation and the resulting corpus luteum is not formed, a dramatic decrease in the production of estrogen and progesterone occurs, along with the resulting physiological changes, including bone loss, urogenital atrophy, and perhaps, incontinence, vasomotor symptoms, enhanced risk of cardiovascular disease, sexual dysfunction including decreased libido, as well as reduced skin elasticity (98). Many, if not most, of these changes have a negative effect on the quality of life for women during what is considered to be an exceptionally productive time in their lives. Identification of pharmacological and nonpharmacological methods to alleviate these symptoms is essential to improving quality of life during this turbulent hormonal phase at the end of a woman's reproductive lifetime.

### History

As early as 1899, the Merck Manual listed several treatments for menopausal symptoms, including the drug Ovarin, which was composed of desiccated and pulverized cow ovaries flavored with vanilla. In 1932, this formulation was largely replaced by products that contained components isolated from the urine of pregnant women. By the late 1930s, these human-derived products were supplanted by Premarin, which contained components isolated from the urine of pregnant mares (99). Other formulations that take advantage of other routes of administration have been available for quite some time as well; for example, in 1928, the first estrogen patch was developed by Searle.

By the 1960s and 1970s, the first studies regarding serious adverse effects associated with estrogen therapy were reported, including severe hypertensive episodes and increased thromboembolic events. In 1978, the U.S. FDA mandated that a comprehensive warning be distributed with all estrogen products, including OCs. This document listed the approved indications and fully described the potential risks of using an estrogen-containing formulation. Despite these warnings, the use of estrogen-containing products actually increased as a result of the U.S. FDA notice that stated that these agents were effective for the prevention of osteoporosis (99).

### Hormone Replacement Therapy

Until mid-2002, hormone replacement therapy (HRT) continued to be considered as first-line therapy for the

[a]Investigational agent.

of a lower drug dose and provides continuous systemic availability.

Intravaginal administration of micronized estradiol tablets (Table 46.14) represents another avenue for effective estradiol absorption without concern about first-pass metabolism (12). Unfortunately, vaginal creams containing estradiol only achieve 25% of the absorption expected for a similar oral dose. As a result, this formulation is best utilized for the treatment of urogenital atrophy. A sustained release depot formulation of estradiol is available in the form of a vaginal ring (Femring, Estring) (Table 46.14). This type of formulation elutes estradiol or estradiol acetate over a 90-day period, thereby limiting the effort required by the patient. Estring delivers 7.5 μg estradiol/day and is indicated for the treatment of urogenital atrophy. Available in two strengths, Femring releases the equivalent of 50 or 100 μg estradiol/day via estradiol acetate, which subsequently is hydrolyzed to estradiol after release. This ring is indicated for the treatment of several urogenital symptoms associated with postmenopausal atrophy as well as for the treatment of vasomotor symptoms as a result of delivery of sufficient systemic estrogen. Although easy to utilize, percutaneous preparations (topical emulsion, topical gel) (Table 46.14) suffer from inconsistent absorption. Estradiol also is formulated as an intranasal spray that is therapeutically equivalent to both oral and transdermal delivery.

In addition to those identified by the WHI study, the adverse effects of ERT include nausea, headache, breast tenderness, and heavy withdrawal bleeding. Transdermal delivery minimizes headache and nausea, and use of a low-dose oral regimen lessens breast tenderness (50).

Table 46.15. Combination Therapies for the Treatment of Menopausal Symptoms (50)

| Type of Therapy | Effect of Therapy | Regimen |
|---|---|---|
| Oral continuous-cyclic (sequential) | Scheduled withdrawal bleeding | CEE (1-14) + [CEE + MPA] (15-28) |
| Transdermal continuous-cyclic (sequential) | Scheduled withdrawal bleeding | 17β-Estradiol + norethindrone acetate |
| Oral continuous-combined | Prevents monthly bleeding; unpredictable breakthrough bleeding likely to occur for first 6–12 months | CEE + MPA, 17β-estradiol + norethindrone acetate, ethynyl estradiol + norethindrone acetate |
| Transdermal continuous-combined | Prevents monthly bleeding | 17β-estradiol + norethindrone acetate |
| Continuous long cycle (cyclic withdrawal) | Reduced monthly bleeding | Estrogen administered daily, progestin given six times/year for 12–14 days |
| Intermittent-combined (Continuous pulse) | Prevents monthly bleeding | 3 days of estrogen alone, followed by 3 days estrogen and progestin combo, repeat continuously |

CEE, conjugated equine estrogen; MPA, medroxyprogesterone acetate.

Micronized progesterone (Table 46.14) in combination with oral CEE provides valuable therapeutic benefit in the treatment of menopausal symptoms without the risk of endometrial hyperplasia. Unless micronized, progesterone is poorly absorbed when administered orally (12). Intravaginal administration of a controlled-release progesterone gel (Table 46.14) results in excellent absorption and more consistent serum levels than orally administered micronized progesterone. Systemic absorption is limited when progesterone is delivered by this route. Intramuscular administration of a progesterone in oil formulation produces the highest serum concentrations but is least likely to be tolerated by patients. The adverse effects associated with the use of oral progestins include irritability, depression, weight gain, and headache. These can be minimized if other routes of administration are utilized (e.g., IUD).

To minimize patient effort and to maximize patient adherence, a number of estrogen/progesterone combination products are commercially available (Table 46.15). Four types of combination regimens are available (oral and transdermal), including both continuous and cyclic therapeutic options. Cyclic regimens require a minimum of 12 to 14 days of progestin administration to prevent endometrial hyperplasia.

Used in perimenopause, administration of a synthetic progestin supplements the waning progesterone produced in the luteal phase of the menstrual cycle. This helps to prevent endometrial hyperplasia and to ensure regular menses despite the irregularity of the menstrual cycle.

Tibolone is a synthetic 19-norpregnane with estrogenic, progestogenic, and androgenic action. With such varied activities, it is no surprise that tibolone is able to treat multiple psychological and physiological menopausal symptoms as well as to confer beneficial health preventive benefits. Administered as a prodrug, tibolone undergoes metabolism in the GI tract to active metabolites ($\Delta^4$ unsaturated, 3α-OH, and 3β-OH derivatives). Although tibolone induces endometrial atrophy in menopausal and postmenopausal women and, therefore, does not cause withdrawal bleeding, it should not be used in perimenopausal women, because it can cause irregular bleeding.

With such concern and confusion surrounding the use of either ERT or HRT for the treatment of menopausal symptoms and postmenopausal health benefits, women have turned to other natural or nonhormonal pharmacological sources of relief (Table 46.16) (105,106). "Hormonal herbs," such as soy, black cohosh, and red clover,

are purported to contain some or all of the phytoestrogens genistein, daidzein, and coumestrol (Fig. 46.18), which possess at least weak estrogenic activity (Table 46.17) (105–107) but structurally are nonsteroidal. Other sources of nonsteroidal phytoestrogens, such as resveratrol from the skin of wine grapes (e.g., *Vitis vinifera*), currently are under investigation for their purported estrogenic effects (108). Small studies have indicated that the phytoestrogens may have additional beneficial effects on lipid profile and bone density (50). There is limited evidence that gabapentin and clonidine are effective in reducing the frequency of hot flashes, but their use is limited because of significant side effect profiles.

Several of the newer antidepressants, specifically those that modulate serotonergic neurotransmission, have become more prominent in the treatment of menopausal symptoms. Some even consider this as first-line treatment when hormone therapy is contraindicated. Venlafaxine, a dual serotonin and norepinephrine reuptake inhibitor, has been found to decrease the frequency and substantially reduce the intensity of vasomotor symptoms as well as to improve problems of fatigue and sleep difficulty in more than 50% of the participants in clinical trials (105,109). In comparison, fluoxetine and sertraline, which are selective serotonin reuptake inhibitors (SSRIs), only modestly improve the frequency and intensity of vasomotor symptoms. The effectiveness of paroxetine, another SSRI, mirrors that of venlafaxine. Interestingly, the SSRI citalopram not only is similarly effective as paroxetine but also is effective in those patients in whom vasomotor symptoms did not resolve with venlafaxine treatment. Mirtazepine is an $\alpha_2$-receptor antagonist as well as a serotonergic (5-$HT_2$) antagonist. The role of serotonin in modulation of the thermoregulatory processes is only starting to become clear. New evidence indicates that activation of central 5-$HT_2$ receptors results in hyperthermia; therefore, administration of a 5-$HT_2$ receptor antagonist should alleviate the thermoregulatory dysfunction associated with estrogen deficiency (105). Interestingly, an endogenous estrogen deficiency causes a reduction in the expression of central 5-$HT_2$ receptors, which is reversible on administration of an exogenous source of estrogen. There are nonpharmacological avenues to consider when trying to limit the rise in body temperature, including avoidance of caffeine, alcohol, spicy foods, anxiety, and physical contact.

## Hormone-Dependent Breast Cancer

### Background and Introduction

In the United States, the lifetime risk of developing breast cancer is one in eight, with the greatest incidence in women older than 60 years of age (110). It is the second leading cause of death from cancer in women (lung cancer is number one). An evaluation of 51 studies that represented 52,000 women with breast cancer

Table 46.17. Herbal Products with Purported Utility in Postmenopausal Women (103–105)

| Herb | Purported Use | Potential Problems |
|---|---|---|
| Soy (beans) *Glycine max* | Contains phytoestrogens—varied evidence for success in treatment of hot flashes | No concurrent treatment with tamoxifen |
| Black cohosh (root) *Actacea racemosa* | Contains phytoestrogens—purported use for hot flashes, additional studies needed | Possible liver issues |
| Sage (leaves, flowers) *Salvia officinalis* | Reduces night sweats and hot flashes | Kidney damage (large amounts) |
| Kava *Piper methysticum* | Reduces anxiety—no evidence for use in hot flashes | Liver damage |
| Red clover (leaf) *Trifolium pretense* | Contains phytoestrogens—not clinically significant reduction in hot flashes | Interaction with warfarin that can cause bleeding issues |
| Dong quai (root) *Angelica sinensis* | Not effective in treating hot flashes | Interaction with warfarin that can cause bleeding issues |
| Valerian (root) *Valeriana officinalis* | Treats hot flashes and insomnia | Morning drowsiness |
| Ginseng (root) *Panax ginseng* | May help with quality of life issues (mood, sleep) but does not help with hot flashes | |
| Flaxseed | No significant evidence that it helps hot flashes | Alters activity of antiplatelet and anticoagulant drugs |

### Menopause and Libido

Despite what you might gather from promotional ads on the television and radio, sexual dysfunction in women occurs much more frequently than in men. Regardless of age (18–59 years), the prevalence of a lack of interest in sex among U.S. women is approximately 30% (113). This loss of sexual desire, a general feeling of lethargy or loss of energy, and reduced muscle strength can be attributed largely to an androgen deficiency. Urogenital atrophy and a decrease in vaginal lubrication in postmenopausal women also are potential reasons for a woman to experience an arousal disorder. These symptoms are directly linked to an estrogen deficiency. Administration of an exogenous androgen, typically testosterone, eases some of these symptoms, but it is unclear if this is a result of androgen receptor activation or of conversion into estradiol. Testosterone can be administered via several routes, including intramuscularly, subcutaneously (implants), or transdermally (patches). Estrogen replacement therapy effectively manages vasomotor symptoms as well as urogenital atrophy and dryness and diminishes some of the psychological symptoms, but it has virtually no effect on the waning libido experienced by many menopausal women. A method to address both sets of symptoms is to administer an oral estrogen/androgen combination (Estratest [methyltestosterone + esterified estrogen]) daily (50). With this type of regimen, it is imperative that the testosterone dose only generates physiological serum testosterone levels so as to maximize therapeutic benefit and minimize undesirable side effects, including virilization and fluid retention (114).

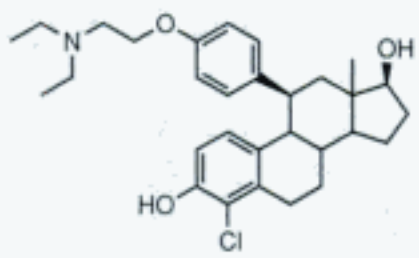
Nonhormonal strategies also are available to treat female sexual arousal disorder. A transdermal formulation of alprostadil, used to treat male erectile dysfunction, has been shown to improve the arousal success rate. Applied 15 minutes before intercourse, this cream can cause local irritation, which is reversible on cleansing (115).

### Menopause and Osteoporosis

Osteoporosis causes 1.5 million fractures annually, including hip and spine fractures that increase both morbidity and mortality. In women older than 50 years, one in six will experience a hip fracture, and only 40% of patients older than 55 years with a hip fracture actually recover their mobility (116). (A comprehensive review of pharmacological therapies available for the treatment and prevention of osteoporosis can be found in Chapter 35.)

The estrogen deficiency associated with menopause has a detrimental effect on bone composition and quality. Before 65 years of age, postmenopausal women lose 3 to 5% of their bone mass on an annual basis. After this point, bone loss occurs at a rate of 0.5 to 1.0% annually. This results, in part, from an increase in circulating cytokines (e.g., tumor necrosis factor $\alpha$, interleukin-1, and interleukin- 6) when estrogen levels are low. These cytokines stimulate differentiation and proliferation of osteoclasts, the cells that normally degrade bone. The WHI study shows a positive correlation between HRT and a substantial decrease in fractures (24%). Currently, HRT (0.625 mg of CEE with 2.5 mg of medroxyprogesterone acetate) is recommended for the prevention, but not the treatment, of osteoporosis. This type of therapy should be initiated shortly after menopause and continued for at least 7 years (102). A lower dose of estrogen (0.3 mg) along with a progestin also may afford ample prevention. Despite the well-documented benefits of HRT in the prevention of osteoporosis, this should not be the primary therapeutic indication. In addition, no estrogen- or progestin-containing products have a U.S. FDA indication for the treatment of osteoporosis (99).

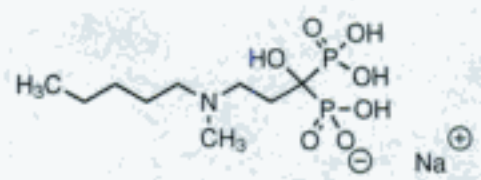
Studies that evaluate the benefit of combination OCs on bone mineral density have produced mixed results. Nearly one-third of these studies indicate no benefit, but the rest show a beneficial effect, including a 25% reduction of hip fractures in postmenopausal women (117). In those patients using a combination OC containing at least 50 μg of the estrogen component, this reduction in the risk of hip fracture improved to 44% (66). In general, the maximal benefits on bone mineral density are observed when the patients are older, have taken OCs for 5 or more years, and have used an OC preparation containing at least 50 μg of estradiol.



Climara Pro (transdermal patch with estradiol [0.045 mg/day] and levonorgestrel [0.015 mg/day]) is indicated for the treatment of the vasomotor symptoms related to menopause. Recently, it has been approved for the prevention of postmenopausal osteoporosis.

Tamoxifen and raloxifene are SERMs and represent effective nonsteroidal therapy for the treatment of breast cancer and bone loss, respectively. The SERMs are a unique drug class in that a single agent may act as a receptor agonist in select tissues but a receptor antagonist in other tissues. In theory, it might be possible to protect a woman from osteoporosis and to reduce her risk for endometrial, breast, and colorectal cancers without worsening menopausal vasomotor symptoms with one drug. To date, no SERM can meet all these goals simultaneously. Raloxifene, a second-generation SERM, is an estrogenic agonist at the bone and is very effective for preventing osteoporosis without negative endometrial consequences or increasing the risk of breast cancer (see Chapter 35) (50). It is classified as an antiresorptive agent and has been approved by the U.S. FDA for both the treatment and prevention of osteoporosis. It also has a beneficial role in reducing the risk of cardiovascular events in postmenopausal women because of its antiatherogenic effects (reduces low-density lipoprotein [LDL] levels) as well as in decreasing the risk of breast cancer (118). Unlike the bisphosphonates, which decrease both hip and vertebral fractures by 30 to 50%, raloxifene reduces only vertebral fracture by the same percentage. Raloxifene only has an effect on skeletal sites composed of cancellous bone. Unfortunately, raloxifene causes or worsens vasomotor symptoms in approximately 25% of patients, which represent a limitation to its use. In addition, raloxifene causes a threefold increase in the risk for venous thromboembolism, which makes it contraindicated in women with a history of thrombosis. Following oral administration,

Copyrighted material



raloxifene undergoes rapid first-pass metabolism to form its glucuronide conjugates (see Fig. 35.4) and, thus, has an oral bioavailability (~2%).

Because raloxifene only reduces the risk of vertebral fracture, there is a need to identify agents that are effective at multiple skeletal sites with minimal side effects. The novel SERM HMR-3339 improves bone mineral density in adult ovariectomized rats at a variety of skeletal sites (e.g., lumbar spine, tibia, and femur), including those sites composed of cortical bone (118,119). An additional benefit afforded by HMR-3339 is a reduction in total cholesterol (10–15%) and LDL (10–24%). This antiatherogenic activity, coupled with promising reductions in fracture risk across multiple skeletal sites, makes HMR-3339 a very exciting drug candidate for the treatment of multiple postmenopausal conditions.

HMR-3339

Additional SERMs are presently undergoing clinical evaluation for treatment of osteoporosis and menopause-related vaginal atrophy (see Chapter 35).

Ibandronate sodium

Ibandronate sodium (Boniva) is one example of the bisphosphonate class of antiresorptive agents and is effective in the treatment and prevention of postmenopausal osteoporosis (see Chapter 35) (120). It was first approved as a tablet (2.5 mg) to be administered daily and later approved as the first once-monthly formulation (150 mg) for the treatment and prevention of osteoporosis (120). In January 2006, the U.S. FDA approved an intravenous formulation of ibandronate sodium (3 mg) to be administered every three months for the treatment of osteoporosis. This type of formulation benefits those patients who have difficulty swallowing oral dosage forms or are unable to remain upright for 30 to 60 minutes. The injectable formulation generated a larger increase in lumbar spine bone mineral density compared to the oral formulations. Bone mineral density in the hip, femoral neck, and trochanter were improved as well. Adverse events associated with the injectable formulation included arthralgia, back and abdominal pain, and hypertension. There is a risk of renal toxicity that is inversely related to the rate of administration of this formulation. Caution is advised in patients who have renal impairment or who are receiving other pharmacological therapy that may negatively affect renal function (118).

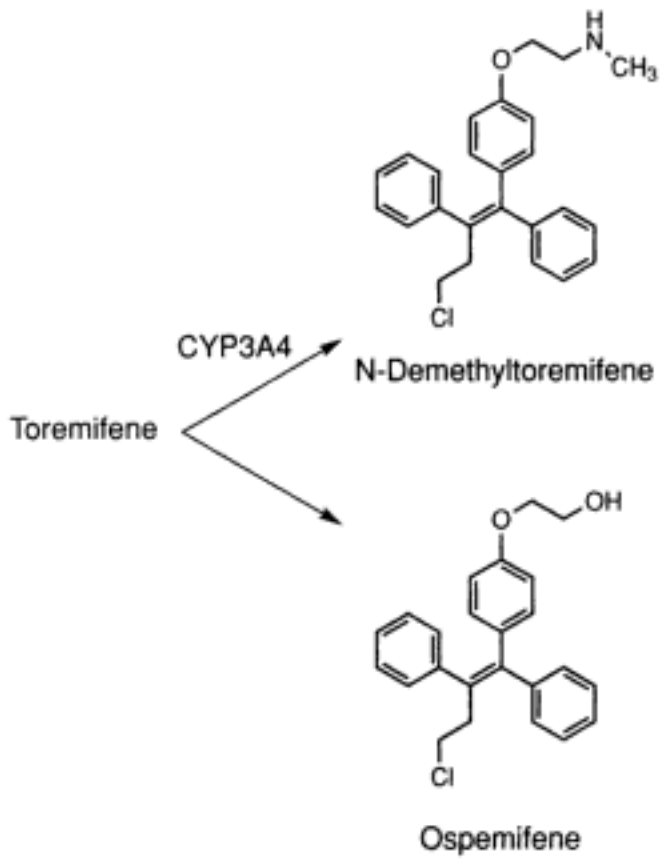
showed a 15% increase in the risk of breast cancer in patients who had taken a combination of estrogen and progestin for less than 5 years. As treatment duration increased, this risk was amplified (111). In the HRT arm of the WHI study, the risk of breast cancer increased, yet in the ERT arm, there was no change in this risk (112). It should be noted that this increase in risk occurred 3 years after initiation of the study. To make matters worse, the breast cancers found in women of the HRT arm were likely to be more advanced than those found in women of the placebo arm of the study. Both arms of the WHI study were terminated prematurely, because the health risks incurred outweighed the benefits. No increased incidence of breast cancer was found in the ERT arm. The incidence of stroke did increase, however, and there was no benefit as it related to coronary heart disease (121).

According to the WHI study, there was no increased risk of endometrial cancer in patients taking HRT. If unopposed estrogen is administered to a patient with an intact uterus, then a significant increase in the risk of uterine cancer occurs within 2 years of treatment initiation (122). As the dose and duration of treatment increase, this risk grows.

Estrogen deficiency has been correlated with the development of colorectal cancer, the third most commonly diagnosed cancer. When estrogen levels are low, expression of the ER diminishes. Colorectal cells without ER expression are ripe to become cancerous. If estrogen levels are boosted by HRT, then ER expression should improve correspondingly, thereby reducing the number of colorectal cells primed to become malignant. The WHI study clearly shows a substantial decrease (37%) in the occurrence of colorectal cancer in patients treated with HRT.

### Molecular Mechanism of Action of the SERMs

The precise mechanism of SERM action is not well understood, but clearly, the ER is a primary target, as a signal transduction pathway, to modulate drug action in different tissues. Different concentrations of ER are present in breast cancers, which can be explained by heterogeneity in the tumor cell population. The more cells in the tumor that contain ERs, the higher the overall ER content, and the more likely the tumor will respond to antiestrogen therapy. Approximately 60% of ER-positive (receptor-rich) tumors are responsive to any form of additive or ablative endocrine therapy, whereas only 10% of ER-negative (receptor-poor) tumors respond to endocrine therapy (123). The current standard of care is to determine the ER status of the tumor in all patients with breast cancer.



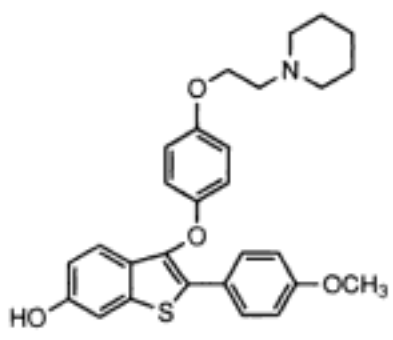


**Fig. 46.22.** Metabolism of toremifene.

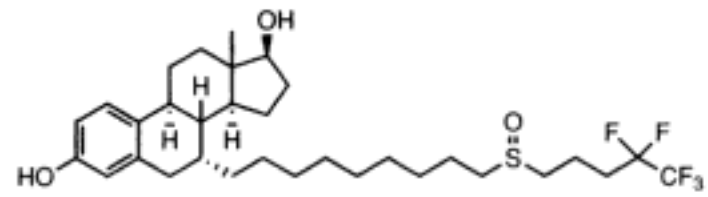
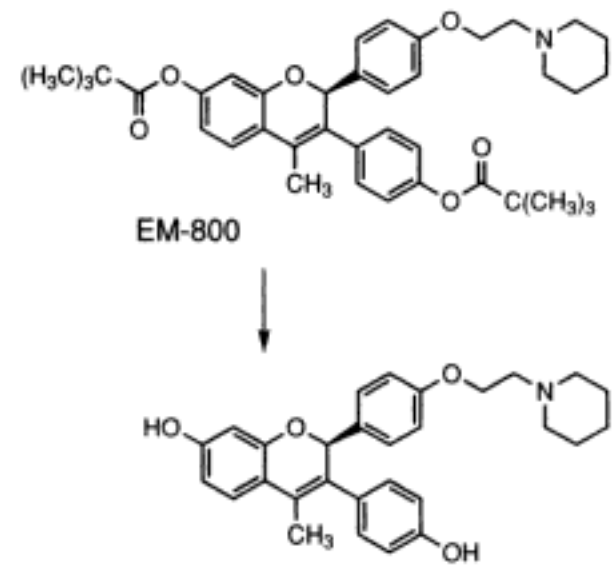
tion to its beneficial effects on the bone, ospemifene lowers LDL levels and improves the symptoms of vaginal dryness.



Arzoxifene

**ARZOXIFENE.** Arzoxifene is a third-generation SERM currently in Phase III clinical trials for the treatment of ER-positive recurrent/metastatic breast cancer. Similar to raloxifene, it is an ER antagonist in both breast and uterine tissues and an ER agonist on bone and the cardiovascular system (142,151). Arzoxifene is able to both preserve and build bone mineral density, which makes it a viable candidate for the treatment of osteoporosis. Ample evidence from early clinical trials indicates that arzoxifene also can be utilized as a chemopreventive agent against breast cancer (151,152). Adverse effects include hot flashes (major) and headache, nausea, vomiting, and constipation (minor) (142).



### Pure Antiestrogens

Despite the fact that 30 to 40% of patients with advanced breast cancer respond to tamoxifen therapy, this response only lasts for 12 to 18 months. Tamoxifen resistance is caused, in part, by its intrinsic agonist activity at the ER. In addition, tamoxifen only inhibits the AF-2 activation pathway but does not play a role in AF-1 pathway inhibition. Pure antiestrogens do not possess any estrogenic activity in any species or target tissue and, therefore, offer an additional avenue of treatment when resistance to tamoxifen occurs. In addition, because they are devoid of estrogenic action, these agents cannot be classified as SERMs.

Fulvestrant

**FULVESTRANT (FASLODEX).** Fulvestrant is effective in preventing the growth of tamoxifen-resistant breast cancers (153) both in the laboratory (154,155) and in clinical trials. It is indicated following antiestrogen therapy for the treatment of ER-positive metastatic breast cancer that has continued to progress (156). Fulvestrant is an estradiol analogue with a hydrophobic side chain in the 7α position. Oral bioavailability is poor despite metabolic protection on the end of the hydrophobic side chain. The rationale for this stems from the fact that fulvestrant is virtually insoluble. As a result, it is administered by intramuscular injection once a month. Metabolism of fulvestrant to both active and less active metabolites is similar to that observed with the endogenous steroids (156). Side effects appear to be minimal and include several GI symptoms, headache, and hot flashes. There is no clinical evidence of uterine stimulation or laboratory evidence of stimulation of endometrial carcinoma models (157). Fulvestrant should not be administered to women who are pregnant, who are taking anticoagulants, or who have thrombocytopenia.

**ACOLBIFENE.** The prodrug EM-800 is an orally active nonsteroidal antiestrogen and is a triphenylethylene rigid analogue. EM-800 undergoes ester hydrolysis to the

Copyrighted material

approved overseas as adjuvant therapy after 2 to 3 years of adjuvant tamoxifen treatment of ER-positive, invasive early breast cancer. The structure of exemastane is related to androstenedione. It is important to consider the woman's menstrual status when utilizing this agent, because the synthesis of ovarian aromatase is part of a negative feedback loop such that decreased levels of circulating estrogen will promote increased biosynthesis of aromatase. As a result, exemastane should not be administered to premenopausal women or those who are pregnant. Exemastane binds irreversibly to aromatase and, therefore, is classified as a suicide inhibitor. Because this agent has high binding affinity and specificity for aromatase, it is able to suppress the activity of this enzyme by 97.7% (anastrozole, 92–96%; letrozole, 98%) (163).

Exemastane is administered orally (25 mg daily); however, only 50% of a given dose is absorbed. Absorption is improved if the medication is taken following a high-fat meal. Approximately 90% of a dose is bound to plasma proteins. Exemastane undergoes extensive metabolism by CYP3A4, and dosage adjustments may be necessary if given concomitantly with a CYP3A4 inducer (163). Adverse reactions reported in patients with early breast cancer include hot flashes, arthralgia, and fatigue, whereas hot flashes and nausea were the primary adverse reactions noted in patients with advanced breast cancer.

## Conclusions

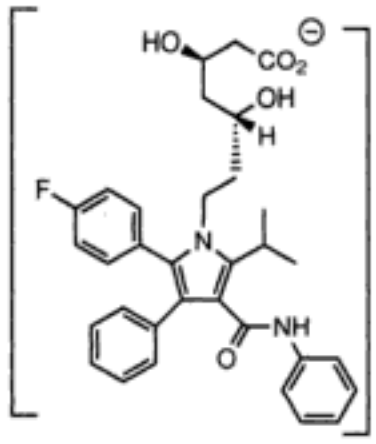
Throughout a woman's reproductive life cycle there are a number of disease states or life circumstances that can be successfully managed with one or more hormone-related therapeutic strategies. Not only is it important to select an appropriate therapeutic regimen for each individual, it also is essential to determine which route of administration and, therefore, which formulation is the most therapeutically advantageous. A number of formulations are available for several single and multicomponent products, and maximizing patient compliance should be considered when recommending a particular product. There are no products devoid of adverse effects, so it is important that these be explained to the patient to minimize discontinuation of the recommended therapy.

The alarming results generated by the WHI studies have fueled the development of new estrogen-containing products designed to deliver lower doses of estrogen to minimize systemic exposure and decrease the risk of cardiovascular disease and development of cancer. In addition, a number of alternative therapies are under investigation for the treatment of menopausal symptoms. Agents that modulate serotonergic neurotransmission seem to be especially promising, because many of these therapies are already known commercial entities.

Pharmacological management of breast cancer continues to make progress with advanced characterization techniques and the use of aromatase inhibitors and SERMs. Future generations of SERMs will need to be completely devoid of estrogenic activity to prevent the development of resistance, as is occurring with tamoxifen.

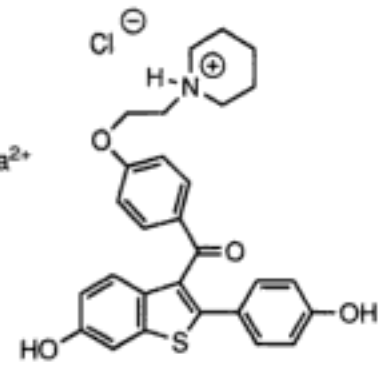
## CASE STUDY

***Victoria F. Roche and S. William Zito***



AF is a 55-year-old female forensic chemist who has always taken pride in her healthy lifestyle. She has exercised regularly all her life and enjoys sports such as tennis, bicycling, and strenuous hiking. More recently, she has been working out in a gym, running approximately 12 to 15 miles per week, and engaging in a strengthening routine using the gym's weight-training machines. The only medicines that she takes are multivitamins and atorvastatin (Lipitor, 10 mg q.d.) to keep her total cholesterol, triglyceride, and LDL levels low. AF's blood pressure is normal, and her cardiac function is good.

AF's medical history includes uterine cysts that developed during her early forties and, ultimately, resulted in hemorrhagic monthly bleeding. After being diagnosed as severely anemic, she underwent a partial hysterectomy (uterus only) when she was 44 years old. When she began to show signs and symptoms of menopause at age 48, her gynecologist put her on HRT to control regular and severe hot flashes and night sweats. She took her HRT religiously for 6 years, until information from the WHI indicated that she might be at risk for ovarian cancer. There is no history of cancer in AF's family, but she was concerned enough to halt HRT even though her hot flashes and night sweats returned with a vengeance. Her intake of calcium is moderate, with the consumption of one to two glasses of milk per day. She tries to avoid cheese because of a slow but steady gain in weight over the past 2 years.



On noting that AF had lost a quarter-inch in height since her last clinic visit, her gynecologist recommended a bone density determination. The results showed a thinning of the bone. That, along with the fact that her 83-year-old mother has significant osteoporosis, prompted a decision to initiate therapy. Consider the structures of the therapeutic agents drawn below, and prepare to make a recommendation to AF's gynecologist.

1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

# APPENDIX A. *$pK_a$ Values for Some Drugs and Miscellaneous Organic Acids and Bases*

DAVID A. WILLIAMS

Table A.1. $pK_a$ Values for Some Drugs and Miscellaneous Organic Acids and Bases

| | $pK_a$ Values | | |
|---|---|---|---|
| Drugs | HA | $HB^+$ | Reference |
| Acebutolol | | 9.2 | 1 |
| Acenocoumarol | 4.7 | | 1 |
| Acetaminophen | 9.7 | | 1 |
| Acetanilide | | 0.5 | 1 |
| Acetazolamide | 7.4, 9.1 | | 3 |
| Acetohydroxamic acid | 9.4 | | 1 |
| α-Acetylmethadol | | 8.6 | 1 |
| Acetysalicylic acid | 3.5 | | 1 |
| Acyclovir | 9.3 | 2.3 | 1 |
| Adriamycin | | 8.2 | 1 |
| Ajamaline | | 8.2 | 1 |
| Albuterol | 10.3 | 9.3 | 9 |
| Alclofenac | 4.3 | | 1 |
| Alfentanil | | 6.5 | 1 |
| Allobarbital | 7.8 | | 1 |
| Allopurinol | 9.4 | | 1,4 |
| Alphaprodine | | 8.7 | 1 |
| Alprenolol | | 9.7 | 1,5 |
| Altretamine | | 10.3 | 1 |
| Amantadine | | 9.0 | 1 |
| Amidinocillin | 3.4 | 8.9 | 1 |
| Amiloride | | 8.7 | 1 |
| Aminoacrine | | 10.0 | 1 |
| p-Aminobenzoic acid | 4.9 | 2.5 | 1 |
| Aminocaproic acid | 4.4 | 10.8 | 1 |
| Aminohippuric acid | 3.8 | | 1 |
| Aminopterin | 5.5 | | 1 |
| Aminopyrine | | 5.0 | 1 |
| p-Aminosalicylic acid | 3.6 | 1.8 | 1 |
| Aminothiadiazole | | 3.2 | 1 |
| Amiodarone | | 6.6 | 1 |
| Amitriptyline | | 9.4 | 15 |
| Amobarbital | 7.8 | | 1 |
| Amoxapine | | 7.6 | 1,4 |
| Amoxicillin | 2.4 | 9.6 | 12 |
| Amphetamine | | 10.0 | 1 |
| Amphotericin B | 5.5 | 10.0 | 11 |
| Ampicillin | 2.5 | 7.2 | 16 |
| Anileridine | | 3.7, 7.5 | 1 |
| Antazoline | | 2.5, 10.1 | 1 |
| Antipyrine | | 1.5 | 1 |
| Apomorphine | 8.9 | 7.0 | 1 |
| Aprobarbital | 8.0 | | 1 |
| Ascorbic acid | 4.2, 11.6 | | 1 |
| Atenolol | | 9.6 | 6 |
| Atropine | | 9.8 | 1 |
| Azatadine | | 9.3 | 1 |
| Azathioprine | 8.0 | | 9 |
| Azlocillin | 2.8 | | 1 |
| Aztrenam | 0.7, 2.9 | 3.9 | 1 |
| Bacampicillin | | 6.8 | 1 |
| Baclofen | 5.4 | 9.5 | 1 |
| Barbital | 7.9 | | 1 |
| Bendroflumethiazide | 8.5 | | 5 |

[a]Determined in methyl cellosolve/water (8:2 w/w mixture).
[b]Determined in 66% dimethylformamide.
[c]Determined in 25 to 30% ethanol.
[d]Determined in 40% methanol.
[e]Prostaglandin $F_{2\alpha}$.
[f]Spectrophotometric determination.
[g]The $pK_a$ values of the four optical isomers are 4.1 for two isomers and 4.25 for two isomers.
[h]Determined in methanol/water (3:1 mixture).
[i]Determined in dimethylformamide/water (1:1 mixture).
[j]Determined in 33% dimethylformamide.

# APPENDIX B. *pH Values for Tissue Fluids*

DAVID A. WILLIAMS

Table B.1. pH Values for Tissue Fluids

| Fluid | pH |
|---|---|
| Aqueous humor | 7.2 |
| Blood, arterial | 7.4 |
| Blood, venous | 7.4 |
| Blood, maternal umbilical | 7.3 |
| Cerebrospinal fluid | 7.4 |
| Colon[a] | |
| Fasting | 5–8 |
| Fed | 5–8 |
| Duodenum[a] | |
| Fasting | 4.4–6.6 |
| Fed | 5.2–6.2 |
| Feces[b] | 7.1 (4.6–8.8) |
| Ileum[a] | |
| Fasting | 6.8–8.6 |
| Fed | 6.8–8.0 |
| Intestine, microsurface | 5.3 |
| Lacrimal fluid (tears) | 7.4 |
| Milk, breast | 7.0 |
| Muscle, skeletal[c] | 6.0 |
| Nasal secretions | 6.0 |
| Prostatic fluid | 6.5 |
| Saliva | 6.4 |
| Semen | 7.2 |
| Stomach[a] | |
| Fasting | 1.4–2.1 |
| Fed | 3–7 |
| Sweat | 5.4 |
| Urine | 5.8 (5.5–7.0) |
| Vaginal secretions, premenopause | 4.5 |
| Vaginal secretions, postmenopause | 7.0 |

[a]Dressman JB, Amidon GL, Reppas C, et al. Dissolution testing as a prognostic tool for oral drug absorption. Pharm Res 1998;15:11–22.
[b]Value for normal, soft, formed stools. Hard stools tend to be more alkaline, whereas watery, unformed stools are acidic.
[c]Studies conducted intracellularly on the rat.

# Drug Index

Page numbers followed by "f" indicate illustrations and chemical structures; those followed by "t" indicate to tables. Drugs are listed under the generic name.

Acetazolamide, 101t, 726t, 727
Acetohexamide, 867t, 868t
Acetohydroxamic acid 101t
Acetylcholine, 26f, 43f, 44f
Acolbifene, 1336–1337
Acrivastine, 1016f, 1018
Acyclovir, 101t, 1207–1209, 1207t, 1208f
Adalimumab, 994f, 995
Adefovir Dipivoxil, 1207t, 1213–1214
4,5α-Epoxymorphinans, 47f
Albendazole, 267t, 1103t, 1104
Albuterol, 393t, 400t, 401, 405, 405f, 406, 1239
Alcohol (ethanol), 272–273
Aldesleukin, 138t
Aldosterone, 882–884, 885f, 886t
Alendronate, 101t, 945f, 946
Alfentanil, 267t
Alfuzosin, 408–409, 409f, 1283, 1284, 1285
Alicaforsen (ISIS 2302), 206–207
Allopurinol, 101t, 1000–1001, 1000f
Almotriptan, 425
Alosetron, 425, 425f, 432, 433f, 436
Alprazolam, 267t, 295t
Alteplase, 136, 138t, 140–141, 842–843, 843f
Altretamine, 1156f, 1162
Amantadine, 687, 1203–1204, 1203t
Amikacin, 1067f, 1068
Amiloride, 726t, 735
4-Aminobenzenesulfonamide, 45f
*p*-Aminobenzoic acid (PABA), 28f
Aminocaproic acid, 101t
Aminoglutethimide, 101t, 903f, 904
Aminoglycosides, 1065–1067
Aminorex, 643–644
Amiodarone, 267t, 718, 718f
Amitriptyline, 260t, 267t, 295t, 555, 557f, 558, 559f, 560t, 576f, 577, 580f
Amlodipine, 267t, 318t, 709–711, 759t, 760, 763t, 764t, 765
Amobarbital, 515–516, 517t
Amoxacillin, 1054
Amoxepine, 565
Amphetamine, 267t, 322t, 407, 407f, 640t, 644–646
Amphotericin B, 1114–1115
Ampicillin, 1031, 1049t, 1054
Amprenavir, 271t, 1219t, 1222–1223
Amyl nitrite (isoamyl nitrite), 707–708, 707f
Amylbarbital, 256t
Amylin, 197, 198, 860, 862t
Anakinra, 138t, 996
Anandamide, 460, 460f
Anastrozole, 267t, 1311, 1337
Anidulafungin, 1117t, 1123, 1123t
Apraclonidine, 403f, 404
Aprepitant, 271t
Aprobarbital, 517t
Aprotinin, 101t, 846
Ardeparin, 831
Argatroban, 832t, 834
Aripiprazole, 614–615, 615f
Aristolochic acid I, 23f
Aristolochic acid II, 23f
Arteether, 20f
Artemether, 20f
Artemisinin, 20f
Articaine, 467t, 468t, 475, 477
Aspart, 864, 864t
Aspartame, 447, 447f
Aspirin, 295t, 836, 836f, 837, 954–957, 963t, 965–968, 966f, 967f

Atazanavir, 1219t, 1223
Atenolol, 773f
Atomoxetine, 267t, 567
Atorvastatin, 101t, 267t, 318t, 807–810, 807f, 812t
Atovaquone, 1091–1092
Atracurium besylate, 388, 388f
Atropine, 18, 18f, 26f, 381, 382, 383, 385
Azacitidine, 1189
Azelastine, 1019, 1019f
Azidothymidine (AZT), 101t, 106, 107
Azithromycin, 1070f, 1071–1072, 1140–1141, 1141f
Aztreonam, 1065, 1065f

**B**

Bacampicillin, 1054
Bacitracin, 101t, 1080
Baclofen, 458, 458f, 693–694
Barbiturates, 271t, 322t
Becaplermin, 138t
Beclomethasone dipropionate, 887t, 894f, 895, 896, 1253
Benznidazole, 1094
Benzocaine, 463, 463f, 467t, 468t, 469, 471, 472, 474, 475–476, 477
Benzodioxanes, 46f
Benzomorphans, 47f
Benzylpenicillin, 19, 1047–1048, 1049t, 1052–1053
Bepridil, 267t, 709–710, 759, 759f
Beraprost, 794–795, 794f
Betamethasone, 886t, 887t, 888f, 893, 895t
Betaxolol, 35f, 773f
Bethanechol chloride, 373
Betoptic, 35f
Biapenem, 19, 19f
Bicalutamide, 1282f, 1289–1290
Bisoprolol, 267t, 773f
Bitolterol, 405–406, 1239, 1239f
Bivalirudin, 17, 833–834
Bleomycin, 1166f, 1171–1173
Bortezomib, 101t
Bosentan, 792, 793, 793f
Bretylium, 718, 718f
Brimonidine, 403f, 404
Bromocriptine, 687–688, 688f
Budesonide, 887t, 895f, 896, 897t, 899, 1253
Bumetanide, 726t, 732
Bupivacaine, 467t, 468t, 472f, 473–474, 476–477
Buprenorphine, 661, 663–664, 665, 673
Bupropion, 267t, 560t, 583–585, 584f, 585t
Buserelin, 1201
Buspirone, 318t, 422, 423
Busulfan, 267t, 1156f, 1162–1163
Butabarbital, 517t
Butenafine, 1116t, 1122
Butorphanol, 664, 673

**C**

Caffeine, 260t, 267t, 323t
Camptothecin, 20, 21f, 22
Candesartan, 753–756, 755t
Cannabidiol (CBD), 18f
Cannabinoids, 267t, 633–634, 633f
Canrenone, 726t, 734
Capecitabine, 1175, 1175f, 1177f
Capreomycin, 1138
Captopril, 38f, 101t, 742–744, 743f, 748t, 749–750, 749f, 752t
Carbachol chloride, 373
Carbamazepine, 267t, 271t, 318t, 523f, 526f, 529t, 530, 531–532, 531f, 532f
Carbaryl, 377
Carbenicillin, 256t, 1047t, 1049t, 1055
Carbenoxolone, 295t
Carbidopa, 101t
Carboplatin, 1156f, 1164
Carebastine, 1016f, 1018, 1018f
Carisoprodol, 267t
Carmustine, 1156f, 1160–1161
Carteolol, 773f
Carvedilol, 267t, 776f
Caspofungin, 20, 20f, 101t, 1117t, 1123, 1123t
Cefaclor, 38f, 1060t, 1061
Cefadroxil, 1058t, 1059
Cefamandole nafate, 1059
Cefazolin, 1058t, 1059
Cefdinir, 1062t, 1063
Cefditoren pivoxil, 1062t, 1063
Cefepime, 1063, 1063f
Cefixime, 1062t, 1063
Cefmetazole, 1060t, 1061
Cefonicid, 1059, 1060t
Cefoperazone, 1062t, 1063
Cefotaxime, 1061, 1062t
Cefotetan, 1060t, 1061
Cefoxitin, 1060t, 1061
Cefpodoxime proxetil, 1062t, 1063
Cefprozil, 1060t, 1061
Ceftazidime, 1062, 1062t
Ceftibuten, 1062t, 1063
Ceftizoxime, 1061, 1062t
Ceftriaxone, 1061–1062
Cefuroxime, 1059–1060, 1060f, 1060t
Celecoxib, 267t, 985–988, 985f, 986t, 987f
Cephalexin, 1058t, 1059
Cephalosporin, 1056–1069, 1058t
Cephapirin, 1058–1059, 1058t
Cephradine, 1058t, 1059
Cerivastatin, 267t, 318t
Cetirizine, 1014t, 1016f, 1017–1018
Cetrorelix acetate, 191
Cevimeline, 267t, 374
Chlorambucil, 1156f, 1157
Chloramphenicol, 42f, 256t, 1077–1078
Chlordiazepoxide, 260t, 267t, 295t, 618, 619f, 622, 623–624
Chlormethiazole, 295t
Chloroprocaine, 467t, 468t, 476
Chloroquine, 267t, 1096–1098
Chlorothiazide, 46f, 728, 730
Chlorpheniramine, 37f
Chlorpromazine, 46f, 256t, 267t
Chlorpropamide, 867t, 868
Chlorthalidone, 730t, 731
Chlorzoxazone, 267t
Cholestyramine, 804–806, 805f
Choriogonadotropin, 196
Ciclopirox, 1116t, 1124
Cidofovir, 1207t, 1209
Cilastatin, 101t
Cilomilast, 482t, 485, 486
Cilostazol, 267t, 837f, 838

Trifluorothymidine, 1207t, 1212
Triflusal, 836–837, 836f
Trilostane, 101t, 903f, 904
Trimegestone, 1313t, 1314t, 1315f, 1317–1318
Trimethaphan, 791, 791f
Trimethoprim, 101t, 1038–1039, 10139f
Trimetrexate glucuronate, 1092
Trimipramine, 560t, 576f, 578t, 580
Tripelennamine, 46f, 49f, 323t
Tripolidine, 39f
Triptorelin pamoate, 189f, 190
Troglitazone, 271t, 870–871, 870f, 871f
Troleandomycin, 268t
Tropisetron, 268t, 432, 432f, 433, 435
*d*-Tubocurarine, 26f, 368t, 385, 387

**U**
Undecylenic acid, 1116t, 1124
Urofollitropin, 194
Urokinase, 822f, 842–843

**V**
Valacyclovir, 1207–1209, 1207t
Valdecoxib, 268t, 985f, 986t, 988
Valproic acid, 101t, 268t, 323t, 529t, 533, 540–541
Valrubicin, 1166t, 1169
Valsartan, 268t, 753–756, 755t
Vancomycin, 1053, 1078–1080, 1078f
Vardenafil, 268t, 481f, 482t, 485, 486, 1292–1295
Vasopressin, 195
Vecuronium bromide, 387
Venlafaxine, 268t, 557f, 560t, 581–582, 581t, 585
Verapamil, 260t, 268t, 295t, 318t, 704, 709–710, 709–711, 714, 758–759, 762t, 763–765, 763t, 764t, 766t
Vidarabine, 1207t, 1212–1213
Vinblastine, 268t, 1182f, 1185
Vinca alkaloids, 268t
Vincristine, 268t, 1182f, 1184–1185
Vinorelbine, 1182f, 1185
Vitamin K, 824–826, 825f, 844, 845, 845f
Voriconazole, 268t, 1117t, 1120–1121, 1120f

**W**
Warfarin, 260t, 268t, 295t, 824–827, 825f, 827t,

**X**
Ximelagatran, 832t, 834, 834f

**Y**
Yohimbine, 268t, 409, 409f

**Z**
Zafirlukast, 268t, 1257f, 1258–1259, 1259f
Zalcitabine, 1215t, 1216
Zaleplon, 268t, 511–513, 512t
Zanamivir, 1205–1206
Ziconotide, 761
Zidovudine, 1214–1215
Zileuton, 101t, 260t, 268t, 1257
Ziprasidone, 613, 614, 614f
Zoledronic acid, 945f, 951
Zolmitriptan, 260t, 425, 425f, 427
Zolpidem, 511–513, 512t, 626
Zonisamide, 523f, 528, 529t, 541–542
Zoplicone, 268t

# SUBJECT INDEX

Page numbers followed by "f" indicate illustrations and chemical structures; those followed by "t" indicate to tables. Drugs are listed under the generic name.

**A**
*Ab initio* methods, 57
Abbreviated New Drug Applications (ANDAs), 334–335
Abortifacients, 1321
Absence seizures, 524
  drugs for, 526f, 542–543
Absence status epilepticus, 524–525
Absorption. *See* Drug absorption
Abuse, neuronal plasticity and drugs of, 649
ACAT inhibitors, 803
  ezetimbe
    history of, 811
    mechanism of action, 811–812
    metabolism, 812
    pharmacokinetic parameters, 812–813
    physiochemical properties, 812
Acetylation, 280–291, 290f, 291f, 299
Acetylcholine, 1240–1241
  action of, 1236–1237
  biosynthesis of, 361, 362f, 1240f
  conformations of, 43–44, 1241f, 1242
  early studies of, 1240
  in local anesthesia, 469
  metabolism of, 361
  neurochemistry of, 361–362, 362f
  release of, 361
  sites of action of, 1240f, 1241f
  sleep/wakefulness and, 507
  stereochemistry of, 1243
  storage of, 361
  structure of, 27f
  structure-activity relationship for, 371–373
Acetylcholine antagonists, 381–385, 1237. *See also* Muscarinic antagonists
Acetylcholine mimetics, 371–374, 1234
Acetylcholine receptors, 362–363
  muscarinic, 363–367, 363f
  structure of, 367–368, 368f
Acetylcholinesterase, 361
  carbamylation of, 376
  hydrolysis of, 375–376
Acetylcholinesterase inhibitors, 108, 374–381
  irreversible (phosphorylated), 378–381
    aging of, 379
    antidotes for, 380–381
    insecticidal, 379
    toxicity of, 379–380
  mechanism of action of, 376, 378–379
  receptor binding to, 87
  reversible, 376–378
  therapeutic applications of, 374
Acid/base properties, 28, 29t
Acid(s)
  aliphatic, conjugation of, 289–290
  common, 29t
  conjugate, 28, 30t
  HSAB theory, 308
  ionization of, 29
    absorption and, 215–218
    calculation of, 30–31
  ionizaton of, 29t
    absorption and, 218t
  relative strength of, 29t
  salts of, dissolution of, 224–227, 225t
  solubility of, 219, 224t
Acinar cells, thyroid, 913
ACTH
  in adrenocorticoid synthesis, 884
  in Cushing's disease, 882
Action potential, 90, 465, 465f
Activated partial thromboplastin time, 824
Activation energy, 109
Activation-aggregation theory, 88
Active site directed irreversible inhibitors, 110–111, 111f
Active transport, 214–215, 214f
Acute bacterial prostatitis, 1292
Acute renal failure, drug metabolism in, 296
Acyl CoAcholesterol acyltransferase inhibitors, 803
Acyl glucuronides, 287
Acylureidopenicillins, 1055
Addiction. *See* Drug abuse/addiction
Addison's disease, 882
Adeno-associated virus vectors, 153t, 154
Adenoma, toxic, 921
Adenosine, sleep/wakefulness and, 507
Adenosine deaminase, transition-state inhibitors of, 110, 110f
Adenosine monophosphate (AMP), 398
Adenosine triphosphate (ATP), 397
Adenoviral vectors, 153–154, 153t
Adenylate cyclase, 94, 94f, 397–398, 397f
Adenylyl cyclase, 94, 94f, 397–398, 397f
Adiponectin, diabetes mellitus, 860
Adjustment disorder with depressed mood, 549
ADME studies, 77–79, 230
Adrenal glands, diseases of, 882–883
Adrenaline. *See* Epinephrine
Adrenergic drugs, 395–399
  agonist
    alpha, 402–404, 775–776
    beta, 404–406, 706
    structure-activity relationships for, 402–404
  antagonist
    alpha (*See* α-adrenergic receptor antagonists)
    beta (*See* β-adrenergic receptor antagonists)
    mixed alpha/beta, 411
  commonly used, 393t
  mechanism of action of, 392, 399–400, 399t
  overview of, 392–393
Adrenergic nervous system. *See* Sympathetic nervous system
Adrenergic neuron blocking agents, 782–784
Adrenergic receptor(s), 90, 90f
  desensitization of, 97
  effector mechanisms of, 397–398
  localization of, 398–399
  postsynaptic, 399
  presynaptic, 398–399
  second messengers of, 398
  stimulation of, tissue response to, 399, 399t
  structure, 395–398, 397f, 398f
  subtypes of, 95–96, 96t, 97t, 363, 399–400
    therapeutic relevance of, 399–400
Adrenoceptors. *See* Adrenergic receptor(s)
Adrenocorticoid antagonists, 903–904, 903f
Adrenocorticoid(s), 877–908. *See also* Corticosteroids
  adverse effects, 907–908
  biosynthesis and secretion, 1245–1246, 1246f
  biosynthesis of, 883–884, 885f, 1304f
  discovery of, 882–883
  HPA suppression, duration of, 907t
  intrasanal and inhaled applications, 906–907
  lipophilicity of, 895–896, 897t
  mechanism of action of, 880–881, 880f, 881f, 904–905, 1248–1249
  metabolism of, 884–886
  nomenclature, 1245
  pharmacokinetics of, 886–893, 886t, 888t
  pharmacological effects and clinical applications, 905–908, 1246–1248
  structure-activity relationships for, 901–903, 901f, 903f, 1249–1250, 1250f
  topical applications, 906
  to treat asthma and COPD, 1245–1252
Adrenocorticotropic hormone
  in adrenocorticoid synthesis, 884
  in Cushing's disease, 882
Afferent neuron, 464, 464f
Affinity
  conformation and, 87–88
  definition of, 86
  stereochemistry and, 88–89
Affinity labeling agents for opioid receptors, 656t, 658–659
Affinity labels, 110–111
African trypanosomiasis, 1086
  treatment of, 1088–1089, 1092–1095
Age
  bone mass and, 935
  depression, 548
  drug metabolism and, 295–297
Agonists
  definition of, 86
  full (strong), 96
  partial, 96
Agriculture
  antibiotics in, 1035–1036
  antifungals in, 1122
Alanine, 177t
Albumin, in thyroid hormone transport, 917, 917t
Alcohol dehydrogenase, 281
Alcohol(s)
  acetaminophen interaction with, 965
  CYP450 induction and, 272–273
  drug metabolism and, 272–273
  oxidation of, 281
  toxicity of, 281
Aldehyde dehydrogenase, 282
Aldehyde oxidase, 282
Aldosterone
  biosynthesis of, 883–884, 885f
  progesterone and, 1317
  structure of, 885f
Aliphatic acids, conjugation of, 289–290
Aliphatic hydroxylation, 274
Alkaloids, plant, 381–382
Alkanes, hydroxylation of, 274
Alkenes, hydroxylation of, 270, 270f, 274, 275, 275f, 276f
Alkyl amines, 1013–1014, 1014f
Alkyl chains, alterations in, 47–48
Alkylaminoketones, 373
Alkylating agents, in cancer chemotherapy, 1154–1155
Allergens, histamine response to, 1006–1007
Allergy
  to aspirin, 967
  immediate reaction in, 1007, 1008f
  to local anesthetics, 469
  to penicillin, 1052, 1055
Allyl amine antifungals, 1121–1122
α-Adrenergic receptor(s), 397–398, 397f. *See also* Adrenergic receptor(s)
  in polyphosphatidylinositol hydrolysis, 398
α-Adrenergic receptor(s) agonists, 402–404, 775–776
  structure-activity relationships for, 402–404
α-Adrenergic receptor(s) antagonists, 407–409, 775–776, 778–782
  general, 407–409
  selective, 409
  structure-activity relationships for, 407–409
α-Alkyltryptamines 637–638
5α-Androstane, 880f
α/β-adrenergic receptor(s) antagonists, 411, 774t, 776, 776f
α-Glucosidase inhibitors, 872–873, 872f
Alpha-helix, 179f
Amebiasis, 1084–1085
  treatment of, 1088, 1089–1091
American trypanosomiasis, 1086
  treatment of, 1088–1089, 1089–1091
Amidases, 180
Amides, hydrolysis of, 284–285
Amines
  metabolism of, 304
  oxidative deanimation of, 283
Amino acid(s), 119. *See also* Peptide(s); Protein(s)
  central nervous system neurotransmitters
    criteria, 445–446
    excitatory, 445f, 446–452
    glycine, 459–460
    historical background, 444–445
    inhibitory, 445f, 452–459

Copyrighted material

Amino acid(s) (*continued*)
conjugation of, 289–290, 290f
linkage of, 117
natural, 178
protection of, in peptide synthesis, 181–184, 182f, 184f
sequence of, 119
stereochemistry of, 178
structure of, 177t, 178–179
trifunctional, in peptide synthesis, 182–184
Aminoacridines, 1095
7-Aminocephalosporanic acid (7-ACA), 1056f
Aminocyclitols, 1065–1069
Aminoglycosides, 1065–1069
2-Aminoimidazolines, 403
Aminopeptidases, 180
4-Aminoquinolines, 991–993
8-Aminoquinolines, 1099
Aminorex, 643–644
Aminotetralins, 422
AMP, 397–398
AMPA, 449t
Amphetamine-related agents, 551, 642–646
Amphoteric compounds, 28
Amylin, in diabetes mellitus, 860
Amylin agonists, in diabetes mellitus, 865
Anabolic steroids, 1274, 1276t, 1279–1281
Analeptics, 642–646
Analgesics. *See also* Opioid(s)
antipyretic, 962–965
definition of, 652
early development of, 4–5
early investigations of, 17–18
opioid, 652–676
*Ancylostoma duodenale*, 1090, 1101, 1103t
Ancylostomiasis, 1101
treatment of, 1102–1107
Androgen antagonists, 1281f, 1288–1290
Androgen receptors, 1281–1282
Androgen(s), 1265–1273. *See also* specific androgens
biosynthesis of, 1268–1270
discovery of, 1267
mechanism of action of, 880, 880f, 1271–1272
in men, 1265
naturally occurring, 1274, 1276t
physiology, 1267–1268
structure-activity relationships for, 1279, 1312–1313
synthetic, 1274
in women, 1288, 1322
Androstane 17β-carbothioates, 900–901
Androstane 17β-carboxylates, 900–901
Androstenedione, 1304f
Androstenedione aromatase inhibitors, 1310–1311, 1310f
Androsterone, 1269f
Anemia, 848
Anesthesia
definition of, 462
general, 490–502 (*See also* General anesthesia; Volatile anesthetics)
local, 462–477 (*See also* Local anesthetics)
Angina pectoris, 706–713
drugs for, 706–713
calcium channel blockers, 709–711, 710f, 758–765
coronary vasodilators, 712–713, 712f
organic nitrates, 707–709, 707f
hyperlipidemia and, 802
Angiotensin antagonists, 738–739
Angiotensin I, 724, 740f. *See also* Renin-angiotensin pathway
Angiotensin II, 739, 740f
in adrenocorticoid synthesis, 884
cardiovascular effects of, 739–740, 741
Angiotensin II receptor antagonists
development of, 752–753
Angiotensin II receptor blockers, 752–757
adverse effects of, 756
dosages of, 756t
mechanism of action of, 754
metabolism of, 755
pharamocokinetics of, 755–756, 756t
physiochemical properties of, 754–755
structure-activity relationships for, 754
therapeutic applications of, 756
types of, 752–754
Angiotensin III, 739, 740f
Angiotensin-converting enzyme, 742
Angiotensin-converting enzyme (ACE) inhibitors, 108–109, 109f, 742–752
adverse effects of, 752
binding of, 742f
in combination products, 751
development of, 742–746
dicarboxylate-containing, 742f, 744–746, 748f
dosages of, 755t
drug interactions with, 752t
mechanism of action of, 746–747
metabolism of, 748–749
pharmacokinetics of, 748t, 749–750
physiochemical properties of, 747–748
structure-activity relationships of, 747, 748t
sulfhydryl-containing, 742–744, 742f
therapeutic applications of, 750–751
Angiotensinogen, 738, 740f
Angiotensis, 740f
Anilidopiperidines, 664
Aniline hydroxylase, 262, 264t
Animal studies
drug discrimination paradigm in, 632–633
stimulus antagonism, 632
stimulus generalization, 632
training drug doses in, 632–633
Ankylosing spondylitis, 956
Antagonists, 86
partial agonists as, 96
Anterior pituitary hormone analogs, 139–140
Anthracyclines, 1165–1170, 1167f
Anthranilic acids, 979–980, 979f–980f, 979t
Antiandrogens, 1281f, 1288–1290
Antianginal drugs, 706–713
beta blockers, 711
calcium channel blockers, 709–711, 710f, 759–766
organic nitrates/nitrites, 707–709, 707f
Antianxiety drugs. *See* Anxiolytics
Antiarrhythmic drugs, 713–719
calcium channel blocker, 719, 759–766
classification of, 714–719, 715t
mechanism of action of, 714–719
structure of, 719f
Antibiotics, 1028–1081, 1046–1081
agricultural use of, 1035–1036
aminocyclitols, 1065–1069
aminoglycosides, 1065–1069
antitumor, 1165–1173, 1167f
antiviral action of, 1202
bacterial cell wall and, 1043f–1045f, 1044–1046
bacteriocidal vs. bacteriostatic, 1033
biphasic effect of, 1034
β-lactam, 1046–1052 (*See also* β-lactam antibiotics)
combinations of, 1034–1035
currently available, 1046–1081
cyclic peptides, 1078–1079
development of, 1029–1031
dosing of, 1035
eagle effect of, 1034
empiric-based therapy with, 1032–1033
historical perspective on, 1029–1031
initiation of, 1035
inoculum effect and, 1034
lincosaminides, 1072–1073
macrolide, 1069–1072
mechanism of action of, 1050–1051
microbial persistence and, 1034
microbial resistance to, 1030–1031, 1033–1034, 1051–1052
inoculum effect and, 1034
Kirby-Bauer susceptibility disk testing for, 1032–1033
microbial susceptibility to, 1033–1034
minimum inhibitory concentration of, 1033
narrow-spectrum, 1031
nomenclature of, 1031
overview of, 1028–1031
postantibiotic effect of, 1034
prophylactic, 1035
protein biosynthesis inhibitors, 1065–1077
reserve/special purpose, 1077–1081
resistance to, 1030–1031, 1033–1034
rifamycin
for MAC complex, 1141–1142
for tuberculosis, 1131–1134, 1134f
route of administration of, 1035
selection of, 1033
serum protein binding of, 1035
streptogramins, 1079–1080
susceptibility to, Kirby-Bauer test for, 1032–1033
tetracyclines, 1073–1077
Antibodies. *See also* Monoclonal antibodies
monoclonal, 148–151
Anticancer drugs. *See* Cancer chemotherapy
Anticholinergics, 381–385. *See also* muscarinic antagonists
acetylcholine as, 371–374
antiparkinsonian, 689, 691t
ethanolamine ethers as, 1011–1016, 1012t
for extrapyramidal side effects, 605–606
hypnotic, 518–519
pharmacokinetic properties of, 381
structure-activity relationships for, 371–373, 382–383
therapeutic applications of, 381
Anticoagulants, 820–845
conditions requiring, 820–824
direct thrombin inhibitors (DTIs), 832–834
heparin-based, 828–832
laboratory assessment and monitoring with, 824
mechanism of action of, 824, 825f
oral, 824–828, 825f, 826t, 827f
recombinant, 138t, 147
structure-activity relationships for, 825–826
thyroid effects of, 925
toxicity of, 844–845
Anticonvulsives. *See* Antiseizure drugs
Antidepressants

solubility of, 34, 34f
Tyrosine hydroxylase, 393–394, 394f, 604, 604f

**U**

UDP-glucuronosyl transferases (UGTs), 286f, 287
Ulcer(s), peptic, 1019–1024, 1020f
treatment of, 1021–1023
Unipolar depression, 549
United States Pharmacopia (USP), 327
Upregulation, receptor, 97
Ureides, 528
Uric acid, in gout, 998, 998f
Uridine diphosphate glucuronic acid (UDPGA), in glucuronic acid conjugation, 285–286
Uridine diphosphate-glucuronosyl transferases (UGTs), 286–287, 286f
Urine
drug elimination via, 295
formation of
physiology of, 722–724, 723f
regulation of, 724
Uronium coupling reagant, in peptide synthesis, 184
Uterus
estrogen effects on, 1311
progestin effects on, 1312

**V**

Vaccines, recombinant, 138t, 147
Valine, 177t
Valley fever, 1114
Vascular disease, in diabetes mellitus, 859
Vasodilators
arterial, 784–789
venous, 787–789
Vasopressin, 595–596
Vasopressin, in urine formation, 724
Vastatins. *See* HMG-CoA reductase inhibitors
Vectors
cationic lipid, 157–159
cloning, 126–127
nonviral, 155–160
plasmid, 155, 155f
viral, 152–155 (*See also* viral vectors)
Venous thrombi, 822–823
thrombolytic drugs for, 841–845, 843f
Venous thromboembolism (VTE), 820
Very low-density lipoproteins, 798, 800–802, 801t
Vesicular transporter protein (VGAT), 453
Villi, intestinal, 211, 211f
Viral infections
antisense therapeutic agents for, 205–207 (*See also* antisense therapeutic agents)
causative viruses in, 1195t
drug therapy for, 1202–1225 (*See also* antiviral drugs)
immune response to, 1198
routes of transmission of, 1197
types of, 1195t, 1199–1202
Viral vectors, 152–155
adeno-associated virus, 153t, 154
adenoviral, 153–154, 153t
herpes simplex virus, 153t, 154–155
retroviral, 153, 153t
Virus, Serum, and Toxins Act, 327
Virus(es). *see also* viral infections
budding of, 1193–1194
classification of, 1193–1194, 1195t
DNA, 1196f
life cycle of, 1199f
oncogenic, 1148t
proviruses and, 1214
replication of, 1194–1199, 1196f
RNA, 1194, 1196
structure of, 1193–1194
Vitamin D
bioactivation of, 937f
in calcium homeostasis, 935, 937–938
deficiency of, osteoporosis from, 941
in hypoparathyroidism, 941
Vitamin D analogues, 941–942
Vitamin D receptors, 937–938
Vitamin K, anticoagulants and, 825, 825f
Volatile anesthetics. *see also* general anesthesia
flammability of, 497t
fluorinated hydrocarbon, 497–500
metabolism of, 278, 278f
toxicity of, 278, 278f
Voltage gated ion channels, 758
calcium, 758
Von Willebrand's disease, 846–847

**W**

Water
as amphoteric compound, 29
leveling effect of, 29
Water solubility, 31–38
hydrogen bonds and, 31–33, 33f, 33t
ionization and, 34
of organic salts, 33
potential for, of functional groups, 36t
prediction of, 34–38
analytic approach to, 36–38
empiric approach to, 34–36
Waxman-Hatch Act, 329
Whipworm infections, 1101
treatment of, 1102–1107
Wiley Act, 327
Withdrawal, opioid, 661
Wolff-Chaikoff block, 920
Women
drug metabolism in, 321
reproductive cycle, 1301–1303, 1302f (*See also* estrogen(s); progestin(s))
sex hormones in, 1301–1338
*Wuchereria bancrofti*, 1102, 1103t

**X**

Xanthine dehydrogenase, 282–283
Xanthine oxidase, 282–283
Xenobiotics
definition of, 253
metabolism of (*See* drug metabolism)

**Y**

Yeast artificial chromosomes, 160
Yeast infections, 1113
treatment for, 1114–1124

**Z**

*Z*-isomer, 42
Zwitterions, solubility of, 34, 34f
Zygomycosis, 1114

MASTER MEDICINAL CHEMISTRY AND APPLY YOUR KNOWLEDGE TO PHARMACY PRACTICE

FOYE'S PRINCIPLES OF

# MEDICINAL CHEMISTRY

SIXTH EDITION

***Edited by:***

Thomas L. LEMKE, PhD • David A. WILLIAMS, PhD

***Assistant Editors:***

Victoria F. ROCHE, PhD • S. William ZITO, PhD

Acclaimed by students and instructors alike, **Foye's Principles of Medicinal Chemistry** is now in its **Sixth Edition**, featuring updated chapters plus new material that meets the needs of today's medicinal chemistry courses. This latest edition offers an unparalleled presentation of drug discovery and pharmacodynamic agents, integrating principles of medicinal chemistry with pharmacology, pharmacokinetics and clinical pharmacy.

All the chapters have been written by an international team of respected researchers and academicians. Careful editing ensures thoroughness, a consistent style and format, and easy navigation throughout the text.

**Features New to the Sixth Edition:**

- **New chapters** cover amino acid neurotransmitters in the central nervous system, phosphodiesterase inhibitors, antidepressants, asthma and chronic obstructive pulmonary disease, and men's and women's health.
- **Color insert** has detailed illustrations of drug-receptor interactions discussed in the text.
- **Clinical significance boxes** explain how chapter content relates to effective pharmaceutical care.
- **Drug lists** at the beginning of most chapters show which drugs are discussed in the chapter.

**More Features to Help You Master Medicinal Chemistry:**

- **Case studies** ask you to evaluate a patient and apply your knowledge of medicinal chemistry to choose the most appropriate therapeutic option.
- **Appendices** offer quick access to selected pH and pKa values.
- **References and additional readings** let you explore individual topics in greater depth.

This **Sixth Edition** emphasizes the growing importance of the pharmacist's role as a therapeutic consultant, giving you the skills you need to use your knowledge of medicinal chemistry to help patients understand the medication choices made for them.
