Treatment for these chip fractures is less controversial since the advent of arthroscopy. The previous morbidity associated with large incisions on the dorsal aspect of the fetlock to remove rather small fragments made surgical treatment much less attractive. With arthroscopic technique, however, the fragments can be easily and atraumatically removed. An excellent prognosis after a short (approximately 4 to 6 weeks) postoperative convalescence can be given if there are no other degenerative changes in the joint.[9-11] In economically unworthy animals a period of 3 to 4 months' rest, followed by intra-articular medications as needed, also affords a favorable prognosis, especially if the fragment is not markedly displaced. In my opinion, superior conditioning when these horses return to work helps prolong careers. Injecting a horse with a corticosteroid after an acute chip fracture also can achieve a favorable short-term result and is always a consideration if the horse's immediate racing demands will not allow a significant period of rest. However, training and racing a horse with an unstable chip fracture may lead to more rapid degenerative changes in the fetlock. Such horses often have extensive score lines, thin cartilage, and more advanced arthritic changes if the fragment is removed arthroscopically at a later date.

Short Sesamoidean Avulsions (Osteochondral Fragments) from the Palmar Aspect of the Proximal Phalanx

Clinical Signs

Characterization of osteochondral fragments arising from the proximal palmar aspect of the proximal phalanx is difficult. Many consider these fragments to be manifestations of osteochondrosis because they are recognized in very young, untrained animals. It seems most probable that the fragments result from avulsion of a portion of the incompletely ossified proximal phalanx followed by development of a traumatic secondary ossification center[12,13] (Fig. 37-8). These fragments are unusual in the forelimbs, much more common in the hindlimbs (see Chapter 43), and most common in the Standardbred (STB) racehorse. They are also commonly recognized in European Warmbloods. Medial fragments are more common than lateral, but fragments can be biaxial and occur in several limbs. These fragments often are found on presale radiographs, and the relevance to lameness should always be questioned. Many successful athletic horses perform with these lesions. Racehorses in which the fragments affect performance rarely show overt lameness. TBs may be unable to maintain a straight path or fail to change leads properly, and STBs tend to ride a shaft or take a line. Horses in which the lesions cause significant lameness usually have an effusion. Most are not painful to fetlock manipulation.

Diagnosis

Oblique radiographic views are best for delineating fragments arising from the palmar, proximal aspect of the proximal phalanx. A flexed view helps to further separate the fragment from the base of the PSBs. This separation is useful with proliferative change at the distal dorsal margin of the PSBs or small, basilar sesamoid fractures. Proximal phalangeal fragments usually are well rounded and often are asymptomatic. It appears that many of these fragments develop in foals without manifestation of clinical signs until training or racing begins.

Training a horse after analgesia of the joint and recognition of improvement in gait should be diagnostic, but the subtle nature of the lameness can make this difficult. Clinical improvement after empirical intra-articular medication also supports the relevance of a radiographic lesion. Scintigraphic localization of a lesion may also help confirm the diagnosis, but in many racehorses, the radiopharmaceutical uptake may be increased in other parts of the joint.

Treatment

Treatment consists of arthroscopic removal of the lesion if the clinician is confident that the fragment or fragments are

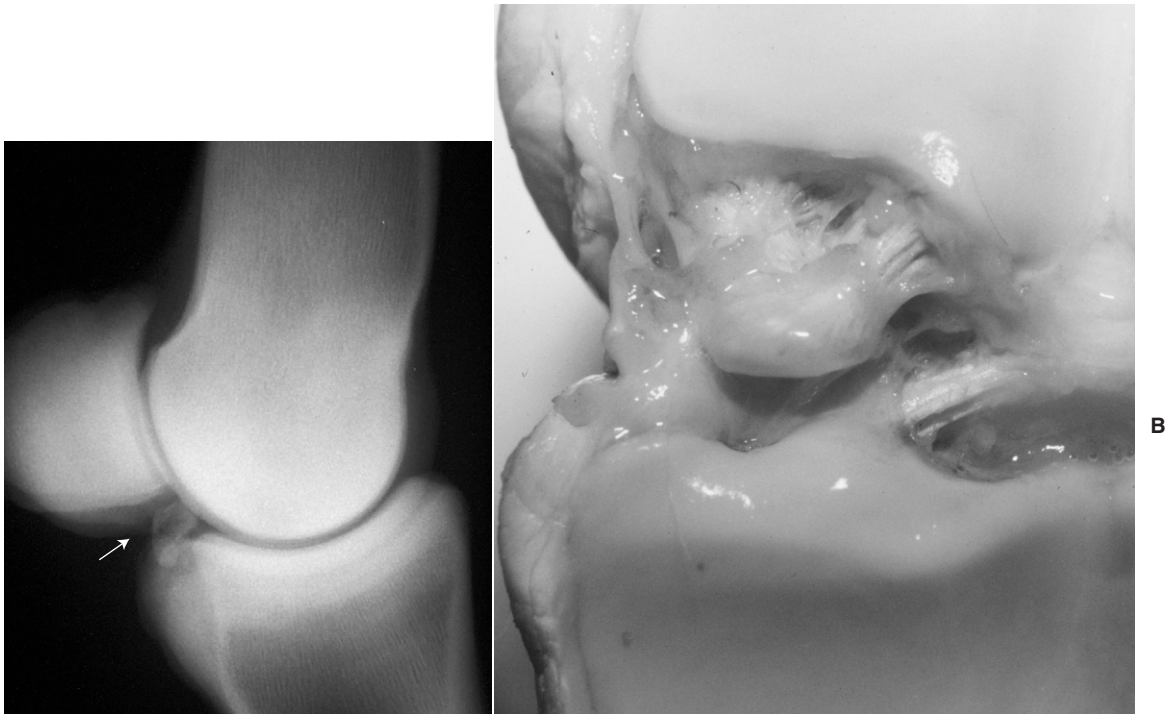

Fig. 37-8 **A,** Lateromedial radiographic view of a typical osteochondral fragment *(arrow)* avulsed from the proximal palmar margin of the proximal phalanx. Some consider this a form of osteochondritis dissecans. **B,** In the dissection the attachment of the fragment to the base of the proximal sesamoid bone by the short sesamoidean ligament is evident, as is the smoothly remodeled defect in the rim of the proximal phalanx.

the source of lameness or if the horse is going to public sale. The most common situation is that the fragments are identified before a horse enters training and the fragments are removed prophylactically. Arthroscopic removal is much less traumatic than arthrotomy for this type of lesion. The prognosis is excellent if the lameness diagnosis is correct.[14] If good arthroscopic technique with minimal soft tissue trauma is used, horses require a short convalescence (4 to 6 weeks). Intra-articular injection of corticosteroids with or without hyaluronan can also improve the clinical signs, but surgery is preferable.

Larger Palmar Fragments of the Proximal Phalanx

Large fracture fragments often cause a more obvious lameness than the more common rounded fragments from the proximal palmar rim of the proximal phalanx. They must be distinguished from more palmar fragments that involve the insertions of the true distal sesamoidean ligaments, because the latter are not equally good candidates for surgical removal. Very large, acute fractures of the palmar process of the proximal phalanx can be repaired with screws if recognized early (see Chapter 36). Large fragments occur in foals and weanlings but clinical signs may abate quickly or be non-existent. Lameness may be evident only when training or racing ensues. In foals, these fragments may be recognized radiographically if there is effusion, mild to moderate lameness, and obvious peri-articular swelling. Lameness is seldom commensurate with fragment size. The lesions in foals are largely cartilaginous and can be followed over time as they develop as a separate center of ossification. These fractures should be differentiated from an avulsion fracture at the site of the medial (or, less commonly, the lateral) collateral ligament (see page 359).

Major Fractures of the Proximal Phalanx: Sagittal Fractures

The most common major fracture of the proximal phalanx is a sagittal crack propagating from the proximal sagittal groove. Horses with long sagittal, displaced sagittal, and comminuted fractures developing from an original fracture in the sagittal or frontal plane have obvious localizing signs of swelling and pain. Horses with shorter sagittal fractures may show more subtle signs. Degree of lameness with short, incomplete sagittal fractures is remarkably variable; some horses are almost unable to bear weight, whereas in others the lameness is barely perceptible (see Chapter 36). There is usually effusion of the fetlock joint, pain on manipulation (flexion and twisting), and pain with firm pressure over the mid-dorsal aspect of the proximal phalanx. Sagittal fractures of the proximal aspect of the proximal phalanx are obvious radiographically if they extend more than a few centimeters from the joint surface, but a short, incomplete fracture is very frequently missed without good-quality radiographs. If a fracture is more than 10 days old, there is usually a definite periosteal change on the dorsal cortex seen on a lateromedial view just distal to the capsular attachments. Initially the change is very indistinct, but within a few more weeks, distinct periosteal new bone is obvious. Whenever proliferative change is seen in this area, the dorsopalmar views should be carefully evaluated for a sagittal fracture. Underexposure results in lesions being missed. These fractures are more common in STBs than TBs and frequently involve more than one limb. Even though these fractures are short and indistinct, they may cause surprisingly severe lameness. The clinician should always suspect such fractures, because blocking followed by high-speed training or pasture exercise may catastrophically propagate the fracture. For management and prognosis, see Chapter 36.

Dorsal Frontal Fractures of the Proximal Phalanx

See Chapters 36 and 43 for a discussion of dorsal frontal fractures of the proximal phalanx.

CONDITIONS OF THE PROXIMAL SESAMOID BONE

Sesamoiditis

Clinical Signs

The PSBs are an integral part of the suspensory apparatus and metacarpophalangeal articulation. They are susceptible to injury in all athletic horses, but particularly in those that perform at speed. Sesamoiditis is a clinically distinctive condition, although it is poorly characterized pathologically. There is usually pain with direct, firm palpation over the abaxial aspect of the affected PSB(s) and sometimes pain with fetlock flexion. Often, however, the lameness is manifest only after hard exercise.

Diagnosis

The lameness is eliminated with perineural, but not intra-articular, analgesia. Radiographic evidence of sesamoiditis involves four basic changes: marginal osteophytes, entheseophytes, enlarged vascular channels, and focal osteolysis. Marginal osteophytes occur at the proximal dorsal and distal dorsal extremities of the PSBs. Best seen on lateromedial views, these lesions represent later changes of generalized osteoarthritis of the fetlock joint and usually can be considered a poor prognostic sign. Entheseophytes occur along the palmar aspect of the proximal half of the abaxial ridge of the PSB or the distal third of the bone at the origin of the sites of the distal sesamoidean ligaments. These changes are frequently abaxial in location and therefore seen best on oblique projections. Interpretation of vascular channels in the PSBs is always subjective. The direction of any linear radiolucency is important to note; vascular channels have a radial orientation, whereas hairline fractures usually are closer to transverse (parallel to the ground).

True lytic change that is not associated with the normal trabecular pattern or vascular channels frequently indicates infection (see Chapters 73 and 75). Nuclear scintigraphy is exceptionally useful for diagnosis of sesamoiditis, can identify early changes, and can help confirm whether a chronic radiographic change is currently active. A complete series of scintigraphic views, including standing lateral, flexed lateral, and dorsal views can aid in exact localization of a lesion within a particular PSB.

Treatment

Treatment of horses with sesamoiditis is difficult and usually involves enforced rest and symptomatic treatment to counter inflammation and pain. Many racehorses with sesamoiditis are clinically helped by post-exercise icing and altered training regimens, such as swimming. It seems to be easier to manage older, proven racehorses with sesamoiditis by such methods than younger, unraced horses. Aspirin and isoxsuprine have been used, but there is no reliable evidence for efficacy. Shock wave therapy is probably the best current therapeutic option for active sesamoiditis, although its efficacy and mechanisms of action are still debatable.

Proximal Sesamoid Bone Fractures

Clinical Signs

Because the PSBs are such important elements in the suspensory apparatus and support of the fetlock joint, fractures are associated with obvious clinical signs of heat, swelling, and pain with flexion or direct pressure, as well as an obvious weight-bearing lameness.

Diagnosis

Lameness caused by most PSB fractures is eliminated or greatly reduced by intra-articular or perineural analgesia. Apical, mid-body, and basilar fractures of the PSBs usually are easy to diagnose radiographically with routine views. Abaxial fractures more frequently are missed and are best demonstrated by a lateral proximal-medial distal or medial proximal-lateral distal oblique projection that is tangential to the abaxial surface of the suspect PSB. This projection also is useful in determining whether the fracture is articular. Axial fractures usually are associated with displaced condylar fractures of the McIII or third metatarsal bone (MtIII). Diagnosis requires a well-penetrated dorsopalmar view that is well positioned. Even slight obliquity obscures the fracture line. Mid-body fractures frequently have wedge-shaped, comminuted fragments present at the abaxial margins. They should not be confused with the overlapping lines of the palmar and dorsal cortices that occur because of fracture displacement and failure to obtain the radiograph directly through the fracture line.

Ultrasonography can be a valuable adjunct in evaluating PSB fractures, because soft tissue insertions of the suspensory ligament (SL), intersesamoidean ligament, and distal sesamoidean ligaments can be simultaneously injured.

Apical fractures. Apical fractures comprising less than 30% of the bone occur primarily in racehorses, but they can occur in all types of horses. These injuries are caused by a combination of bending and suspensory tensile forces. In young STBs the fracture is particularly common in the right hind lateral PSB. Horses with apical PSB fractures are usually mildly to moderately lame unless a concomitant SL injury is present. Although lameness in some horses has been managed successfully with rest alone, arthroscopic removal of the fractured fragment generally is recommended. Both prognosis and convalescent time are dependent on fragment size and presence of suspensory desmitis. Horses with small, apical fragments without major SL ligament injury can resume training within 4 to 6 weeks after surgery, especially if they were fit at the time of injury. Horses with large fragments usually associated with suspensory branch injury may need 6 to 12 months of convalescence and have a poor prognosis.

Abaxial fractures. Abaxial fractures are true avulsion injuries involving the insertion of the SL on the abaxial surface. Most involve a narrow rim of the articular surface and can be removed by an arthroscopic approach. Displaced fragments should be removed, whereas extremely large fragments can be repaired with 3.5-mm screws. Horses with non-displaced fragments sometimes can be treated with rest. The prognosis depends on the size of the fragment and the concomitant suspensory compromise.

Basilar fractures. Basilar fractures of the PSBs are seen in all athletic horses and are treated according to configuration.[15,16] Smaller, wedge-shaped fragments that do not extend more than 50% to 75% of the dorsopalmar width of the PSB are clear candidates for surgical excision of the fragment (Fig. 37-9). Such fragments do not heal with rest and cause persistent lameness, presumably because of instability and incongruity at the articular surface. The prognosis with arthroscopic technique is at least 50% for return to athletic function because the distal sesamoidean ligaments are not disrupted. Horses are usually given 4 to 6 months of rest after removal of such fragments (3 months with very small pieces).

Horses with larger, basilar PSB fractures that extend to the palmar aspect of the bone have the poorest prognosis, because fractures often are significantly displaced, involve a greater proportion of distal sesamoidean ligament origin, and have more metacarpal or metatarsal injury (Fig. 37-10). They also are more difficult to repair than mid-body fractures because of the size and shape of the fracture. The prognosis for horses with large, displaced, or comminuted basilar PSB fractures is very poor for return to any significant level of athletic activity.

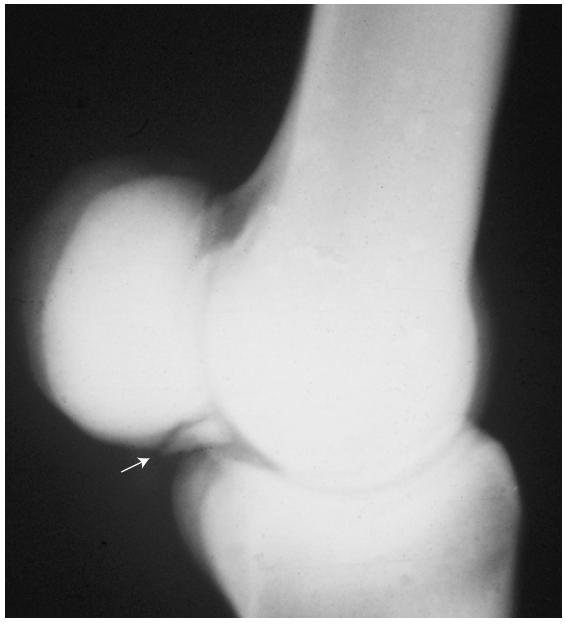

Fig. 37-9 Lateromedial view of a metacarpophalangeal joint. There is a basilar sesamoid fracture *(arrow)*. Small, triangular, basilar sesamoid fragments that do not involve the major distal sesamoidean ligaments are appropriate candidates for arthroscopic removal.

Fig. 37-10 Flexed lateromedial radiographic view of a metacarpophalangeal joint. There is a large displaced basilar sesamoid fracture *(arrow)*. Large basilar fractures are very difficult to successfully repair. Because there are extensive attachments of the distal sesamoidean ligaments, the prognosis associated with surgical removal is poor.

Some horses with severe osteoarthritis develop small basilar fractures. These fractures typically are more rounded or multiply fragmented than acute chip fractures (Fig. 37-11). Acute chip fractures have a sharply demarcated triangular shape. Horses with these degenerate basilar fractures are very poor candidates for any surgical treatment, and horses have a grave prognosis for return to athletic activity. Radiographic narrowing of the joint space between the PSB and McIII (Fig. 37-12), as well as the development of a radiographic "waist" in the distal aspect of McIII, are associated signs of severe osteoarthritis (Fig. 37-13).

Fig. 37-11 Dorsomedial-palmorolateral radiographic view of a metacarpophalangeal joint. There are fragments distal to the proximal sesamoid bone *(arrow)*. Irregular, "crumbled" fragments from the base of the sesamoid usually are seen in joints with moderate to severe osteoarthritis. Note also the modeling of the articular margins of the proximal phalanx.

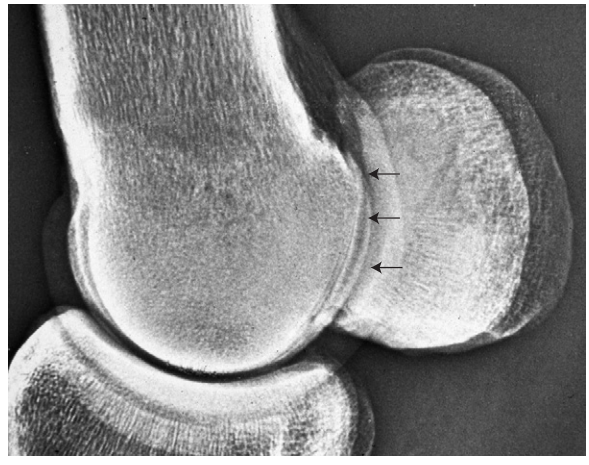

Fig. 37-12 Lateromedial radiographic view of a metacarpophalangeal joint. Note the loss of space between the proximal sesamoid bones and the third metacarpal bone *(arrows)*. Near complete loss of joint space between the third metacarpal bone and the proximal sesamoid bones can precede that between the distal third metacarpal bone and the proximal phalanx. Horses with this degree of cartilage damage are often candidates for euthanasia or arthrodesis.

Mid-body fractures. Mid-body fractures of the PSB can occur in any horse, but they usually are seen in racehorses. In North American TBs the medial bones of the forelimb are most commonly affected. In the STB, hind lateral PSB fractures are most common. Numerous surgical techniques have been used to repair such fractures, including cast coaptation alone, bone grafting and casting, lag screws (distal to proximal or proximal to distal) with or without cancellous grafting, and hemicerclage wiring and graft.[17,18] Regardless of the technique used, mid-body PSB fractures are serious injuries and require an extended period of rest after surgery. With surgery, 60% to

Fig. 37-13 Slightly oblique flexed lateromedial radiographic view of a metacarpophalangeal joint. Development of a "waist" around the proximal joint margin on the third metacarpal bone, both dorsally and palmarly *(closed arrows)*, is indicative of severe, chronic osteoarthritis. There is a pronounced defect of the distal palmar aspect of the third metacarpal bone *(open arrow)*.

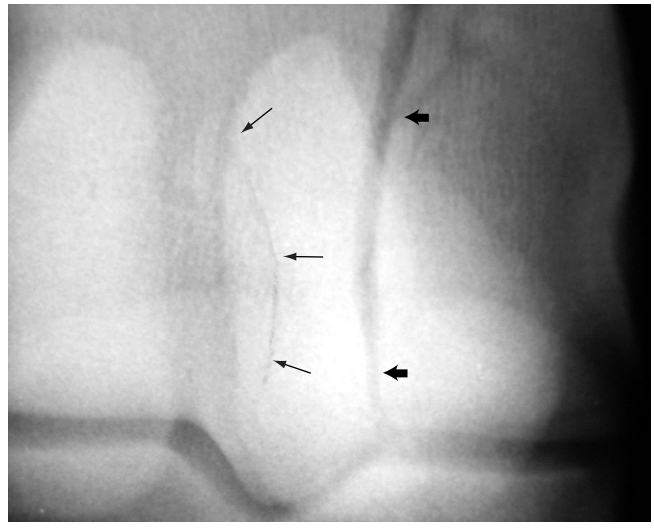

Fig. 37-14 Dorsopalmar radiographic view of a metacarpophalngeal joint. There is a displaced lateral condylar fracture of the third metacarpal bone *(short bold arrows)* and an axial fracture of the lateral proximal sesamoid bone *(arrows)*. Clinicians should look for axial proximal sesamoid bone fractures in every horse with a displaced lateral condylar fracture. This unusual type of fracture is associated with a poor prognosis for return to racing.

70% of horses with mid-body fractures can return to athletic function, but most horses drop substantially in class. The owner or trainer should be advised that almost a year of convalescence is required for horses with such injuries.

Axial PSB fractures. Axial PSB fractures are nearly always seen in combination with displaced lateral condylar fractures of the McIII or MtIII. They are recognized radiographically only on a dorsopalmar view and it is difficult to determine fracture depth (Fig. 37-14). Some fractures involve deep gouges in the articular surface, and most are avulsions by the intersesamoidean ligament. They usually are not treated specifically because of inaccessibility and the likelihood that the condylar fracture and overall joint damage will limit return to function. Recognition of an axial PSB fracture is important primarily as an indicator of more severe trauma to the joint and a poorer prognosis. The prognosis for a horse returning to race after this injury is extremely poor.[19] Early metacarpophalangeal arthrodesis should be seriously considered in horses with a displaced axial sesamoid fracture.

Intersesamoidean ligamentous injury without fracture is difficult to diagnose unless it is accompanied by radiographic lysis along the axial aspect of one or both PSBs (see Fig. 73-18, *A*). Affected horses often are extremely lame even at a walk. Scintigraphy frequently identifies an area of intense, focal increased radioisotope uptake. The intersesamoidean ligament also can be evaluated ultrasonographically to a limited extent. The ligamentous lesion may be visible and debrided arthroscopically, but it is not known if this alters the outcome. Horses generally are treated with support bandages and stall rest for several months. The prognosis for return to high-level athletic activity appears to be guarded, but a large series of horses has not been reviewed. A differential diagnosis for lytic lesions in the intersesamoidean region also includes osteomyelitis.[20] If an infection is the cause of the bone lysis, horses typically have more dramatic localizing signs, and the prognosis is extremely poor.

PSB fractures in young foals. PSB fractures in young foals (apical, abaxial, mid-body, and basilar) can occur at pasture and appear to be underdiagnosed, because clinical signs are surprisingly subtle and foals often are not thoroughly examined for mild lameness. Because most fractures involve only one PSB and the suspensory apparatus is still functional, severe lameness does not develop. Clinicians should look for subtle clinical signs of fetlock region swelling, pain with flexion, and pain with pressure over the PSBs in any foal with mild to moderate lameness. Several bones can be affected. Signs often abate quickly, especially in young foals (<2 months), in which these fractures are most common. Good-quality radiographs are essential, because the fractured apical, basilar, or abaxial fragments are often poorly mineralized. Unlike older horses, PSB fractures in foals frequently progress to form a bony union (Fig. 37-15). If the fragments have any displacement, however, an enlarged PSB can result. These oversized PSBs often are diagnosed in yearlings or 2-year-olds on prepurchase or presale radiographs. Surprisingly, enlargement of the fetlock joint is usually difficult to detect. Although some horses have raced successfully with enlarged PSBs, this abnormality can be a source of lameness as the horse proceeds in training.

PSB fractures in foals are essentially a management problem. Avoidance of situations in which a young, weak foal has to chase its dam around a large pasture to the point of exhaustion can prevent many fractures. It is essential to slowly return foals back to pasture if they have been stall confined for any reason. Early recognition of lameness in foals can allow diagnosis before the fragments become markedly displaced. Early diagnosis improves prognosis considerably, because minimally displaced fractures nearly always heal completely with rest alone. Uncontrolled exercise by the foal must be avoided, because the degree of displacement dictates the eventual PSB deformity.

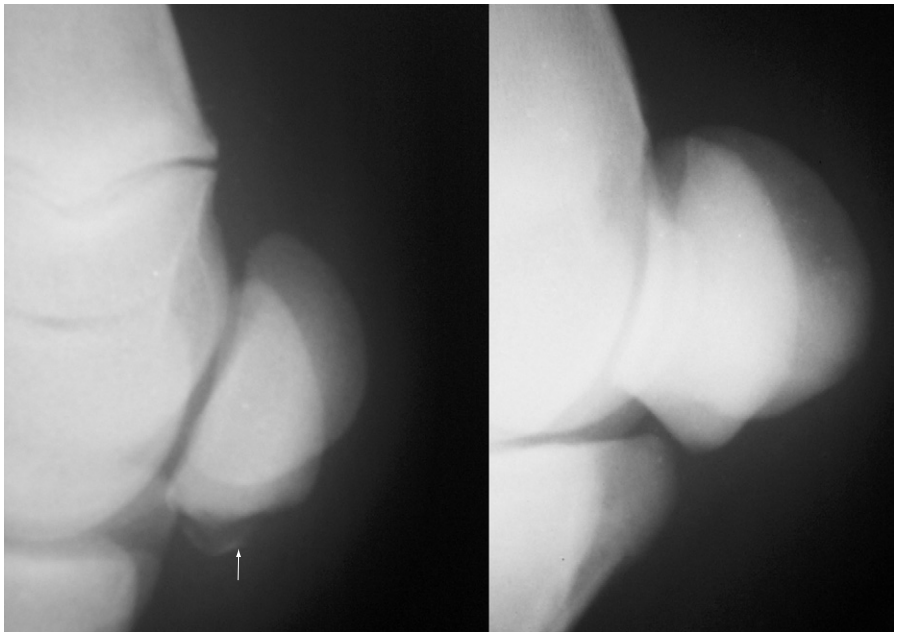

Fig. 37-15 Lateromedial radiographic views of a metacarpophalangeal joint of a foal. There is a displaced basilar fracture *(arrow)* from one of the proximal seasamoid bones on the first radiograph *(left)*. Radiographs obtained 4 months later *(right)* reveal healing of the fracture. Proximal sesamoid bone fractures in foals can heal, although displaced fractures result in an enlarged bone.

FRACTURES OF THE THIRD METACARPAL BONE

Condylar Fractures

Clinical Signs

The most important fracture of the fetlock joint is that involving the condyles of the McIII. They occur almost exclusively in racehorses and usually only when horses are running at racing speeds. Because the fractures involve a major weight-bearing surface, most horses are overtly lame, with clear localizing signs of pain and swelling. Most are very positive to any manipulation of the fetlock. Degree of lameness often does not directly correlate with the degree of displacement. Many horses with incomplete, acute fractures are more lame than one with a clearly displaced, complete fracture. This is particularly true with incomplete medial fractures. Although it appears that many horses that develop condylar fractures have preexisting subchondral damage of the distal, palmar condyle,[5] the majority do not have a strong history of previous fetlock lameness. (See Chapter 43 for fractures of the MtIII.)

Diagnosis

Radiographic diagnosis is not difficult in most horses. A dorsopalmar view should be centered over the condyle and the beam directed 15° to 20° downward. If the beam is too horizontal, the PSBs may obscure the distal articular surface of the McIII. Lesions may be missed if films are under exposed. The most common fractures involve the lateral condyle and clearly propagate toward the lateral cortex. Some extend only 1 to 2 cm proximally from the joint surface, and these can be particularly difficult to see without good-quality radiographs. Lateral condylar fractures rarely spiral or extend into the mid-diaphysis. Medial condylar fractures, however, usually extend up the diaphysis in a spiraling fashion or have an occult Y-shaped configuration at the mid-diaphysis. *It is essential to remember the difference between lateral and medial fractures*. Horses with medial condylar fractures *must* have a complete, high-quality set of radiographs that encompass the entire length of the McIII in an attempt to identify fracture configuration. Most importantly, the owner or trainer must be informed immediately of the significant risk associated with medial fractures.

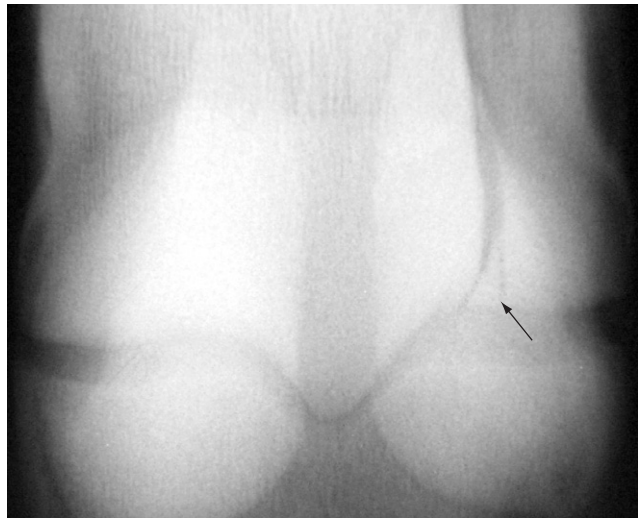

Fig. 37-16 Flexed dorsopalmar radiographic view of the metacarpophalangeal joint that shows a triangular-shaped defect *(arrow)* at the distal aspect of a lateral condylar fracture of the third metacarpal bone. Comminution can be seen only in this radiographic view and worsens the prognosis.

The prognosis for horses with displaced, lateral condylar fractures, regardless of treatment, is much poorer for return to function compared with those with non-displaced fractures. This is almost certainly the result of a combination of preexisting disease of the fetlock joint and the magnitude of damage done to the joint when the fracture occurs. Accurate prognosis requires radiographic examination of the palmar distal aspect of the McIII. The radiographer should slightly flex the fetlock and use a horizontal beam to obtain a dorsopalmar view (Fig. 37-16). This helps to define comminution of the condyle along the fracture margin, as well as subchondral lysis that may have preceded the fracture.

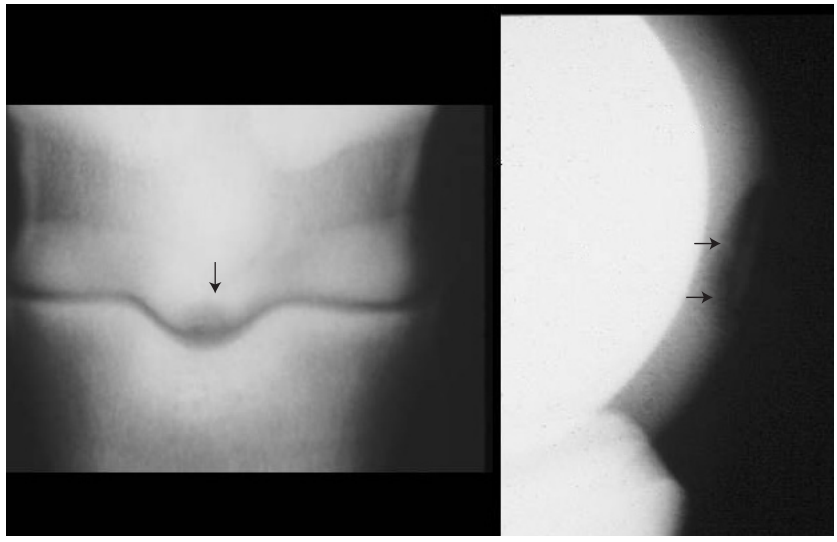

Fig. 37-17 Dorsopalmar *(left)* and flexed lateromedial *(right)* views of metacarpophalangeal joints. Note the radiolucent defect *(arrow)* in the sagittal image in the dorsopalmar view and the smoothly outlined defect in the dorsal aspect of the sagittal ridge *(arrows)* of the third metacarpal bone in the lateromedial view. Osteochondritis dissecans lesions of the sagittal ridge usually can be identified on dorsopalmar and flexed lateromedial views.

Most horses with condylar fractures are best treated with lag screws. Non-displaced or minimally displaced fractures can be repaired through stab incisions alone, but arthroscopic evaluation of the joint should allow a more accurate assessment of the prognosis. Displaced fractures require accurate reduction of the distal articular surface, so they must be reduced under arthroscopic guidance or through an open incision. Horses with medial condylar fractures should undergo surgery with extreme caution, because catastrophic failure in the mid-diaphysis can occur during anesthetic recovery or even several days to weeks after repair (see Chapter 43). Spiral fractures extending the length of the diaphysis may be successfully repaired with carefully positioned lag screws alone, but medial fractures that disappear in the mid-diaphysis should be repaired with a bone plate combined with lag screws across the condyle. Most complications of condylar fractures occur because of a failure to recognize potential problems before surgery. Even if certain complications cannot be entirely avoided, forewarning the owner of the risks is advisable.

Osteochondrosis

Sagittal Ridge of the Third Metacarpal Bone

The most common site of osteochondrosis in the metacarpophalangeal joint (excluding proximal palmar lesions) is the dorsal sagittal ridge of the McIII/MtIII (Fig. 37-17).[21] These lesions often are clinically silent, but mild to moderate effusion and lameness may be noted. They are often diagnosed in weanlings or on yearling presale radiographs. They are best seen on a dorsopalmar view or a slightly under-exposed flexed lateromedial projection. If no fragment is obvious and clinical signs are minimal, it is advisable to rest the horse for a couple of months, because some healing may occur, especially in younger animals. Arthroscopic debridement is an option, but the resulting bony defect will remain evident and the likelihood of a rewarding sale price is thus lessened. If the lesion does not fill in radiographically by the spring of its yearling year, arthroscopic evaluation may be suggested. A completely conservative (i.e., non-surgical) approach is justified if the clinical signs are minimal. The prognosis likely depends on the size of the lesion. Lesions more proximal on the sagittal ridge may have a better outcome than those closer to its distal aspect.

In older horses, traumatic chip fractures may occur on the distal sagittal ridge in a similar location to that of typical osteochondrosis (Fig. 37-18). This injury may occur in jumpers striking an obstacle with the fetlock joint in a palmarly flexed position. These fragments usually are unstable and should be arthroscopically removed. The prognosis is favorable if the fragment is fairly small.

Fig. 37-18 Flexed lateromedial radiographic view of a metacarpophalangeal joint. There is a chip fracture on the distal dorsal aspect of the sagittal ridge *(arrow)* of the third metacarpal bone. Chip fractures of the sagittal ridge in older horses occur occasionally from direct trauma. In this radiograph the osteochondral fragment is located somewhat more distal than most, and they may be missed in a weight-bearing projection.

Osseous Cyst-Like Lesions of the Third Metacarpal Bone

Osseous cyst-like lesions of the distal Mc III/Mt III occur on the weight-bearing surface of the condyle and may be a manifestation of osteochondrosis. Most occur in the medial condyle and are diagnosed in yearlings or early in training as a 2-year-old. The lesions are easy to recognize radiographically, and horses have obvious lameness exacerbated by lower limb flexion. Perineural analgesia and scintigraphy also localize the problem. Surgical debridement has been the typical treatment, and the reported results are unexpectedly favorable.[22]

Collateral Ligament Injury

The fetlock joint has strong anatomical constraints, and the equine limb and gait have a strongly sagittal orientation; therefore mediolateral instability is relatively uncommon except after severe trauma (e.g., foot in a hole or lower limb in a gate or fence). Mild forms of collateral desmitis are suspected in horses with pain on fetlock manipulation, focal pain, and swelling over the affected ligament or lameness exacerbated with valgus or varus stress. The diagnosis is confirmed by ultrasonographic examination. Radiographs usually are not helpful unless there is an avulsion fracture or obvious asymmetry of the joint surface. Asymmetry is more likely to be demonstrated on non–weight-bearing, valgus or varus stressed dorsopalmar (plantar) radiographs.

Treatment of collateral ligament injury usually consists of rest and adequate external coaptation. The fetlock is an inherently stable joint in the sagittal plane; thus minimal support is necessary unless the injury is severe. If the joint is very unstable, a cast extending to the proximal metacarpal region is maintained for 4 to 6 weeks. If the injury is not overtly unstable, a single polyvinyl chloride pipe splint applied on the side ipsilateral to the collateral injury should be adequate. The duration of rest should be based on clinical soundness, palpable stability, and the ultrasonographic appearance of the ligamentous tissues (see Chapter 17). Shock wave therapy for insertional desmopathies may be beneficial, but firm data are still unavailable.

In young horses (usually yearlings or 2-year-olds), fragments can be avulsed from the collateral ligament's insertion on the proximal phalanx. These sometimes are mistaken for dorsal chip fractures on oblique views, but careful scrutiny reveals that the fragment is too far abaxial for a typical chip fracture (Fig. 37-19). The fracture can also usually be seen on a dorsopalmar (dorsoplantar) view. These fragments often are along the articular margin and do cause lameness. Arthroscopic removal should be performed, but it can be difficult because of the limited space on the medial or lateral aspects. The arthroscope portal should be dorsoproximal on the same side as the lesion. The instrument portal should be just dorsal to the edge of the collateral ligament. The fragments may be tightly attached along the abaxial margin, and an arthroscopic scalpel or other sharp dissection tool may be needed to separate them.

Fig. 37-19 Dorsomedial-palmarolateral oblique radiographic view of a metacarpophalangeal joint. Note the extensive periarticular soft tissue fragments *(arrows)* on the dorsal aspect of the joint. Collateral ligament avulsion results in dramatic swelling of the fetlock region. Removal of loose articular fragments and external coaptation can result in athletic soundness. This horse became a highly successful steeplechaser.

Traumatic Disruption of the Suspensory Apparatus

Traumatic disruption of the suspensory apparatus is almost exclusively an injury that occurs in the forelimbs of TB racehorses. It occurs more often in North America than Europe, although any horse running at high speed may suffer it, including young foals that are chasing the dams in the pasture. Speed alone does not account for the injury, and it is likely that fatigue of the flexor muscles supporting the fetlock and digit leads to higher stresses in each component of the suspensory apparatus. There also may be a history of the horse being bumped or making a misstep.

The history and clinical presentation of traumatic disruption of the suspensory apparatus in adult horses are straightforward, since the horses are either breezing or racing and come up acutely and severely lame. The fetlock joint drops as the horse attempts to bear weight. Many horses become anxious or even frantic as they attempt to control the injured limb. There is obvious swelling and pain over the site of the injury. In foals the diagnosis is often not made as quickly.[23] The typical history of a foal with traumatic disruption of the suspensory apparatus (or lesser injuries of the suspensory apparatus) is of being turned out in a large field with its dam and other mares and foals shortly after birth, or after confinement to a box stall for an extended period. As the mare runs with the other horses, the foal attempts to keep up, running at speed and to the point of exhaustion. This results in the same combination of speed and fatigue that leads to this injury in the racehorse. The clinical signs of complete disruption of the suspensory apparatus are similar, but less dramatic than in adult horses.

Fetlock drop and severe lameness are seen with complete disruption of any portion of the suspensory apparatus. The most common injury in both adults and foals is fracture of both PSBs. The fractures are often comminuted, especially in the basilar portions. The second most common type of traumatic disruption of the suspensory apparatus is complete avulsion of the distal sesamoidean ligaments. This is easily recognized radiographically by the proximal displacement of the intact PSBs (Fig. 37-20). The least frequently recognized type of traumatic disruption of the suspensory apparatus is a complete tear of the SL body or both branches. The Paso Fino, Peruvian Paso, and some other older horses have a degenerative condition of the SL that leads to suspensory apparatus failure that is particularly problematic in the hindlimbs. These horses do not have acute severe lameness (see Chapter 73). In horses with any traumatic disruption of the suspensory apparatus, the excessive extension of the fetlock may result in stretching and damage to the digital vessels, which may cause avascularity or hypovascularity of the digit. Simultaneous damage to the superficial and deep digital flexor tendons is also common and should be assessed ultrasonographically. Although PSB fractures and suspensory injuries are both common hindlimb injuries, the severe, breakdown injuries usually involve forelimbs.

Traumatic disruption of the suspensory apparatus is virtually always a career-ending injury. The only exceptions are

Fig. 37-20 Lateromedial *(left)* and dorsopalmar *(right)* radiographic views of a metacarpophalangeal joint. Note the overextension of the joint in the lateromedial view and the extreme proximal displacement of the proximal sesamoid bones, which are intact. This is the result of disruption of the distal sesamoidean ligaments, which is a clear-cut indication for metacarpophalangeal arthrodesis.

simple, displaced mid-body fractures of both PSBs that can be individually repaired and suspensory body or branch injuries in some STBs. It is important to recognize the severity of the injury so that an informed decision can be made concerning treatment. Most horses can be saved as pasture sound or breeding animals, but treatment often is prolonged and expensive regardless of the therapeutic approach selected.

First Aid

The most important first aid treatment is application of an appropriate splint that aligns the McIII and phalanges in a column to prevent bending of the fetlock and loading of the suspensory apparatus. Although homemade splints can be fashioned to accomplish the same objective, commercially available splints are quick, easy to apply, and very effective for temporary immobilization (Kimzey LegSaver splint; Kimzey, Inc., Woodland, CA). Most horses are less anxious and able to move comfortably immediately after the splint is applied. If a prefabricated splint is not available, a lightly padded bandage with a splint applied to the dorsal aspect of the metacarpal region, phalanges, and hoof serves the same purpose if the heel is kept elevated. This can be done by taping the heel and a heel wedge with non-elastic tape (e.g., duct tape) to the dorsal splint. Excessive padding should be avoided because it allows dorsal flexion within the bandage and shifting of the splint. Other first aid measures include the administration of NSAIDs, intravenous fluids to replace water and electrolytes lost through sweating, and broad-spectrum antibiotics. Antibiotics should be given even if the fracture is ostensibly closed. High concentrations of antibiotics in the fracture hematoma are desirable, because skin abrasions and lacerations over hypovascular tissue are common. The vascularity of the foot should be assessed by palpation of the digital vessels and assessment of hoof temperature. Horses that are extremely anxious and difficult to calm should be given xylazine, with or without butorphanol, as needed for restraint and to prevent further self-injury by the horse.

Non-Surgical Management

Non-surgical management involves long-term splinting of the injury in an attempt to achieve sufficient fibrosis of the injured tissues so that satisfactory support of the fetlock returns. The primary advantage of this approach is the avoidance of the obvious risks associated with operating in a hypovascular and possibly contaminated site. The surgical and technical expertise and equipment required are modest, and the expense of *initial* treatment is relatively small. There are some disadvantages of non-surgical management. The fibrosis that develops may not be adequate to support the fetlock in a horse exercising at pasture; this is more problematic with distal sesamoidean ligament avulsions than fractured PSBs. Many horses are uncomfortable on the splinted limb and unable to use it normally because of the abnormal posture, and they are at risk of supporting limb breakdown and laminitis. Long-term splinting also demands meticulous daily bandage changes to prevent rub sores at the proximal dorsal metacarpal region and suppurative dermatitis of the palmar pastern and heel bulbs.

The technique of successful long-term splinting of horses with traumatic disruption of the suspensory apparatus primarily involves meticulous nursing care. Most clinicians use a prefabricated splint because of the ease of its removal and application. The Kimzey splint can be improved for long-term use by welding a heel extension on it to increase its bearing surface area. This helps minimize the tendency to develop rub sores at the proximal, dorsal edge of the splint. The prefabricated splints are not perfectly fitted for every horse. Therefore some modifications in padding may be required to avoid excessive pressure on the proximal, dorsal metacarpal region. Regardless of which type of splint is used, the leg should be checked daily for developing sores or dermatitis, particularly in the palmar pastern. If the leg is washed, it should be dried before applying the bandage. If skin infection develops, it can be very difficult to manage. Both systemic and local antibiotics are usually necessary.

The most critical decisions in management of a traumatic disruption of the suspensory apparatus with splints concern removal of the splints and a gradual return to more normal fetlock and digit joint angles. Upright splinting is used for most horses for approximately 6 weeks but many, particularly those with distal sesamoidean ligament avulsions, may require much longer. The process of dropping the fetlock should be gradual. This can be done by splinting at decreasing angles (which is difficult with prefabricated splints), or using a fetlock support shoe incorporating an adjustable sling. Horses should be confined to a stall for a prolonged period (4 to 6 months), because a single misstep can lead to tearing of the still maturing scar tissue. Although external coaptation has worked well in individual horses and in some clinicians' hands, the long-term results do not appear to be as good as surgical arthrodesis. Although surgical fusion has considerable potential complications, the solid fusion of the joint is not likely to slowly fail and cause progressive discomfort when a mare or stallion enters the breeding shed. Horses with conservatively managed injuries appear to have more problems with long-term comfort.

Surgical Management

Surgical management of traumatic disruption of the suspensory apparatus generally involves fetlock arthrodesis, although repair of simple, displaced mid-body proximal sesamoid bone fractures can be performed to preserve some joint function. The major advantage of arthrodesis is that the procedure usually affords the horse immediate, comfortable use of the limb and avoids the complications of prolonged overuse of the contralateral limb. Because the fixation is usually very stable, post-operative immobilization is minimal and the various complications of casts and splints can be avoided. The primary disadvantage of surgical arthrodesis is the increased risk of infection. An additional consideration is that successful

Fig. 37-21 Dorsal plating with a palmar tension band is the standard technique for metacarpophalangeal arthrodesis after traumatic disruption of the suspensory apparatus.

arthrodesis requires both surgical expertise and investment in equipment and facilities.

The most widely used technique for fetlock arthrodesis is that of a dorsal plate with creation of a tension band on the palmar aspect (Fig. 37-21).[24] Dorsal plating without a tension band on the palmar aspect of the fetlock is ill advised because the plate is cycled in bending on the joint's dorsal surface and fatigues and eventually breaks. The specific technique used to create the tension band depends on the type of traumatic disruption of the suspensory apparatus, but both methods involve the same surgical approach. After luxation of the metacarpophalangeal joint, the articular cartilage is removed and multiple holes are drilled into the subchondral bone. Holes are drilled in the McIII and proximal phalanx, through which wires are passed to form a figure-eight tension band. A 14-hole dynamic compression plate is pre-bent to a fetlock angle of 150° to 160° and positioned dorsally using 5.5-mm screws.

If the distal sesamoidean ligaments are intact and the attached PSB fragments are large enough, the tension band wiring can be avoided. Instead, the fetlock is positioned in approximately 5° of palmar flexion and a 5.5-mm lag screw is placed through the McIII into each PSB. When the pre-bent plate is placed, the distal sesamoidean ligaments then serve as the tension band that prevents the plate from bending and eventual fatigue failure. This is the preferred surgical technique in horses with the less common injury involving disruption of the suspensory ligament body or both branches.

A fiberglass cast is placed for anesthetic recovery and is left in place for 10 to 14 days if the horse wears it comfortably. If the cast creates obvious discomfort, it should be removed immediately because cast sores can be a serious problem and the fixation is secure enough that the cast is unnecessary. If the horse wears the cast well, it should be changed with the horse standing at 10 to 14 days. The second cast is left in place 4 to 5 weeks if the horse wears it comfortably. If there is any evidence of a cast complication, it should be replaced with a bandage. Radiographs are obtained at regular (approximately 6-week) intervals. If healing is routine, most horses have a solid fusion by 3 to 4 months after surgery and can begin some limited turnout in a small paddock.

The major complication of bone plating for fetlock arthrodesis is infection. However, because this repair is very strong and stable, healing can occur even in the face of infection. The combination of instability and infection, however, rarely succeeds and reoperation of unstable, infected sites is usually necessary to achieve fusion. Implant failure also is a concern, but proper technique and the use of 5.5-mm screws prevent this complication. Additional strength and fatigue life can be obtained by luting the plate, although this is not usually necessary.

A common long-term complication associated with traumatic disruption of the suspensory apparatus is osteoarthritis of the proximal or distal interphalangeal joints. The joints are stressed more by the fusion of the fetlock joint and often by the presence of serious injury to the flexor tendons and distal sesamoidean ligaments that insert on the phalanges.

Many horses with traumatic disruption of the suspensory apparatus sustain open, contaminated fractures or such extensive soft tissue damage that internal fixation may carry an unacceptable risk of infection. External skeletal fixation is an alternative means of managing such injuries (see Chapter 88).[25]

The prognosis for any horse with traumatic disruption of the suspensory apparatus depends on the specific nature and severity of the injury. Horses with distal sesamoidean ligament avulsions have a poorer prognosis than those with displaced PSB fractures, since the latter tend to form fibrous scar tissue more quickly. Horses with the relatively uncommon suspensory body or bilateral branch tears have the best prognosis, because they seem to heal more quickly and have less fetlock joint instability. At least 60% to 75% of horses with closed disruptions of the suspensory apparatus and an intact blood supply should be saved with proper treatment. Open injuries obviously have a much poorer prognosis regardless of the therapy chosen, and open injuries with vascular compromise have a very poor prognosis.

Complications of traumatic disruption of the suspensory apparatus, regardless of treatment, include laminitis or breakdown of the contralateral limb. The primary complications of long-term splinting are rub sores and inadequate fibrosis, which lead to instability and chronic pain. Surgical arthrodesis offers the advantage of comfort more quickly, but the risks of infection are much greater. Incorrect surgical technique also can lead to mechanical failure of the internal fixation.

CHAPTER • 38

The Metacarpal Region

Sue J. Dyson

ANATOMY

This chapter discusses the examination and diagnosis of injuries to the metacarpal region of the horse. The detailed anatomy of the deep digital flexor tendon (DDFT) (see Chapter 71), the accessory ligament of the deep digital flexor tendon (ALDDFT) (see Chapter 72), the superficial digital flexor tendon (SDFT) (see Chapter 70), and the third interosseous muscle or suspensory ligament (SL) (see Chapter 73) is discussed elsewhere.

In the metacarpal region the interosseous ligaments attach the second (McII) and fourth (McIV) metacarpal bones to the third metacarpal bone (McIII). These ligaments ossify to a variable extent during skeletal maturation. Fibrous bands extend from the distal aspect of McII and McIV to the medial and lateral proximal sesamoid bones (PSBs).

The proximal aspect of the third interosseous muscle or SL attaches to the proximal palmar aspect of McIII and the palmar carpal ligament and lies between McII and McIV. Large exostoses on the axial aspect of McII or McIV have the potential to impinge on the abaxial border of the SL. The carpal sheath (see Chapter 76) extends through the proximal one third of the metacarpal region. The amount of fluid in the carpal sheath varies between individuals but is usually bilaterally symmetrical.

The digital flexor tendon sheath (DFTS) envelops the SDFT and DDFT from the distal third of the metacarpal region to the middle of the middle phalanx. Palmar to the

CHAPTER • 38

The Metacarpal Region

Sue J. Dyson

ANATOMY

This chapter discusses the examination and diagnosis of injuries to the metacarpal region of the horse. The detailed anatomy of the deep digital flexor tendon (DDFT) (see Chapter 71), the accessory ligament of the deep digital flexor tendon (ALDDFT) (see Chapter 72), the superficial digital flexor tendon (SDFT) (see Chapter 70), and the third interosseous muscle or suspensory ligament (SL) (see Chapter 73) is discussed elsewhere.

In the metacarpal region the interosseous ligaments attach the second (McII) and fourth (McIV) metacarpal bones to the third metacarpal bone (McIII). These ligaments ossify to a variable extent during skeletal maturation. Fibrous bands extend from the distal aspect of McII and McIV to the medial and lateral proximal sesamoid bones (PSBs).

The proximal aspect of the third interosseous muscle or SL attaches to the proximal palmar aspect of McIII and the palmar carpal ligament and lies between McII and McIV. Large exostoses on the axial aspect of McII or McIV have the potential to impinge on the abaxial border of the SL. The carpal sheath (see Chapter 76) extends through the proximal one third of the metacarpal region. The amount of fluid in the carpal sheath varies between individuals but is usually bilaterally symmetrical.

The digital flexor tendon sheath (DFTS) envelops the SDFT and DDFT from the distal third of the metacarpal region to the middle of the middle phalanx. Palmar to the

metacarpophalangeal joint the sheath passes through the inelastic canal created by the palmar annular ligament (PAL), the palmar fibrocartilaginous surfaces of the PSBs, and the intersesamoidean ligament. Within the DFTS, proximal to the sesamoidean canal, the SDFT forms a ring (the manica flexoria) around the DDFT. In the palmar mid-sagittal plane a synovial reflection, the vincula, attaches the SDFT to the DFTS wall. Proximal to the manica flexoria the DDFT is attached medially and laterally by mesotendon to the DFTS wall. The lateral mesotendon is more substantial and extends farther distad.

The palmar and palmar metacarpal nerves innervate the palmar metacarpal region. The SL is innervated by the medial and lateral palmar metacarpal nerves, branches of the deep branch of the lateral palmar nerve. This nerve receives contributions from the ulnar and median nerves. The medial palmar metacarpal nerve has fibers only from the median nerve, whereas the lateral palmar metacarpal nerve has fibers from the ulnar and median nerves.[1] The SDFT and DDFT are innervated by the palmar nerves.[2]

In the proximal metacarpal region the palmar nerves lie beneath relatively thick fascia, whereas farther distally they are more superficial. In the proximal 5 cm of the metacarpal region the palmar metacarpal nerves and the distal palmar outpouching of the carpometacarpal joint capsule are in close proximity.

DIAGNOSIS

Clinical Examination

The metacarpal region should be examined visually from all angles to identify any changes in contour caused by swelling. If the limb is hairy, subtle swellings may easily be missed, especially in heavier breeds of horses, and if injury to the metacarpal region is suspected, then clipping the hair to facilitate examination can be useful. Palpation of the metacarpal region should be performed systematically with the limb bearing weight and with the limb semi-flexed. With the limb bearing weight the contour of the dorsal and palmar aspects of the limb should be straight. Distention of the medial palmar vein may reflect local inflammation. The size of the SL and its branches is assessed by running both thumbs down the dorsal and palmar borders from proximally to distally, medially and laterally. With the limb lifted the margins of each of the SDFT, DDFT, ALDDFT, and SL should be carefully palpated to detect rounding of the margins or enlargement. Each structure should be squeezed, starting proximally and working distally, gently at first and then with increasing pressure to determine whether pain can be elicited. Careful comparison should be made with the contralateral limb, bearing in mind that lesions may be present bilaterally. Assess the response in light of the horse's temperament and the recent work history. Abnormal stiffness of a structure may reflect previous injury. It is necessary to roll away the flexor tendons and compress the SL against the palmar aspect of the third metacarpal bone to assess the most proximal part of the SL.

The axial and palmar margins of McII and McIV should be palpated to identify any new bone formation (a splint) and to determine whether applied pressure causes pain. It is also important to assess whether the axial margin of the splint is clearly demarcated from the SL. Firm pressure should be applied to the dorsal aspects of McIII to identify pain.

Local Analgesic Techniques

When local analgesic techniques are performed in the metacarpal region, it is important to recognize the potential for local anesthetic solution to diffuse proximally from the site of injection and thereby desensitize structures farther proximally, partially or completely. Minimum volumes of local anesthetic solution should be used (maximum 2 ml per site and less in ponies) to minimize the risks of misinterpretation. The horse should stand still after injection before reassessment of the gait and should be re-evaluated no more than 10 minutes after injection. Even then false-positive results may be seen.

The metacarpal region seems particularly prone to development of swelling at the site of injection, which potentially may be permanent. The limb should be thoroughly scrubbed with chlorhexidine before injection to minimize the risk of adverse reaction and because of the potential for inadvertent injection into a synovial cavity (the DFTS, carpal sheath, or carpometacarpal joint capsule). The use of non-irritating local anesthetic solution (mepivacaine) is strongly recommended. It is also suggested that a stable bandage be applied to the limb for about 18 hours after injection.

Perineural analgesia of the palmar nerves at the level of the base of the PSBs desensitizes the foot and pastern regions, but in some horses it may also alleviate pain from the metacarpophalangeal joint, PAL, and DFTS. In horses with pain arising from the metacarpal region, lameness often appears paradoxically worse after palmar (abaxial sesamoid) nerve blocks. Complete desensitization of the distal third of the metacarpal region requires perineural analgesia of the palmar nerves in the mid-metacarpal area and the palmar metacarpal nerves distal to the distal aspect of McII and McIV, the so-called low palmar or four-point block. Care should be taken to avoid inadvertent injection into the DFTS. Proximal diffusion may result in partial alleviation of pain associated with a proximal metacarpal lesion, especially proximal suspensory desmitis. If a unilateral lesion is suspected, the block may be performed medially or laterally alone.

Desensitization of one specific PSB can be achieved by blocking the sesamoidean nerve by introducing a needle between the insertion of the SL and the dorsal aspect of the abaxial surface of the sesamoid bone. The needle is directed toward the apex of the bone, and 0.5 ml of local anesthetic solution is injected.[3]

Elimination of pain from the entire metacarpal region requires blocking the palmar nerves immediately distal to the carpus and the deep branch of the ulnar nerve (and thus the palmar metacarpal nerves). However, often it is useful to be more specific and desensitize the deep structures (the palmar aspect of McIII and the SL) or the more superficial structures (SDFT, DDFT, and ALDDFT). Perineural analgesia of the deep branch of the lateral palmar nerve or of the palmar metacarpal nerves by subcarpal injection should not remove pain from the fetlock or distal limb. Blocking the palmar metacarpal nerves immediately distal to the carpus runs the risk of inadvertent injection into the distopalmar outpouchings of the carpometacarpal joint or spread of the local anesthetic solution by diffusion. Theoretically the risk of failure to desensitize the most proximal aspect of the SL exists, but diffusion of local anesthetic solution usually removes pain. The response should be compared with that following intra-articular analgesia of the middle carpal joint. Occasionally subcarpal analgesia of the palmar metacarpal nerves relieves pain associated with a primary middle carpal joint lesion better than intra-articular analgesia. Intra-articular analgesia of the middle carpal joint may relieve pain associated with proximal suspensory desmitis or a palmar cortical fatigue fracture of McIII.

Perineural analgesia of the lateral palmar nerve[4] entails less risk of affecting the middle carpal joint, but it does not eliminate it totally. The potential to remove pain from the lateral aspect of the more distal part of the limb also exists.

Theoretically, blocking the ulnar nerve should not completely remove pain associated with the proximal SL or the

proximal palmar aspect of McIII because of the contribution of fibers from the median nerve to the medial and lateral palmar metacarpal nerves. However, in practice it generally does.

Perineural analgesia of the palmar nerves (2 ml per site) should not desensitize the deeper structures (McIII, SL) but should alleviate pain from the more superficial structures (SDFT, DDFT, and ALDDFT). Local infiltration around a painful exostosis of McII or McIV seems to be the most effective way of determining whether pain from the exostosis is contributing to the lameness observed.

Intra-thecal analgesia of the DFTS usually results in improvement in lameness associated with pain from within the sheath, but a better response is frequently seen after perineural analgesia of the palmar and palmar metacarpal nerves. Injection into the DFTS is most easily performed on the palmar midline of the pastern region, distal to the proximal digital annular ligament. The likelihood of inducing iatrogenic hemorrhage at this site is small, and retrieval of synovial fluid usually is easier. If distention of the DFTS is only mild, compression of the proximal part of the sheath by an assistant to increase distention in the palmar pouch in the pastern can be helpful. Injection into the carpal sheath is usually only indicated if the sheath is distended (see Chapter 76).

IMAGING

Radiography

Radiographic examination of the metacarpal region is usually tailored to each particular horse concerning the views required and the exposure factors used. With localized periosteal new bone, often finely coned-down views, use of soft exposures (low kilovolts [peak]) is required to demonstrate the lesion best. Several similar views varying slightly in obliquity may be required, rather than a full series of dorsopalmar, lateromedial, dorsolateral-palmaromedial oblique, and palmarolateral-dorsomedial oblique projections. Therefore a flexible approach must be used, depending on the initial clinical signs. Little soft tissue covers the metacarpal region; therefore a grid is not required. A high-definition screen with slow-speed film provides the best detail. Diffuse swelling in the metacarpal region makes images appear flatter, lacking contrast. Exposure factors may need to be increased slightly.

Superimposition of McII and McIV over McIII can create confusing radiolucent Mach lines (see page 158). The nutrient canal in McII and McIV varies in prominence[5] and should not be confused as a fracture. Ossification varies between McII and McIV and McIII in normal horses.

Ultrasonography

Ultrasonographic examination of the metacarpal region is discussed in detail elsewhere (see Chapters 16 and 70 to 73). In large, cob-type animals the skin and underlying subcutaneous tissues in the metacarpal region may be thick, making it difficult to obtain high-resolution images. Dense stubble may persist after fine clipping of the hair coat, making it difficult to maintain good contact. Deep skin folds may further complicate the issue. For these horses it may be necessary to amplify the power and gain controls of the ultrasound machine and increase the focal depth of the transducer. Image quality may be enhanced by application of copious amounts of the ultrasound coupling gel to the skin for at least 15 minutes before imaging.

Nuclear Scintigraphy

Blood pool (soft tissue phase) and bone-phase (delayed) images of the metacarpal region are particularly useful in horses in which pain has been localized to the metacarpal region but in which no significant radiological or ultrasonographic abnormalities have been identified. Many exostoses involving McII and McIV, although clinically inactive, are associated with moderately increased uptake of the radiopharmaceutical. Clinically silent enostosis-like lesions also may have increased radiopharmaceutical uptake.

DIFFERENTIAL DIAGNOSIS

Bucked or Sore Shins and Saucer (Dorsal Cortical) Fractures of the Third Metacarpal Bone

See Chapter 109 for a discussion of bucked shins and saucer fractures of the third metacarpal bone.

Medial and Lateral Condylar Fractures of the Third Metacarpal Bone

See Chapter 37 for a discussion of medial and lateral condylar fractures of the third metacarpal bone (page 357).

Incomplete, Longitudinal Palmar Cortical Fatigue Fractures of the Third Metacarpal Bone and Stress Reactions

Incomplete palmar cortical fatigue fractures of McIII are relatively common and invariably involve the medial aspect of the bone,[6-9] may involve the metaphyseal and proximal diaphyseal region, and sometimes extend proximally to involve the carpometacarpal joint. They are believed to be fatigue or stress fractures, because sclerosis may be present radiographically when lameness is first recognized, indicating previous bony reaction.

These fractures occur most commonly in young horses, but they also occur in skeletally mature horses. In some horses a recent increase in work intensity can be identified, which may be a predisposing factor. These fractures have been identified in a variety of sport horses, including horses used for flat and harness racing, National Hunt racing and point-to-point racing, dressage, horse trials, and endurance riding.

Clinical Signs

Lameness usually is sudden in onset and may be unilateral or bilateral. In some horses with bilateral injury, lameness is insidious in onset and the horse has loss of forelimb action. Lameness varies from moderate to severe and tends to be worst on hard ground, and often the horse appears to become lamer the farther it trots. After the horse turns at the walk, the lameness then improves and again deteriorates as the horse trots. If the lameness is bilateral and similar in degree in each limb, the horse moves with a short striding, stilted gait.

Usually no localizing clinical signs suggest the source of pain. Often the horse does not react to palpation of the proximopalmar aspect of McIII, unless the injury is acute.

Diagnosis

Lameness is substantially improved or alleviated by palmar metacarpal (sub-carpal) nerve blocks or perineural analgesia of the deep branch of the lateral palmar nerve. Lameness may be improved in some horses by intra-articular analgesia of the middle carpal joint.

Dorsopalmar radiographic views of the proximal metacarpal region may reveal sclerosis of the proximal medial aspect of McIII, with or without a longitudinal lucent line extending a variable distance proximodistally (Fig. 38-1). If present, the radiolucent line is invariably located medial to the axis of McIII. Generally no radiological abnormality is detectable in other views. In some horses, no detectable radiological abnormality exists.

Diagnostic ultrasonography usually reveals no detectable abnormality. Nuclear scintigraphic images usually demon-

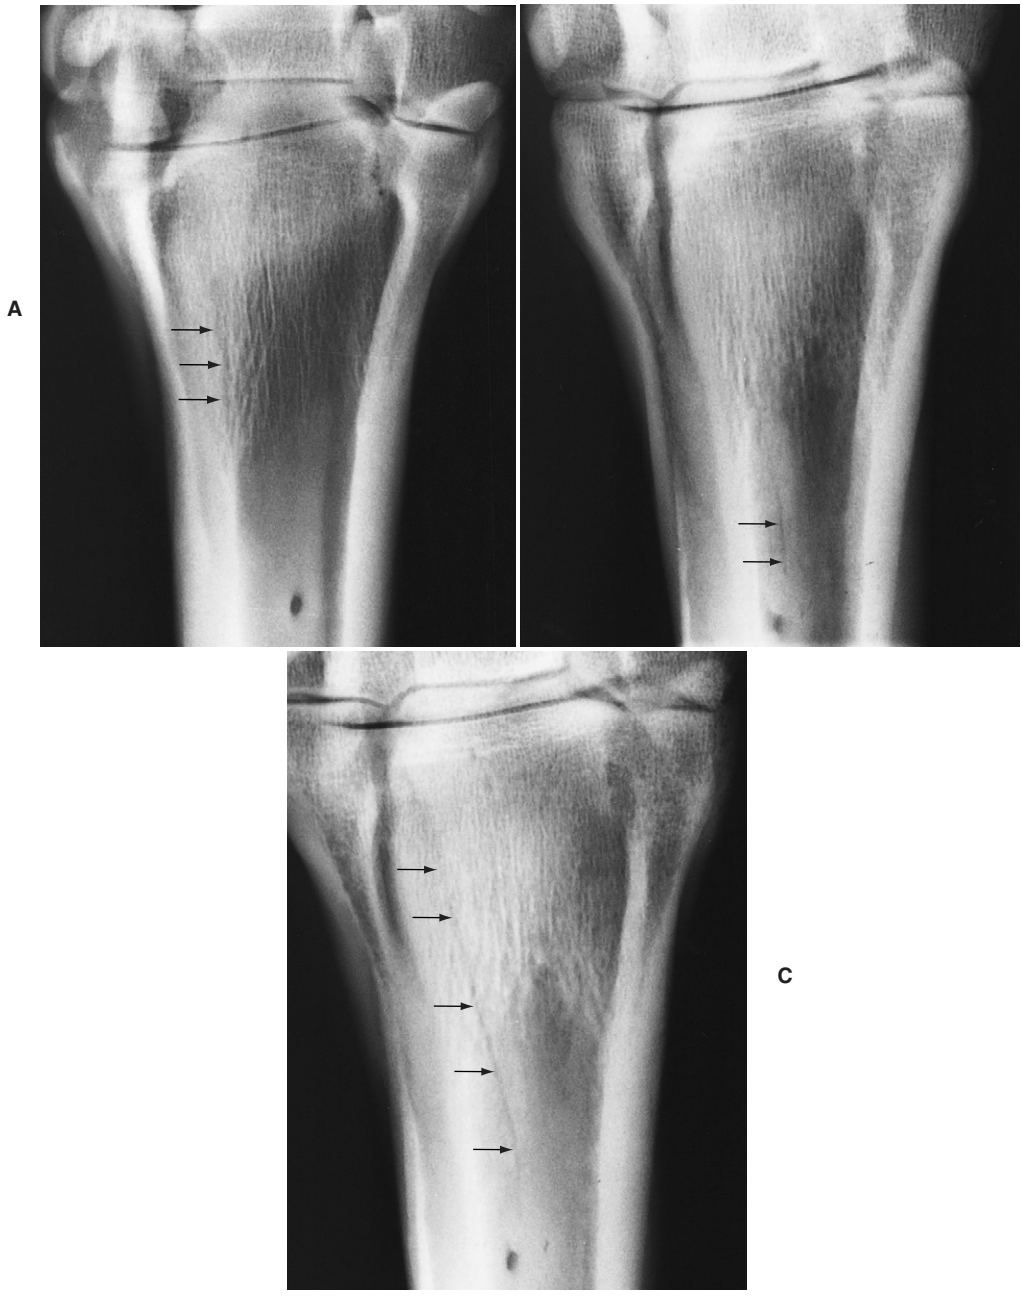

Fig. 38-1 **A,** Dorsopalmar radiographic view of the right third metacarpal bone of a 6-year-old Thoroughbred hurdler with moderate right forelimb lameness recognized 7 days previously and alleviated by subcarpal analgesia of the palmar metacarpal nerves. Medial is to the left. The medial aspect of the metaphyseal and proximal diaphyseal regions of the third metacarpal bone is sclerotic. A poorly defined longitudinal radiolucent line *(arrows)* represents an incomplete longitudinal palmar cortical fatigue fracture. **B,** Dorsopalmar radiographic view of the right proximal metacarpal region of a 6-year-old Arab endurance horse with a moderate right forelimb lameness of 3 weeks' duration. Lameness was alleviated by perineural analgesia of the deep branch of the lateral palmar nerve. Well-defined sclerosis immediately proximal to the nutrient foramen surrounds a longitudinal lucent line in the third metacarpal bone *(arrows)*. **C,** The same horse as in **B** after 4 weeks of box rest. The radiolucent line extends further proximally *(arrows)*.

strate abnormal patterns of uptake of ^{99m}Tc–methylene diphosphonate (^{99m}Tc-MDP) in dorsal and lateral projections. Even in the pool phase, uptake in the proximal palmar aspect of McIII may be abnormal. Bone-phase images show moderate to intense increased uptake of the radiopharmaceutical in the proximal aspect of McIII (Fig. 38-2). This pattern of uptake is indistinguishable from that associated with an avulsion fracture of McIII at the attachment of the SL. Currently unknown is whether horses without radiological change, but with scintigraphic evidence of a stress reaction (i.e., abnormally accelerated bone modeling) in the proximal aspect of McIII, would develop a radiographically evident incomplete

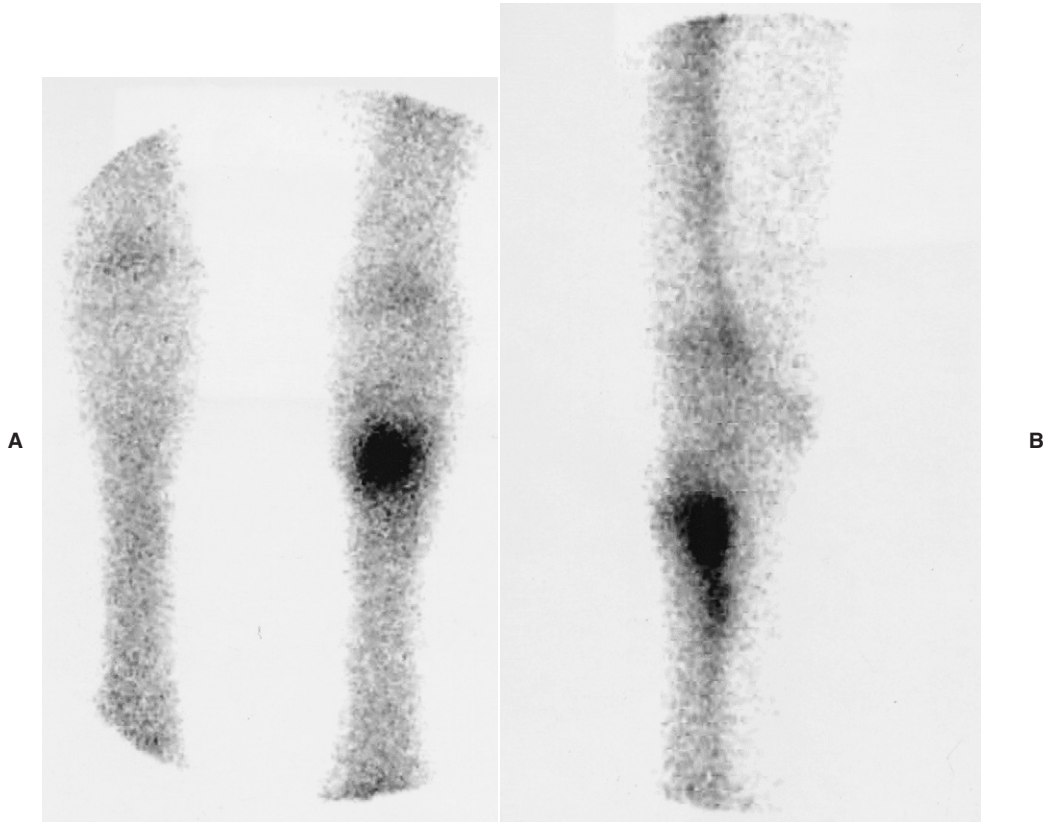

Fig. 38-2 Dorsal (**A**) and lateral (**B**) scintigraphic images of the carpal and proximal metacarpal regions of the forelimbs of an 8-year-old advanced event horse with acute-onset moderate left forelimb lameness of 3 weeks' duration. The left forelimb is on the right in the dorsal view (**A**). Lameness was alleviated by subcarpal analgesia of the palmar metacarpal nerves. The character of the lameness was typical of a palmar cortical fatigue fracture, but no radiographic or ultrasonographic abnormality was detected. Intense focal increased uptake of radiopharmaceutical in the proximal, medial, palmar aspect of the third metacarpal bone is compatible with a stress or fatigue fracture.

palmar cortical fracture of McIII if the horses were kept in work, or whether this is a different manifestation of the response of bone to exercise.

Treatment

Most horses respond well to rest, with box rest for 1 month and then box rest and controlled walking exercise for another 2 months. Horses are then able to slowly and progressively resume normal work. The incidence of recurrent injury is small. Every attempt should be made to identify any problem with the previous training program that may have predisposed the horse to injury.

Transverse Stress Fractures of the Distal Metaphyseal Region of the Third Metacarpal Region

Transverse stress fractures of the distal metaphyseal region of McIII are relatively uncommon. I have seen this fracture in horses of 4 to 7 years of age in the first season of racing over fences and in pleasure horses that have galloped on the beach. These fractures are believed to be stress fractures because endosteal and periosteal callus has been identified radiographically at the first recognition of the lameness.

Clinical Signs

Lameness is usually acute in onset after fast work, is moderate to severe, and may be unilateral or bilateral. Lameness may improve rapidly with the horse appearing sound within a few days. In horses with long-standing lameness a change in contour of the distal dorsal aspect of McIII is visible and is associated with periosteal callus formation. In these horses, pain may be elicited by firm pressure applied to the distal dorsal or palmar aspects of McIII. Twisting McIII may also induce pain. However, horses with acute lameness often have no localizing signs.

Diagnosis

If lameness persists, local analgesic techniques can be used to isolate the pain, but in some horses this is not possible because of the rapid resolution of lameness, unless the horse is maintained in full work. Lameness is eliminated by palmar (midcannon) and palmar metacarpal (distal to the button of McII and McIV) nerve blocks, but it is not influenced by intra-articular analgesia of the metacarpophalangeal joint.

Dorsopalmar, dorsolateral-palmaromedial oblique, dorsomedial-palmarolateral oblique and lateromedial radiographic views of the fetlock region should be obtained. Flexed lateromedial views are preferable, because this technique lifts the PSBs away from the palmar cortex of McIII, allowing better evaluation. Radiographic abnormalities may include a horizontal fracture line and endosteal and periosteal callus (Fig. 38-3). Some horses, in particular those with acute lameness, may have no detectable abnormality.

Nuclear scintigraphy is invaluable for determining the likely presence of a stress fracture in those horses that lack radiographic abnormalities or in which lameness rapidly resolves. Increased uptake of ^{99m}Tc-MDP appears in the distal metaphyseal region of McIII.

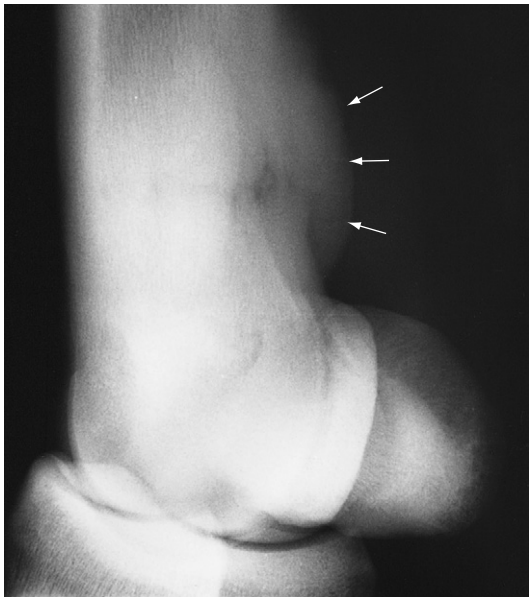

Fig. 38-3 Dorsolateral-palmaromedial oblique radiographic view of fetlock region of 6-year-old Thoroughbred used for point-to-point racing. There is a transverse stress fracture of the distal metaphyseal region of the third metacarpal bone with periosteal callus *(arrows)*.

Treatment

Most horses respond well to 3 months rest, with 1 month of box rest and then box rest combined with walking exercise. Work intensity can then be progressively increased. The previous training program should be reviewed to try to identify any features that may have predisposed the horse to fracture.

Dorsomedial Articular Fractures of the Third Metacarpal Bone

Dorsomedial articular fractures of McIII have only been recorded in the Standardbred racehorse,[10] although similar fractures have been identified in McIII of Thoroughbreds. The condition usually affects horses 2 to 4 years of age and occurs most commonly in pacers.

Clinical Signs

Lameness is acute in onset, after racing or training, and severe. Lameness persists despite rest. A bony swelling may be palpable on the proximal, dorsomedial aspect of McIII. Direct pressure may elicit pain.

Diagnosis

Lameness is generally improved by intra-articular analgesia of the middle carpal joint. Diagnosis is based on radiographic identification of the fracture, best viewed in a dorsolateral-palmaromedial oblique view. The fracture is articular, nondisplaced, and usually incomplete (Fig. 38-4). Active periosteal new bone invariably exists at the distal aspect of the fracture, close to the insertion of the extensor carpi radialis tendon, even in an acute injury.

Treatment

Treatment consists of rest for a minimum of 3 months. The fractures usually heal with modeling of the periosteal reaction and progressive loss of distinction of the fracture line. Lameness resolves, and horses are able to withstand training before the fracture line completely disappears radiographically.

Stress Reactions in the Condyles of the Third Metacarpal Bone

See Chapter 37 for a discussion of stress reactions (see page 350).

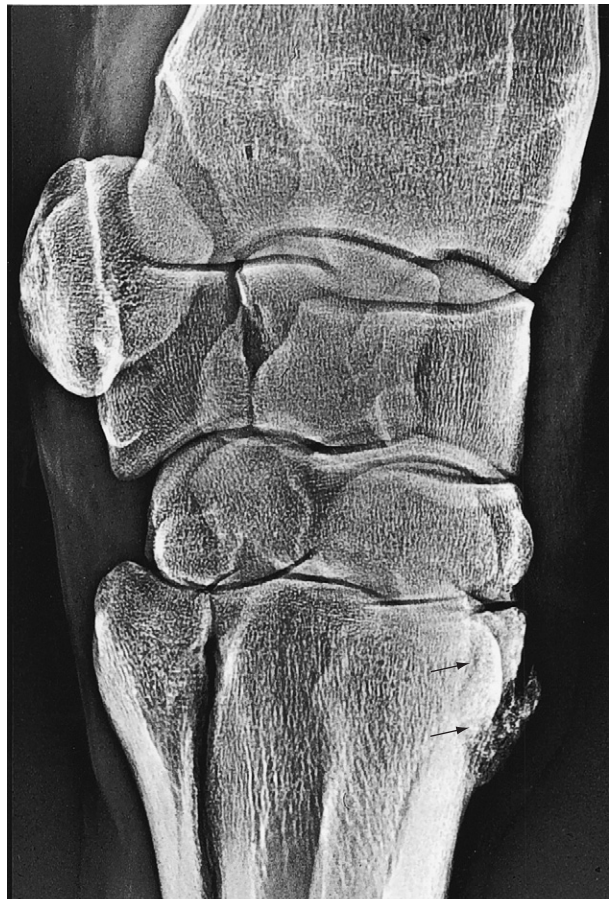

Fig. 38-4 Dorsolateral-palmaromedial oblique xeroradiographic view of the proximal metacarpal region of 3-year-old Standardbred male with a dorsomedial articular fracture of the third metacarpal bone. The wide oblique incomplete fracture line *(arrows)* and presence of proliferative new bone along the dorsomedial aspect of the third metacarpal bone indicate that bone activity in this region preceded the development of acute lameness. (Courtesy Mike Ross, Kennett Square, Pennsylvania.)

Avulsion Fracture of the Third Metacarpal Bone at the Origin of the Suspensory Ligament

Avulsion fracture of McIII at the origin of the SL occurs most commonly in young racehorses (Standardbreds more than Thoroughbreds).[11-14] Some fractures described as avulsions appear to occur immediately distal to the site of attachment of the SL.

Clinical Signs

Onset of lameness usually is acute and lameness is generally moderate to severe and unilateral. In the acute stage the horse generally resents pressure applied over the palmar proximal aspect of McIII. Eliciting pain may be more difficult in horses with chronic lameness. Lameness generally improves but may not resolve by box rest.

Diagnosis

In horses with acute lameness, diagnosis usually can be based on the clinical signs and ultrasonographic or radiographic demonstration of a fracture. In horses with more chronic lameness, local analgesic techniques may be required. Perineural analgesia of the palmar metacarpal (subcarpal) nerves or of the deep branch of the lateral palmar nerve usually improves lameness substantially. Intra-articular analgesia of the middle carpal joint, performed by palmar or dorsal approaches, may also improve the lameness.

An avulsion fracture is best detected radiographically in dorsopalmar or slightly oblique dorsopalmar views and lateromedial, or flexed lateromedial, projections. The fracture may appear as an almost straight or saucer-shaped lucent line (with the base proximal or distal) (Fig. 38-5) or as a punched-out lesion.

An avulsed fragment is usually easiest to detect by ultrasonography in longitudinal images and, if displaced, appears as a discontinuity of the palmar cortex of McIII. An incomplete fracture may be more difficult to detect. Examining the limb while the horse is bearing weight and not bearing weight can be helpful. Slight periosteal callus may be seen in horses with a more chronic fracture. A small focal tear in the dorsal aspect of the SL at the site of the fracture may be visible in transverse and longitudinal images. Nuclear scintigraphy has been used diagnostically.[15]

Treatment

The horse should be restricted to box rest for 6 weeks, followed by box rest and controlled exercise for at least another 6 weeks. The horse should be monitored clinically, radiographically, and ultrasonographically. Lameness caused by avulsion fracture generally takes longer to resolve than in horses with primary proximal suspensory desmitis, sometimes up to 2 months. A fracture may remain detectable radiographically for between 2 and 4 months. Periosteal callus is best seen by ultrasonography and usually is undetectable until 4 to 6 weeks after injury. The total convalescent period is usually between 4 and 6 months. Most Thoroughbreds ultimately make a complete recovery and return to full athletic function without recurrent injury. Occasionally the fracture fragment may sequestrate, or suspensory desmitis may progress, which results in a more guarded prognosis. However, some Standardbreds have long-term lameness that is refractory to treatment.

Osteoarthritis of the Carpometacarpal Joint

Osteoarthritis of the carpometacarpal joint is an unusual cause of forelimb lameness. It usually occurs in mature horses used for any discipline.

Clinical Signs

Lameness may be acute or insidious in onset and is mild to moderate. Usually no localizing clinical signs are present. Carpal flexion is not restricted or resented.

Diagnosis

Lameness may be improved by palmar metacarpal (subcarpal) nerve blocks, probably because of proximal diffusion of the local anesthetic solution. Intra-articular analgesia of the middle carpal joint also improves lameness. Radiographic examination usually reveals that changes are restricted to the medial or lateral side of the joint, with narrowing of the joint space between the carpus and McII or McIV, with subchondral sclerosis (Fig. 38-6) and often periosteal new bone extending along the proximal metaphyseal region of McII or McIV. Lucent zones may appear in the base (head) of McII or McIV.

Treatment

Response to intra-articular medication of the carpometacarpal joint has been poor. Palliative treatment with a non-steroidal anti-inflammatory drug may allow the horse to be maintained in work.

Osseous Cyst-Like Lesions in the Proximal Aspect of the Second Metacarpal Bone

Osseous cyst-like lesions sometimes are identified in the proximal aspect of McII (Fig. 38-7) in association with lameness that is localized to the proximal metacarpal or distal carpal regions. These osseous cyst-like lesions occur most commonly in the presence of a first carpal bone,[6] which also may have radiolucent zones. These lesions often occur bilaterally, although lameness may be unilateral. These lesions are gener-

Fig. 38-5 **A,** Dorsopalmar radiographic view of the proximal aspect of the left metacarpal region of 4-year-old Thoroughbred with acute-onset moderate left forelimb lameness. Lameness was alleviated by perineural analgesia of the lateral palmar nerve just distal to the accessory carpal bone. The curved lucent line *(arrows)* in the proximal aspect of the third metacarpal bone represents an avulsion fracture at the insertion of the suspensory ligament. **B,** Dorsopalmar radiographic view of the proximal metacarpal region of 3-year-old Thoroughbred with lameness of 2 weeks' duration. A punched-out opacity distal to a crescent-shaped lucent area *(arrows)* in the third metacarpal bone represents an avulsion fracture at the insertion of the suspensory ligament.

ally considered incidental abnormalities unassociated with pain, and the clinician should search for another potential cause of lameness.

Exostoses of the Second and Fourth Metacarpal Bones (Splints)

Exostoses on McII or McIV (splints) may develop because of direct trauma, resulting in sub-periosteal hemorrhage and lifting of the periosteum, or instability between McII (or McIV) and McIII. However, many splints do not involve the interosseous space between McII (or IV) and McIII and develop without evidence of trauma. Some splints develop without associated pain and lameness, with little evidence of active inflammation, whereas others result in a localized soft tissue inflammatory reaction, pain, and lameness. The reasons for these differences are not known. Splints may occur at any level but most commonly involve the proximal one half of the bone. Lesions involving McII occur most commonly.

Lesions may develop in young, immature horses or, less commonly, in older horses. Horses with bench (offset) carpal conformation seem particularly prone to develop splints involving McII, but often these develop without associated lameness.

Clinical Signs

Lameness may be sudden or insidious in onset and tends to deteriorate with work and be worst on hard ground. There is usually an obvious palpable swelling comprising a bony exostosis, surrounded by an edematous soft tissue reaction, with localized heat and pain on firm palpation. The swelling should be palpated carefully with the limb not bearing weight, because sometimes only focal areas of the swelling appear to be painful.

Fig. 38-6 Dorsopalmar radiographic view of the proximal metacarpal region of a 10-year-old gelding. Medial is to the left. Narrowing of the carpometacarpal joint on the medial aspect of the joint and radiolucent areas in the subchondral bone indicate osteoarthritis of the carpometacarpal joint.

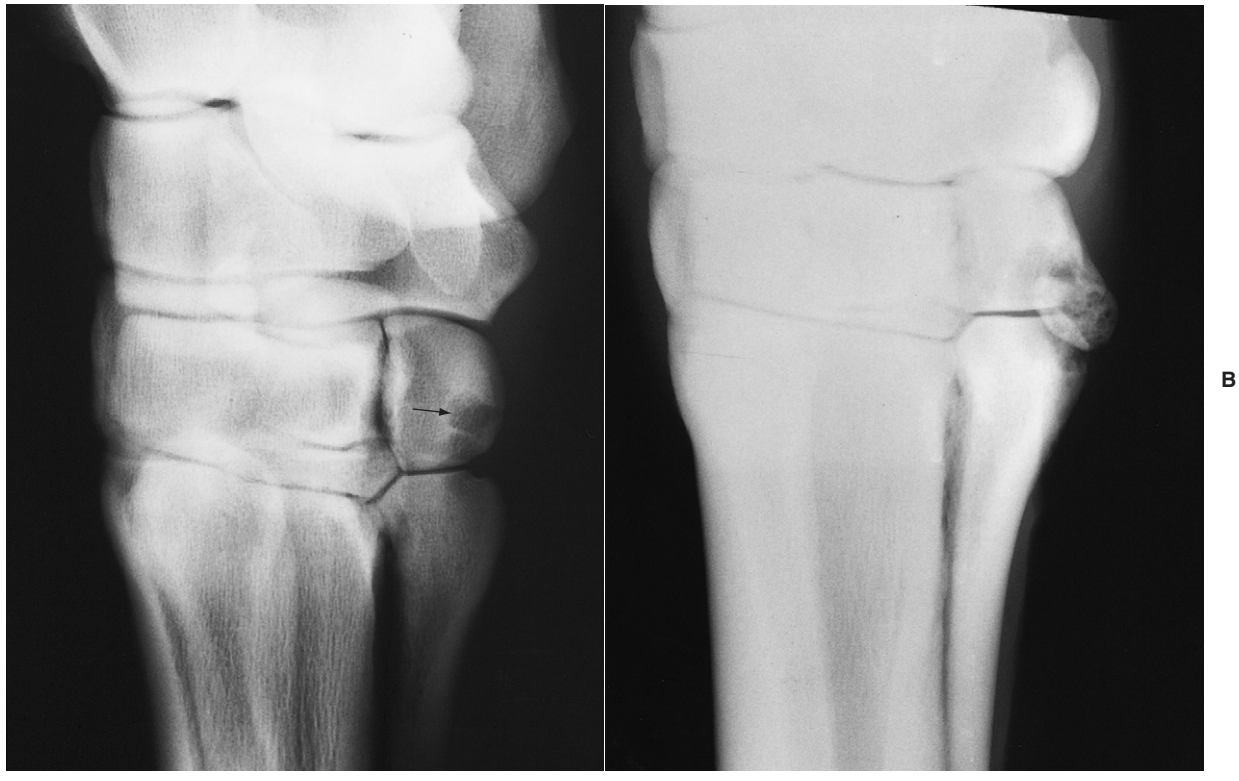

Fig. 38-7 **A,** Dorsomedial-palmarolateral oblique radiographic view of the proximal metacarpal region of 3-year-old Thoroughbred. There is an an osseous cyst-like lesion in the second carpal bone *(arrow)*. **B,** Dorsomedial-palmarolateral oblique view of the proximal metacarpal region of a 6-year-old riding horse. The lucent area in the proximal aspect of the second metacarpal bone is associated with the presence of a first carpal bone. These were incidental radiological findings not related to lameness.

It is important to assess the axial aspect of the exostosis to determine whether there may be impingement on the adjacent SL. Such horses may have had a pre-existing splint that was previously inactive. The horse often has a history of more extensive soft tissue swelling developing with hard work. Lameness may be provoked by hard work but rapidly improves with rest or light work. With the limb not bearing weight it may be difficult to palpate the border of the SL adjacent to the exostosis, and pain may be elicited by firm pressure applied to this localized area of the SL.

Diagnosis

Diagnosis of a straightforward splint often can be based on clinical signs, and further diagnostic procedures may not be necessary. Radiography may be useful to document the size and activity of the exostosis (Fig. 38-8). Several oblique projections using soft exposures are required. Care should be taken not to confuse as a fracture radiolucent lines that are caused by layers of new bone being superimposed, by incorporation of fibrous tissue, or an edge effect created by the parent bone. Radiography cannot properly document the axial extent of any exostosis.

Nerve blocks or local infiltration may be necessary to prove or disprove that an exostosis is the primary cause of pain resulting in lameness and to identify any concurrent problem(s). Diagnostic ultrasonography is essential if an impingement on the SL is suspected. Identification of echogenic tissue axial to the exostosis and contiguous with the SL may be possible (Fig. 38-9). The ipsilateral border of the SL may be irregular and reduced in echogenicity.

Nuclear scintigraphy is generally unnecessary, but it should be noted that even long-standing splints, which appear to be insignificant clinically, often have mild to moderate increased uptake of ^{99m}Tc-MDP compared with the parent bone. Why active bone modeling occurs is not known.

Treatment

Lameness associated with a clinically active exostosis usually resolves with rest, and the surrounding soft tissue swelling resolves. The exostosis remodels and is usually ultimately somewhat smaller. However, sometimes irregular-appearing, palisade-like new bone may persist radiographically. The time taken for the bony reaction to settle is extremely variable, ranging from 2 to 3 weeks to 2 to 3 months. This can be difficult to predict accurately and may reflect how quickly the condition was recognized and box rest instituted. Local infiltration with corticosteroids may facilitate reduction of the soft tissue reaction, but whether this alters the course of the condition is debatable. Topical application of dimethylsulfoxide has a similar effect.

Work should not resume until firm palpation of the exostosis fails to induce pain. A premature return to work is likely to exacerbate the problem. Some degree of fitness may be maintained by swimming exercise.

Some horses seem particularly predisposed to produce large amounts of new bone. The reason for this is unknown. Large exostoses on McII are vulnerable to direct trauma from the contralateral limb, especially if the horse moves closely in front, or dishes. Some protection may be provided by always applying

Fig. 38-8 Dorsomedial-palmarolateral oblique view of the metacarpal region. There is smoothly outlined enlargement of the middle of the diaphysis of the second metacarpal bone, with ill-defined, irregularly outlined periosteal new bone at the distal end of the middle third of the bone. The ill-defined lucent lines *(arrows)* within the bone result from new bone formation and should not be confused with fractures.

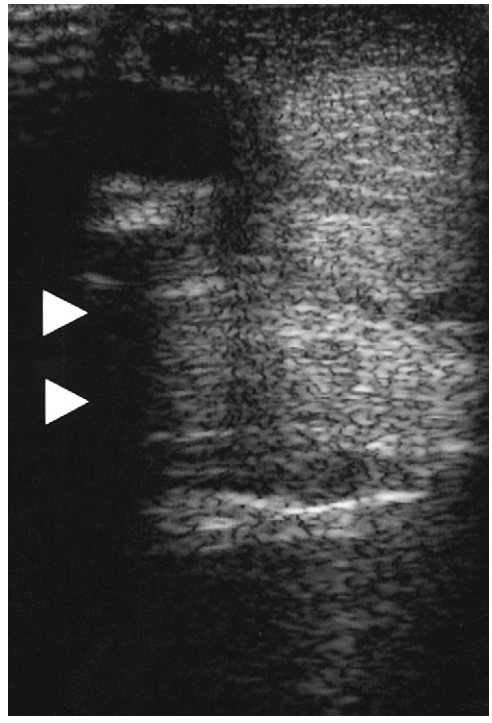

Fig. 38-9 Transverse ultrasonographic image of the palmar metacarpal soft tissues at 14 cm distal to the accessory carpal bone. Medial is to the left. The irregular medial border of the suspensory ligament and the echogenic material *(arrowsheads)* medial to it are apparent. A moderate size exostosis (splint) on the second metacarpal bone extended axially to impinge on the suspensory ligament. Granulomatous-like tissue was interposed between the splint and the suspensory ligament.

protective boots when the horse is worked or turned out. In horses with severe exostoses, surgical amputation of the exostosis and more distal aspect of the metacarpal bone should be considered. Ostectomy of the exostosis and liberal removal of the surrounding periosteum from the splint bone and McIII without removing the distal segment of the splint bone also has been cosmetically and functionally successful in some horses.

In some horses chronic pain associated with a splint persists, despite appropriate conservative management. Pin-firing is suggested if pain persists longer than 6 weeks after lameness was first recognized (see Chapter 89). An additional 6 weeks of walking is required before normal work can be resumed after firing.

If axial impingement of the exostosis on the SL occurs, surgical treatment is required. Amputation of McII or McIV proximal to the exostosis is the treatment of choice, assuming that this leaves the proximal one third of the bone intact, providing stability to the carpus. Often a granulomatous-type reaction occurs between the exostosis and the ipsilateral margin of the SL; this material should also be removed.

Fractures of the Second and Fourth Metacarpal Bones

Fractures of the McII and McIV bones may result from direct external trauma or internal forces, frequently in association with suspensory desmitis.[16-19] The latter is particularly common in horses that race over fences, Standardbreds and, less frequently, event horses.

Fractures caused by internal forces usually occur at the junction between the proximal two thirds and distal one third of the metacarpal bone. The distal ends of McII and McIV are connected by fibrous bands to the abaxial surface of the medial and lateral PSBs. Hyperextension of the fetlock and stretching of these fibrous bands may predispose to fracture. Suspensory desmitis may precede fracture and result in modeling and progressive deviation of the distal part of the bone away from McIII because of pressure or adhesions, thus predisposing to fracture. Fractures at this location unassociated with suspensory desmitis are relatively uncommon, but they do occasionally occur.

Fractures Caused by Internal Trauma

Clinical signs Lameness is acute in onset and moderate. Diffuse edematous soft tissue swelling rapidly develops in the distal half of the metacarpal region, more extensively medially if McII is fractured and laterally if McIV is involved. Occasionally McII and McIV are fractured simultaneously. One or both forelimbs may be affected. Careful palpation reveals enlargement of the body and or branch of the SL. Palpating instability of the distal piece of the fractured bone may be possible, but extensive soft tissue swelling may prevent this.

Diagnosis Radiographic examination should include the metacarpal bone and the ipsilateral PSB, because lesions may occur at both sites concurrently. Pre-existing abnormalities of McII or McIV suggest long-term suspensory desmitis (Fig. 38-10, *A*). The fracture should be evaluated to determine the degree of displacement and the presence of comminution and callus. Ultrasonographic examination is performed to assess the degree of suspensory desmitis, which is the most important prognostic factor.

Treatment Some controversy exists concerning the optimal treatment for horses with fractures of the distal one third of McII and McIV. Some infer that most horses can be managed conservatively, whereas others advocate surgical removal of the fracture fragment. Non-displaced or slightly displaced fractures usually heal satisfactorily within 4 to 6 weeks if the horse is

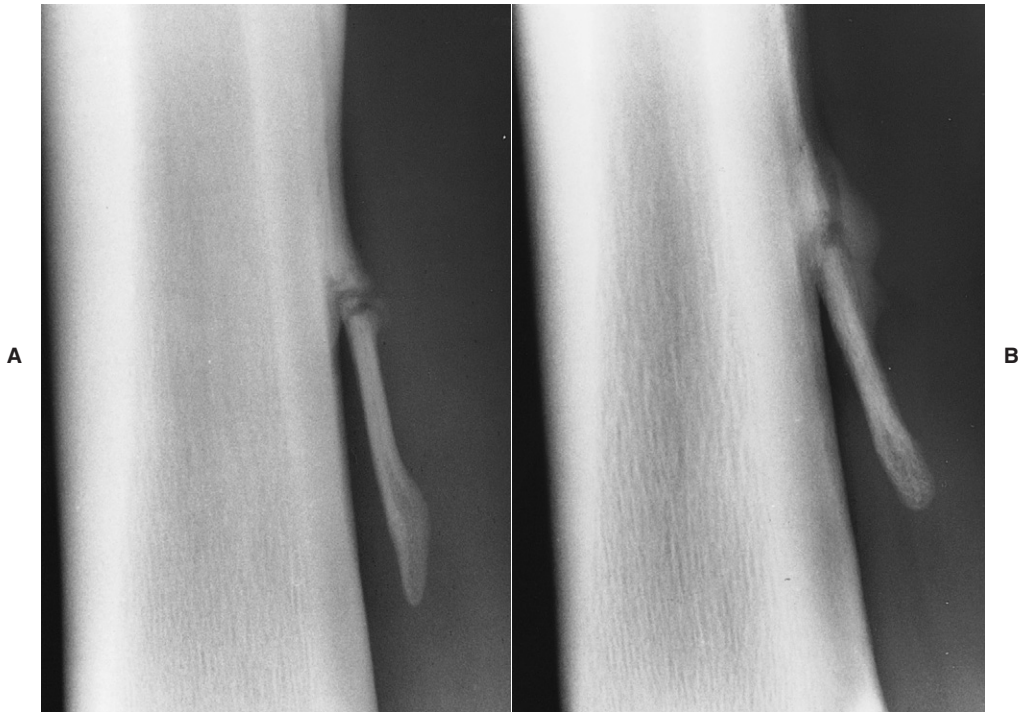

Fig. 38-10 **A,** Dorsomedial-palmarolateral oblique radiographic view of the second metacarpal bone of 7-year-old Thoroughbred steeplechaser. There is a complete, displaced fracture at the junction between the middle and distal one thirds of the bone. The axial deviation of the bone indicates previous distortion of the bone in association with desmitis of the medial branch of the suspensory ligament. Some endosteal and periosteal callus is present. **B,** Dorsomedial-palmarolateral aspect of the second metacarpal bone of an endurance pony. There is a healing fracture of the second metacarpal bone, associated with desmitis of the medial branch of the suspensory ligament.

confined to box rest. Only a small amount of callus develops, which subsequently remodels (Fig. 38-10, *B*). Small radiolucent defects may persist because of incorporation of fibrous tissue. If a fracture is moderately displaced, a larger amount of callus may develop, or a thick layer of fibrous tissue may be laid down, which envelops the entire distal aspect of the metacarpal bone. A large exostosis may impinge on the SL. Surgical removal of these fragments is therefore recommended. The convalescent program is dictated by the degree of suspensory desmitis. Prognosis is better in Standardbreds than in Thoroughbreds.

Fractures Caused by External Trauma

Fractures of McII or McIV caused by external trauma may be simple or comminuted, open or closed.

Clinical signs Lameness is acute in onset and is associated with soft tissue swelling around the fracture site, heat, and pain. An open wound may be present. Thorough debridement, cleaning, and lavage of open wounds are important to minimize the risks of infection.

Diagnosis Radiographic examination is essential to determine the precise position and nature of the fracture (Fig. 38-11). If the fracture is chronic or associated with an open wound, the radiographs should be appraised carefully for evidence of infectious osteitis.

Treatment Fractures involving the proximal one third of the bone may require surgical stabilization of the bone to prevent carpal instability, especially if the fracture involves McII. Insertion of small plates with screws into McII without traversing the interosseous space is the preferred method of management. Alternatively, screws placed between McII and McIII can be used, but fixation may be unstable, and chronic lameness could develop because of synostosis between the two bones or reaction from the implants themselves. When horses have simple displaced or comminuted fractures of McII or McIV, but with infection, all efforts should be made to resolve infection before surgical fixation is attempted. However, if the fracture is comminuted and the carpus appears to be stable, conservative management may be satisfactory. Simple or more complicated fractures in the distal two thirds of the bone can be treated either conservatively or by surgical removal, depending on the size of the pieces and their location.

Fig. 38-11 Dorsolateral-palmaromedial oblique radiographic view of the metacarpal region. There is a comminuted, displaced articular fracture of the proximal third of the fourth metacarpal bone. The fracture was repaired surgically using a small plate, but osteoarthritis of the carpometacarpal joint developed subsequently.

DIFFERENTIAL DIAGNOSIS OF DIFFUSE FILLING IN THE METACARPAL REGION

Diffuse filling in the metacarpal region, with or without stiffness or lameness, is common. The clinician makes a diagnosis of the cause through review of the history of the horse and careful clinical examination. (Box 38-1).

The clinician should assess the following points:
- Is the swelling symmetrical, or does it predominantly involve only one side of the limb?
- Does swelling extend the entire length of the metacarpal region, or only part of it?
- Has any filling occurred in the pastern region, or the carpus and proximally?
- Does the palmar aspect of the limb have a straight contour?
- Is the swelling edematous?
- What is the intensity of the digital pulses?
- Is the limb hot or cold?
- Is the horse febrile?
- Is the horse bright and alert, or depressed?
- Is more than one limb involved?
- Are any skin lesions apparent?
- What color is the limb?
- Is the horse sound, stiff or lame?
- What is the intensity of lameness?
- Is each anatomical structure palpable?
- Is each structure intact and of normal size and shape?
- Does palpation of a specific structure elicit pain?

Hemorrhage

Hemorrhage in the proximal metacarpal region is an occasional cause of acute-onset, severe lameness during work. Extensive soft tissue swelling rapidly develops, mimicking a severe tear of the ALDDFT. The swelling makes it difficult to palpate accurately specific structures. However, ultrasonographic examination reveals no detectable structural abnormality of the flexor tendons and the ALDDFT. Application of a large support bandage and treatment with non-steroidal anti-inflammatory drugs brings rapid relief. The bandage should be maintained and changed as needed for approximately 7 to 10 days. When the bandage is removed, the limb is usually of normal contour. The limb should be re-examined by ultrasonography to confirm that no structural abnormalities exist before allowing the horse to resume normal work. The cause of this condition is unknown and the likelihood of recurrence is small.

Thrombosis

Thrombosis of the medial palmar vein is a rare cause of lameness in the horse. Partial thrombosis may result in periodic diffuse filling of the distal limb associated with lameness. Complete occlusion may result in severe lameness and distal limb swelling soon after starting any exercise. Diagnosis is based on careful palpation of the vasculature combined with ultrasonography, including Doppler. Treatment requires vascular surgery.

Infection of Tendons

Infection of the SDFT or DDFT, without any evidence of a penetrating wound, is an unusual cause of lameness, but unless infection is recognized early and treated aggressively, it can have catastrophic consequences.[20]

Clinical Signs Sudden-onset, severe unilateral lameness involves a forelimb or a hindlimb. Frequently this follows within 24 hours of strenuous exercise. The horse is usually reluctant to bear weight on the limb, and effective control of pain can be difficult. Considerable peritendonous edema develops rapidly, precluding accurate palpation of the flexor tendons. Palpation reveals localized heat and exquisite pain. The skin may become tight, and if the infection is unrecognized and untreated, within several days pus may exude through defects in the skin.

Diagnosis Ultrasonographic evaluation reveals a central anechoic defect within the infected tendon (Fig. 38-12) that progresses rapidly and may within a few days extend the length of the metacarpal or metatarsal region. In the early stages lameness may be disproportionately severe relative to the perceived amount of tendon damage. Bacterial culture has frequently yielded a coagulase-positive *Staphylococcus*.

Treatment Aggressive systemic antimicrobial therapy with crystalline penicillin, gentamicin, and metronidazole has usually proved inadequate, with progression of tendon destruction despite therapy. Drainage of pus and lavage combined with antimicrobial therapy has successfully controlled infection in some, but not all, horses. However, the prognosis for return to athletic function is extremely guarded.

Box • 38-1

Differential Diagnosis of Diffuse Filling in the Metacarpal Region

- So-called cold edema
- Cellulitis
- Edema and inflammatory reaction associated with a sub-solar abscess
- Scabby skin lesions on the palmar aspect of the fetlock
- Mud fever
- Lymphangitis
- Purpura hemorrhagica
- Hemorrhage
- Filling caused by direct trauma
- Tendonous or ligamentous injury
- Thrombosis
- Fracture
- Equine viral arteritis
- Infection of a tendon
- Infection of the digital flexor tendon sheath
- Photosensitization
- Hypertrophic osteopathy

Fig. 38-12 Transverse ultrasonographic image of the palmar metacarpal region. There is extensive subcutaneous edema. The superficial digital flexor tendon has a large anechoic region extending through the dorsal and palmar borders that progressed rapidly. The horse had extensive peritendonous soft tissue swelling and severe lameness associated with the infected tendon.

Cellulitis, Skin Necrosis, and Necrosis of the Superficial Digital Flexor Tendon after Topical Applications

Cellulitis, skin necrosis, and subsequent necrosis of the SDFT are poorly understood conditions. The syndrome has been recognized in National Hunt racehorses.[21] After racing, many horses receive a topical application of a clay-like substance to the metacarpal regions, with or without overlying bandages.

Clinical Signs Clinical signs are apparent within 24 to 72 hours and include peritendonous edema and serum ooze progressing to skin slough and exposure of the SDFT. The tendon may also be affected, without evidence of pre-existing strain-type injury. Lameness varies from moderate to severe. The condition may be unilateral or bilateral. The horse may have had the same topical application previously, but not necessarily so. Frequently other horses have been treated with the same batch of the proprietary clay-like substance with no adverse effects. A variety of different proprietary products have been incriminated. Curiously, to my knowledge, the condition has not been seen in event horses, although many receive similar treatments after competing.

Treatment The condition usually progresses to a huge area of skin loss on the palmar aspect of the metacarpal region, with or without major damage to the underlying SDFT. No therapy has successfully halted this progression. Healing is by granulation tissue and fibrosis. If the horse survives, it has a massively thickened limb, and most horses have not been returned to racing.

Cellulitis Associated with Superficial Digital Flexor Tendonitis

Cellulitis sometimes occurs with superficial digital flexor tendonitis. Clinical signs are usually recognized within 24 to 48 hours after competition. The horse has diffuse filling in the metacarpal region(s), and within several days pinpoint pricks appear in the skin through which serum oozes. The horse may be slightly lame or have a stiff gait. Symptomatic therapy usually resolves the majority of filling and lameness, and without careful inspection a primary tendon injury may go unrecognized. Careful ultrasonographic evaluation is mandatory, because almost invariably primary tendonitis is present. Care should be taken in the presence of significant subcutaneous edema, because acoustic enhancement may mask a subtle tendon lesion. Such horses should be re-evaluated after resolution of the edema.

Enostosis-like Lesions

Enostosis-like lesions are focal areas of new bone formation within the medullary cavity of a bone, occurring on the endosteal surface or close to a nutrient foramen. They occasionally occur in McIII and may be single or multiple. They can occur as incidental radiographic abnormalities or in association with lameness. Nuclear scintigraphy may reveal increased uptake of ^{99m}Tc-MDP at the site of these lesions, but this does not necessarily imply that associated pain exists. Clinical significance can only be ascribed by eliminating all other sources of pain.

Hypertrophic Osteopathy

Hypertrophic osteopathy, or Marie's disease, frequently involves the metacarpal region, resulting in localized or diffuse soft tissue swelling that overlies new bone formation.[22] Hypertrophic osteopathy has been associated with thoracic disease, a variety of vascular lesions, granulomatous enteritis, and some tumors in the thorax and abdomen. Identification of the primary lesion and successful treatment may result in resolution of the bony lesions and associated clinical signs.

Clinical Signs

The acute stage of hypertrophic osteopathy produces heat and edematous swelling overlying areas of new bone formation. Palpation of the affected bones produces pain. All the limbs should be inspected carefully to establish the extent of the lesions. Depending on the limbs affected, the horse may show overt lameness or generalized stiffness.

Although careful clinical appraisal of the entire horse may reveal clinical signs of an underlying disease process, often no clues are present. Clinical evaluation should include palpation of all lymph nodes, auscultation of the heart and lungs, and rectal examination.

Diagnosis

Radiographic examination, using soft exposures, reveals palisading periosteal new bone in the diaphyseal and metaphyseal regions of McIII and other affected bones but usually excluding the joints (Fig. 38-13). The palisading new bone, perpendicular to the cortices, is pathognomonic.

Every effort should be made to try to define the primary causal lesion. Additional diagnostic tests should include thoracic radiography and echocardiography, examination of a tracheal aspirate and peritoneal fluid, and routine hematological and clinical biochemistry testing. If weight loss is evident, an oral glucose tolerance test should be performed to assess small intestinal absorption of disaccharide sugars. A labeled white blood cell nuclear scintigraphic examination of the thorax and abdomen may be helpful. Skin biopsies may reveal evidence of vasculitis.

Treatment

If the primary cause of the condition can be identified and successfully treated, then the bony lesions will resolve spontaneously. The new bone becomes progressively more radiopaque and corticalized and gradually models to restore a more normal contour. Occasionally lesions have resolved spontaneously after treatment with phenylbutazone.

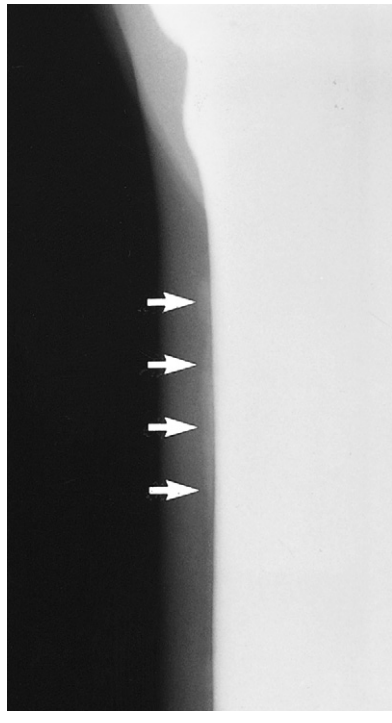

Fig. 38-13 Dorsolateral-palmaromedial oblique radiographic view of the proximal metacarpal region, using soft exposure factors to show palisading new bone *(arrows)* on the dorsal aspect of the third metacarpal bone typical of hypertrophic osteopathy. The 7-year-old breeding stallion had avian tuberculosis and was successfully treated, with the bony lesions resolving.

Osteitis or Osteomyelitis

Infectious osteitis or osteomyelitis occurs commonly in the metacarpal region because of the relative lack of soft tissue coverage of the bones and is usually a sequel to known trauma, with or without an open wound.

Clinical Signs

There is localized soft tissue swelling and mild to moderate lameness, and usually a draining tract is apparent.

Diagnosis

Ultrasonographic evaluation reveals an anechogenic region adjacent to the bone in the acute stage, and the accumulation of pus, before radiographic changes are evident. Radiographic abnormalities may include a radiolucent region within the cortex of the bone, periosteal new bone, and in horses with advanced infection, a sequestrum and involucrum (Fig. 38-14).

Treatment

Aggressive antimicrobial therapy sometimes successfully resolves the infection, but in horses with advanced sequestration, surgical debridement is indicated.

USE OF BOOTS AND BANDAGES TO PREVENT INJURY

The use of stable bandages, protective boots and bandages for exercise, and proprietary clays and cooling agents after exercise is common among horse owners in their efforts to protect horses from injury and to help to manage pre-existing injuries. Bandages that are applied too tightly have tremendous potential to cause local damage, not only to the underlying skin on the dorsal and palmar aspects of the metacarpal region, but also to the underlying tendons. The mid-metacarpal region appears to be particularly vulnerable. Transient (a few hours') application of an overly tight bandage results in a "bandage bow," localized subcutaneous edema overlying the SDFT. More prolonged application of a bandage that is too tight results in hair loss and skin necrosis. Hair that regrows is white. Excessive sustained pressure causes tendon necrosis.

Fig. 38-14 Dorsolateral-palmaromedial oblique view of the metacarpal region. A lucent zone (an involucrum) surrounds a separate radiopaque fragment within the fourth metacarpal bone (a sequestrum). Periosteal new bone appears on the diaphysis of the fourth metacarpal bone, through which is a lucent canal (a cloaca).

Persistent bandaging at appropriate pressures does not cause damage but leaves permanent rings in the hair; if these rings are visible at a prepurchase examination, they should alert the veterinarian that the horse usually stands in bandages. Properly applied stable bandages can be used to control filled legs and in horses prone to distention of the fetlock joint capsule or the digital flexor tendon sheath.

The use of bandages or boots during exercise is somewhat controversial. A properly applied bandage should aim to permit a normal range of motion, but protect against movement in an abnormal range. Little evidence exists that a bandage applied circumferentially around the limb reduces loads on the flexor tendons and thereby reduces the risk of over-stretch injury. Studies on cadaver models have shown that distal limb bandages may increase the amount of energy a limb can absorb during repeated loading.[23,24] Strain on the proximal aspect of the SL may be decreased in a standing or walking horse.[25] In exercising horses, fetlock extension was reduced.[26] However, shock attenuation was unaffected.[27] The effectiveness of stabilizing support bandages in people decreases rapidly with exercise, and in healthy athletes restriction in motion may have an adverse effect on performance. In exercising horses the core temperature within the SDFT increases substantially, and although the role of temperature in tendon injury remains uncertain, bandaging has the potential to promote heating. Therefore little current rationale exists for use of bandages or boots to prevent tendon strain injuries.

Boots and bandages have the potential to attenuate forces from direct trauma to the limb, for example, as the result of a horse hitting a fixed fence. However, without reinforcement, none properly protects against strike injuries from the hindlimb of the same horse or from strike injuries from adjacent horses. Such strike injuries can result in severe tendon injuries. The introduction of a more resilient bullet-proof type of material into part of a boot, or applied as a palmar reinforcement under a bandage, can provide some protection against these devastating injuries, but the effect of such rigid material on normal movement of the flexor tendons is not known.

Carpus

Mike W. Ross

ANATOMY

The carpus comprises the antebrachiocarpal, middle carpal, and carpometacarpal joints. The antebrachiocarpal and middle carpal joints are considered gingylmi, but they are not typical of hinge joints; the carpometacarpal joint is arthrodial.[1] Arthrodial joints also exist between carpal bones in each respective row. Effective movement of the carpus originates from the antebrachiocarpal and middle carpal joints. The carpometacarpal joint does not open, but it is subject to shear stress. The antebrachiocarpal joint lies between the distal radius and proximal row of carpal bones. The distal, dorsal aspect of the radius has deep grooves in which run the tendons of the extensor carpi radialis and common digital extensor muscles. In flexion the tendons compress the dorsal aspect of the antebrachiocarpal joint, limiting visibility when performing arthroscopic examination. The proximal row includes the accessory carpal bone that articulates with the distal radius and the ulnar carpal bone. The accessory carpal bone forms the lateral border of the carpal canal. From lateral to medial, the ulnar carpal, the intermediate carpal, and the radial carpal bones complete the proximal row.

The middle carpal joint lies between the proximal and distal row of carpal bones. The number of bones in the distal row varies but always includes from medial to lateral, the second, third, and fourth carpal bones. A first carpal bone is present unilaterally or bilaterally in approximately 50% of horses[1] and should not be mistaken on radiographs for an osteochondral fragment. The first carpal bone articulates with the second metacarpal bone (McII) and the second carpal bone, and its presence is often associated with radiolucent areas in McII. A fifth carpal bone is rare, but if present is small, articulates with the fourth carpal bone and the proximal aspect of the fourth metacarpal bone (McIV), and can be confused with an osteochondral fragment. The second, third , and fourth carpal bones articulate with McII, the third metacarpal

CHAPTER • 39

Carpus

Mike W. Ross

ANATOMY

The carpus comprises the antebrachiocarpal, middle carpal, and carpometacarpal joints. The antebrachiocarpal and middle carpal joints are considered gingylmi, but they are not typical of hinge joints; the carpometacarpal joint is arthrodial.[1] Arthrodial joints also exist between carpal bones in each respective row. Effective movement of the carpus originates from the antebrachiocarpal and middle carpal joints. The carpometacarpal joint does not open, but it is subject to shear stress. The antebrachiocarpal joint lies between the distal radius and proximal row of carpal bones. The distal, dorsal aspect of the radius has deep grooves in which run the tendons of the extensor carpi radialis and common digital extensor muscles. In flexion the tendons compress the dorsal aspect of the antebrachiocarpal joint, limiting visibility when performing arthroscopic examination. The proximal row includes the accessory carpal bone that articulates with the distal radius and the ulnar carpal bone. The accessory carpal bone forms the lateral border of the carpal canal. From lateral to medial, the ulnar carpal, the intermediate carpal, and the radial carpal bones complete the proximal row.

The middle carpal joint lies between the proximal and distal row of carpal bones. The number of bones in the distal row varies but always includes from medial to lateral, the second, third, and fourth carpal bones. A first carpal bone is present unilaterally or bilaterally in approximately 50% of horses[1] and should not be mistaken on radiographs for an osteochondral fragment. The first carpal bone articulates with the second metacarpal bone (McII) and the second carpal bone, and its presence is often associated with radiolucent areas in McII. A fifth carpal bone is rare, but if present is small, articulates with the fourth carpal bone and the proximal aspect of the fourth metacarpal bone (McIV), and can be confused with an osteochondral fragment. The second, third , and fourth carpal bones articulate with McII, the third metacarpal

bone (McIII), and fourth metacarpal bone (McIV), respectively. The articulation of the second carpal bone and McII is broader than is that of the fourth carpal bone and McIV, and hence McII receives greater load, an important fact to consider with fractures of McII and McIV. The third carpal bone, the largest bone in the distal row, has two fossae separated by a distinct ridge, the intermediate (lateral) and radial (medial). The radial fossa is largest, receives greater load, and is more commonly injured. The third carpal bone is L-shaped and has a large, dense palmar portion that is rarely injured.

The carpal bones are held together by intercarpal ligaments: the dense palmar carpal ligament from which the accessory ligament of the deep digital flexor tendon arises, the long and short medial and lateral collateral ligaments that originate on the radius and attach to the proximal aspects of McII and IV, and the abaxial surface of the carpal bones, respectively. The collateral ligaments provide the major resistance to dorsal displacement of the proximal row of carpal bones. The strong intercarpal ligaments play a major role in stability, and the palmar intercarpal ligaments were shown to provide more resistance to extension of the carpus than does the palmar carpal ligament.[2] When large medial and lateral corner osteochondral fragments of the third carpal bone are removed, the intercarpal ligaments and capsular attachments must be incised. These dense attachments provide stability that can be advantageous when repairing slab fractures. The dorsomedial intercarpal ligament courses between the medial aspect of the second carpal bone and the dorsomedial aspect of the radial carpal bone,[3] but during arthroscopic examination it appears to blend with the joint capsule. A theory was proposed that the dorsomedial intercarpal ligament became hypertrophied and impinged on the articular surface of the radial carpal bone, causing secondary modeling in young racehorses and lameness.[4] Recent studies of normal carpi found that the dorsomedial intercarpal ligament was neither hypertrophied nor impinging on the radial carpal bone. A definite relationship exists between the development of pathological conditions on the distal radial carpal bone and the attachment of the dorsomedial intercarpal ligament, but I have not observed hypertrophy or impingement. The majority of radial carpal bone osteochondral fragments occur within or just lateral to the attachment site of the dorsomedial intercarpal ligament. Because the dorsomedial intercarpal ligament resists dorsomedial displacement of the radial carpal bone,[3] this site is prone to develop osteochondral fragments. In abnormal carpi, hypertrophy of the dorsomedial intercarpal ligament was apparent, but no correlation existed between hypertrophy and cartilage or subchondral bone damage.[5]

The medial and lateral palmar intercarpal ligaments resist displacement and dissipate axial forces by allowing abaxial translation of carpal bones.[6,7] Whereas the collateral ligaments provided the majority of resistance to dorsal displacement of the carpus during experimental loading, the small but important palmar intercarpal ligaments contributed 23% resistance.[2] The lateral palmar intercarpal ligament mostly attaches proximally on the ulnar carpal bone and distally on the third carpal bone and may be divided,[3] findings different from those previously reported that the distal attachment was mostly on the fourth carpal bone.[8] The medial palmar intercarpal ligament has four bundles that vary in size, and it courses between the radial carpal bone proximally and the palmaromedial surface of the third carpal bone and palmarolateral surface of the second carpal bone distally.[3] Tearing of the medial palmar intercarpal ligament and to a lesser extent the lateral palmar intercarpal ligament was observed in horses with carpal disease and was recently proposed to be associated with cartilage and subchondral bone damage (see the following discussion).[8,9]

The carpus has a dense joint capsule dorsally that blends with the overlying fascia and retinaculum. Synovium in young horses is often thickened or folded dorsally in the middle carpal joint and can interfere with visibility during arthroscopic surgery. This fold appears to smooth as horses age or as osteoarthritis develops. The antebrachial fascia blends with the retinaculum that functions to restrain extensor tendons. Retinaculum thickens and forms the medial and palmar borders of the carpal canal. The palmar retinaculum is sometimes severed in horses with carpal tenosynovitis and tendonitis (see Carpal Canal, Chapter 76). Anatomical considerations and flexor and extensor tendons injuries are discussed elsewhere (see Chapters 70 and 78). The sheathed extensor carpi radialis and common digital extensor tendons, located dorsal and dorsolaterally, respectively, limit carpal palpation and restrict access. Cul-de-sacs of distended antebrachiocarpal and middle carpal joint capsules can be palpated medial to the extensor carpi radialis tendon or between the extensor carpi radialis and common digital extensor tendons in the standing horse. Athrocentesis and arthroscopic examination require careful placement of needles and instruments in these portals to avoid injury to tendons and sheaths. These portals can be easily felt as distinct depressions when the carpus is flexed. The sheathed lateral digital extensor tendon, located on the lateral aspect, should be avoided during arthrocentesis of the palmarolateral pouches. The sheathed extensor carpi obliquus tendon is small and passes obliquely over the antebrachiocarpal joint from lateral to medial to attach to McII. This tendon can readily be seen medially during arthroscopic examination of the antebrachiocarpal joint. Extensor tenosynovitis must be differentiated from middle carpal and antebrachiocarpal joint effusion and hygroma.

Knowledge of the communications and boundaries of the carpal joints is important in understanding the extent of disease processes and the results of diagnostic analgesia (see Chapter 10).The antebrachiocarpal joint is considered solitary, although in a single specimen in a cadaver study the joint communicated with the middle carpal and carpometacarpal joints.[10] In some horses a communication appears between the antebrachiocarpal joint and the carpal sheath. The middle carpal and carpometacarpal joints always communicate. Communication between the middle carpal and carpometacarpal joints and the carpal sheath is rare (see Fig. 10-4). The carpometacarpal joint has distinct distopalmar outpouchings located axial to McII and McIV that have secondary pouches interdigitating within the proximal aspect of the suspensory ligament (SL). These outpouchings explain inadvertent analgesia of the carpometacarpal and middle carpal joint during performance of high palmar analgesia and possibly why lameness abates during middle carpal analgesia in horses with avulsion fractures of McIII or proximal suspensory desmitis.[11]

CONFORMATION

Racehorses, especially Thoroughbreds (TBs), with offset-knee (bench-knee) and back-at-the-knee (calf-knee) conformation are predisposed to develop carpal lameness. Mild in-at-the-knee (carpus valgus) deformity is common and of little concern, but if the deformity is severe, it can predispose to carpal lameness similar to that in horses with out-at-the-knee (carpus varus) conformation (see Chapter 4).

CLINICAL CHARACTERISTICS AND DIAGNOSIS OF CARPAL LAMENESS

Carpal lameness is a common finding in many sport horses, but it is most common in racehorses. Former racehorses used in other disciplines may suffer from chronic osteoarthritis or have recurrence of osteochondral fragmentation. Primary carpal

lameness in non-racehorses occurs from trauma such as from falls, kick wounds, and hitting fences; hyperextension injury resulting in fractures of the accessory carpal bone; and occasionally primary osteoarthritis. Old horses appear prone to develop inexplicable chronic, often severe osteoarthritis of the carpometacarpal joint. Few historical facts are pathognomonic for carpal lameness except if severe swelling and lameness develop acutely or a trauma is observed. TB racehorses may lug (bear) in, lug out, or fail to change leads. A Standardbred (STB) racehorse may be on a line. Horses may be racing poorly, particularly those with bilaterally symmetrical lameness. In racehorses with right forelimb carpal lameness, signs may be worse on the turns. Although most STBs are on the ipsilateral line, rarely a horse with right forelimb carpal lameness will be on the left line, presumably because the horse is bearing away from medially located pain or has a shortened stride in the right forelimb. Non-racehorses may have poor performance, fail to change leads, and hit or refuse fences.

Degree of lameness varies with the type and severity of carpal injury. Horses with early or mild, chronic osteoarthritis have mild lameness, whereas those with acute osteochondral fragments, slab fractures, or other more serious injuries have more severe lameness. Horses with infectious arthritis and comminuted carpal or other severe fractures may not bear weight at the walk. Lameness may be intermittent in horses with early and incomplete osteochondral fragments and may be apparent only after training or racing. Racehorses with bilaterally symmetrical lameness may not show overt lameness but have a wide, short gait bilaterally. Advancing and placing the affected limb wide while walking or trotting (pacing) is typical of carpal lameness (see Chapter 7). Horses with severe osteoarthritis and natural carpal ankylosis or surgical arthrodesis swing (abduct) the limb because the carpus cannot flex. Advancement and placement of the limb in a lateral (abducted) position is not pathognomonic for carpal lameness, and horses with proximal palmar metacarpal pain or those with pain originating laterally in the digit may manifest similar signs. However, carpal tenosynovitis does not result in this typical carpal gait. Horses with carpal lameness have a shortened cranial phase of the stride. Lameness can be worse with the limb on the inside or outside of the circle depending on whether the location of pain is medial or lateral, but in general lameness in most horses with carpal lameness is worse with the limb on the *outside* of the circle.

Increased temperature (heat) over the dorsal surface of the carpus is a reliable indicator of carpal disease, but false positive and negative findings occur. If horses have been clipped for painting or blistering, or effects of topical counterirritation are still present, the area can be warm and sensitive without carpal lameness. The dorsal surface of each carpus should be evaluated and compared, but differences are difficult to detect if lameness is bilateral. Effusion is usually a reliable indicator for carpal synovitis, but it is not pathognomonic for carpal lameness. Horses with subchondral bone injury without overlying cartilage damage or incomplete osteochondral fragments often have carpal lameness without effusion. Effusion is suppressed in horses that have recently had corticosteroid injections. Effusion occurs commonly in young horses with early carpitis and in horses with advanced cartilage damage, osteochondral fragments, and infectious arthritis. With the horse's limb in a weight-bearing position, the clinician's fingers are used to ballot fluid between extensor tendons. Older horses with chronic carpal changes often have mild or moderate effusion but can perform satisfactorily.

Horses with acute carpal lameness, especially those with synovitis, often show a marked response to static flexion of the carpus. Horses with carpal tenosynovitis or other palmar carpal lameness also respond. Horses with pain from the proximal limb, such as myositis in the proximal antebrachium or elbow region pain, respond to carpal flexion (false-positive response). Static and dynamic flexion can be negative in horses with carpal lameness, especially in those with subchondral bone pain. Degree of flexion is usually decreased in horses with chronic osteoarthritis because of joint capsule fibrosis. Careful palpation of all bony and soft tissue structures of the carpal region should be performed with the limb in standing and flexed positions, and responses should be compared with the contralateral limb. Swellings are best felt with the horse's limb in a standing position. Swellings of nearby sheaths should be differentiated from authentic carpal effusion by location and ballottement. Horses with chronic osteoarthritis often have firm, fibrous thickening at joint capsule attachments. Dorsomedial bony swelling of the radial and third carpal bones is observed and palpated in horses with chronic severe osteoarthritis. The proximal aspect of McII and McIV should be palpated for bony and soft tissue swelling associated with fracture or exostoses. The proximal palmar metacarpal region should be palpated with the horse in the standing and flexed positions to differentiate pain in this region from carpal pain.

In my experience, the carpal flexion test is the most specific of any flexion test used, and if the test result is positive, carpal pain is highly probable. A negative test result does not rule out carpal pain. Horses with subchondral bone pain, usually young racehorses with sclerosis of the third carpal bone, often have a negative or equivocal response to flexion. Horses with palmar metacarpal or elbow pain can respond positively.

Diagnostic Analgesia

In many horses, clinical signs and characteristic gait may allow a tentative diagnosis of carpal lameness, but in most horses diagnostic analgesia should be performed. Analgesia of the middle carpal and antebrachiocarpal joints should be performed independently and sequentially. Dorsal intra-articular techniques are most common, but in horses with scurf from previous counterirritant application or dorsal wounds, the palmarolateral pouches are used. Careful selective perineural and intra-articular analgesic techniques should be performed to differentiate between proximal palmar metacarpal pain and authentic carpal pain (see Chapter 10). Intra-articular analgesic techniques are highly specific, but false-negative results may occur.[12] Subchondral bone pain may not always be eliminated by intrasynovial deposition of local anesthetic solution, because nerve fibers may be located in bone or travel to the site by another extrasynovial route. The median and ulnar nerve block, although lacking specificity, is useful in horses with suspected carpal region pain that is not abolished by intra-articular techniques.

Laboratory analysis of synovial fluid is reserved for horses in which acute inflammation or infectious arthritis is suspected, but color and viscosity should be evaluated, and abnormalities may help to convince an owner or trainer of a carpal problem. In a normal flexed carpus, fluid does not readily drain from a small-gauge needle, and compression of the joint capsule at a distant site is usually necessary. Horses with effusion have thin synovial fluid that drips spontaneously without compression of the nearby capsule. Horses with true serosanguineous (as opposed to contamination by capsular or synovial vessels) fluid likely have cartilage damage with exposed subchondral bone or an osteochondral fragment. Hemarthrosis can be caused by trauma or bleeding from a torn intercarpal ligament.

Imaging

Radiography

A minimum of six well-exposed and positioned radiographic views are necessary for comprehensive examination of the carpus, including the dorsopalmar (DPa), lateromedial (LM),

dorsal 45° lateral-palmaromedial oblique (DL-PaMO), dorsal 45° medial-palmarolateral oblique (DM-PaLO), and flexed lateromedial views and the dorsoproximal-dorsodistal (tangential, skyline) view of the distal row of carpal bones. The skyline view is most important for assessing subtle radiographic changes of the third carpal bone, but well-positioned views are often difficult to obtain. Evaluation of the radial fossa requires flexion of the limb in the sagittal plane with the metacarpal region beneath the antebrachium (Fig. 39-1). Lateral positioning of the distal part of the limb results in overlap of the radial fossa of the third carpal bone and the radial carpal bone. The skyline view underestimates the amount of sclerosis of the third carpal bone and magnifies normal anatomy and lesions approximately twofold.[13] The skyline view is not a true proximal to distal view of the second, third, and fourth carpal bones, and therefore lesions located palmar to the dorsal edge of the radial carpal bone cannot be seen. The skyline view cannot be used to evaluate fracture lines located more than 8 to 10 mm from the dorsal edge of the third carpal bone or to differentiate large osteochondral fragments from frontal slab fractures of the third carpal bone. Additional views, such as the tangential view of the proximal row of carpal bones (used to identify osteochondral fragments and unusually located frontal or sagittal slab fractures), flexed oblique views (e.g., DL-PaMO view with the limb held in flexion to evaluate the articular surfaces of the third and radial carpal bones), and weight-bearing, oblique views of different obliquity (e.g., off DPa views, used to identify sagittal slab fractures of the third carpal bone) are sometimes useful. Considerable confusion arises in description of oblique views, with the use of terms *lateral* and *medial oblique*, instead of naming the views according to the direction of the radiographic beam. To most clinicians, the lateral oblique is equivalent to a DL-PaMO view, but to others it is just the opposite. Follow-up radiographic examination is recommended in 10 to 14 days if fracture is suspected but initial radiographic findings are negative or equivocal.

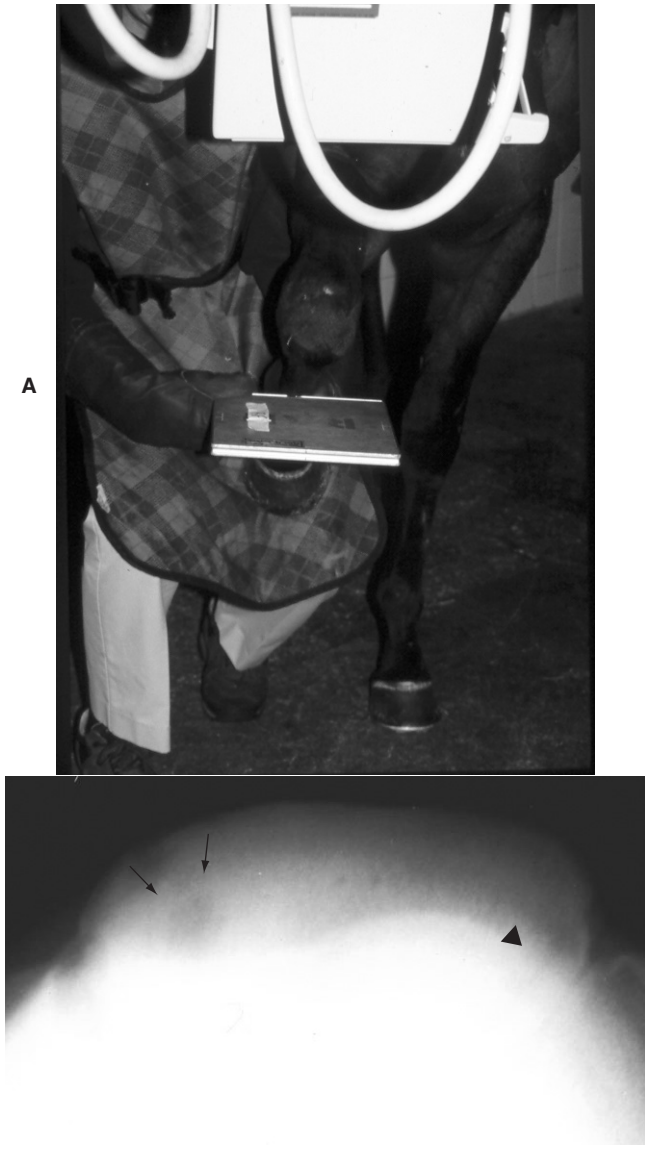

Fig. 39-1 **A,** A well-positioned skyline radiographic view of the distal row of carpal bones requires that the third metacarpal bone be aligned directly under the radius. This makes the radial facet visible. **B,** Resulting radiographic projection shows radial and intermediate (right) facets of the third carpal bone. Sometimes overlap of the normal articulation between the third and fourth carpal bones appears as a linear radiolucent defect *(arrowhead)* in the lateral aspect of the third carpal bone, a finding confused with sagittal fracture of that bone. There is a subchondral lucency of the third carpal bone (round radiolucent defect deep within the radial fossa; *arrows*) and a marginal defect of the bone.

Normal radiographic anatomy of the carpus is difficult because carpal bones overlap considerably, bones shift during flexion, and normal radiolucent defects and aberrant carpal bones can be difficult to interpret. In the skyline view of the distal row, the normal articulation between the third and fourth carpal bones and can be superimposed on the lateral aspect of the third carpal bone and confused with a sagittal fracture (Fig. 39-1, B). On a DM-PaLO view the normal articulation between the second and third carpal bones should not be confused with a sagittal slab fracture, but this view is essential to diagnose sagittal fracture of the third carpal bone correctly, which runs parallel to this articulation. Radiolucent defects or osseous cyst-like lesions are often seen in the ulnar carpal bone and are considered incidental findings, but when they appear in other bones, they can cause lameness regardless of whether communication with a joint exists. In LM and oblique views, the first and fifth carpal bones can be confused with osteochondral fragments. Radiolucent defects in McII and McIV often occur in the presence of the first and fifth carpal bones but are normal (Fig. 39-2). In the flexed LM view the radial carpal bone moves distally relative to the intermediate carpal bone. This normal finding is quite useful in determining the exact positioning of osteochondral fragments or other lesions on the proximal or distal surfaces of the radial and intermediate carpal bones. Xeroradiography and computed radiography are available at some institutions and practices and can be useful for diagnosing centrally located carpal pathological conditions, although xeroradiographs may not depict marginal changes as well as plain films because of edge enhancement. Computed tomography and magnetic resonance imaging (MRI) would be most useful to determine precise diagnosis and location of bone and soft tissue injuries, but availability is currently limited. Ultrasonographic examination of the carpus can be useful to determine the extent of soft tissue damage, if wounds or fistulous tracts communicate with carpal joints, and for diagnosis of extensor and flexor tendon injury, carpal tenosynovitis, and desmitis.

Scintigraphy

Scintigraphy is especially useful to diagnose early stress-related subchondral bone injury and differentiate carpal lesions from those of the proximal metacarpal region. A common finding in young racehorses is carpal lameness localized by clinical signs and diagnostic analgesia with negative or equivocal radiological abnormalities. Focal areas of increased

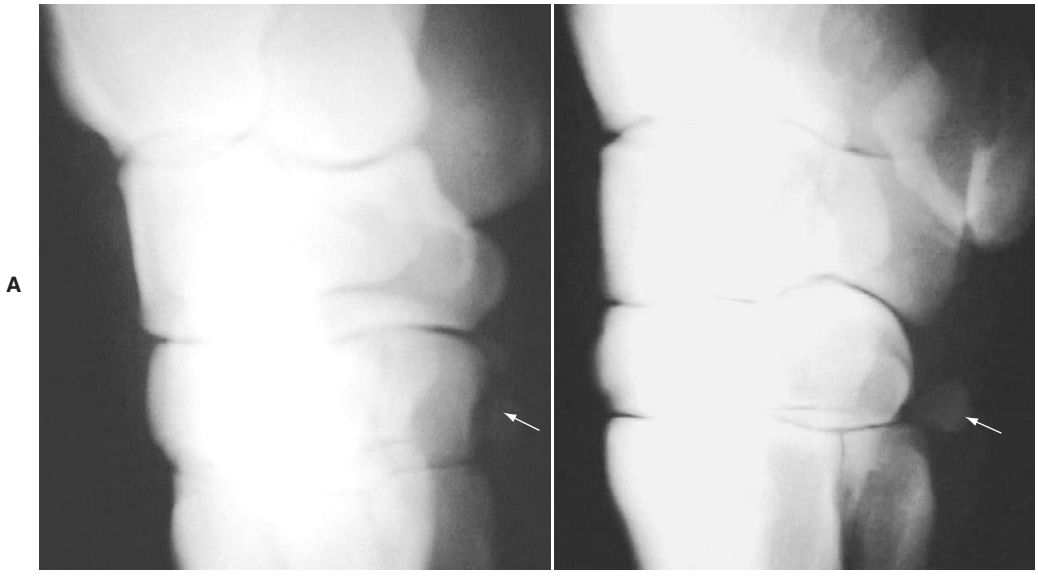

Fig. 39-2 **A,** Dorsomedial-palmarolateral oblique radiographic view of a carpus. A first carpal bone is present *(arrow)*. Note also the lucent zones in the second carpal bone and in the proximopalmar aspect of the second metacarpal bone. Such lucent areas are often seen as incidental findings in the presence of a first carpal bone. **B,** Dorsolateral-palmaromedial oblique radiographic view of a carpus. A fifth carpal bone is present *(arrow)*. Note the lucent area in the proximal aspect of the fourth metacarpal bone. The first and fifth carpal bones should not be confused with osteochondral fragments.

radiopharmaceutical uptake (IRU) are often found unilaterally or bilaterally, most commonly in the third carpal bone (see Fig. 19-16). Scintigraphy can be used to verify or refute the importance of sclerosis in the third carpal bone. Scintigraphy is useful in diagnosing unusual fractures of the palmar aspect of the third carpal bone, corner fractures or table surface collapse of the third carpal bone or other carpal bones, and lesions that are not apparent or are located in obscure areas not depicted radiographically. Focal areas of IRU occur with many carpal injuries, and although sensitivity is high, the specificity of scintigraphic images is low and differentiation of specific types of injuries is difficult. Scintigraphy is most useful in localizing the site of injury, based on which additional radiographic views are obtained, or rest is recommended, followed by repeated radiographic examination.

In general, scintigraphic examination is used when lameness is localized but a specific diagnosis cannot be made. In racehorses referred for evaluation of poor performance and obscure high-speed lameness, comprehensive scintigraphic examination of all limbs often reveals focal areas of IRU in the carpus, even when evidence of overt lameness is lacking. Areas of IRU are in locations typical for horses to develop osteochondral fragments and signs of osteoarthritis. Whether these areas of IRU represent sources of pain causing high-speed or subtle lameness is unknown, but often radiographic evidence of bone modeling (sclerosis, marginal osteophytes) or incomplete osteochondral fragments exists.

Diagnostic Arthroscopy

Specific diagnosis is usually made before surgery, and in most horses arthroscopy is interventional rather than diagnostic. When results of thorough clinical, radiographic, and scintigraphic examinations are combined, a specific site of injury is usually identified. In racehorses, lameness of the carpus without scintigraphic or radiographic abnormalities is unusual. Lack of subchondral bone involvement leads the veterinarian to suspect soft tissue diseases such as synovitis and intercarpal ligament tearing. In these horses, careful examination of the proximal palmar metacarpal region and carpal canal should be performed to avoid inadvertent misdiagnosis. Arthroscopic examination then is used to eliminate primary cartilage damage or intercarpal ligament tearing, but often arthroscopic findings can be unrewarding. Without overt cartilage damage the prognosis is favorable, so information gained by arthroscopic examination is useful, even if a primary diagnosis cannot be made.

In horses with scintigraphic evidence of IRU and those with osteoarthritis but without radiographic confirmation of osteochondral fragmentation, arthroscopic examination usually reveals cartilage damage, the extent of which can be graded. Prognosis is inversely related to degree of cartilage damage (see Figs. 23-2 and 23-3). Occult osteochondral fragments, most commonly involving the third and radial carpal bones, and intercarpal ligament tearing are found frequently in these horses.

SPECIFIC CONDITIONS OF THE CARPUS

Osteoarthritis

Osteoarthritis is the most common carpal problem, but clear differentiation of osteoarthritis from osteochondral fragmentation is difficult, because both problems are intertwined. Horses with osteochondral fragments often develop osteoarthritis, and horses with early osteoarthritis, and some with

chronic osteoarthritis, develop osteochondral fragments. Pathogenesis of osteoarthritis and osteochondral fragmentation appears similar if not identical in some horses, but osteoarthritis of the equine carpus has two forms. The most common form is seen in racehorses or ex-racehorses that initially develop stress-related subchondral bone injury of the middle carpal and antebrachiocarpal joints that leads to, or accompanies, overlying cartilage damage and osteochondral fragmentation. A second form of osteoarthritis develops in non-racehorses and is less common. Horses are usually middle aged or older, but occasionally it occurs in younger horses. Typical clinical and radiographic evidence of osteoarthritis exists, but osteochondral fragments are unusual (see Chapters 63 and 85).

Osteoarthritis in racehorses develops from a continuum of stress-related subchondral bone injury and cartilage damage, resulting from impact loading of the carpal bones during training and racing. This process has been studied most thoroughly in the third carpal bone but also occurs in other bones of the middle carpal and antebrachiocarpal joints. Sclerosis of the dorsal aspect of the third carpal bone is an adaptive response in racehorses.[14,15] With continued loading the third carpal bone becomes densely sclerotic, and in this stage the response becomes non-adaptive and pathological. Subchondral changes precede those in overlying cartilage, a finding seen experimentally[16] and clinically during arthroscopic examination in horses with primary stress-related subchondral bone injury. Sclerotic subchondral bone may induce overlying cartilage damage from abnormal shear forces existing between normal and sclerotic areas.[17] In most horses sclerosis leads to areas of resorption and necrosis, which then lead to osteochondral fragmentation, and eventually to more advanced osteoarthritis.[6,14,18,19] Because many of the changes in early osteoarthritis in racehorses are mechanically induced, factors such as faulty conformation, intense exercise programs, and differences between racing breeds alter rate of development and severity of osteoarthritis. The pathological process continues, and some horses develop osteoarthritis without osteochondral fragments, whereas others develop osteochondral fragments initially and then osteoarthritis secondarily.

In many racehorses extensive osteoarthritis and osteochondral fragmentation lead to retirement, but some are able to compete in other sporting events. Progressive osteoarthritis can then develop later in life. In middle-aged to old non-racehorses primary osteoarthritis develops without stress-related subchondral bone injury, high-impact loading, or development of osteochondral fragmentation. This condition can be seen in Western performance horses, other sports horses, or even in horses and ponies used for pleasure riding. Often severe radiographic evidence of osteoarthritis is seen on initial examination when lameness is subtle. Faulty conformation such as carpus valgus, back at the knee, or bench knee is seen in some horses, but in others neither mechanical nor training-related factors are present. Osteoarthritis in these horses can involve the antebrachiocarpal and middle carpal joints together or separately, but when disease involves the carpometacarpal joint, chronic and severe lameness develops (see Fig. 3-2).

Clinical Signs and Diagnosis

Clinical signs of osteoarthritis vary depending on age and use of horse, but they are similar to those of other carpal diseases. Classic signs of osteoarthritis, such as obvious lameness, typical carpal gait, effusion, and a painful response to static and dynamic flexion, may be present, particularly in horses with advanced osteoarthritis and in old horses with severe changes, but clinical signs can be subtle in young racehorses. In racehorses with early osteoarthritis, historical information such as lugging in or out, being on a line, or poor performance may be present. Effusion varies and lack of this clinical sign does not preclude the carpus as the source of pain. Racehorses in early training are prone to develop effusion primarily of the middle carpal joint, but the antebrachiocarpal joint can also be involved. Effusion may be most evident after work, but lameness usually is not present. Effusion usually results from strain of soft tissues, such as intercarpal ligaments or joint capsule. Clinical signs resolve after a brief period of rest or reduction in training. Most commonly, racehorses with early osteoarthritis manifest clinical signs later in training as a 2-year-old or when racing begins.

Diagnosis should be confirmed using diagnostic analgesia of the involved joint(s). In horses with severe osteoarthritis, complete resolution of lameness may not occur until median and ulnar blocks are performed. After pain in the primary limb is abolished, lameness may be seen in the contralateral limb, indicating bilateral carpal lameness.

Radiographic evidence of osteoarthritis in young horses is often lacking, but sclerosis of the third carpal bone may be seen in a skyline view. Early radiographic changes include mild enthesophyte formation, most common on the radial carpal bone, and subtle marginal osteophytes on the carpal bones and distal radius. In horses with advanced osteoarthritis, marginal osteophytes and enthesophytes become numerous and large, sometimes causing obvious visible bony swelling (Fig. 39-3). Loss of joint space occurs late in osteoarthritis, but it is not an obvious radiographic sign. Osteochondral fragments may be present and can be numerous and may have occurred earlier during a racing career or can develop when marginal osteophytes break. Radiographs of the contralateral carpus should also be obtained.

Scintigraphic examination is an excellent tool for diagnosis of early osteoarthritis in racehorses. Initially, focal areas of IRU are located on one side of a joint, such as in the third carpal bone, but later, subchondral IRU can be seen diffusely in one or more joints. Arthroscopic examination may be useful to establish prognosis and to evaluate possible soft tissue injury, such as intercarpal ligament tearing, and may be useful therapeutically.

Management

Management of osteoarthritis is discussed in Chapter 85. Because pathogenesis involves stress-related subchondral bone injury, an important part of management of osteoarthritis in racehorses involves stress relief by enforced rest or a reduction in training or racing intensity. Racehorses (STBs) without obvious radiographic changes are given 2 to 3 weeks of hand walking or walking in the jog cart, non-steroidal anti-inflammatory drugs (NSAIDs), and local therapy such as cold water hosing or icing. Topical counterirritation is still a popular management technique administered to young racehorses early in training. Intra-articular administration of hyaluronan, with or without a short-acting corticosteroid, may help in horses with synovitis, but it is of limited value if the primary source of pain is subchondral bone with intact overlying cartilage. In racehorses with advanced sclerosis of the third carpal bone and early enthesophyte and marginal osteophyte formation, extended rest of 3 to 4 months is recommended. However, economic factors may dictate that these horses remain in training; thus work intensity often is decreased and horses receive a single or a series of intra-articular injections with hyaluronan or polysulfated glycosaminoglycans (PSGAGs). Horses with radiographically apparent osteochondral fragments are surgical candidates, but post-operative progression of osteoarthritis and recurrence of fragmentation are common. As osteoarthritis progresses in horses with or without osteochondral fragments, numerous intra-articular injections, often including methylprednisolone acetate, may be necessary to reduce inflammation, but if training and racing continue, osteoarthritis progresses in accelerated fashion.

In ex-racehorses or non-racehorse sport horses with primary osteoarthritis, radiographic changes may be advanced

Fig. 39-3 Dorsolateral-palmaromedial oblique radiographic view of a horse with chronic, severe osteoarthritis of the antebrachiocarpal joint showing extensive marginal osteophyte formation and osteochondral fragmentation.

when lameness is first recognized, because osteoarthritis is chronic and well tolerated. Conservative management is recommended and includes rest, NSAID therapy, and intra-articular injections. Horses with radiographic evidence of large intact or broken osteophytes or old osteochondral fragments may be considered candidates for arthroscopic surgery, but although arthroscopic examination may be important to establish prognosis, surgical removal of osteophytes and old osteochondral fragments does not often result in long-term clinical improvement and may accelerate radiographic progression of osteoarthritis (see Fig. 39-3). Involvement of the carpometacarpal joint warrants a guarded prognosis.

Prognosis depends on the number of joints and limbs affected, rate of progression of clinical signs, severity of cartilage damage, presence of osteochondral fragments, and level of competition. Most racehorses with early osteoarthritis and even those with radiographic evidence of osteophytes and enthesophytes can race at some level, if horses have raced before diagnosis. Horses with advanced changes before racing begins, particularly those with faulty conformation, are unlikely to race but can be sound enough to perform other sporting activities. Valuable horses with severe osteoarthritis, such as broodmares or breeding stallions, may be candidates for partial (intercarpal) or pan-carpal arthrodesis.

Osteoarthritis of the Carpometacarpal Joint

Primary osteoarthritis of the carpometacarpal joint is unusual to rare but occurs primarily in old horses and is insidious and progressive (see Fig. 3-2 and Chapter 38).

Osteochondral Fragmentation

Small Fragments

Osteochondral fragmentation is a disease primarily of racehorses or ex-racehorses, and pathogenesis is identical to that described for osteoarthritis. I prefer to use the terms *carpal osteochondral fragments* (osteochondral fragments) and *osteochondral fragmentation* instead of *carpal chip fractures* to emphasize the importance of pathogenesis. The term *chip fracture* implies a single event traumatic injury. Although trauma plays a role, osteochondral fragments are not single event injuries but are the end result of stress-related subchondral bone injury caused by repetitive loading, initially an adaptive response, but later becoming non-adaptive remodeling and pathological.[14,16,18,19] Sites located dorsally are prone to develop osteochondral fragments. Osteochondral fragments differ in size and number of joints affected. Small osteochondral fragments are those that involve one joint surface, such as either the middle carpal or the antebrachiocarpal joints. Large osteochondral fragments refer to slab fractures that involve two joint surfaces. Often advanced changes occur in subchondral bone, such as sclerosis of the third carpal bone or other evidence of modeling or remodeling that preceded development of lameness and osteochondral fragments, findings that support the concept that osteochondral fragments are not single event injuries. The antebrachiocarpal joint is more susceptible to injury from supra-physiological loads or acute overload injury,[6] particularly in fatigued horses, but fractures still occur associated with pathological conditions of the bone. Palmar carpal osteochondral fragments, such as those involving the accessory carpal bone, occur as single event injuries such as falls, carpal hyperextension, or recovery from general anesthesia.

In my experience, faulty conformation such as back-at-the-knee predisposes TB and STB racehorses to develop osteochondral fragments, and trotters are more at risk than pacers. However, in a study attempting to evaluate the role of back-at-the-knee conformation in the development of osteochondral fragments in 21 horses, no differences in carpal angle were found compared with 10 horses without osteochondral fragments.[20]

Carpal osteochondral fragments occur in defined locations in all racehorses, but distribution varies depending on the type of racehorse. In the STB, osteochondral fragments occur almost exclusively in the medial aspect of the middle carpal joint and rarely in the antebrachiocarpal joint.[21] Although rare, osteochondral fragments in the STB antebrachiocarpal joint are most common in trotters and usually involve the distal radius. In the middle carpal joint we found a nearly equal distribution of osteochondral fragments between the radial and third carpal bones, but in another study those of the third carpal bone outnumbered osteochondral fragments of the radial carpal bone by 2:1.[21,22] The preponderance of osteochondral fragments in the medial aspect of the middle carpal joint in the STB is interesting, because training involves clockwise and counterclockwise exercise, whereas racing is counterclockwise. The assumption is that counterclockwise direction of training and racing places asymmetrical and uneven load distribution on each forelimb and may predispose the lateral left forelimb and medial right forelimb to compression injury. In two STB studies a nearly equal distribution of osteochondral fragments was noted between left and right middle carpal joints,[21,22] but in another study osteochondral fragments of the third carpal bone occurred more commonly in the right carpus.[19] Trotters were more likely to have right osteochondral fragments and had significantly more osteochondral fragments of the third carpal bone than the radial carpal bone compared with pacers.[21]

In TBs in North America, third carpal bone fractures occur more commonly in the right carpus, but considering all small osteochondral fragments, the distribution between left and right is similar.[18,19,22] In TB and Quarter Horse (QH) racehorses, osteochondral fragments are commonly seen in the middle carpal and antebrachiocarpal joints.[22-24] These breeds in North America have a predilection for development of osteochondral fragments in the lateral left antebrachiocarpal

joint and the medial right middle carpal joint, a distribution supporting the concept that osteochondral fragments develop on the compression side during counterclockwise training and racing. Overall, in TB and QH racehorses the most common sites for osteochondral fragments are the proximal aspect of the third and distal aspect of the radial carpal bones,[22,24] followed by the proximal aspect of the intermediate carpal bone and the distal lateral aspect of the radius. Osteochondral fragments often develop on apposing surfaces, supporting the concept that certain sites are biomechanically at risk. This may be evident radiographically, but in some horses apposing fragmentation is only identified at arthroscopic surgery and both limbs should be examined radiographically routinely, even if clinical signs are absent. Osteochondral fragments can be found at numerous sites in one or both carpi. Differences between racing breeds in distribution of osteochondral fragments may be explained by gait and sites predisposed to stress-related subchondral bone injury. Almost all STB osteochondral fragments occur medially, equally in both middle carpal joints. Most forelimb scintigraphic changes in STBs occur medially, indicating that the medial aspect in both forelimbs is at risk of stress-related subchondral bone injury. Classic training programs include many miles each day of jogging (trotting or pacing) clockwise (the wrong way of the track), and training one to two times each week, counterclockwise (the right way). Although all speed is performed in one direction, STBs jog many more miles in the other direction, and the number of loading cycles may be more important than speed. Direction of training and racing is not the only factor influencing fracture location because QHs and TBs have a similar distribution yet race differently. The two-beat trot and pace and a more caudal center of balance with a cart and driver result in reduced carpal loads in STBs at speed compared with galloping racing breeds. The low occurrence of osteochondral fragments in the antebrachiocarpal joint of STBs may reflect absence of supraphysiological loads. Racing speeds in the STB are lower than the TB and substantially lower than in the QH. Fatigue rather than speed of racing may be a factor.

Clinical signs. Lameness in horses with small osteochondral fragments varies from subtle to severe. In most horses, prominent to severe lameness is seen immediately after the fracture occurs, but subtle prodromal clinical signs are often present. Historically, horses may have been treated for suspected carpal lameness, may be on a line (STB), lug in or out, or fail to take a lead or change leads. Degree of lameness depends on location and number of osteochondral fragments and whether osteochondral fragments are present bilaterally. Horses with third carpal bone osteochondral fragments, and in particular incomplete fractures, show more pronounced lameness than those with osteochondral fragments elsewhere. Lameness is increased when the affected limb is on the outside of the circle in horses with osteochondral fragments in the middle carpal joint, but this response varies with those with osteochondral fragments in the antebrachiocarpal joint. TB and QH racehorses with osteochondral fragments of the distal, lateral radius or proximal intermediate carpal bone may only show mild signs of lameness. Horses with bilateral osteochondral fragments may show minimal overt lameness. Horses with lameness inappropriately severe for the location, number, or size of fragment(s) present may have substantial cartilage damage.

There is generally effusion and heat over the carpus, but in horses with incomplete fractures, clinical signs can be subtle. Palpation may reveal a focal painful response over the site of fragmentation, and occasionally fragments can be palpated directly. Degree of flexion varies, but usually the response to a carpal flexion test is positive. Signs of osteoarthritis including joint capsule fibrosis and enthesophyte production are common, particularly in horses with chronic lameness.

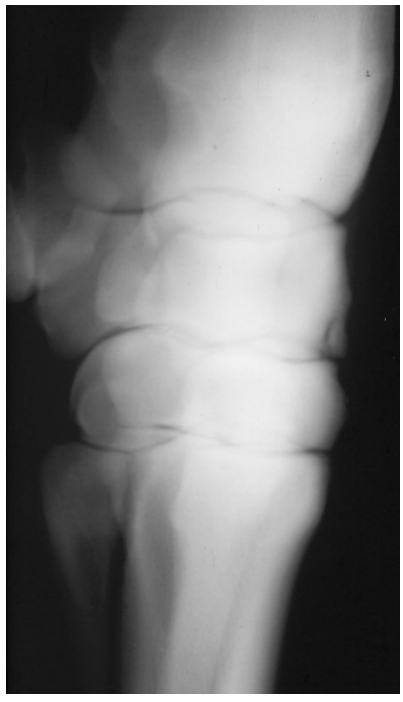

Fig. 39-4 Dorsolateral-palmaromedial oblique radiographic projection of a Thoroughbred racehorse with a typical distal radial carpal bone chip fracture, the most common small osteochondral fragment.

Arthrocentesis usually reveals serosanguineous fluid, particularly if lameness is acute. Intra-articular analgesia usually, but not always, abolishes signs of pain.

Radiographic examination is usually diagnostic, and all views should be obtained. In STBs abnormalities are usually only detected in DL-PaMO and LM views and a skyline view of the distal row of carpal bones. All common osteochondral fragment locations should be carefully evaluated. Fragments involving the distal aspect of the radial carpal bone are most visible on a DL-PaMO view and can vary in size, can be displaced or non-displaced, and may extend to the level of the joint capsule attachment (Fig. 39-4). Osteochondral fragments involving the third carpal bone most commonly affect the radial fossa and can be seen on the DL-PaMO, LM, and skyline views (Fig. 39-5). Small osteochondral fragments involve only the middle carpal joint surface and usually break out dorsally, near the joint capsule attachment on the third carpal bone. It is important to differentiate small osteochondral fragments from frontal or sagittal slab fractures. Third carpal bone osteochondral fragments can be singular or numerous, involve only the radial or intermediate (rare) fossa or both, can be complete or incomplete, or involve the medial (most common) or lateral corners of the bone. Medial corner fragments of the third carpal bone may resemble subchondral lucency and sagittal slab fracture, so other views must be carefully interpreted. Authentic sagittal slab fractures must be confirmed using a DM-PaLO view. Osteochondral fragments of the distal, lateral radius are the largest of the small osteochondral fragments and are often bipartite. The large dorsal fragment is separated from the parent radius by a small separate fragment in the interposed trough (Fig. 39-6). The large dorsal fragment can extend proximal to the joint capsule attachment on the distal lateral radius. Concomitant osteochondral fragments frequently involve the proximal medial aspect of the intermediate carpal bone. Osteochondral fragments of the proximal aspect of the intermediate carpal bone may occur alone or in combination with osteochondral fragments of the distal lateral radius

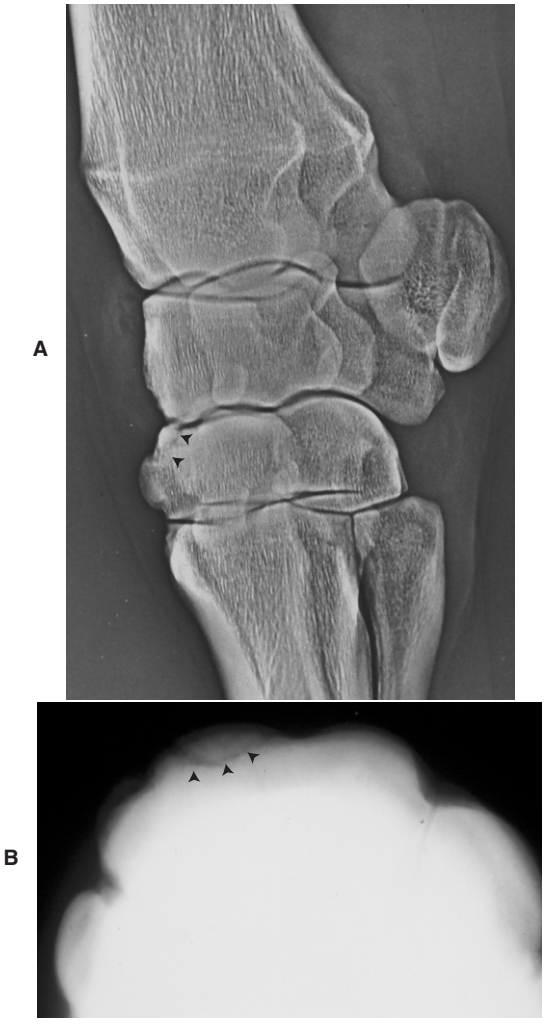

Fig. 39-5 **A,** Dorsolateral-palmaromedial oblique xeroradiographic and **B,** skyline radiographic views of a horse with a third carpal bone small osteochondral fragment. The osteochondral fragment *(arrowheads)* breaks out of the dorsal aspect of the third carpal bone in the dorsolateral-palmaromedial oblique view, confirmation that it does not span both articular surfaces of the third carpal bone.

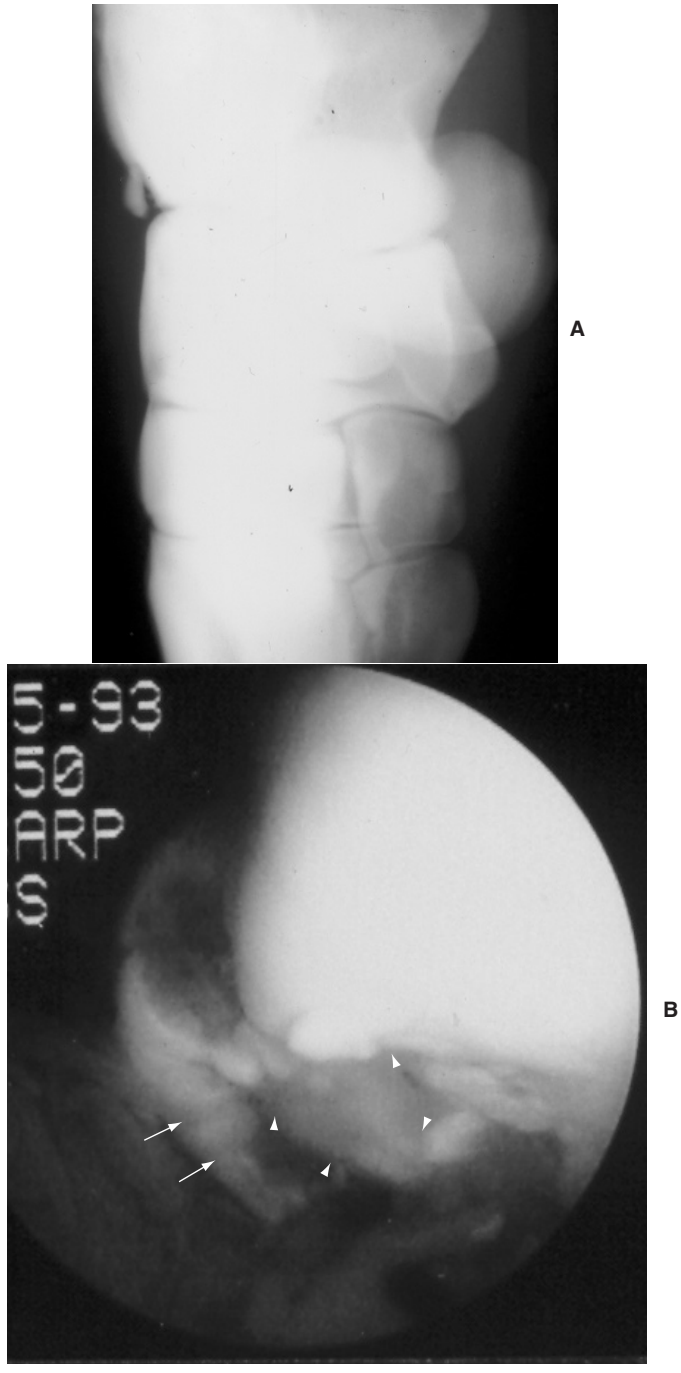

Fig. 39-6 **A,** Dorsomedial-palmarolateral oblique radiographic view showing typical distal lateral radius small osteochondral fragment in a Thoroughbred. **B,** Intra-operative photograph (dorsal is to the left; proximal is up) shows large dorsal fragment *(arrows)* separated from the parent radius by a small, interposed wedge-shaped fragment *(arrowheads)*.

(Fig. 39-7). Other, less common osteochondral fragments do occur alone but usually in combination with other osteochondral fragments. Evidence of osteoarthritis such as enthesophytes and marginal osteophytes may be present. Sclerosis of the third carpal bone is common in horses with osteochondral fragments of the third and radial carpal bones. Degree of sclerotic change is important, because in my experience a positive correlation exists between the degree of the third carpal bone sclerosis and the extent of cartilage damage on the third and radial carpal bones. However, a recent radiographic study showed no significant relationship between degree of sclerosis and prognosis.[25]

Scintigraphic examination is an excellent method to diagnose incomplete or occult osteochondral fragments and to evaluate other sites of stress-related subchondral bone injury in the involved or contralateral carpus. Focal IRU on one side of a joint seen in several scintigraphic views, including a flexed dorsal view, can help pinpoint exact location of osteochondral fragments.

Management The ideal treatment is surgical removal of osteochondral fragments, because unstable surfaces and fragment movement predispose to additional synovitis and development of osteoarthritis. Fragments left in place to heal in displaced fashion cause uneven joint surfaces and are prone to re-fracture. Arthroscopic examination also allows evaluation and grading of cartilage damage and intercarpal ligament integrity and identification of occult fragments. However, factors such as economic value, racing class, and time of year relative to upcoming races and location of osteochondral fragments are relevant. Horses not worthy of arthroscopic surgery are managed with short-term rest and intra-articular injections of hyaluronan and corticosteroids, or they are given 3 to

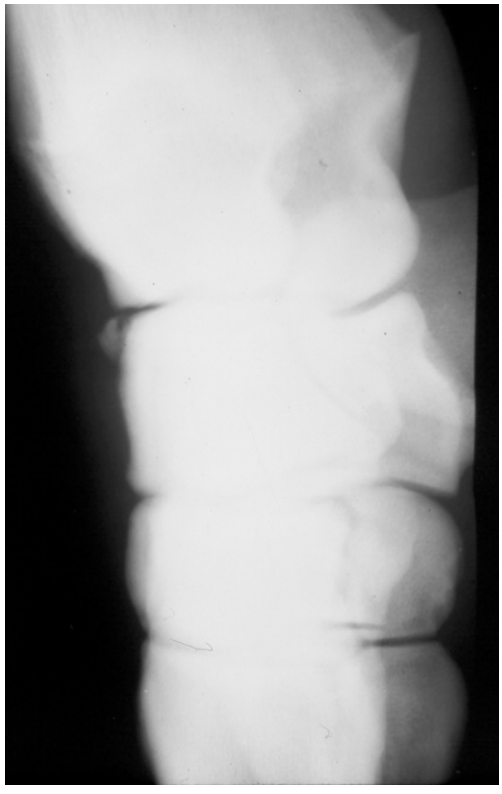

Fig. 39-7 Dorsomedial-palmarolateral oblique radiographic view of a typical osteochondral fragment of the proximal intermediate carpal bone. These fragments often appear in combination with osteochondral fragments of the distal lateral radius and vary in size, but they generally occur slightly more medial than those of the distal, lateral radius.

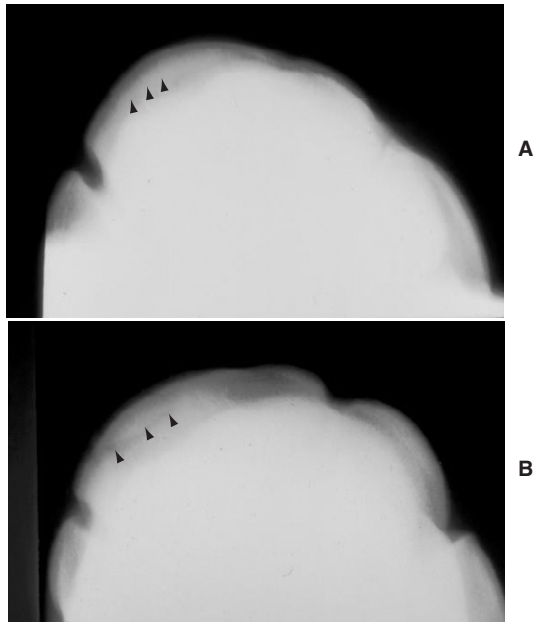

Fig. 39-8 **A,** Skyline radiographic view of 2-year-old Standardbred colt with incomplete osteochondral fragment of the third carpal bone. In this view there is predominantly dense sclerosis of the radial fossa and the faint fracture is difficult to identify *(arrowheads)*. **B,** Seven months later lameness and fracture recurred when the horse was 3 years old. The horse was given inadequate rest to allow the fracture to heal completely.

6 months of rest. When conservative management procedures are used, fractures develop fibrous unions and become stable, but they are usually displaced and may resemble marginal osteophytes when healed. Many horses that are managed conservatively, especially those with fractures in the antebrachiocarpal joint, return to racing successfully, but recurrence of osteochondral fragments and development of osteoarthritis is likely. It is difficult to convince owners and trainers to give horses long-term (>6 months) rest. However, rest, with or without arthroscopic surgery, is critical not only for healing of incomplete fractures, or if osteochondral fragments are removed, the fracture site, but also for healing of the surrounding cartilage and subchondral bone. Horses with incomplete osteochondral fragments are candidates for conservative management, but if horses are not given adequate time for fracture healing, recurrence is likely (Fig. 39-8). Alternatively, I have recommended arthroscopic surgery and fragment removal in horses with incomplete fractures if I know the client will not opt for long-term rest without surgical intervention. Although carpal lameness may recur, at least the original osteochondral fragment will not re-fracture. During arthroscopic surgery, cartilage damage is graded as mild, moderate, severe, or global and prognosis is inversely proportional to the extent of damage, a clinical finding substantiated in studies in STB, TB, and QH racehorses[21,24] (see Figs. 23-2 and 23-3). During arthroscopic surgery, the osteochondral fragment(s) are removed and the surrounding cartilage and bone are curetted, depending on the amount of damage seen. Damage on apposing surfaces is common, and occult osteochondral fragments are often found there or at distant locations. Bilateral carpal arthroscopic surgery is commonly performed in all racing breeds and in the TB and QH it may be necessary to evaluate all major joints.

After arthroscopic surgery horses are given a progressively increasing exercise program, the length of which depends on severity of damage and location of osteochondral fragments. For instance, in TB racehorses with osteochondral fragments of the distal, lateral radius and proximal intermediate carpal bone, I recommend 2 weeks of stall rest, followed by 4 weeks of stall rest with hand walking (or walking in a caged walker), followed by 2 to 4 weeks of turnout or swimming physiotherapy. Lameness is less pronounced initially, and horses appear able to return to work earlier when osteochondral fragments involve the antebrachiocarpal joint rather than the middle carpal joint. In horses with routine distal radial carpal bone and proximal third carpal bone fragments, I recommend 4 weeks of stall rest, followed by 4 weeks of stall rest with hand walking, followed by 8 weeks of turn out or swimming physiotherapy. In horses with numerous fragments and severe or global cartilage damage, I recommend 4 to 6 months of total rest.

After arthroscopic surgery I recommend the use of intra-articular injections of hyaluronan at 14 and 28 days in horses with mild or moderate cartilage damage, and a series of intra-articular PSGAGs injections at 3, 5, and 7 weeks after surgery. I recommend intra-muscular administration of PSGAGs once weekly for 8 weeks, beginning 14 days after surgery. Little concrete evidence shows that any form or combination of intra-articular therapy is of benefit for cartilage healing after surgery, although anti-inflammatory effects are likely mildly beneficial.

Cartilage resurfacing techniques have been used experimentally and in a limited number of horses with osteochondral fragments and osteoarthritis (see Chapter 23). Cell-based techniques such as injection of cloned chondrocytes in autogenous fibrin loaded with growth factors appear promising. Microfracture of calcified cartilage appears promising in

experimental trials, but seeing horses with partial-thickness cartilage damage is unusual. Subchondral bone is usually already exposed, obviating the need to use this.

Prognosis depends on several factors, including type and age of horse, racing class, limb(s) affected, number and location of osteochondral fragment(s), and amount of cartilage damage. Intuitively, a better prognosis would be expected in the STB than the TB and QH, because load is better shared by the hindlimbs and gait allows compensation by a lateral or diagonal limb. However, in STBs osteochondral fragments develop later in the non-adaptive remodeling process, when osteoarthritis is already well beyond that in TBs with comparable lesions. In most racehorses any damage of the third carpal bone is a major limiting factor in prognosis, and because osteochondral fragments of the third carpal bone are common in STBs, overall prognosis for STBs might be expected to be lower than for TBs and QHs. The prognosis for lesions in the antebrachiocarpal joint is better than for the middle carpal joint, and because osteochondral fragments occur with similar frequency in both joints in TBs and QHs, the overall prognosis is better. The prognosis for return to racing is good to excellent, but the likelihood of racing at the pre-injury level is inversely proportional to the degree of cartilage damage. Seventy-four percent of STBs with osteochondral fragments returned to racing after arthroscopic surgery, whereas only 61% raced at or above the pre-injury level. Pacers were more likely than trotters to start a race and to have five starts before and after injury.[21] Kinematic studies show that the pace may slow forelimb fatigue and reduce forelimb load.[26] Median earnings per start decreased significantly after injury and arthroscopic surgery, but horses went significantly faster after surgery.[21]

Of 445 TB and QH racehorses, 303 (68%) raced at a level equal to or better than the pre-injury level, but when grouped according to cartilage damage, only 53% of horses with the most severe cartilage damage raced at these levels. Eleven percent of horses had decreased performance and had carpal lameness, 6% developed additional osteochondral fragments, and 2% developed collapsing slab fractures while racing.[24] Prognosis was worse for horses with osteochondral fragments of the third carpal bone.

Unusual Articular Osteochondral Fragments

Osteochondral fragments do occur in the palmar aspect of the carpus, but they result from a single event injury. Trauma may result from falling, hitting a fence, or landing with subsequent hyperextension of the carpus. Osteochondral fragments usually involve the palmar aspect of the radial and intermediate carpal bones and the articular surface of the accessory carpal bone, can be singular or numerous, and occur medially and laterally. Articular osteochondral fragments of the accessory carpal bone are usually comminuted and involve at least two to three pieces. In horses with known chronic osteochondral fragments in the dorsal aspect of the carpus and those with osteoarthritis, radiographs occasionally reveal what appear to be small fragments or mineralization in the palmarolateral or palmaromedial aspects of the middle carpal joint (Fig. 39-9). One suggestion is that this represents dystrophic mineralization following corticosteroid injections, but in most horses these small fragments migrate from the dorsal to the palmar aspect of the joint and occur when training and racing continues in horses with existing osteochondral fragments, which then become macerated. When the condition is observed, osteoarthritis is usually extensive, and prognosis is guarded.

Lameness is acute in onset, with effusion of the middle carpal or antebrachiocarpal joints. Often the response to static flexion of the carpus is profound. Careful interpretation of radiographs is necessary to confirm the presence of osteochondral fragments, locate precisely the parent bone from which the osteochondral fragment arose, and determine the number of fragments. The clinician should recognize that osteochondral fragments in the palmar aspect of the carpus may represent only one aspect of more global damage to the joint(s). Any evidence of fragmentation dorsally, or active osteoarthritis if trauma occurred at least 10 to 14 days before radiographic examination, is a poor prognostic indicator, because this reflects substantial subchondral bone and cartilage injury dorsally and perhaps soft tissue instability. Osteoarthritis and chronic lameness are inevitable, regardless of management.

Fig. 39-9 A flexed lateromedial radiographic view. There is debris (*arrowheads*) in the palmar pouch of the middle carpal joint. This Standardbred had a large, loose, macerated third carpal bone chip fracture, and debris migrated to the palmar pouch. A first carpal bone can be seen distal to the loose debris and should not be confused with an authentic osteochondral fracture.

Palmar osteochondral fragments can be removed using arthroscopic surgery or arthrotomy,[27] but access can be difficult. The palmarolateral pouch of the antebrachiocarpal joint is large, and osteochondral fragments involving the accessory and intermediate carpal bones can be removed from this approach. Osteochondral fragments involving the palmaromedial or the palmarolateral aspect of the middle carpal joint can be removed using arthroscopic surgery, but both portals must be made within a small joint pouch, making triangulation difficult. Prognosis for future soundness is fair in nonracehorses, unless osteochondral fragments were associated with substantial instability or bone and cartilage damage at more distant sites. Prognosis is guarded in racehorses.

Large Fragments: Slab Fractures

Slab fractures are defined as fractures that involve a proximal and distal articular surface and thus traverse the entire depth

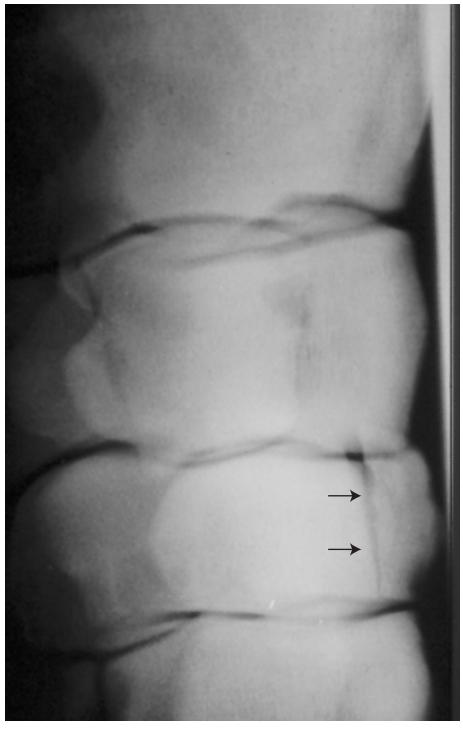

Fig. 39-10 Dorsolateral-palmaromedial oblique radiographic view showing a complete, non-displaced frontal slab fracture of the radial fossa of the third carpal bone *(arrows)*. The fracture line traverses the entire depth of the third carpal bone involving the middle carpal and carpometacarpal joints.

Fig. 39-11 Dorsomedial-palmarolateral oblique radiographic view showing a displaced frontal slab fracture of the intermediate fossa of the third carpal bone *(arrows)*.

(proximal-distal direction) of the bone. Size and involvement of two articular surfaces differentiate these fractures from small osteochondral fragments. Slab fractures of the third carpal bone are by far the most common form of large osteochondral fragments in the carpus, but slab fractures of the radial, fourth, and intermediate carpal bones occasionally occur. A combination of radial and third carpal bone slab fractures occurs in TB racehorses and may lead to instability and carpal collapse. In most instances, slab fractures develop as a terminal event in the cascade of non-adaptive remodeling changes leading to sclerosis, biomechanical weakness, and subsequent fracture. When slab fractures occur in unusual locations, the possibility of single-event injury must be considered. Slab fractures occur almost exclusively in racehorses.

Frontal slab fractures of the third carpal bone. The most common large osteochondral fragment in the carpus is a frontal slab fracture of the third carpal bone. A frontal slab fracture of the third carpal bone usually involves the radial fossa, but fractures of the intermediate fossa alone or in combination with fracture of the radial fossa do occur (Figs. 39-10 and 39-11). Frontal slab fractures of the third carpal bone involving the radial fossa vary in size and can involve the entire medial-to-lateral width of the fossa, or any portion of it, and range from the common size of 8 to 10 mm in the dorsal to palmar direction up to 20 to 25 mm. These latter, large fragments cannot be seen on a skyline radiographic view and extend across the entire medial to lateral width of the third carpal bone involving both fossae and are L-shaped (Fig. 39-12).

Lameness in horses with a frontal slab fracture is acute and severe and is generally worse than those with small osteochondral fragments, but chronic, subtle prodromal lameness may have been present. A previous history of small osteochondral fragments and arthroscopic surgery is common. Lameness may be less than expected in horses recently injected with corticosteroids and in those with bilateral frontal slab fractures of the third carpal bone. Clinical signs such as heat, effusion, and response to static and dynamic flexion are pronounced and horses are usually lame at the walk. Horses with non–weight-bearing lameness may have unstable carpi and should be evaluated carefully for collapse from comminuted fractures. The contralateral carpus should always be evaluated and palpation should be complete to uncover compensatory lameness problems. In TB racehorses in North America the right third carpal bone is affected more commonly than the left,[28] but in STBs the distribution between right and left is similar.[29]

Frontal slab fractures of the third carpal bone are usually obvious radiographically. If they involve the radial fossa, fractures are best seen on the LM, flexed LM, and DL-PaMO views and a skyline view. Because frontal slab fractures of the third carpal bone by definition involves the middle carpal and carpometacarpal joint surfaces, if a fracture line breaks out dorsally before reaching the carpometacarpal joint, the fragment is not a true slab fracture. This is important when determining a management plan. A frontal slab fracture of the third carpal bone can be incomplete, complete but non-displaced, or complete and displaced and may be associated with other small osteochondral fragments. Degree of displacement is worse on a standing LM view, but when the carpus is flexed, the fracture returns to near normal alignment. Flexion is a

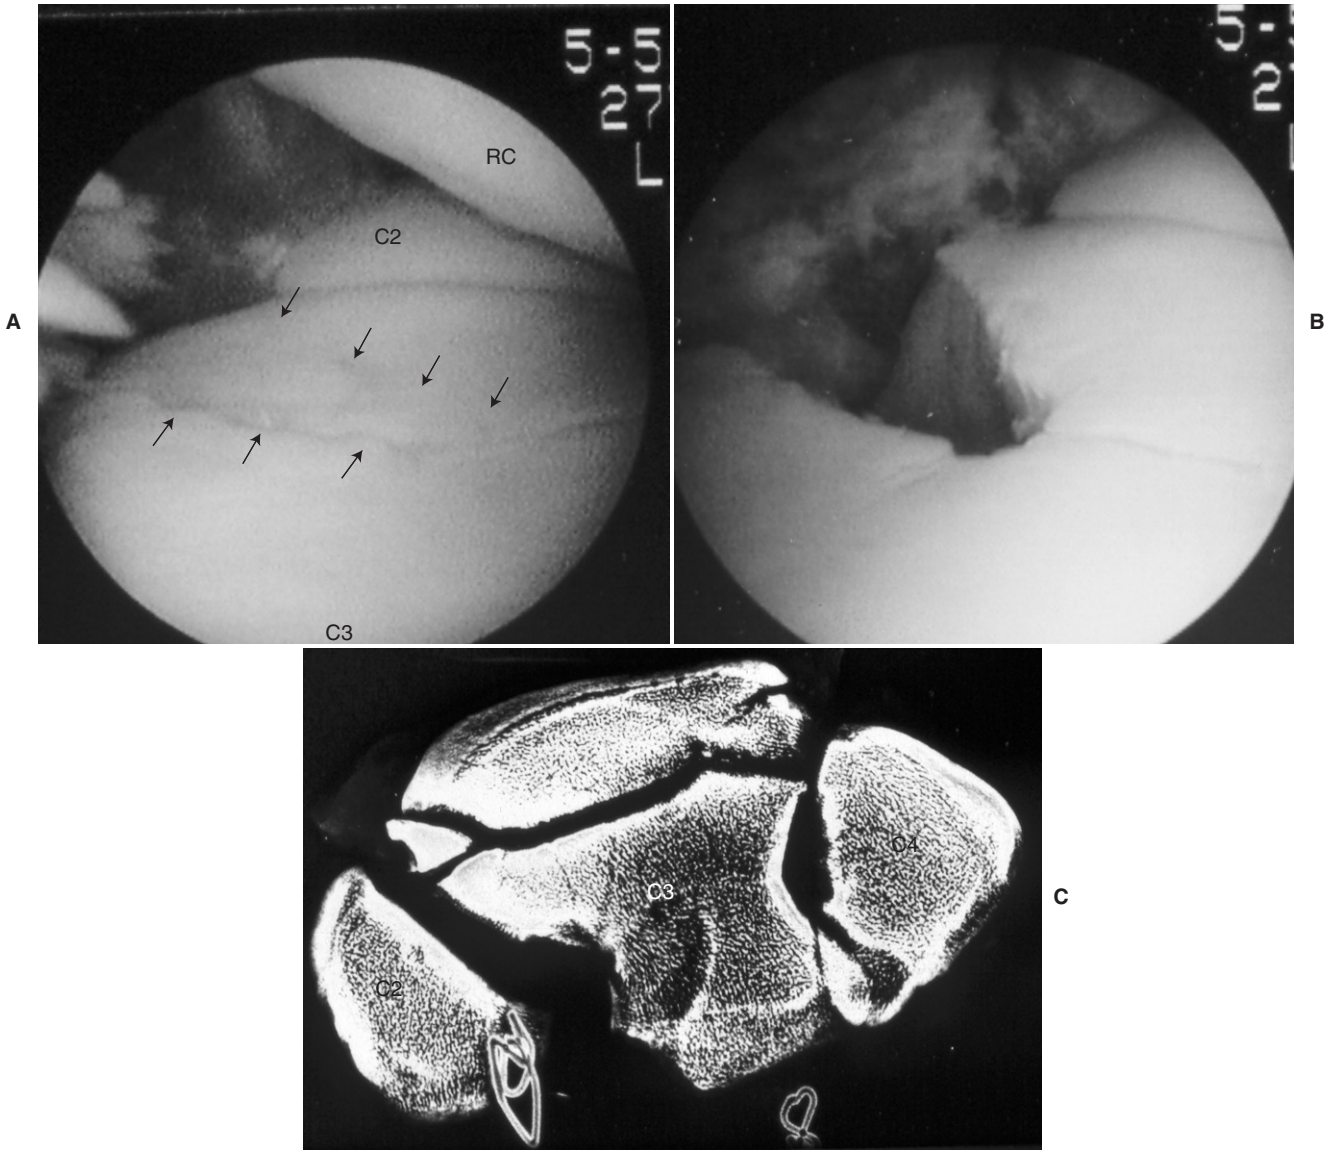

Fig. 39-12 This pacer had an L-shaped fracture of the third carpal bone that involved a sagittal and frontal component. **A,** The initial intra-operative photograph shows the sagittal component *(arrows)* and crushed medial aspect of the third carpal bone. **B,** This area was debrided and the fracture healed without internal fixation. The sagittal component of the fracture appears palmar to the defect. **C,** True proximal to distal radiographic view of a trotter taken at necropsy shows that the large slab fracture of the third carpal bone has frontal and sagittal components. *C2*, Second carpal bone; *C3*, third carpal bone; *RC*, radial carpal bone; *C4*, fourth carpal bone.

useful maneuver during reduction. In most instances a triangular, wedge-shaped fragment appears in the trough between the frontal slab fracture fragment and the parent bone, and this accounts for the appearance of many fracture lines in a skyline view. Careful examination of the overlying radial carpal bone is required in TB racehorses, because concomitant slab fracture of the radial carpal bone can accompany a frontal slab fracture of the third carpal bone.

Management depends on several factors including the horse's value, age, racing class, presence of other lameness problems, and specifically whether the frontal slab fracture of the third carpal bone is incomplete, displaced, or comminuted. Long-term rest (6 months) is successful in horses with incomplete or complete non-displaced fractures. However, surgical fixation can help preserve articular surfaces by preventing displacement. Frontal slab fracture fragments that are thin (<5 mm in the dorsal to palmar direction) can be removed using arthroscopic surgery or conventional arthrotomy techniques or, if the articular surface is intact, can be repaired. Surgical removal of small frontal slab fractures of the third carpal bone can be difficult using arthroscopic techniques and can leave a large defect radiographically but is successful. Horses with large frontal slab fragments that are displaced are usually managed with arthroscopic surgery and internal fixation, using one or two cortical screws placed in lag fashion. Either 3.5- or 4.5-mm screws can be used, but I prefer using one or two 3.5-mm screws because the screw heads are smaller and countersinking in the dorsal aspect of the third carpal bone is not necessary. Use of needles and intra-operative radiographs to position and guide screw insertion accurately is preferred.[30]

A single bone screw provides adequate fixation in horses with most frontal slab fracture of the third carpal bone involving only the radial fossa, because capsular attachments maintain rotational stability. Two or three 3.5-mm screws are necessary to repair large fragments traversing both fossae. The fracture line is debrided, often before screw placement, and the wedge-shaped trough fragment is removed leaving a gap at the fracture line. Loose cartilage is curetted, cartilage damage is graded, and other small osteochondral fragments are removed if present. Alternatively the proximal articular surface of the fragment may be removed, with repair of the distal aspect, leaving the portion of the fragment with capsular attachments intact. Occasionally, additional slab fractures of the third or radial carpal bones are found and repaired. In horses with more than one slab fracture a Robert Jones bandage or cast is used for recovery from general anesthesia. In TB racehorses with a frontal slab fracture of the third carpal bone, an ominous defect in the articular cartilage of the radial carpal bone is often seen, caused by the incongruent apposing surface of the third carpal bone, but in most horses subchondral bone fracture is not present. Horses are typically given stall rest for 4 weeks, followed by stall rest with hand walking for 8 weeks, followed by turnout in a small paddock for 2 to 3 months before beginning race training. Recommendations for intra-articular therapy are similar to those in horses with small osteochondral fragments.

In a large retrospective study of TB and STB racehorses with a frontal slab fracture of the third carpal bone, the radial fossa was involved in 87% of horses, and females of both breeds were less likely to race after injury and surgery, but treatment and fracture characteristics had no effect on outcome.[29] Fracture characteristics such as size and degree of displacement did influence treatment selection, so thin frontal slab fractures of the third carpal bone were removed, displaced fractures were repaired, and horses with incomplete or non-displaced frontal slab fracture of the third carpal bone were managed conservatively.[29] All STBs that raced before, raced after surgery and overall 77% raced after surgery. Sixty-five percent of TBs with frontal slab fractures of the third carpal bone raced after surgery, and although earnings per start decreased in both breeds, the decrease was more pronounced in TBs.[29] In another study, 67% of TBs with a frontal slab fracture of the third carpal bone raced at least once after surgery, but the mean claiming value in horses decreased significantly.[28]

Sagittal slab fractures of the third carpal bone Sagittal slab fractures of the third carpal bone are much less common than frontal slab fractures, usually involve the medial aspect of the radial fossa (Fig. 39-13, *A*), and occur in a direction parallel to the articulation between the second and third carpal bones. However, sagittal slab fractures of the third carpal bone can occur in the intermediate fossa, and fractures can be bilateral. Authentic sagittal slab fractures of the third carpal bone involve both articular surfaces of the bone and can be best seen radiographically in skyline and DM-PaLO views. Sagittal slab fractures of the third carpal bone must be differentiated from corner fractures, subchondral lucency, and other crushing type of injuries that occur in the radial fossa. Clinical signs associated with sagittal slab fractures of the third carpal bone are similar to those of other osteochondral fragments but are usually less severe than a frontal slab fracture of the bone. Lameness is usually prominent, but in horses with bilateral fracture or substantial osteoarthritis or osteochondral fragments in the contralateral carpus, diagnostic analgesia may be required. Often horses have a prominent history of chronic carpal lameness before acute lameness develops. Of 28 horses with sagittal slab fractures of the third carpal bone, 17 were TBs, 9 were STBs, and 2 were Arabian racehorses, and fractures were found in the right forelimb (17), left forelimb (10), and bilaterally in one horse.[31]

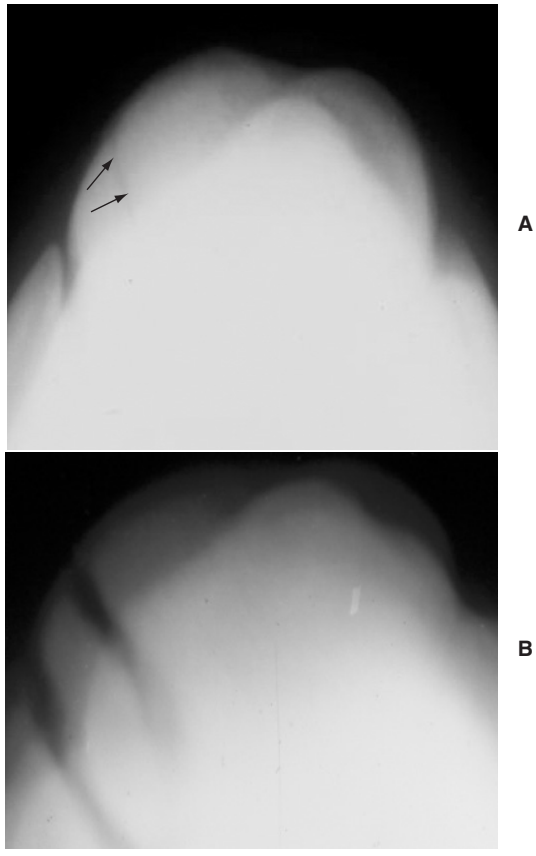

Fig. 39-13 **A,** Initial and **B,** 8-month follow-up skyline radiographic views of the third carpal bone showing a sagittal slab fracture *(arrows)* that failed to heal and became a non-union **(B).** This Standardbred trained and raced with the non-union fracture but dropped substantially in class. Results such as this have prompted me to manage sagittal slab fractures of the third carpal bone surgically.

Conservative management can be successful, but only 7 of 12 horses with sagittal slab fracture of the third carpal bone managed conservatively raced.[32] Fracture healing takes extensive time, and a chronic non-union often develops (Fig. 39-13, *B*). Horses can be sound enough to race with chronic non-unions, but this is undesirable. I have seen one STB and one TB racehorse with bilateral lateral, non-union sagittal slab fractures of the third carpal bone racing successfully, but with conservative management comes a risk of chronic high-speed lameness, worse if fracture involves the right forelimb, and horses drop substantially in racing class. If any doubt exists about the nature of a lesion affecting the medial aspect of the third carpal bone, arthroscopic examination can be performed to formulate a surgical plan. If an authentic sagittal slab fracture of the third carpal bone does not exist, but medial corner osteochondral fragments, necrotic subchondral bone, or other crush type of injuries are found, a combination of fragment removal and curettage is performed. I currently recommend surgical management for most horses with sagittal slab fractures of the third carpal bone. I prefer a direct view provided by arthrotomy, because positioning a screw perpendicular to the fracture line using arthroscopic surgery and stereotactic techniques is difficult and because the fracture is closely associated with the second carpal bone. A single 3.5-mm screw is placed in lag fashion. Management after surgery is similar to that described for a frontal slab fracture of the third carpal bone. Results using screw fixation appear superior to those with conservative management.[31]

Slab fractures of other carpal bones Slab fractures of carpal bones other than the third are unusual. Whenever slab fractures of the radial carpal or other unusual slab fractures are discovered, all radiographic views should be evaluated carefully. Slab fractures of the radial carpal bone can occur independent of or in combination with frontal slab fracture of the third carpal bone. When frontal slab fractures of the medial and third carpal bones occur simultaneously and carpal instability results, the fracture is called a *comminuted carpal fracture*. Repairing both bones by placing numerous screws using arthroscopic surgery may be possible. A sleeve or full-limb fiberglass cast is placed, and an assisted recovery from general anesthesia is recommended.

Slab fractures of the intermediate, fourth, and ulnar carpal bones occur rarely. In five horses with intermediate and fourth carpal bone slab fractures, outcome was poor because of delay in diagnosis, and four horses were only pasture sound.[33] Surgical repair should proceed as early as possible, but prognosis is limited by cartilage damage and other osteochondral fragments.

Subchondral Lucency of the Third Carpal Bone

Subchondral lucency of the third carpal bone is an unusual condition occurring almost exclusively in STB racehorses and seen radiographically as single or multiple central areas of bone loss in the radial fossa of the third carpal bone (see Fig. 39-1, *B*). Lesions can be seen in a DL-PaMO view in horses with advanced subchondral lucency of the third carpal bone and in xeroradiographs. Mild to severe sclerosis may surround radiolucent defects,[34] but in a recent study no relationship was found between radiolucency of the third carpal bone and sclerosis.[25] The lesion was more common in the right carpus, and although pacers predominated, distribution was similar to the racing population in the United States.[34] Pathogenesis is identical to that described for osteoarthritis, osteochondral fragments, and slab fractures of the third carpal bone, but in horses with subchondral lucency of the third carpal bone, necrosis of subchondral bone causes table surface collapse, rather than osteochondral fragments or slab fractures involving the dorsal margin. Subchondral lucency of the third carpal bone is not a disease of young STBs, because the mean age was 4.1 years (range, 3 to 7 years) and chronic stress-related subchondral bone injury is required. The condition is rarely recognized in TBs probably because of gait differences and the fact that often osteoarthritis is more advanced in the STB before overt signs of lameness are seen.

Prodromal clinical signs of mild carpal lameness and a history of numerous intra-articular injections are present before onset of acute lameness, usually graded between 2 to 4 on a 5-point scale. Heat, effusion, and a positive response to flexion may be absent, and diagnostic analgesia is usually required to confirm diagnosis. The results of initial radiographic examination may be equivocal, and follow-up radiographic and scintigraphic examinations can help pinpoint subchondral lucency of the third carpal bone.

Surgical debridement is the treatment of choice. During arthroscopic examination, soft crumbly necrotic subchondral bone and damaged overlying cartilage are found. In some horses only a small full-thickness cartilage defect can be probed, but deep extensive subchondral bone softening is later found, whereas in others, fibrin-filled, full-thickness defects resembling subchondral bone collapse or table surface fracture are found. The damaged tissue is curetted, and if the resulting lesion is <5 mm palmar to the dorsal margin of the third carpal bone, this lip is removed, creating a defect that resembles removal of an osteochondral fragment. If subchondral lucency of the third carpal bone lesions are deep within the third carpal bone, the dorsal margin is not removed. Cartilage resurfacing could be considered, but it is not necessary for a successful outcome.

Prognosis is excellent for return to racing, particularly in pacers, but horses drop in racing class. Prognosis is guarded in 3- or 4-year-old trotters to return to racing the next year, but some make useful older racehorses. Of nine horses, eight returned to racing, but only six raced at the previous level.[34]

Comminuted Fractures

Comminuted fractures are unusual, but they occur occasionally in TB and QH racehorses and other horses that suffer injury while turned out in a field. Comminuted in this sense refers to numerous fractures in more than one carpal bone. In STB racehorses large, comminuted fractures of the third carpal bone can occur, but I have not seen a STB with a large osteochondral fracture involving more than one bone. The most common combination of fractures in TB and QH racehorses involves the third carpal bone and either the radial or intermediate carpal bone, or both. Carpal instability, most commonly carpus varus, is usually readily apparent if horses bear weight, but they are usually non–weight bearing. These injuries occur almost exclusively in racehorses, and often horses have chronic carpal lameness before injury, but fracture can occur in other types of horses without previous lameness during turnout exercise. Effusion and edema of surrounding soft tissues occurs. Diagnosis is confirmed radiographically (Fig. 39-14). If fractures involve only the distal row of carpal bones, instability is minimal and prognosis is better than if the middle carpal and antebrachiocarpal joints are involved. Consideration should be given for euthanasia if the horse is a gelding or intact male with limited breeding potential. Conservative management using sleeve or full-limb casts, or a combination of splints with a Robert Jones bandage, may give support and provide comfort, but usually instability is pronounced, horses develop extensive cast sores, and they are at risk to develop laminitis in the contralateral limb. Severe osteoarthritis, collapse, and angular limb deformity generally result in an unacceptable outcome in horses managed conservatively. Surgical management using carpal arthrodesis should be considered.

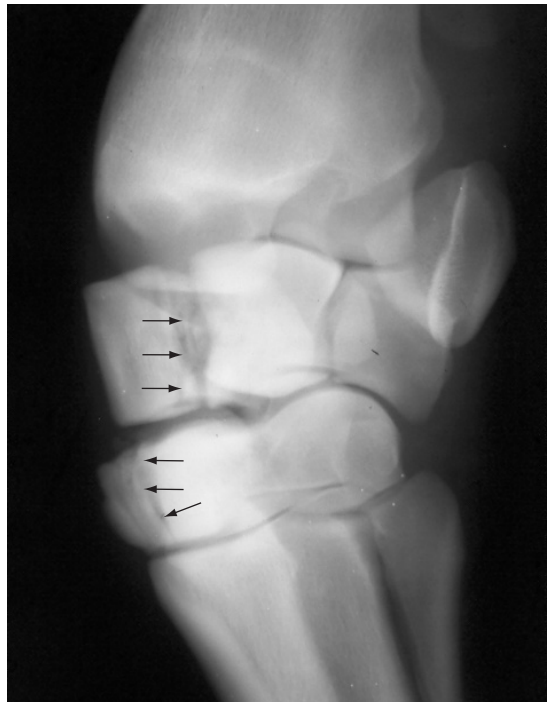

Fig. 39-14 Non–weight-bearing dorsolateral-palmaromedial oblique radiographic view of a Thoroughbred with a comminuted carpal fracture. The radial carpal and third carpal bones have frontal slab fractures *(arrows)*.

Carpal Arthrodesis

Arthrodesis is indicated when horses have comminuted carpal fractures and instability, severe lameness and osteoarthritis of one or more carpal joints, or when osteoarthritis is severe with collapse and angular deformity of the carpus. Partial (intercarpal) carpal arthrodesis involves fusing the middle carpal and carpometacarpal joints using bone plates applied to the proximal row of carpal bones and McIII. Pan-carpal arthrodesis involves bridging the entire carpus with bone plates applied to the distal radius, both rows of carpal bones, and McIII, fusing all three joints. Two dynamic compression plates are used for either technique, and in one study allografts were used in some horses to provide axial support for horses with collapsed carpi undergoing pan-carpal arthrodesis. In one horse, I successfully used acrylic to create an artifical fourth carpal bone to maintain axial stability, in addition to two bone plates and interfragmentary repair of fractures. Prognosis for salvage was good in horses with partial carpal arthrodesis[35] and fair to good in horses requiring pan-carpal arthrodesis.[35,36]

Accessory Carpal Bone Fractures

Fracture of the accessory carpal bone results from trauma, such as a fall while jumping, a hyperextension injury when landing, or an accident while turned out. Acute, severe lameness and swelling involve the palmar aspect of the carpus. Horses have severe pain during carpal flexion. Carpal tenosynovitis may occur acutely, but it is difficult to differentiate from diffuse swelling. Pronounced lameness lasts for several days, but horses are rarely non–weight bearing, and swelling resolves in 2 to 3 weeks. Horses with a chronic fracture may have little to no swelling, and diagnosis may be difficult, unless carpal tenosynovitis is present, because the lameness is not typical of carpal pain.

The most common fracture of the accessory carpal bone is a vertical slab fracture that involves the palmar aspect of the bone in the frontal plane (Fig. 39-15). Most fragments are simple, but small fragments at the proximal aspect of the fracture may occur. Fractures can be incomplete, but most are complete with mild displacement. Gross displacement and large comminuted fragments are unusual. Articular fractures were discussed previously.

Conservative management of non-articular fractures of the accessory carpal bone is recommended. The forces on the accessory carpal bone are substantial and result in failure of screw fixation, chronic instability, implant loosening, and osteitis (Fig. 39-15). Surgical fixation using the tension band principle may be successful, but I have not attempted repair because prognosis is favorable with conservative management. Horses are given NSAIDs, and a heavy full-limb cotton bandage is applied. Horses are given stall rest for 8 weeks, followed by stall rest with hand walking for 8 weeks, followed by walking with a rider up for 8 weeks. Radiographs most often reveal bony proliferative changes and fibrous rather than bony union of the fracture. Even with fibrous union, horses are usually serviceably sound. Prognosis for TB racehorses appears to be worse than for field hunters, jumpers, and other horses that may be able to perform with a mild gait restriction from chronic fibrosis. Carpal canal syndrome and carpal tenosynovitis may result (see Chapter 76).

Osteochondrosis

Osteochondrosis of the carpus is rare. In experimental studies extensive cartilage lesions histologically similar to those in naturally occurring osteochondritis dissecans have been produced. Rarely, radiographs of yearlings before or after public sales reveal rounded osteochondral fragments, usually involving the distal medial radius or the distal medial aspect of the radial carpal bone or proximal aspect of the third carpal bone. These fragments appear as solitary osteochondral fragments and do not have associated marginal osteophytes or enthesophytes, unlike osteochondral fragments caused by trauma at a young age. At the time of surgery these unusual fragments appear intercalated in dense joint capsule attachments, are rounded, and often have a smooth defect in the distal radius or third carpal bone, apparently the origin of the fragment. Whether these fragments represent a form of osteochondritis dissecans or old trauma is not known, but they appear similar to forms of osteochondritis dissecans found elsewhere.

Osseous Cyst-like Lesions

Osseus cyst-like lesions do occur in the carpus. Those of the ulnar carpal bone are common, appear to be incidental radiographic findings, are usually non-articular, and have sclerotic borders. Incidental osseous cyst-like lesions may also be seen in the second carpal bone, often in the presence of the first carpal bone, and also in the base (head) of McII. Osseous cyst-like lesions of the radial carpal bone and distal radius can cause lameness.[37] Effusion, heat, and a positive response to flexion are inconsistent and diagnostic analgesia is usually necessary. Radiographic signs may be obvious, but in some horses they are subtle, and scintigraphic examination is useful to pinpoint the area of modeling. In horses with an osseous cyst-like lesion that communicates with an articular surface, I have performed debridement and curettage, but results have been unfavorable to fair at best.

Osteochondromatosis

Osteochondromatosis is rare but has been seen in the carpometacarpal joint.[38] Progressive enlargement of the carpometacarpal joint and numerous unusual radiopacities were seen radiographically.[39] Arthroscopic examination of the carpometacarpal joint was possible, and osteochondral fragments were removed[38] (see Chapter 68).

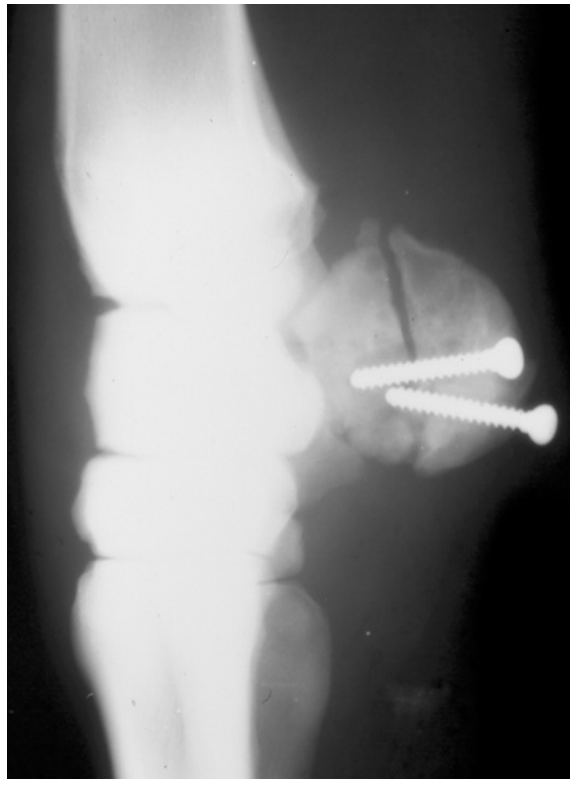

Fig. 39-15 A lateromedial radiographic view of a horse with a failed attempt at surgical management of a frontal slab fracture of the accessory carpal bone. These fractures are best managed conservatively without attempting repairs such as this one.

Infectious Arthritis

See Chapter 66 for a discussion of infectious arthritis.

Other Fractures Involving the Carpus

Avulsion Fracture of the Third Metacarpal Bone Associated with the Origin of the Suspensory Ligament

See Chapter 38 for a discussion of avulsion fracture of the third metacarpal bone associated with the origin of the suspensory ligament (page 367).

Incomplete, Longitudinal Fracture of the Proximal Palmar Cortex of the Third Metacarpal Bone

See Chapter 38 for a discussion of incomplete, longitudinal fracture of the proximal palmar cortex of the third carpal bone (page 364).

Dorsomedial Articular Fracture of the Proximal Aspect of the Third Metacarpal Bone

See Chapter 38 for a discussion of dorsomedial articular fracture of the proximal aspect of the third metacarpal bone (page 367).

Fracture of the Proximal Aspect of the Second and Fourth Metacarpal Bones

See Chapter 38 for a discussion of the proximal aspect of the second and fourth metacarpal bones (page 371).

Articular Fracture of the Distal Radius

Fractures of the distal radius rarely involve the antebrachiocarpal joint. Complete or incomplete, displaced or nondisplaced fractures of the radius in the sagittal plane and resembling condylar fractures of McIII/MtIII can occur.[39] Horses should be managed conservatively using full-limb bandages, NSAIDs, and absolute stall rest if fractures are nondisplaced. Some consideration should be given to cross-tying the horse for 3 to 6 weeks. Comminuted fractures of the radius, or those involving the distal radial physis and epiphysis that involve the antebrachiocarpal joint, should be repaired.

Soft Tissue Injuries of the Carpus and Carpal Region

Intercarpal Ligament

Various degrees of tearing of the medial palmar intercarpal ligament have been observed during arthroscopic examination of horses with osteochondral fragments or osteoarthritis and in some horses with occult carpal lameness. The medial palmar intercarpal ligament has recently been the source of considerable study and supposition, but whether tearing of this ligament observed in horses with carpal disease is causative or simply results from other pathological conditions is not yet known. The anatomy of the medial palmar intercarpal ligament and the relationship between osteochondral fragments and the dorsomedial intercarpal ligament were previously discussed (see page 377).

Because tearing of the medial palmar intercarpal ligament is an observation during arthroscopic examination of the middle carpal joint and a diagnosis impossible currently to make before surgery, specific clinical signs cannot be described. Once MRI becomes more widely available, diagnosis in horses with occult carpal lameness suspected to originate from the medial palmar intercarpal ligament may be possible before arthroscopic examination. Tearing of the medial palmar intercarpal ligament was observed in 27 joints in 20 horses with carpal lameness.[5] No correlation was found between tearing and severity of clinical signs. Joints with more medial palmar intercarpal ligament tearing had significantly *less* cartilage and subchondral bone damage, and an inverse relationship existed between the size and number of osteochondral fragments and ligament damage.[5] Therefore, although tearing of the medial palmar intercarpal ligament occurred commonly in horses with middle carpal joint damage, tearing was not seen with severe subchondral bone damage, and what role damage plays in the development of joint disease remains questionable.

In my experience, tearing of the medial palmar intercarpal ligament is unusual without at least mild cartilage damage or osteochondral fragmentation, but I have seen a small number of horses in which the only identifiable lesion was tearing and hemorrhage of the frayed ends, resulting in hemarthrosis. In these horses examining the palmar aspect of the middle carpal joint from the routine dorsal approach was possible. Rupture of the medial palmar intercarpal ligament has been seen in a small number of non-racehorse competition horses with pain localized to the middle carpal joint.[40] No other lesion was identified during arthroscopic examination. I suspect tearing of the medial palmar intercarpal ligament in horses with confirmed carpal lameness, but in which scintigraphic and radiographic examination findings are negative or equivocal, and in those with unexplained hemarthrosis of the middle carpal joint. Because horses that fall into this category are rare, prognosis is difficult to estimate.

Collateral Ligament

Injury of the dense collateral ligaments of the carpus is rare (see Chapter 68). Usually fracture of the distal radius, carpal bones, or the proximal aspect of McII and McIV occurs instead of collateral ligament damage. In foals, collateral ligament laxity is seen commonly and is self-limiting but can contribute to the development of angular limb deformity.

Carpal Tenosynovitis and Flexor Tendonitis

See Chapters 70 and 76 for a discussion of carpal tenosynovitis and flexor tendonitis (pages 629, 637, and 686).

Extensor Tendon

See Chapter 78 for a discussion of extensor tendon injury (pages 693 to 695).

Proximal Suspensory Desmitis

See Chapter 73 for a discussion of proximal suspensory desmitis (pages 654 to 662).

Synovial Ganglion

See Chapter 68 for a discussion of synovial ganglion injury (page 611).

Carpal Hygroma

Hygroma refers to a sac, bursa, or cavity filled with fluid. Carpal hygroma usually results from direct and blunt trauma to the dorsal aspect of the joint, including the capsule and overlying extensor tendons and sheaths. Carpal hygroma is an occasional complication after arthroscopic surgery or arthrotomy of the carpus. During arthrotomy, a distinct subcutaneous space over the dorsal aspect of the carpus is encountered, but in most instances this is a potential rather than a real space. When traumatized, this space fills with fluid, resulting in a large sac. Initially, diffuse edema may be present, and horses may be lame, particularly after flexion, but lameness soon abates. A large, fluid filled, non-painful swelling results that must be differentiated from extensor tenosynovitis (longitudinal swellings) and herniation of the middle carpal and antebrachiocarpal joint capsules (horizontal swellings). Lameness is usually not observed in horses with chronic hygroma unless a large swelling prohibits carpal flexion. Communication with an extensor sheath or joint capsule is rare, unless previous arthroscopic surgery has been performed and a portal inadvertently was made through a tendon sheath. In naturally occurring carpal hygroma a secretory lining is present, but it must develop from cell differentiation because communication with a source of synovial cells is lacking. Diagnosis is based on clinical signs. Positive contrast radiography and ultrasonographic examination are used to determine extent and communication with nearby structures.

The swelling is usually persistent, but it often does not compromise gait, although swelling does result in a cosmetic blemish. I have heard of resolution after injection with oxytetracycline, atropine, or contrast material. Drainage, with or without corticosteroid injection, and chronic bandaging are

usually unsuccessful in permanently resolving swelling. Surgical management in the form of en bloc resection is the treatment of choice for cosmetic results. Simply draining the cavity and inserting through-and-through or closed-suction drains may temporarily resolve swelling, but recurrence is likely. I attempt resection en bloc without entering the hygroma cavity, but invariably the lining is penetrated. The lining is dissected from all overlying subcutaneous tissues and underlying capsule and tendon sheaths. Once removed, Penrose drains are placed, a light sterile bandage is applied, and horses recover with a sleeve cast-bandage that is left in place a minimum of 7 to 10 days. Drains are removed between 7 and 10 days when cast material is cut, and then the cast material can be used as a splint over a heavy padded bandage. Horses are given absolute stall confinement for 3 weeks. This treatment is successful but expensive.

Neoplasia

A rare cause of carpal region lameness is neoplasia. Lameness and progressive swelling were seen in a 20-year-old horse with chondrosarcoma of the distal radius that caused bony proliferation and swelling of the antebrachiocarpal joint.[41] I have seen an undifferentiated sarcoma of the distal antebrachium causing progressive swelling, mild lameness, and a reduction in carpal flexion in a TB broodmare.

Hypertrophic Osteopathy

Lameness associated with hypertrophic osteopathy (see Chapters 15 and 38) is usually mild, and the condition does not directly affect the carpus, but fibrous and bony swelling of the distal radius may cause enlargement of the antebrachiocarpal joint region, prompting radiographic examination.

CHAPTER • 40

Antebrachium

Lance H. Bassage and Mike W. Ross

ANATOMY

The antebrachium lies between the elbow and carpus and comprises principally the radius and small vestigial portion of the ulna and the flexor and extensor muscles. The tendons of the superficial and deep digital flexor muscles, the accessory ligament of the superficial digital flexor tendon and the carpal sheath are discussed elsewhere (see Chapters 70, 71, and 76). The medial aspect of the antebrachium is relatively devoid of soft tissue coverage and this is important when considering fractures of the radius. Major neurovascular structures include the median artery (continuation of the brachial artery in the proximal antebrachium), vein, and nerve; the radial, ulnar, and cutaneous antebrachial nerves; and the accessory cephalic and cephalic veins.

CLINICAL DIAGNOSIS AND IMAGING CONSIDERATIONS

Lameness associated with the antebrachial region is relatively unusual. Clinical signs are obvious in horses with unstable radial fractures or in those with marked soft tissue swelling. In others diagnosis can be challenging and ruling out other causes of forelimb lameness and then using diagnostic imaging to reach a definite diagnosis may be necessary. Perineural analgesia of the median and ulnar nerves (see Chapter 10) is performed to rule out more distal sources of pain.

Definitive diagnosis of most lameness problems of the antebrachium can be made using conventional radiography and ultrasonography, but nuclear scintigraphy is useful for diagnosing incomplete and stress fractures of the radius, enostosis-like lesions, and enthesopathy at the origin of the accessory ligament of the superficial digital flexor tendon.

Osteochondroma of the Distal Radius

See Chapter 76 for a discussion of osteochondroma of the distal radus.

Physeal Dysplasia of the Distal Radius (Physitis)

See Chapter 59 for a discussion of physitis.

Traumatic Physitis and Closure of the Distal Radial Physis

A syndrome of vague forelimb lameness believed to be associated with inflammation or pain originating from the distal radial physis has been recognized in young racehorses in early training. Anecdotally the condition appears to be more prevalent in 2-year-old colts. Distal radial physeal closure measured radiographically occurred earlier in fillies (701 days) than in colts (748 days).[1] Presumably the condition results from repetitive trauma to an open physis. The term *open knees* is commonly used to describe the state of skeletal immaturity. This condition is distinct from physeal dysplasia (physitis), because the condition is not a developmental abnormality, is not associated with clinically apparent enlargement of the metaphyseal region, and occurs in 2-year-old horses in active training.

Mild to moderate forelimb lameness is vague, without indications of a problem elsewhere in the limb. The condition is usually bilateral, but horses can show unilateral lameness, because one limb is more painful than the other. Horses often have a choppy stride, with the legs carried wide. Focal heat may be present, but swelling is usually absent or minimal and pain may be difficult to detect. Presumptive diagnosis is made on the basis of history, clinical signs, and ruling out other causes of lameness. A positive response to median and ulnar nerve blocks can be used to confirm that the distal antebrachium is the source of pain, but this can also abolish subchondral bone pain in the carpus. Definitive radiographic abnormalities are rarely present, but a radiographically open physis supports the diagnosis. Nuclear scintigraphy is generally not helpful, because all horses of this age have moderate to intense increased radiopharmaceutical uptake at the physis. However, scintigraphy is useful for identifying or ruling out other potential causes of lameness, and asymmetrical radiopharmaceutical uptake (greater in the affected physis of the more severely affected limb) may support the diagnosis.

Treatment consists primarily of rest or a reduction in exercise intensity and systemic non-steroidal anti-inflammatory drugs (NSAIDs). Duration of rest varies with the skeletal maturity of the horse and severity of the condition. Local injection of corticosteroids or other drugs, such as homeopathic remedies, and systemic treatment with anabolic steroids

CHAPTER • 40

Antebrachium

Lance H. Bassage and Mike W. Ross

ANATOMY

The antebrachium lies between the elbow and carpus and comprises principally the radius and small vestigial portion of the ulna and the flexor and extensor muscles. The tendons of the superficial and deep digital flexor muscles, the accessory ligament of the superficial digital flexor tendon and the carpal sheath are discussed elsewhere (see Chapters 70, 71, and 76). The medial aspect of the antebrachium is relatively devoid of soft tissue coverage and this is important when considering fractures of the radius. Major neurovascular structures include the median artery (continuation of the brachial artery in the proximal antebrachium), vein, and nerve; the radial, ulnar, and cutaneous antebrachial nerves; and the accessory cephalic and cephalic veins.

CLINICAL DIAGNOSIS AND IMAGING CONSIDERATIONS

Lameness associated with the antebrachial region is relatively unusual. Clinical signs are obvious in horses with unstable radial fractures or in those with marked soft tissue swelling. In others diagnosis can be challenging and ruling out other causes of forelimb lameness and then using diagnostic imaging to reach a definite diagnosis may be necessary. Perineural analgesia of the median and ulnar nerves (see Chapter 10) is performed to rule out more distal sources of pain.

Definitive diagnosis of most lameness problems of the antebrachium can be made using conventional radiography and ultrasonography, but nuclear scintigraphy is useful for diagnosing incomplete and stress fractures of the radius, enostosis-like lesions, and enthesopathy at the origin of the accessory ligament of the superficial digital flexor tendon.

Osteochondroma of the Distal Radius

See Chapter 76 for a discussion of osteochondroma of the distal radus.

Physeal Dysplasia of the Distal Radius (Physitis)

See Chapter 59 for a discussion of physitis.

Traumatic Physitis and Closure of the Distal Radial Physis

A syndrome of vague forelimb lameness believed to be associated with inflammation or pain originating from the distal radial physis has been recognized in young racehorses in early training. Anecdotally the condition appears to be more prevalent in 2-year-old colts. Distal radial physeal closure measured radiographically occurred earlier in fillies (701 days) than in colts (748 days).[1] Presumably the condition results from repetitive trauma to an open physis. The term *open knees* is commonly used to describe the state of skeletal immaturity. This condition is distinct from physeal dysplasia (physitis), because the condition is not a developmental abnormality, is not associated with clinically apparent enlargement of the metaphyseal region, and occurs in 2-year-old horses in active training.

Mild to moderate forelimb lameness is vague, without indications of a problem elsewhere in the limb. The condition is usually bilateral, but horses can show unilateral lameness, because one limb is more painful than the other. Horses often have a choppy stride, with the legs carried wide. Focal heat may be present, but swelling is usually absent or minimal and pain may be difficult to detect. Presumptive diagnosis is made on the basis of history, clinical signs, and ruling out other causes of lameness. A positive response to median and ulnar nerve blocks can be used to confirm that the distal antebrachium is the source of pain, but this can also abolish subchondral bone pain in the carpus. Definitive radiographic abnormalities are rarely present, but a radiographically open physis supports the diagnosis. Nuclear scintigraphy is generally not helpful, because all horses of this age have moderate to intense increased radiopharmaceutical uptake at the physis. However, scintigraphy is useful for identifying or ruling out other potential causes of lameness, and asymmetrical radiopharmaceutical uptake (greater in the affected physis of the more severely affected limb) may support the diagnosis.

Treatment consists primarily of rest or a reduction in exercise intensity and systemic non-steroidal anti-inflammatory drugs (NSAIDs). Duration of rest varies with the skeletal maturity of the horse and severity of the condition. Local injection of corticosteroids or other drugs, such as homeopathic remedies, and systemic treatment with anabolic steroids

have been used but are of dubious value. For some horses slow jogging for 4 to 6 weeks may be all that is required, and for others stall confinement with hand walking exercise progressing to paddock turnout for several months may be necessary. Follow-up radiographs can be used to monitor physeal closure, which is often used to determine the appropriate time to resume harder training.

The issue of distal radial physeal closure, the role of radiographs in making this determination, and how to determine the point when training should commence are controversial. Many trainers and veterinarians customarily radiograph the distal radius of 2-year-olds, and those with open knees (radiographic evidence that bony union at the physis is incomplete) are withheld from hard training until the physes have closed. Radiographic closure of the distal radial physis generally occurs by 20 to 24 months of age[2] or slightly later.[1] Scintigraphic activity of the distal radial physis persists well after radiographic evidence of closure is observed.[3] However, endochondral ossification ceases (biological closure) before fusion is evident radiographically, and in our experience horses with a thin or faintly visible physeal remnant visible radiographically are at low risk of traumatic physitis.

Because the diagnosis is difficult to substantiate and pain may originate from an undetermined source, giving an accurate prognosis is difficult. If other more common conditions have been ruled out and the diagnosis of traumatic physitis is accurate, the prognosis is excellent. Many horses remaining in training develop signs of carpal lameness, and traumatic physitis may simply represent a prodromal phase of early osteoarthritis and bone pain. Finally, no correlation between age or month of closure of the distal radial physes and money won, races won, fastest mile, or fastest win mile during the 2-year-old year was found in Standardbreds.[4]

Radial Fractures

Radial fractures almost always result from external trauma, often a kick from another horse in adults, or from being stepped on or kicked by a mare in foals. Stress fractures of the radius also occur,[5,6] but in our experience true stress fractures of the radius are rare, and the description of those reported by others is similar to what we have termed *enostosis-like lesions* (see the following discussion).

Clinical signs depend on the severity and location of the fracture. Horses with complete fractures (which are nearly always displaced) are severely lame (non–weight bearing, grade 5) and have marked soft tissue swelling associated with the fracture itself or the site of the original wound. The limb may have an unusual angle and crepitus is usually audible and palpable. Often an associated wound results from the initial injury or is caused by fragment penetration, especially on the medial aspect of the antebrachium. Horses with incomplete or non-displaced fractures have moderate to severe lameness (grade 3 to 5) shortly after the injury, but within 12 to 72 hours they are often fully weight bearing and walking with minimal lameness. However, resumption of exercise or turn out often results in the fracture becoming displaced within 1 to 2 days. Horses with true stress fractures have mild to moderate lameness (grade 1 to 3) at a trot.

For horses with complete, displaced (unstable) fractures of the radius the diagnosis is straightforward. Radiography is only needed to define fracture configuration, and to determine if repair is possible. Radiographs are *essential* in the initial evaluation of *any* horse with a wound in the antebrachium or over the proximal aspect of the carpus that has a history of acute, moderate to severe lameness associated with the injury. Lameness associated with incomplete or hairline fractures of the radius may be transient, but radiographs often reveal obvious or suspicious fracture lines (Fig. 40-1, *A*). Any radiographic evidence of bone injury, often a localized cortical fragmentation or compression fracture, warrants high suspicion of an incomplete fracture, and a full series of radiographs should be obtained. Any horse that has persistent lameness after antebrachial trauma in which original radiographs were negative should be re-evaluated within 7 to 10 days, when a fracture may be evident. The horse should be confined to box rest in the interim. Diagnosis in horses with incomplete fractures or stress fractures can sometimes be difficult. Scintigraphic examination is important to differentiate fracture from other problems of the radius, such as enostosis-like lesions.

Emergency management of horses with long-bone fractures has been well described[7] (see Chapter 87). Horses with unstable fractures should be sedated, wounds should be treated, and a full-limb Robert Jones dressing with splints should be applied. A caudal splint extending from the ground to the point of the elbow (olecranon process) and a lateral splint extending to the withers are attached with tape. The bandage should have a flat surface to allow the lateral splint to be *in contact with* the skin of the upper limb and torso to prevent distal limb abduction. An oversized bandage reduces the effectiveness of the splints. Properly applying external coaptation is time consuming and difficult, but appropriate stabilization is essential to reduce the risks of further fracture displacement and skin penetration. NSAIDs and broad-spectrum antimicrobial therapy should be administered. Horses should travel facing backward.

Confinement to a stall is *mandatory* for any horse with any radiographic abnormality, including focal cortical defects, or if there is known trauma but with no detectable lesions. Catastrophic failure of the radius often results when small cortical defects or incomplete fractures become displaced (Fig. 40-1, *B*). We recommend conservative management in adult horses with incomplete or non-displaced radial fractures. If possible, the horse should be transported to a surgical facility even if conservative management is chosen, because the fracture could become displaced and immediate surgical repair may be necessary. However, transport also involves risks that must be weighed against economic considerations and

Fig. 40-1 **A,** Craniocaudal radiographic view of the distal radius of a horse revealing a non-displaced fracture (*arrows*). The horse was found acutely severely lame with a small wound over the distal cranial aspect of the antebrachium earlier that day. **B,** Craniocaudal radiographic view 1 day later. Catastrophic fracture occurred even though the horse was confined to a box stall. The original fracture line (*arrows*) and the edge of a plastic fence post used as a splint are visible.

other factors affecting prognosis. Horses with incomplete fractures should be strictly confined to a stall for 8 weeks. External coaptation is applied as described previously for 4 to 8 weeks but can be difficult to maintain. Cross-tying is generally unnecessary, because horses tend not to lie down with bulky external coaptation in place. If radiographs reveal acceptable progression of healing after 8 weeks, the horse is restricted to box stall rest with hand-walking exercise for another 2 months. The majority of fractures are clinically healed in 4 months, although complete radiographic healing may take up to 6 months or more in adult horses. Paddock turnout is generally allowed after 4 months, and horses return to work 5 to 6 months after injury.

NSAIDs are administered as needed to provide comfort and minimize the potential for contralateral limb laminitis. NSAID administration is usually only necessary for 7 to 10 days, and if pain is not adequately controlled, the horse should be reassessed carefully for fracture displacement or progression or infection associated with any wounds. Antibiotic therapy should be given to horses with wounds or deep pressure sores associated with the bandage and splints.

Complete or displaced radial fractures require open reduction and internal fixation, but the prognosis in adult horses is poor to grave. The current method of choice is the application of two dynamic compression plates, one on the cranial surface and one on the lateral or medial surface, depending on fracture configuration.[8,9] In adult horses use of the dynamic condylar screw plate should be considered. Repair of fractures located at the most proximal or distal aspect of the radius, or those with severe comminution is considerably more difficult, and these horses have a grave prognosis. In foals surgical repair is more successful, and a mid-shaft transverse or short oblique fracture with minor comminution is most common. Although infection is still a concern, implant or bone failure, seen commonly in adult horses, is less frequent. Physeal fractures result in premature closure of the physis, even if repaired surgically. Plate removal is necessary for foals intended to be used for racing.

Management of horses with rare radial stress fractures consists of rest for 4 months. Horses are given 2 months of box stall rest and 2 months of individual turnout in a small paddock before begin returned to training. Follow-up radiographic and scintigraphic examinations are recommended.

Prognosis for horses with incomplete or non-displaced fractures of the radius is good, but clients should be warned of the possible complications of fracture propagation and contralateral laminitis, if initial lameness is severe. Those that do not develop complications, and in which fractures heal uneventfully, have an excellent prognosis for return to full athletic function. Prognosis for surgical repair of radial fractures in adult horses is poor but depends greatly on fracture configuration and whether the fracture is open. Horses with open fractures have a worse prognosis, because infection is an important and frequent complication. Adult horses with long spiral or oblique fractures are the best surgical candidates, whereas those with comminution or fractures involving the proximal and distal aspects of the radius, in particular those involving the antebrachiocarpal or elbow joints, have a poor to grave prognosis. Overall the success rate of surgical management of an adult horse with a complete radial fracture is no better than 10% and is expensive. If severe comminution exists, the fracture is open, or it involves a joint, euthanasia should be recommended. In foals, prognosis is considerably better, with a good prognosis for survival and a fair to good prognosis for future athletic use.[8,9] Foals with radial fractures involving the distal physis will likely develop angular limb deformity, and prognosis for athletic use is worse than in those with mid-diaphyseal fractures. The prognosis for horses with rare radial stress fractures is excellent.

Enostosis-like Lesions of the Radius

Enostosis-like lesions are an unusual condition affecting many long bones, including the radius. Enostosis is defined as "bone within a bone," and because the cause has yet to be determined, the term *enostosis-like lesion* is used. Enostosis-like lesions are focal or multifocal intramedullary mild to dense radiopacities. Scintigraphically, enostosis-like lesions are associated with mild to intense increased radiopharmaceutical uptake (IRU) on delayed (bone phase) images (Fig. 40-2, *A*). Lesions may occur in one or more bones simultaneously but are not necessarily associated with lameness.[10,11] Previously, enostosis-like lesions have been described as bone infarcts or bone islands. Histological examination of specimens harvested from an enostosis-like lesion in a humerus revealed changes compatible with ischemia of cancellous bone and bone marrow.[12] Histological changes were similar to those in specimens examined from patients with medullary infarcts or those in bone adjacent to diaphyseal fractures and cortical stress fractures. However, the findings were not pathognomonic or exclusively characteristic of either of these entities.[12] One of us (L.H.B.) believes enostosis-like lesions may be caused by primary disruption of medullary vasculature and secondary development of bone sclerosis. Enostosis-like lesions are possibly an atypical form of bone infarct. Enostosis-like lesions are frequently found close to a nutrient foramen.[10] Because enostosis-like lesions occur in adult horses of all ages and performance categories, they are not likely to be stress fractures.

Although enostosis-like lesions can be an incidental radiographic or scintigraphic finding of the radius, or most long bones, lameness apparently attributable to the condition occurs in approximately 50% of affected horses. In horses with clinically relevant enostosis-like lesions, lameness is usually mild but may be severe.[13] Although enostosis-like lesions can affect many bones simultaneously, lameness is usually restricted to a single limb.

Because completely abolishing pain originating from the radius may be difficult using diagnostic analgesia, in most horses with enostosis-like lesions diagnosis is made by ruling out other potential causes of lameness. Enostosis-like lesions must be differentiated from true stress fractures. It is imperative that two perpendicular scintigraphic views are obtained to allow differentiation of cortical and medullary IRU. Although treatment of horses with enostosis-like lesions or stress fractures is similar, cause and recurrence are different. Enostosis-like lesions are associated with mild to intense IRU in the medulla. In our experience enostosis-like lesions causing lameness are usually moderately to intensely active. Radiographs reveal corresponding single or multiple, focal or multifocal sclerotic lesions within the medullary cavity (Fig. 40-2, *B*). The lesions are frequently in contact with the endosteal surface and are most often in close proximity to the nutrient foramen. In the radius, follow-up scintigraphic and radiographic evaluation between 4 and 9 months after initial diagnosis often reveals resolution of the enostosis-like lesions, although resolution of radiographic changes lags behind that visible scintigraphically.

Treatment of horses with enostosis-like lesions thought to be causing lameness is nearly identical to that for those with stress fractures. NSAIDs (phenylbutazone, 2.2 mg/kg, bid) are administered for 5 to 10 days or longer depending on degree of lameness. Horses are restricted to stall rest with hand-walking exercise for 2 months, followed by a minimum of 2 months in an individual small paddock. Follow-up clinical, scintigraphic, and radiographic evaluation is recommended. Prognosis for most horses with enostosis-like lesions is excellent, and recurrent lameness is rare, although occasionally longer (6 to 9 months) convalescence is required.

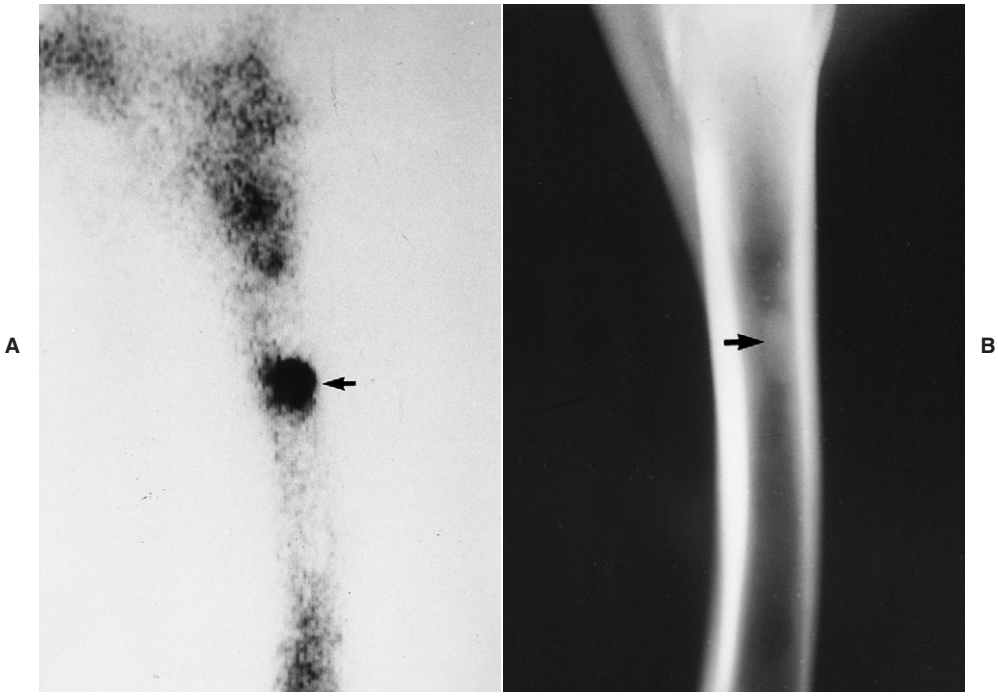

Fig. 40-2 **A,** Lateral or delayed (bone) phase scintigraphic view showing focal, intense increased radiopharmaceutical uptake (*arrow*) in the medullary cavity consistent with an enostosis-like lesion. Two scintigraphic views were compared and increased radiopharmaceutical uptake determined to involve the medullary cavity rather than the cortex. **B,** Lateromedial radiographic view reveals intramedullary sclerosis (*arrow*) on the endosteal surface and adjacent to the nutrient foramen, radiographic signs typical in horses with enostosis-like lesions.

Osseous Cyst-Like Lesions of the Distal Radius

Osseous cyst-like lesions occur in immature[14] and adult horses[15] and may result from osteochondrosis or trauma. Occasionally, osseus cyst-like lesions occur secondary to severe osteoarthritis of the antebrachiocarpal joint. Lameness ranges from mild to severe (grade 1 to 4) and may be sudden or insidious in onset.[14,15] Often no localizing clinical signs are present, unless osseus cyst-like lesions are secondary to osteoarthritis of the antebrachiocarpal joint, when effusion may be present.

Lameness is localized to the antebrachiocarpal joint and distal radius by intra-articular analgesia or by using median and ulnar nerve blocks. Response to intra-articular analgesia of the antebrachiocarpal joint is inconsistent; most horses show partial improvement. Scintigraphy is useful in horses in which diagnostic analgesia fails to localize lameness. Radiographs reveal a well-defined radiolucent defect in the subchondral bone, often with a sclerotic margin (Fig. 40-3), with or without communication with the antebrachiocarpal joint.

Management remains controversial, and a universally accepted method is not currently available. Successful surgical management using an extra-articular approach, debridement, and cancellous bone grafting has been described.[15] Osseus cyst-like lesions that enter the antebrachiocarpal joint can be debrided using an intra-articular approach, whereas those without communication are best managed using an extra-articular approach. Non-surgical management was successful and consisted of restricted exercise, with or without intra-articular administration of hyaluronan.[14] We treat horses conservatively. Duration of restricted exercise and number and type of intra-articular injections are determined on a case-by-case basis. Horses are given a minimum of 6 months of rest and longer if gradual improvement in clinical signs is seen. Conservative management is the first choice in immature

Fig. 40-3 Craniocaudal radiographic view of the distal radius showing an osseous cyst-like lesion (*arrow*).

horses (<2 years of age). Extra-articular corticosteroid injection using a small drill bit has been successful in other sites and may be applicable for distal radius lesions. If little improvement is seen after 6 months, then surgical debridement (with or without grafting) should be considered. Limited data are available on which to base prognosis, which may be better in immature horses (<2 years of age).

Desmitis of the Accessory Ligament of the Superficial Digital Flexor Tendon

See Chapter 76 for a discussion of desmitis of the accessory ligament of the superficial digital flexor tendon.

Acute Caudal Antebrachial Myositis

Myositis and traumatic injury of the muscles in the caudal antebrachium are relatively rare. Horses that compete over jumps at speed such as Three-Day Event, timber, and steeplechase horses appear to be at risk to traumatize these muscles, presumably as a result of hyperextension of the metacarpophalangeal and carpal joints during landing. Occasionally, horses develop inexplicable myositis or injury of these muscle unassociated with a known traumatic event. Infectious myositis can result from puncture or kick wounds (see the following discussion).

Clinical signs include acute, mild to severe soft tissue swelling of the caudal antebrachium, along with a variable degree of lameness. Lameness may be relatively severe immediately after the injury (grade 4, lameness evident at a walk), but with rest and anti-inflammatory treatment for 12 to 72 hours the lameness improves to grade 1 to 3. Lameness is usually proportional to the degree of swelling but in some horses may be inappropriately severe. Even mild swelling of muscles located deep to the dense antebrachial fascia can cause profound lameness, presumably from compartment syndrome (swelling within a rigid tissue compartment). Horses commonly stand with the carpus held in partial flexion. Carpal flexion is usually severely restricted initially because of extensive swelling and pain. It is important to differentiate traumatic injury from infectious myositis or cellulitis. Horses with diffuse swelling caused by infection often have fever, severe lameness, and pain on palpation.

Presumptive diagnosis can usually be made on the basis of history and clinical signs. The antebrachium should be carefully evaluated for even small puncture wounds. A recent but seemingly unrelated area of injury or small wound in the elbow or axillary region may be an important part of the history or physical examination. The clinician should measure rectal temperature. Pyrexia indicates infection. Radiography should be performed to rule-out bony injury, such as an incomplete fracture of the radius. Ultrasonographic examination reveals heterogeneous echogenicity within the bellies and between the fascia of the affected muscles, compatible with fiber disruption and hematoma formation.

Treatment consists of systemic NSAID administration (7 to 10 days) and hydrotherapy. Cold water hosing is administered for 15 to 20 minutes twice a day for 5 days and then warm water hosing is initiated for 5 days. Horses are confined to a stall for 6 weeks and hand-walking exercise is initiated, beginning at 5 minutes twice a day and increasing by 5 minutes each week. Passive flexion and extension of the carpus (30 to 50 repetitions daily) helps to improve range of motion and possibly fiber alignment. Clinical and ultrasonographic evaluation is recommended after 6 weeks. Work should not commence until carpal flexion is normal and the horse is sound. The prognosis for return to full athletic function is good.

Infectious Myositis and Cellulitis

Small puncture wounds in the antebrachium, elbow, and pectoral region can result in infections that cause tremendous antebrachial swelling associated with subcutaneous or deeper tissues. Small wounds may seal over quickly but result in inoculation of bacteria into deeper tissues, causing diffuse cellulitis or infectious myositis. Abrasions from equipment such as hobbles in a Standardbred racehorse can lead to deep infections of the proximal antebrachium. Usually swelling is also present in the distal limb and the carpal sheath may show sympathetic effusion. Infectious myositis may lead to deep abscess formation. Lameness is usually moderate to severe. The horse may be depressed and is usually pyrexic. White blood cell count and fibrinogen concentration are raised. Skin sloughing may develop with aggressive infections caused by *Streptococcus* or *Staphylococcus* species. Radiographs should be obtained, because a radial or ulnar fracture may occur concurrent with infection, but are usually negative unless osteitis of the radius or ulna exists.

Treatment involves administration of broad-spectrum antimicrobial drugs and NSAIDs and the application of topical warm water hydrotherapy. Full-limb bandaging is recommended to reduce swelling in the antebrachium and distal limb. Horses with diffuse cellulitis usually respond quickly (within 3 to 5 days), whereas those with deeper infections require prolonged therapy and an abscess needs surgical drainage.

Swelling of the Antebrachium Associated with Other Conditions

Horses with infectious arthritis of the elbow joint, fractures of the proximal radius or ulna, or distal humeral fractures often have swelling of the antebrachium. These conditions should be kept in mind if diagnosis of a primary problem in the antebrachium cannot be made.

Hypertrophic Osteopathy

Hypertrophic osteopathy is an unusual disorder involving bilaterally symmetrical proliferation of fibrous tissue and periosteal bone in the appendicular and, less frequently, the axial skeleton, involving the metaphyseal and diaphyseal regions of several bones of all limbs.[16,17] Hypertrophic osteopathy may be associated with disease in the thorax or abdomen or with vascular abnormalities. Cause is unknown but may be neurogenic, mediated by the vagus nerve, or hormonal, leading to changes in regional blood flow. Clinical signs include soft tissue swelling and stiffness or lameness, often associated with elevated fibrinogen levels. Radiography of affected bones reveals palisading periosteal new bone. Identification of the primary lesion is important, because bony lesions may resolve with successful treatment of the underlying disease.[16-19] NSAIDs may ameliorate clinical signs.

CHAPTER • 41

The Elbow, Brachium, and Shoulder

Sue J. Dyson

ANATOMICAL CONSIDERATIONS

The elbow joint comprises the humerus, radius, and ulna. The distal humerus develops from three ossification centers: the diaphysis, the distal epiphysis, and the epiphysis of the medial condyle. These close radiographically between 11 and 24 months of age. The radius and ulna have a single proximal epiphysis. The radial physis closes radiographically between 11 and 24 months of age, but the ulnar physis does not close until 24 to 36 months of age. Physeal closure occurs later in non-Thoroughbred breeds.

The cranial aspect of the olecranon of the ulna has articular and non-articular components. The anconeal process and trochlear notch articulate with the humerus. At the distal part of the trochlear notch is a distinct ridge. Distal to this is a large, non–weight-bearing synovial fossa.

The elbow is a ginglymus joint, supported medially and laterally by collateral ligaments. The medial collateral ligament comprises a long superficial part and a deeper short part. The medial collateral ligament arises from an eminence on the medial epicondyle of the humerus. The deep part inserts on the radial tuberosity; the superficial part inserts on a more distal prominence, just distal to the interosseous space between the radius and ulna. The lateral collateral ligament arises from a depression in the lateral epicondyle of the humerus and inserts on the lateral tuberosity of the radius, just distal to the joint margin. The joint capsule is extremely thin caudally, where it forms a pouch in the olecranon fossa. Cranially the joint capsule is strengthened by oblique fibers and blends with the collateral ligaments medially and laterally.

The most readily palpable landmarks are the olecranon of the ulna and the lateral collateral ligament of the humeroradial joint. Minimal soft tissue covers the lateral aspect of the elbow, making it vulnerable to the effects of direct trauma and penetrating wounds.

The humerus is surrounded by muscles, which largely protect it from the effects of direct trauma. The deltoid tuberosity on the craniolateral aspect is usually readily palpable and is potentially vulnerable to the effects of direct trauma. The deltoid tuberosity is the most useful landmark for identifying the point for needle insertion for synoviocentesis of the intertubercular (bicipital) bursa. The proximal humerus has several centers of ossification for the humeral head and the greater and lesser tubercles, which gradually fuse from 3 to 5 months of age. Radiographic closure of the proximal humeral physis occurs between 24 and 36 months of age.

The scapula has four centers of ossification: the scapular cartilage, body of the scapula, cranial part of the glenoid cavity of the scapula, and supraglenoid tubercle and coracoid process. The ossification center for the cranial part of the glenoid cavity fuses directly with the body of the scapula, and this is complete radiographically by 5 months of age. The physis between the supraglenoid tubercle and coracoid process and the body of the scapula closes radiographically between 12 and 24 months of age, being earlier in Thoroughbred and Thoroughbred crossbreeds than in ponies. These physeal lines remain weak links and it is through these that fractures of the supraglenoid tubercle and cranial part of the glenoid cavity of the scapula tend to occur.

The scapula is attached by the serratus ventralis muscles to the axial skeleton. Other muscles involved in attachment of the thoracic limb to the trunk and neck are the four pectoral muscles, the braciocephalicus, and omotransversarius.

The brachial plexus lies on the axial aspect of the scapula and is derived from the sixth, seventh, and eighth cervical nerve roots and the first thoracic nerve. These nerve roots are potentially vulnerable to trauma where they exit the cervical

The Elbow, Brachium, and Shoulder

Sue J. Dyson

ANATOMICAL CONSIDERATIONS

The elbow joint comprises the humerus, radius, and ulna. The distal humerus develops from three ossification centers: the diaphysis, the distal epiphysis, and the epiphysis of the medial condyle. These close radiographically between 11 and 24 months of age. The radius and ulna have a single proximal epiphysis. The radial physis closes radiographically between 11 and 24 months of age, but the ulnar physis does not close until 24 to 36 months of age. Physeal closure occurs later in non-Thoroughbred breeds.

The cranial aspect of the olecranon of the ulna has articular and non-articular components. The anconeal process and trochlear notch articulate with the humerus. At the distal part of the trochlear notch is a distinct ridge. Distal to this is a large, non–weight-bearing synovial fossa.

The elbow is a ginglymus joint, supported medially and laterally by collateral ligaments. The medial collateral ligament comprises a long superficial part and a deeper short part. The medial collateral ligament arises from an eminence on the medial epicondyle of the humerus. The deep part inserts on the radial tuberosity; the superficial part inserts on a more distal prominence, just distal to the interosseous space between the radius and ulna. The lateral collateral ligament arises from a depression in the lateral epicondyle of the humerus and inserts on the lateral tuberosity of the radius, just distal to the joint margin. The joint capsule is extremely thin caudally, where it forms a pouch in the olecranon fossa. Cranially the joint capsule is strengthened by oblique fibers and blends with the collateral ligaments medially and laterally.

The most readily palpable landmarks are the olecranon of the ulna and the lateral collateral ligament of the humeroradial joint. Minimal soft tissue covers the lateral aspect of the elbow, making it vulnerable to the effects of direct trauma and penetrating wounds.

The humerus is surrounded by muscles, which largely protect it from the effects of direct trauma. The deltoid tuberosity on the craniolateral aspect is usually readily palpable and is potentially vulnerable to the effects of direct trauma. The deltoid tuberosity is the most useful landmark for identifying the point for needle insertion for synoviocentesis of the intertubercular (bicipital) bursa. The proximal humerus has several centers of ossification for the humeral head and the greater and lesser tubercles, which gradually fuse from 3 to 5 months of age. Radiographic closure of the proximal humeral physis occurs between 24 and 36 months of age.

The scapula has four centers of ossification: the scapular cartilage, body of the scapula, cranial part of the glenoid cavity of the scapula, and supraglenoid tubercle and coracoid process. The ossification center for the cranial part of the glenoid cavity fuses directly with the body of the scapula, and this is complete radiographically by 5 months of age. The physis between the supraglenoid tubercle and coracoid process and the body of the scapula closes radiographically between 12 and 24 months of age, being earlier in Thoroughbred and Thoroughbred crossbreeds than in ponies. These physeal lines remain weak links and it is through these that fractures of the supraglenoid tubercle and cranial part of the glenoid cavity of the scapula tend to occur.

The scapula is attached by the serratus ventralis muscles to the axial skeleton. Other muscles involved in attachment of the thoracic limb to the trunk and neck are the four pectoral muscles, the braciocephalicus, and omotransversarius.

The brachial plexus lies on the axial aspect of the scapula and is derived from the sixth, seventh, and eighth cervical nerve roots and the first thoracic nerve. These nerve roots are potentially vulnerable to trauma where they exit the cervical

and cranial thoracic vertebrae, and these are relatively common sites for neuroma formation after trauma. The nerves of the brachial plexus are responsible for innervation of many of the principal muscles of the shoulder region.

The scapulohumeral or shoulder joint is unusual because of the absence of collateral ligaments. Stability therefore depends on muscular support on the medial and lateral aspects by the subscapularis, infraspinatus, supraspinatus, and teres minor. Cranial support is provided by biceps brachii and supraspinatus, and caudal support is rendered by the long head of triceps brachii. Overlying muscles make it impossible in mature horses to appreciate distention of the joint capsule by palpation. The joint capsule attaches closely to the margins of the scapulohumeral joint, and this, together with the surrounding muscles, restricts arthroscopic evaluation within the joint. The suprascapular nerve wraps around the cranial margin of the scapula proximal to the supraglenoid tubercle and provides innervation to the infraspinatus and supraspinatus muscles.

Considering its embryological development and function the so-called intertubercular (bicipital) bursa would be more appropriately called a tendon sheath.[1] The bursa surrounds the tendon of biceps brachii, which originates from the supraglenoid tubercle of the scapula. The craniodistal pull of biceps brachii results in cranial and distal displacement of fractures of the supraglenoid tubercle. Communication was identified between the scapulohumeral joint capsule and the intertubercular bursa using contrast arthrography in 3 of 18 limbs (17%)[2]; thus in some horses intra-articular analgesia of the scapulohumeral joint has the potential to cause improvement in lameness caused by pain arising from the intertubercular bursa. The tendon of biceps brachii is partially cartilaginous proximally and passes over the smooth intertuberal groove of the humerus and then becomes predominantly muscular with a tendonous core.

The most important palpable landmarks in the shoulder region are the cranial and caudal eminences of the greater tubercle of the humerus. The notch between these eminences provides the portal for arthrocentesis of the scapulohumeral joint. The scapular spine is usually readily palpable except in exceptionally fat horses or heavily muscled individuals and becomes more prominent if the supraspinatus or infraspinatus muscles show atrophy.

DIAGNOSIS

Clinical Signs

In the adult horse lameness associated with the elbow or shoulder regions is comparatively rare, except after direct trauma caused by a fall, collision with a solid object such as a gatepost, or collision with another horse. In immature athletic horses, stress fractures of the scapula, humerus, and radius; osseous cyst-like lesions; and osteochondrosis are quite common.

Lameness associated with the shoulder or elbow regions is usually sudden in onset and generally moderate to severe. After trauma to the shoulder or elbow, or in association with severe lameness, the horse tends to stand with its weight inclined toward the contralateral limb, not fully load bearing on the lame limb. The horse may resent turning on the limb. Muscle atrophy in the shoulder region is not specific for lameness associated with the proximal limb but is often more severe than if the pain arises farther distally. Rapid loss of the bulk of supraspinatus and infraspinatus muscles alone is likely to reflect damage to the suprascapular nerve, whereas involvement of additional muscles is more likely to reflect a brachial plexus injury. Swelling in the elbow or shoulder regions usually reflects direct trauma but may be seen with subluxation or luxation of the shoulder or elbow joints. Patchy sweating is sometimes seen with a lesion of the brachial plexus. Pain elicited by deep palpation is relatively unusual and is generally associated with direct trauma. Care should always be taken to compare the reaction to palpation of the contralateral limb. The reaction to manipulation of the proximal limb joints should also be interpreted with care because many normal horses resent extreme flexion, extension, or abduction.

Many normal horses show some resentment of firm palpation of the braciocephalicus muscles at the base of the neck. These muscles often become sore with a more distal source of pain causing lameness. Primary muscle pain causing lameness does sometimes occur and is associated with a more marked pain reaction on palpation and muscle spasm.

If lameness is mild, then the character of the lameness is non-specific, but if lameness is moderate to severe, it is often characterized by a shortened cranial phase to the stride, a reduced height of the arc of foot flight, and a marked head lift and nod. These gait characteristics are evident at the walk and the trot. Observation of the moving horse from the front and the side is particularly useful. The horse may pivot on the lame limb when turning. Lameness is frequently accentuated with the lame limb on the outside of a circle. In horses with proximal limb lameness, especially associated with muscle fibrosis, lameness may only be evident when the horse is ridden, performing specific movements. Manipulative tests of the proximal limb joints are rather non-specific and frequently unrewarding.

Lameness may fluctuate in degree under different circumstances and within an examination period; therefore it is important to observe the horse for a sufficient length of time before proceeding with local analgesic techniques. If lameness is only apparent when the horse is ridden, the horse may be sensitive to the diagonal on which the rider sits.

Lameness caused by trauma resulting in only bruising usually improves rapidly, within a few days. Persistence of lameness merits further investigation.

Local Analgesia

It is important to recognize the potential effect of a median nerve block, performed in the proximal antebrachium, on elbow pain. Elbow lameness may be substantially improved, presumably because of local diffusion of the local anesthetic solution. Techniques for intra-articular analgesia of the elbow and shoulder and intra-thecal analgesia of the intertubercular bursa are described in detail in Chapter 10. Intra-articular analgesia of the elbow and shoulder joints usually improves but rarely eliminates pain associated with either joint. The elbow and shoulder joints are relatively large, therefore at least 10 ml of local anesthetic solution (mepivacaine, 2%) is recommended for the elbow joint and 20 ml for the shoulder joint. Retrieving synovial fluid from each joint is usually possible. Absence of resistance to injection is not a guarantee that the needle is in an intra-articular location. Walking the horse after the block facilitates circulation of the local anesthetic solution throughout the joint. Although improvement in lameness may be seen rapidly, within 10 to 15 minutes after injection, at least 1 hour should elapse after the block before the result is considered negative. The block generally is effective for up to 2 hours. The block usually has no influence over pain associated with peri-articular structures.

When performing intra-articular analgesia of the shoulder, it is important to recognize that there is communication with the intertubercular bursa in some horses. In some horses instability of shoulder, so-called shoulder slip, appears transiently (for up to 2 hours) after injection of local anesthetic solution. This prohibits interpretation of the nerve block. The cause is presumably diffusion of local anesthetic solution to nerves

innervating the muscles responsible for maintaining stability of the shoulder. Positive-contrast arthrography showed that injection of volumes greater than 20 ml posed a danger of pooling at the site of injection or leakage from the joint capsule.[1]

Intra-thecal analgesia of the intertubercular bursa usually improves lameness associated with lesions of the tendon of biceps brachii, the bursa itself, or the humeral tubercles. The bursa is large, and 20 ml of local anesthetic solution is recommended.

Many other potential sources of pain in the proximal limb cannot be desensitized by local analgesic techniques. If the response to distal limb analgesia and the blocks described previously is negative, nuclear scintigraphic evaluation is warranted.

Assessment of Muscles

Electrical stimulation of muscles may help identify muscle-related pain (see page 728).

IMAGING

Radiography

Radiographic examination of the elbow requires mediolateral and craniocaudal views.[3] The limb should be pulled forward sufficiently to avoid the pectoral muscle mass to evaluate properly the distal humerus. Routine radiographic examination of the scapulohumeral joint should include mediolateral and craniomedial-caudolateral oblique views. In some horses cranioproximal-craniodistal oblique views of the humeral tubercles are useful. Examination of the entire length of the humerus can be difficult, because often when such examination is indicated, the horse has pain and is reluctant to allow the limb to be adequately protracted. Accurate evaluation of the entire scapula is also not easy because of superimposition over the thoracic vertebrae and the contralateral limb.

Fast-speed, rare earth screens and appropriate film are essential. Use of a grid will greatly enhance image quality, especially in the shoulder region. High exposure factors are required (e.g., 100 kV, 100 mAs, for a mediolateral view of the shoulder). Underexposure will result in lesions being missed.

It is important to recognize that the cranial articular margin of the proximal radius has several lips that should not be confused with osteophytes (Fig. 41-1). The cranial tuberosity of the proximal radius may appear roughened in slightly oblique mediolateral views.

In the scapulohumeral joint a small circular radiolucent region is sometimes seen in the subchondral bone in the middle of the glenoid cavity of the scapula (Fig. 41-2). A radiolucent edge effect is often seen in the proximal humerus, the result of superimposition of the lateral rim of the glenoid cavity of the scapula.

Ultrasonography

Diagnostic ultrasonography is invaluable for assessing muscle structure in the shoulder region. Normal muscle has a homogeneous echogenicity. Identification of hyperechogenic regions indicative of muscle necrosis, fibrosis, or mineralization is usually associated with lameness.

Evaluation of the elbow joint itself is limited in the weight-bearing position because of the difficulty in getting access medially. Examination of the lateral collateral ligament of the humeroradial joint is straightforward. To evaluate the medial aspect, the limb should be pulled forward, but unless the medial collateral ligament is under tension, its echogenicity may lack homogeneity.

In the shoulder region ultrasonography is important for assessing the intertubercular bursa, humeral tubercles, tendon of biceps brachii (Fig. 41-3, *A* and *B*), tendons of insertion of supraspinatus and infraspinatus muscles (Fig. 41-3, C and *D*) and infraspinatus bursa (Fig. 41-3, *B*).[4-7] Care should be taken to ensure that the horse is fully load bearing on the limb, because hypoechogenic artifacts can be created, especially in the tendon of biceps brachii, unless the musculature is under tension. The medial and lateral lobes of the tendon of biceps brachii and the isthmus between them should each be evaluated individually, because getting the entire structure into focus simultaneously is difficult.

Fig. 41-1 Mediolateral radiographic view of the elbow joint of a normal adult horse. The lips on the cranioproximal aspect of the radius are a normal radiographic feature.

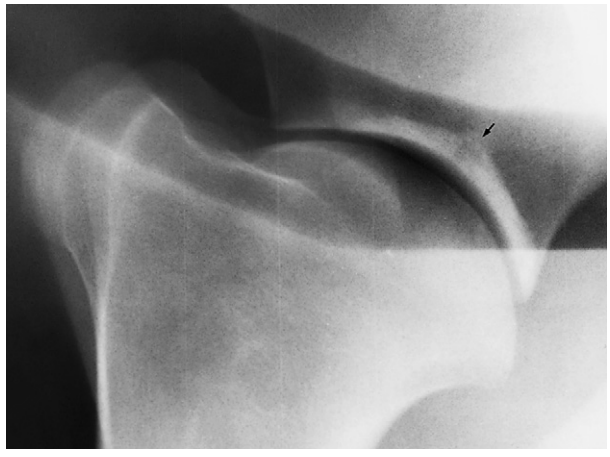

Fig. 41-2 Mediolateral radiographic view of a scapulohumeral joint of a normal adult horse. A small lucent zone appears in the subchondral bone in the middle of the glenoid cavity of the scapula (*arrow*). Note also the lucent band crossing the humeral head and the edge effect caused by superimposition of the articular margins of the scapula.

Nuclear Scintigraphy

Nuclear scintigraphic evaluation of the proximal forelimbs is indicated if the response is negative to median and ulnar nerve blocks, intra-articular analgesia of the elbow and shoulder joints, and intrathecal analgesia of the intertubercular bursa. Scintigraphy is also indicated if history and clinical signs suggest a stress fracture. Scintigraphy has also been useful for identifying enostosis-like lesions (bone islands) in the humerus

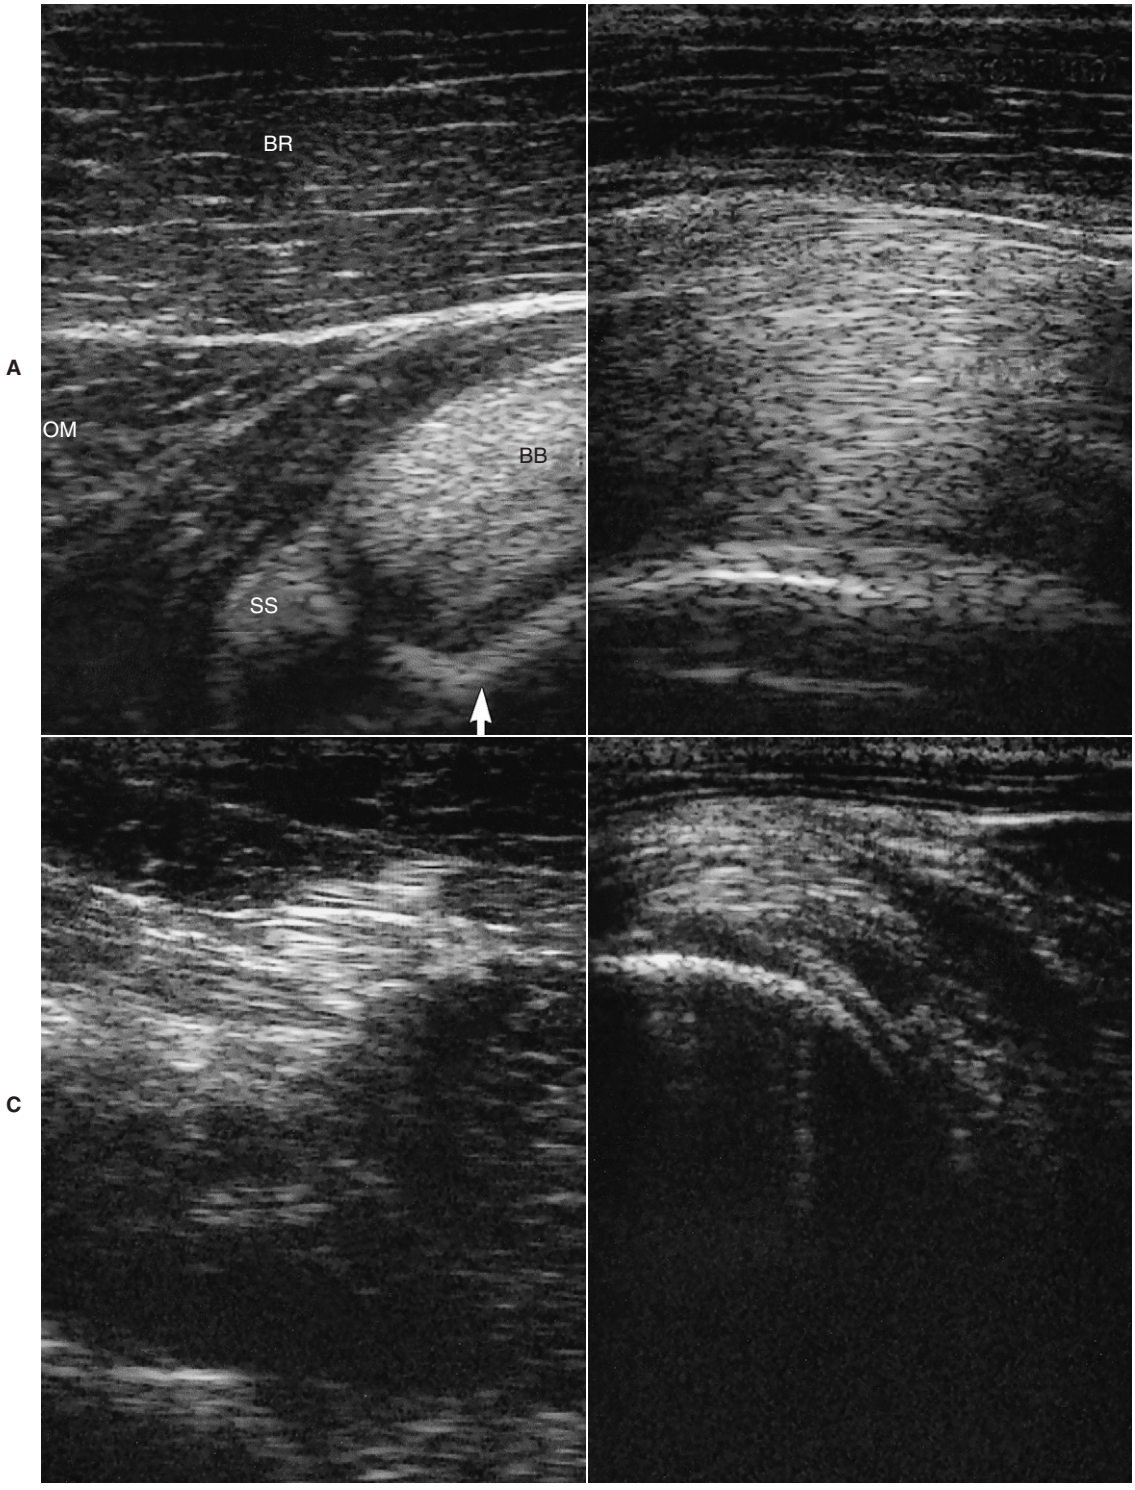

Fig. 41-3 **A,** Transverse ultrasonographic image of the cranial aspect of the proximal humerus of a normal horse. Medial is left. A small amount of anechoic fluid appears within the intertubercular bursa, and the contour of the humeral tubercle is smooth (*arrow*). **B,** Longitudinal ultrasonographic image of the tendon of biceps brachii and the overlying braciocephalicus muscle. Proximal is left. **C,** Transverse image of the tendon of infraspinatus within the infraspinatus muscle. **D,** Transverse ultrasonographic image of the insertion of infraspinatus on the proximal humerus. The anechoic space, the infraspinatus bursa, appears between the tendon of insertion and the bone. *OM*, Omotransversarius; *BR*, braciocephalicus; *BB*, medial lobe of the tendon of biceps brachii; *SS*, medial tendon of insertion of supraspinatus.

and fractures of the deltoid tuberosity of the humerus. Care should be taken to localize any region of increased radiopharmaceutical uptake as precisely as possible to identify the likely underlying pathological condition. Examination of the scintigraphic images should include careful assessment of the soft tissues, because abnormal uptake of the radiopharmaceutical in muscle can sometimes be identified in bone-phase images.

DIFFERENTIAL DIAGNOSIS

Elbow

Osteoarthritis

Osteoarthritis of the elbow is relatively unusual and tends to be seen in older athletic horses. Often the horse has a history of trauma. The horse may resent manipulation of the elbow, but appreciating joint effusion is usually not possible. Lameness often varies in degree, within and between examinations, and is usually worst on a hard surface, especially on a circle.

Intra-articular analgesia improves lameness. Peri-articular osteophyte formation, alterations in subchondral bone opacity, and narrowing of joint space width may be seen radiographically (Fig. 41-4). Care should be taken not to misinterpret normal bony lips as osteophytes on the dorsoproximal aspect of the radius.

The repeated use of intra-articular polysulfated glycosaminoglycans has been most effective in resolving lameness, but the long-term prognosis for return to full athletic function is guarded.

Osseous Cyst-like Lesions

Osseous cyst-like lesions occur most commonly medially in the proximal radial epiphysis (Fig. 41-5) and usually result in acute onset, relatively severe lameness in immature athletic horses.

Lameness may be vary greatly in degree, within and between examinations, and is usually substantially improved by intra-articular analgesia. In addition to a well-defined osseous cyst-like lesion, there is often periosteal new bone on the proximal medial metaphyseal region of the radius. Intra-articular medication with hyaluronan or corticosteroids (methylprednisolone acetate) has resulted in successful resolution of lameness.[8,9] In some horses the osseous cyst-like lesions have resolved radiographically. Surgical treatment by curettage of the cyst using an extra-articular approach has been successful in some horses, but fracture through the cyst has been a recognized complication.[10] Recurrent lameness after surgical treatment is also possible.[11]

Less commonly, large, less well-defined osseous cyst-like lesions have been identified in the distal humerus in young Thoroughbreds being prepared for the yearling sales or just after entering training.[9] Lameness is acute in onset, persists despite box rest, and is generally not influenced by intra-articular analgesia of the elbow. Nuclear scintigraphic examination reveals a region of increased radiopharmaceutical uptake in the distal humerus, more centrally located than that associated with a stress fracture (see page 405). Careful radiographic examination reveals a less well-defined osseous cyst-like lesion. Conservative management has resulted in persistent lameness, and the results of surgical treatment have been disappointing. Young horses with smaller osseous cyst-like lesions in the distal medial humerus have been identified and have responded to conservative management.[8]

Osteochondrosis

The elbow is a relatively rare location for osteochondrosis, but occasionally lameness is identified in young Thoroughbreds and Standardbreds in training associated with osteochondritic lesions of the distal humerus or proximal radius. Lameness is improved by intra-articular analgesia. A variety of radiological changes have been identified. Results of medical and surgical management have been disappointing. Osteochondritic lesions of the anconeal process of the ulna also occur rarely,[12] but they should not be confused with a separate ossification center in young foals.[13]

Fig. 41-4 **A,** Mediolateral and **B,** craniocaudal (medial is to the left) radiographic views of the elbow joint of a 9-year-old event horse with left forelimb lameness alleviated by intra-articular analgesia of the elbow. The periarticular osteophytes (*arrows*) and subtle narrowing of the joint space medially indicate osteoarthritis. The horse failed to respond to intra-articular medication.

Stress Reactions in Subchondral Bone

Intermittent lameness has been identified in a small number of event horses associated with an assumed stress reaction in the subchondral bone of the distal humerus.[9] Lameness is induced by jumping but tends to resolve if the horse is not jumped. Lameness may be improved by intra-articular analgesia of the elbow (curious). No bony abnormalities have been identified radiographically. Nuclear scintigraphic examination reveals a region of increased radiopharmaceutical uptake in the subchondral bone of the distal humerus. Box rest and controlled walking exercise for 3 months has resulted in resolution of lameness and a normal distribution of the radiopharmaceutical. Horses have been able to return to full athletic function without recurrent injury.

Fig. 41-5 Craniocaudal radiographic view of the proximal radius of 3-year-old Thoroughbred racehorse with left forelimb lameness, which substantially improved with intra-articular analgesia of the elbow. There is a well-defined osseous cyst-like lesion in the proximomedial aspect of the radius. Note also the periosteal new bone on the proximomedial aspect of the radius. Intra-articular medication with hyaluronan resolved lameness, and the horse raced successfully.

Fig. 41-6 Craniocaudal radiographic view of the elbow of 15-year-old pony that had chronic left forelimb lameness after a fall. There is entheseous new bone at the attachments of the lateral collateral ligament of the humeroradial joint (*white arrows*) with mineralization within the ligament. There is also new bone on the proximomedial aspect of the radius (*black arrows*). Periarticular osteophyte formation was also visible in a mediolateral view. Ultrasonographic examination revealed poor fiber pattern within the lateral collateral ligament. Post-mortem examination confirmed desmitis of the lateral collateral ligament and osteoarthritis of the elbow joint.

Collateral Ligament Injury

Injury to the collateral ligaments of the elbow is not common and usually results from a traumatic injury such as a fall. Damage to the lateral collateral ligament has been identified most frequently. Severe injuries may also be associated with injury to the joint capsule, and osteoarthritis may ensue. Lameness is acute in onset. Subtle soft tissue swelling may be appreciated in the elbow region, and manipulation of the elbow may induce pain. Lameness may be partially improved by intra-articular analgesia of the elbow. If damage is restricted to extra-articular structures, then the response may be negative. Nuclear scintigraphic examination may be helpful in these horses. Increased radiopharmaceutical uptake occurs at the sites of ligament attachment on the distal humerus and proximal radius.

Definitive diagnosis requires ultrasonographic examination and identification of disruption of the normally linear pattern of echoes within the ligament. Sometimes periosteal new bone or avulsion fractures can be identified at the region of ligamentous attachment.[14] Radiographic examination should also be performed to identify any concurrent pathological condition of the bone (Fig. 41-6).

Minor lesions have responded well to a period of box rest and controlled walking exercise, but lesions that have been associated with periosteal new bone formation have often been associated with persistent lameness and the development of osteoarthritis.

Luxation

Luxation of the elbow joint is usually seen with a fracture of the olecranon or proximal radius or separation of the radius and ulna, although luxation occasionally occurs alone. Lameness is acute in onset and severe and is associated with considerable swelling in the elbow region. Comprehensive radiographic examination is essential to determine if one or more concurrent fractures are present. Surgical repair can be considered, but the prognosis for athletic function is poor.

Enthesopathy of Biceps Brachii

Tearing of the attachment of biceps brachii from the craniproximal aspect of the radius may be associated with a traumatic injury such as a fall, but frequently history does not suggest the cause. Lameness is sudden in onset and often not associated with any localizing signs, except pain on manipulation of the elbow in horses with acute lameness. The lameness has no particular characteristics. The response to local analgesic techniques is negative. Radiographic examination may reveal periosteal new bone on the cranioproximal aspect of the humerus in horses with chronic lameness[15] (Fig. 41-7). Sometimes an adjacent mineralized fragment is present, an avulsion fracture or dystrophic mineralization. Some new bone formation on the cranioproximal aspect of the radius can be seen in normal horses, reflecting previous injury, thus care should be taken in interpreting its current clinical significance. Nuclear scintigraphic examination is helpful for acute lameness before periosteal new bone develops and in horses with chronic lameness. Ultrasonographic evaluation has not been helpful. Treatment is by rest. The prognosis is guarded to fair.

Fracture of the Olecranon

Fracture of the olecranon of the ulna usually results from a kick or fall, resulting in acute onset, severe lameness. The horse may stand with the elbow dropped because of lack of an effective

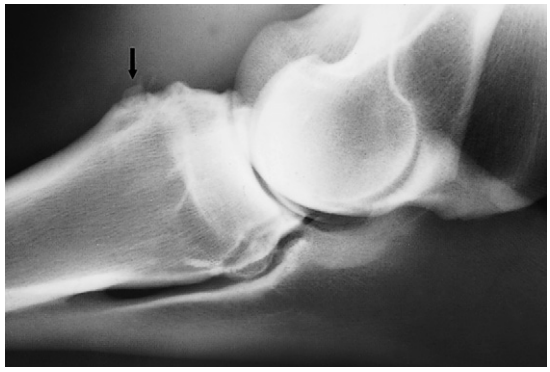

Fig. 41-7 Mediolateral radiographic view of the right elbow of 9-year-old show jumper with chronic right forelimb lameness that no local analgesic technique influenced. There is new bone on the cranial tuberosity of the radius at the site of insertion of biceps brachii (*arrow*). Nuclear scintigraphy gave evidence of increased bone modeling at this site. The horse had persistent lameness despite prolonged rest.

attachment of triceps, the principle extensor of the elbow. Soft tissue swelling may or may not be palpable. Traction on the summit of the olecranon elicits pain. Although many fractures are comminuted, detecting crepitus is unusual. Radiographic examination should include mediolateral and craniocaudal views to assess the configuration of the fracture and to identify any other bony lesions (see Fig. 11-4). Fractures have been classified into five types[16]:

- Type 1. Fractures of immature horses that involve the growth plate and the metaphysis: These are subdivided into type 1a, a non-articular fracture involving only the growth plate, and type 1b, a Salter-Harris type II articular fracture involving the anconeal process and proximal part of the trochlear notch.
- Type 2. A simple articular fracture involving the middle of the trochlear notch
- Type 3. A non-articular fracture involving the proximal metaphyseal region
- Type 4. Comminuted articular fractures
- Type 5. A fracture involving the distal olecranon/ulnar shaft, extending proximally and entering the distal, non-articular part of the trochlear notch

A fracture that enters the trochlear notch should be examined carefully to determine whether it involves the articular or non-articular portion. Treatment by internal fixation usually warrants a fair to good prognosis,[17,18] provided that the fracture is identified early and unless comminution is excessive. Conservative management has also been successful if the fracture is not displaced; the best results are achieved with type 5 fractures.[19] If the horse is treated conservatively, healing should be monitored radiographically to ensure that no displacement has occurred. Potential complications of conservative management include non-union, osteoarthritis, development of a flexural deformity or contralateral laminitis, or development of an angular limb deformity in the contralateral limb.

Olecranon Bursitis

See Chapter 80 for a discussion of olecranon bursitis.

Humerus

Fractures of the Deltoid Tuberosity

Fracture of the deltoid tuberosity of the humerus occurs occasionally.[3,20] Often no cause is identifiable, although in some horses trauma has been recognized. Lameness is acute in onset and moderate to severe, depending on the configuration of the fracture. Generally no soft tissue swelling is detectable, although deep palpation in the region may cause pain in acute, but not chronic, injuries. Turning on the limb induces pain. In the absence of localizing signs, nuclear scintigraphic examination may be the best indicator of the injury (Fig. 41-8, *A*).

Diagnosis is by radiographic examination. A craniomedial-caudolateral oblique view is essential (Fig. 41-8, *B*), because abnormalities may not be detectable in mediolateral projections. Two configurations of fracture have been identified: a longitudinal fracture through the tuberosity itself and an incomplete oblique fracture extending proximocaudally through the humeral diaphysis and metaphysis. Conservative management results in a favorable outcome, unless an oblique fracture is displaced, for which internal fixation is recommended. The prognosis is good.

Stress Fractures

Stress fractures of the humerus are relatively common in young Thoroughbreds in training. The most common locations are the proximocaudal aspect of the humerus and the distal cranial and caudal aspects.[21-23] Unilateral lameness is usually acute in onset and relatively severe. This lameness often improves relatively rapidly with box rest. Despite preexisting callus formation indicative of previous ongoing bony reaction, previous lameness has often not been recognized. Usually no localizing signs are apparent, and the response to distal limb nerve blocks is negative. Nuclear scintigraphic examination is the most sensitive means of detecting a fracture and should be performed if a stress fracture is suspected on clinical grounds, because premature return to work may potentially result in a more catastrophic fracture. A focal region of increased radiopharmaceutical uptake is identified in the proximocaudal aspect of the humerus or the distal cranial or caudal aspects (Fig. 41-9). Fractures are usually medial. Radiographic examination is less sensitive, although in some horses new bone formation can be identified on the caudal aspect of the proximal epiphysis, sometimes with increased opacity of the subchondral bone or new bone on the cranial aspect of the distal metaphysis and physis. Identification of new bone associated with a distal caudal fracture is rare.[23] With treatment of box rest and controlled walking exercise for a minimum of 3 months, followed by a graduated return to work, the prognosis is good.

Fractures of the Greater or Lesser Tubercles

A fracture of the greater or lesser tubercle of the humerus is an occasional cause of unilateral forelimb lameness.[5,24-26] The history is often unknown and usually no localizing clinical signs are apparent. Lameness varies in degree. Intrathecal analgesia of the intertubercular bursa may improve the lameness. Although some fractures may be suspected on a mediolateral radiographic view, craniomedial-caudolateral oblique and cranioproximal-craniodistal (skyline) oblique radiographic views are often necessary. Fracture fragments may also be accurately localized using diagnostic ultrasonography[26] and in some horses are only detectable ultrasonographically (Fig. 41-10). The overlying intertubercular bursa and tendon of biceps brachii should be inspected carefully. Small fractures may be removed surgically. Endoscopy of the intertubercular bursa permits reasonable access to the greater tubercle but not the lesser tubercle.[24]

Diaphyseal Fractures

Diaphyseal fractures of the humerus usually result from a fall or other traumatic incident and may be oblique, spiral, or severely comminuted. Lameness is acute in onset and severe, associated with considerable swelling, pain, and crepitus. The horse may stand with the elbow dropped, slight carpal flexion, and the weight only on the toe. Radial nerve paralysis may occur concurrently (see pages 132 and 414). The diagnosis is usually obvious, and the prognosis is poor, so humane destruction is justified.[27] Successful repair may be achieved in selected horses younger than 3 years of age.[28] Conservative

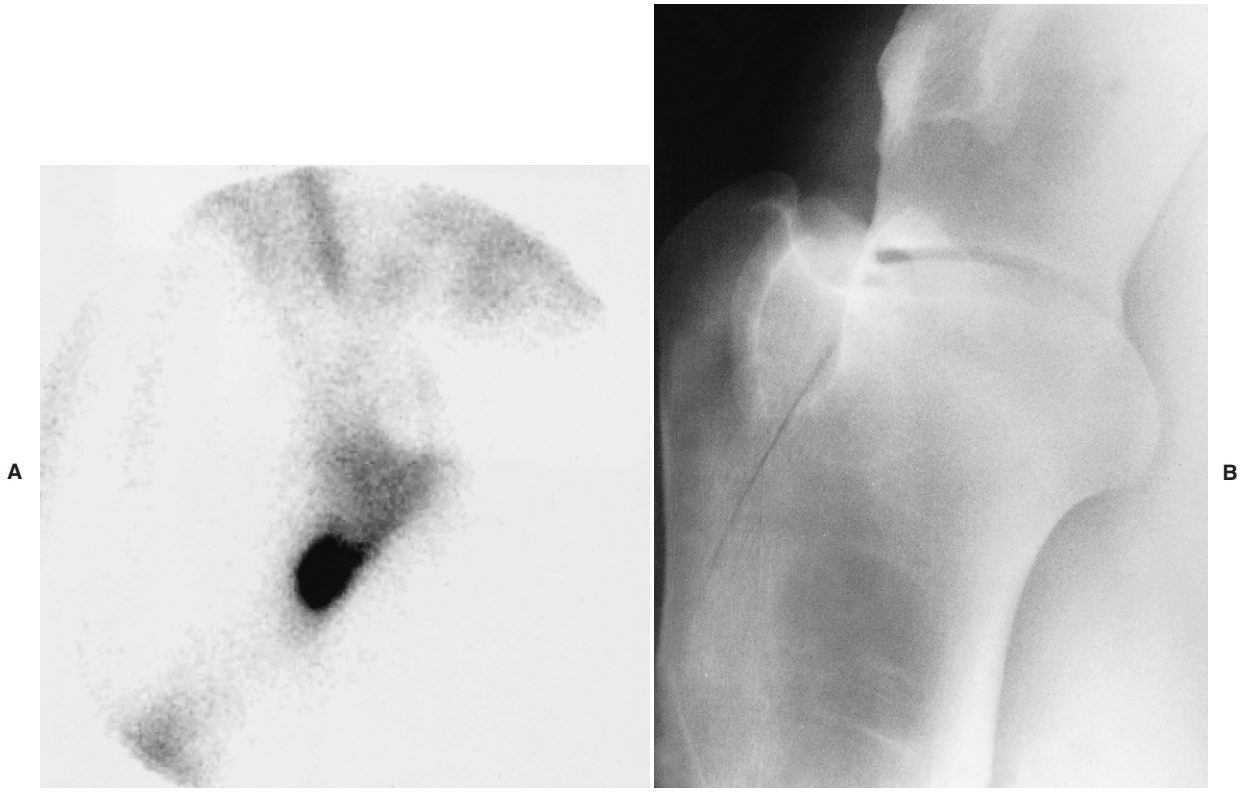

Fig. 41-8 **A,** Lateral scintigraphic image of the right shoulder of 7-year-old dressage horse with acute-onset, moderately severe lameness of 2 weeks' duration with no associated localizing clinical signs. There is marked focal increased radiopharmaceutical uptake in the region of the deltoid tuberosity of the humerus. Radiographic examination revealed an incomplete fracture line through the base of the tuberosity and slight periosteal callus. **B,** Craniomedial-caudolateral oblique radiographic view of the proximal humerus of 3-year-old Thoroughbred broodmare with acute-onset, severe right forelimb lameness. There is an incomplete fracture of the deltoid tuberosity of the humerus. The mare made a complete functional recovery, but a radiographically visible osseous cyst-like lesion developed distal to the greater tubercle of the humerus.

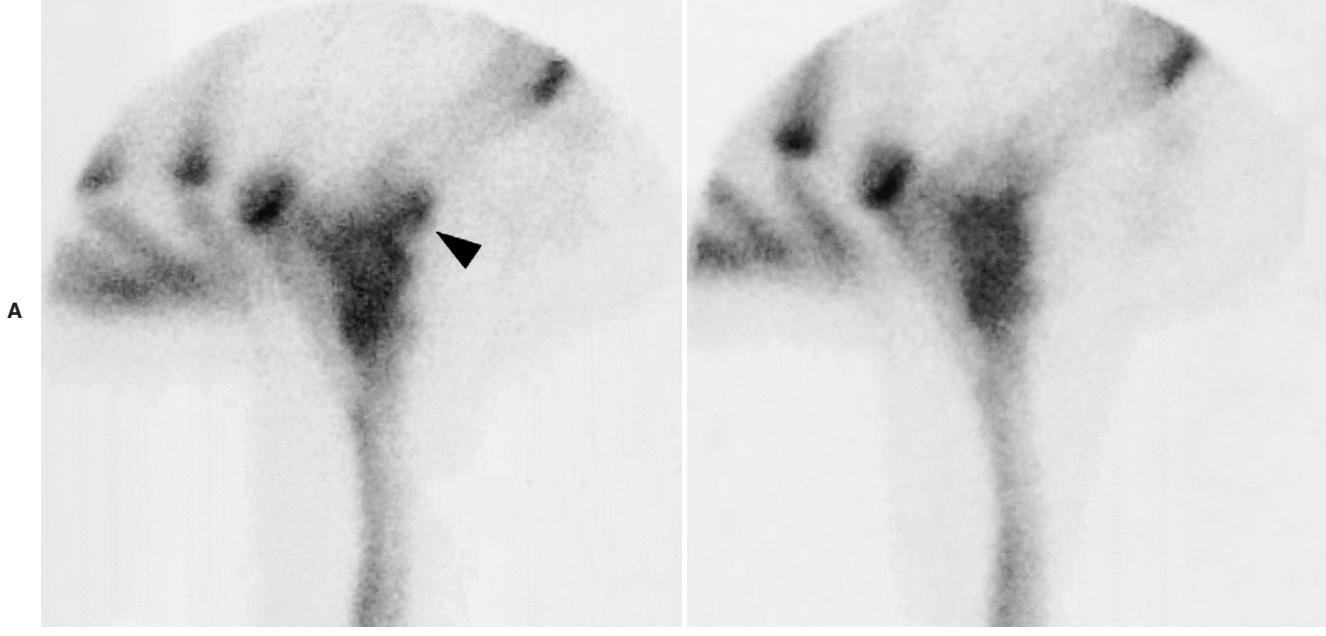

Fig. 41-9 Lateral scintigraphic images of the left **(A)** and right **(B)** elbows of 2-year-old Thoroughbred racehorse with acute onset, severe left forelimb lameness that improved rapidly with rest. The image of the left elbow is reversed to facilitate comparison with the right. There is moderate, focal increased radiopharmaceutical uptake in the craniodistal aspect of the right humerus (*arrow*), compatible with a stress fracture. Radiographic examination revealed slight periosteal and endosteal callus on the craniodistal aspect of the humerus.

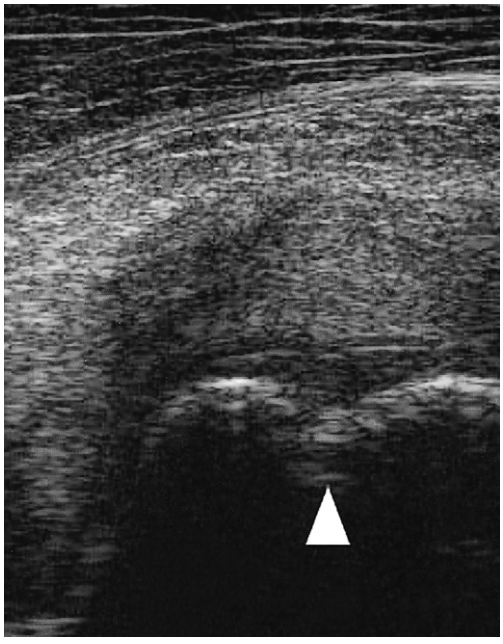

Fig. 41-10 Transverse ultrasonographic image of the humeral tubercles and tendon of biceps brachii of 2-year-old Thoroughbred filly with severe lameness at the walk. Lateral is to the right. There was slight soft tissue swelling in the shoulder region, but no focus of pain could be identified. Nuclear scintigraphic examination revealed marked focal increased radiopharmaceutical uptake in the humeral tubercles. Radiographic examination was negative. Cortical disruption (*arrow*) is apparent.

management in foals with diaphyseal fractures is a reasonable choice, but breakdown of soft tissues and angular limb deformities of the contralateral limb are potential complications.

Proximal Physeal Injuries

Injuries of the proximal humeral physis are rare, but Salter-Harris type I and II fractures have been seen in horses younger than 2 years of age.[29] The prognosis with conservative management is poor.

Enostosis-like Lesions (Bone Islands)

Enostosis-like lesions, or solitary bone islands, have only been recognized since the advent of nuclear scintigraphy. An *enostosis* is defined as bone developing within the medullary cavity or on the endosteum, resulting in a relatively sclerotic region. In the horse, enostosis-like lesions have been described as focal or multifocal intramedullary sclerosis in the diaphyseal region of long bones, near the nutrient foramen, often developing on the endosteal surface of the bone. The cause of these lesions is unknown. Such endosteal reactions must be differentiated from endosteal callus secondary to a fatigue fracture. The presence of such sclerotic lesions radiographically is not always associated with lameness.

In the humerus, enostosis-like lesions occasionally cause acute-onset, moderate to severe lameness in young Thoroughbreds, but they may be present asymptomatically. Usually no localizing clinical features are present. Lameness resolves relatively rapidly with rest, thus mimicking the behavior of a stress fracture and therefore warranting nuclear scintigraphic examination. A region of intense increased radiopharmaceutical uptake occurs in the distal caudal aspect of the humerus, distinguishable from a stress fracture because of its slightly more proximal and medullary location (Fig. 41-11, *A*). Radiographic examination reveals a relatively large, oval-shaped opacity within the medulla, adjacent to the nutrient foramen (Fig. 41-11, *B*). Because lesions may be present asymptomatically, it is important to rule out other potential causes of lameness.

Fig. 41-11 **A,** Lateral scintigraphic image and **B,** mediolateral radiographic view of the left humerus of 3-year-old Thoroughbred filly in race training with right forelimb lameness of 3 weeks' duration. The lameness was not altered by local analgesic techniques. **A,** The nuclear scintigraphic image shows a region of intense focal increased radiopharmaceutical uptake in the distal diaphyseal region of the humerus, proximal to the usual site of stress fractures. **B,** Radiographically a well-circumscribed area of increased opacity (*arrows*) appears adjacent to the principal nutrient foramen. This is an enostosis-like lesion. Lameness resolved after 2 months of box rest, and the lesion was scintigraphically silent, although there was no change in radiographic appearance. The horse remained sound when returned to training.

Treatment is similar to that for a stress fracture: box rest and controlled walking exercise for approximately 3 months. Although a relatively sclerotic region may persist radiographically, follow-up scintigraphic evaluation reveals normal radiopharmaceutical uptake. The prognosis is good.

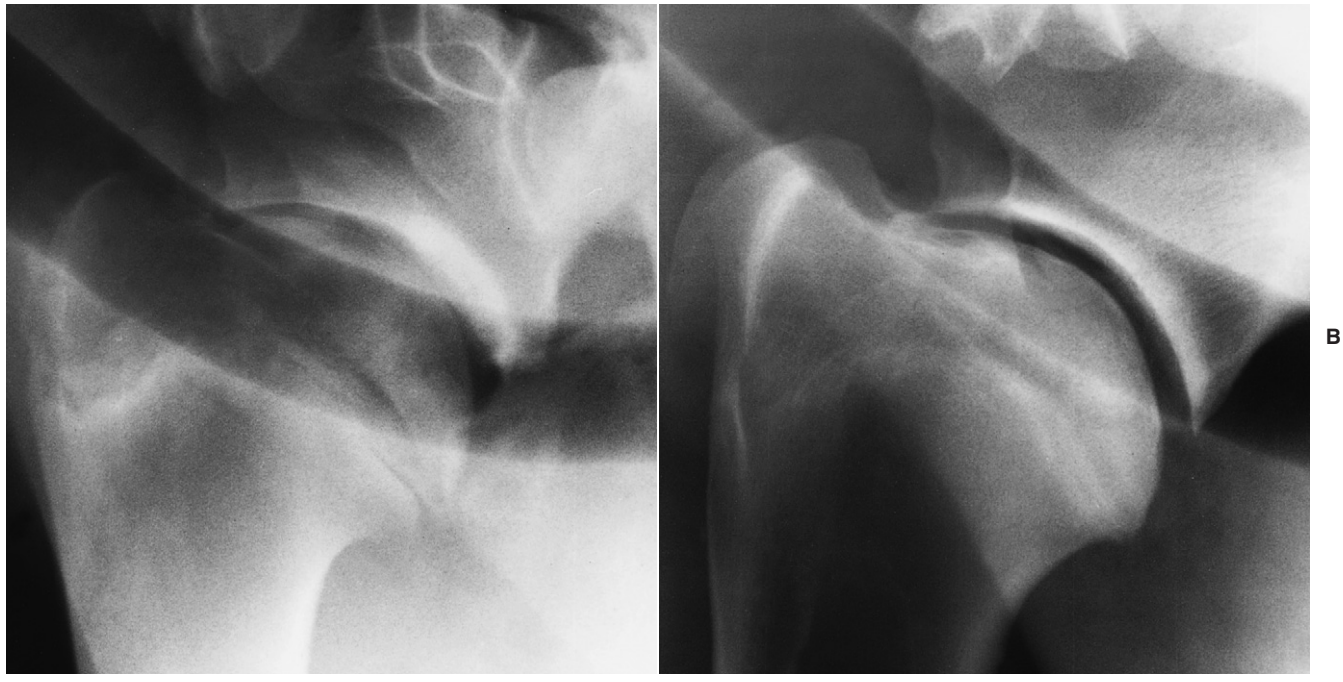

Fig. 41-12 **A,** Mediolateral radiographic view of the scapulohumeral joint of an 8-month-old Thoroughbred colt with severe left forelimb lameness. Lucent areas in the subchondral bone of the distal scapula and sclerosis and modeling of the glenoid cavity and ventral angle of the scapula are compatible with osteochondrosis. The humeral head also has variable opacity. **B,** The same horse 15 months after surgical debridement. The horse was sound. Significant modeling of the glenoid cavity of the scapula has occurred. The horse trained and raced.

Scapulohumeral Joint

Osteochondrosis

Osteochondrosis of the scapulohumeral joint is often clinically evident in the first year of life, but in some horses it is not manifested until the horse is between 2 and 5 years of age, although periods of unexplained lameness may occur. Delayed-onset lameness is often associated with relatively subtle radiological changes, which are more localized compared to those in horses that have lameness evident earlier. Lameness is often acute in onset and moderate to severe and is generally characteristic of proximal limb lameness. Often the foot of the most severely affected limb rapidly becomes more upright and boxy. In young, immature athletic horses radiographic changes are often present bilaterally, although clinical signs may only be evident unilaterally. Intra-articular analgesia usually results in improvement in lameness rather than complete alleviation; therefore the clinical significance of lesions in the contralateral limb can be difficult to interpret.

Radiographic abnormalities involve the glenoid cavity of the scapula, the humeral head, or both and include flattening of the articular surfaces, resulting in loss of congruity of the articular surfaces, irregular lucent zones in the subchondral bone, modeling of the ventral angle of the scapula, and blurring of the normally sharp outline of the glenoid cavity, because of modeling of the articular margins (Figs. 41-12 and 41-13). Generally a good correlation exists between the degree of lameness and the severity of clinical signs.

If lameness is recognized in a horse younger than 18 months of age, conservative management usually results in persistent lameness. Surgical treatment by radical arthroscopic debridement has resulted in some young horses being able to withstand race training, although their longer-term future has been poorly documented. Forty-five percent of treated horses were able to return to athletic activity.[30] In horses treated early, the bone shows a remarkable capacity to remodel (Fig. 41-12). Most horses show significant clinical improvement, even if lameness persists. However, surgical treatment in older horses is much less rewarding. In horses with minor radiographic abnormalities, identified when in race training, periodic intra-articular medication with sodium hyaluronan and triamcinolone has permitted the horses to remain in training and race, although lameness has tended to recur. In weanlings and yearlings with moderate to severe lesions, conservative management, including stall rest, intra-articular injections of hyaluronan, and periodic radiographic assessment of healing, has been successful.[31]

Subchondral Bone Cysts and Other Osseous Cyst-like Lesions

True subchondral bone cysts occur in the middle of the glenoid cavity of the scapula (Fig. 41-14). Other osseous cyst-like lesions have been identified less frequently in the humeral head. Subchondral bone cysts in the distal scapula and other osseous cyst-like lesions most commonly cause lameness in immature athletic horses, between 1 and 3 years of age, but subchondral bone cysts in the distal scapula have also been identified in much older horses, with no history of lameness. Trauma may be an inciting cause. Lameness is usually acute in onset and moderate to severe. In some horses the lameness varies extremely, within and between examination periods, from barely detectable at any gait to obvious at the walk. Lameness is usually significantly improved by intra-articular analgesia of the scapulohumeral joint. However, interpretation can be extremely difficult in those horses that show significant, spontaneous variations in lameness.

Small radiolucent zones are occasionally seen in the middle of the opaque band of subchondral bone of the glenoid cavity of the scapula in clinically normal horses and in the contralateral limb of horses with lameness associated with a large subchondral bone cyst in the distal scapula. Lameness that is improved by intra-articular analgesia associated with such

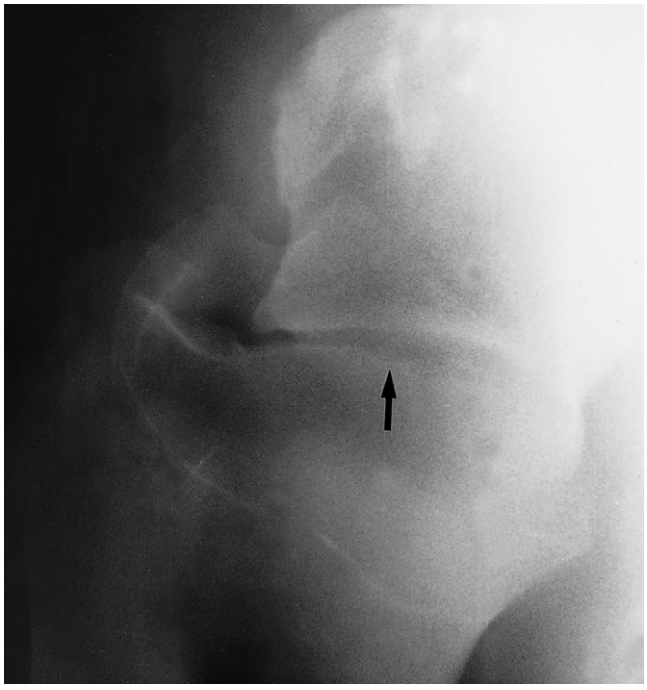

Fig. 41-13 Craniomedial-caudolateral oblique view of the scapulohumeral joint of 3-year-old Thoroughbred with lameness alleviated by intra-articular analgesia of the scapulohumeral joint. A well-defined depression in the proximal articular surface of the humerus is compatible with mild osteochondrosis (*arrow*). This was the only detectable radiographic abnormality. With repeated intra-articular medication the mare raced successfully, winning several more Group 1 races.

lesions but no other radiological change is seen infrequently.[2,9,32] This has been correlated with defects in the articular cartilage extending into the subchondral bone.[32] More commonly a large circular or dome-shaped radiolucent area is seen, surrounded by a narrow rim of sclerosis. In some older horses in which such subchondral bone cysts have been identified, the cysts have been less well defined because they are less radiolucent. In skeletally mature horses similar lesions have occasionally been identified bilaterally associated with apparently unilateral lameness.

In skeletally immature horses subchondral bone cysts have been seen to enlarge progressively, and some appear to move proximally in the bone. Those identified in skeletally mature horses seem to persist unchanged. Osseous cyst-like lesions in the proximal humerus occur as circular radiolucent regions in the middle to caudal aspect. Some of these have been seen to fill in radiographically with time. Subchondral bone cysts in the distal scapula are generally not associated with any other detectable radiological change, whereas other osseous cyst-like lesions are sometimes seen together with remodeling of the ventral angle of the scapula.

Nuclear scintigraphic examination may be helpful in horses in which lameness varies extremely in degree within an examination period. Subchondral bone cysts are associated with active bone modeling; therefore an intense focal region of increased radiopharmaceutical uptake in the bone is seen.

Intra-articular medication of the scapulohumeral joint using hyaluronan and methylprednisolone acetate has been successful in resolving lameness in immature athletic horses, but results have been poorer in older horses.

Surgical treatment of subtle, small lucent zones has been successful,[32] but effective debridement of large lesions is impractical.

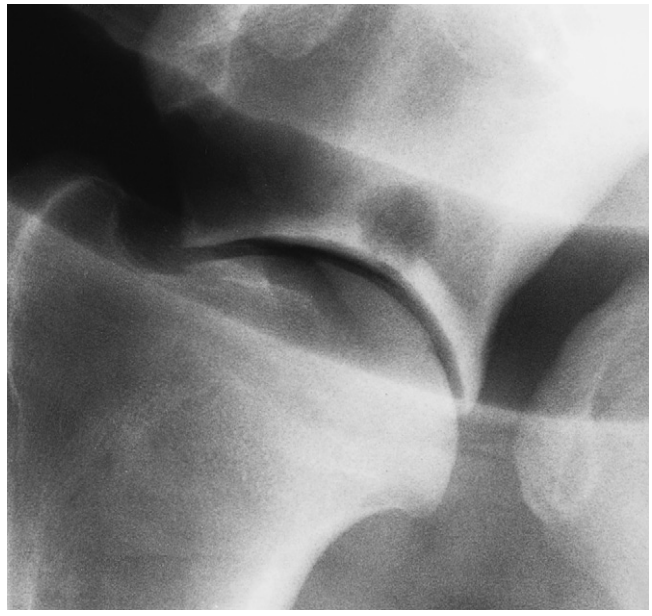

Fig. 41-14 Mediolateral radiographic view of the scapulohumeral joint of 9-year-old hunter with episodic severe right forelimb lameness. There is a large, well-defined subchondral bone cyst in the middle of the distal scapula. The lameness responded to intra-articular medication with corticosteroids (triamcinolone).

Osteoarthritis in Miniature Breeds

Sudden onset, severe lameness is sometimes seen in Shetland and Falabella ponies and Miniature horses.[33] The cause of this condition is not known, although dysplasia of the joint predisposing to instability may be a predisposing factor in some.[33,34] Usually no known history of previous lameness or trauma exists. Lameness is typical of proximal limb pain. Manipulation of the shoulder may cause pain. Lameness is improved but rarely alleviated by intra-articular analgesia. Radiographic examination sometimes reveals evidence of advanced osteoarthritis, including periarticular osteophyte formation, and modeling of the ventral angle of the scapula (Fig. 41-15). Occasionally, fragmentation of the ventral angle of the scapula occurs. Often new bone forms on the distal caudal border of the scapula and the proximal caudal aspect of the humerus in the regions of attachment of the joint capsule. In some ponies the contour of the glenoid cavity of the scapula appears flattened (see "Dysplasia," page 410), resulting in loss of congruity between the distal scapula and the humeral head. In ponies with less severe abnormalities, radiographic abnormalities may only be detectable in a craniomedial-caudolateral oblique projection. In those ponies with minor radiological change at the time of onset of clinical signs, changes tend to have been rapidly progressive.

Arthroscopic evaluation of the joint reveals extensive softening of the articular cartilage, and surgical debridement has resulted in some clinical improvement, although lameness has persisted. The prognosis for athletic function is guarded.

Osteoarthritis in Non-Miniature Breeds

Osteoarthritis in the scapulohumeral joint is relatively uncommon,[29] except as a sequel to osteochondrosis, an intra-articular fracture, or a tear of the scapulohumeral joint capsule. Lameness is mild to moderate and is improved by intra-articular analgesia. Radiographic abnormalities include loss of congruity between the glenoid cavity of the scapula and the humeral head, because of flattening of the humeral head or modeling of the ventral angle of the scapula; periarticular osteophyte formation, most easily seen on the cranial articular

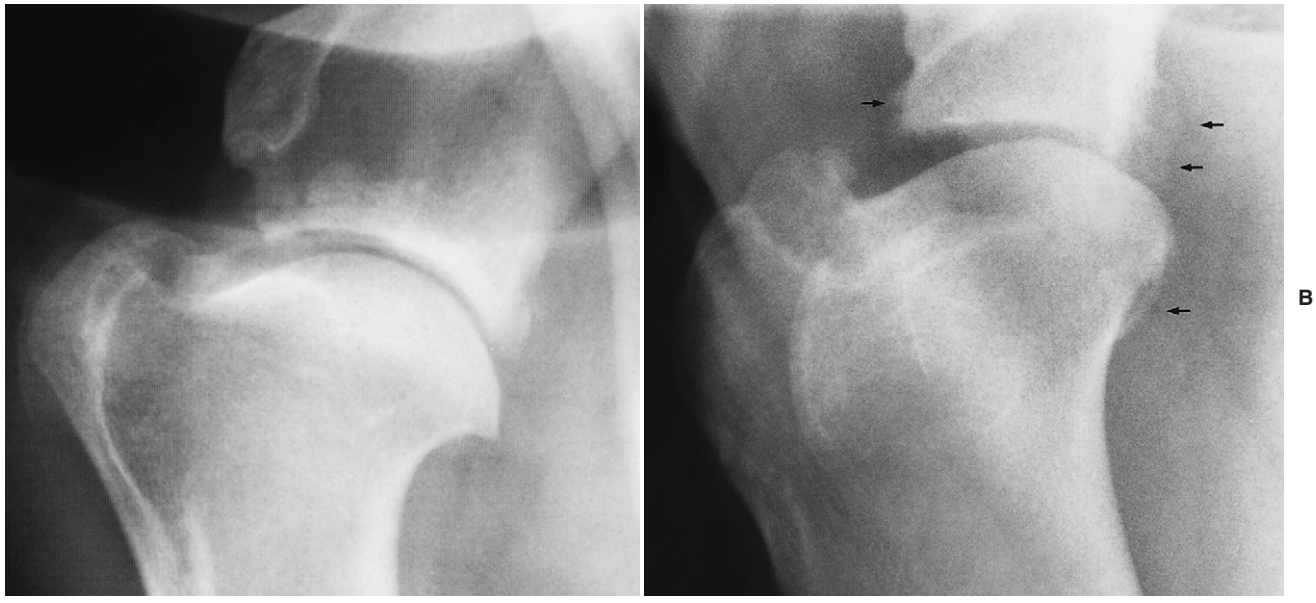

Fig. 41-15 **A,** Mediolateral radiographic view of the scapulohumeral joint of a 4-year-old Shetland pony with acute onset, severe lameness that improved with intra-articular analgesia. There is marked modeling of the ventral angle of the scapula, periosteal new bone formation, and generalized increased opacity of the distal scapula caused by extensive new bone. **B,** Craniomedial-caudolateral oblique radiographic view of a scapulohumeral joint of 5-year-old Miniature horse. There is poor congruity between the glenoid cavity of the scapula and the humeral head. Note also the periarticular periosteal new bone (*arrows*).

margins of the scapula; and lucent areas in the subchondral bone. The response to intra-articular medication is usually poor, and the prognosis for athletic function is guarded.

Care should be taken when evaluating the scapulohumeral joint arthroscopically, because widespread aging changes occur in the articular cartilage, especially of the distal scapula.[2] These include softening of the articular cartilage and extensive fissure formation (Fig. 41-16). Modeling changes of the articular margins of the glenoid cavity of the scapula may also occur.

Tearing of the Scapulohumeral Joint Capsule

Localized tearing of the scapulohumeral joint capsule is an unusual cause of lameness, which is improved by intra-articular analgesia. In the acute stage no detectable radiographic abnormalities may be apparent, but with more chronic lameness entheseous new bone may be seen in the region of damage. Nuclear scintigraphic examination may reveal focal or more generalized radiopharmaceutical uptake in the region of the scapulohumeral joint. Although ultrasonographic examination may be helpful if the lesion is lateral, medial lesions cannot be seen. Definitive diagnosis is based on diagnostic arthroscopy of the scapulohumeral joint. The prognosis for recovery for athletic function is guarded.

Dysplasia

Dysplasia of the scapulohumeral joint has been identified in Shetland ponies[34] and Miniature horses,[9] sometimes together with subluxation of the joint or with osteoarthritis (see the previous discussion, "Osteoarthritis in Miniature Breeds," page 409). Flattening of the radius of curvature of the glenoid cavity of the scapula occurs.

Luxation

Luxation of the scapulohumeral joint has been seen in ponies[2] more frequently than in horses, and results in acute onset, severe lameness associated with extensive swelling in the shoulder region (Fig. 41-17, *A*). If the humerus has luxated laterally, the scapular spine is less easy to palpate than usual. The horse is reluctant to bear full weight on the limb at rest and is usually non–weight bearing at the walk. Diagnosis is confirmed by radiographic examination (Fig. 41-17, *B*). Mediolateral and craniomedial-caudolateral oblique views should be obtained to determine whether a concurrent fracture is present and whether the luxation is medial or lateral. The humerus can luxate cranioproximally or caudoproximally.

A horse with simple acute luxation, without any concurrent fracture, can be treated by manual reduction of the luxa-

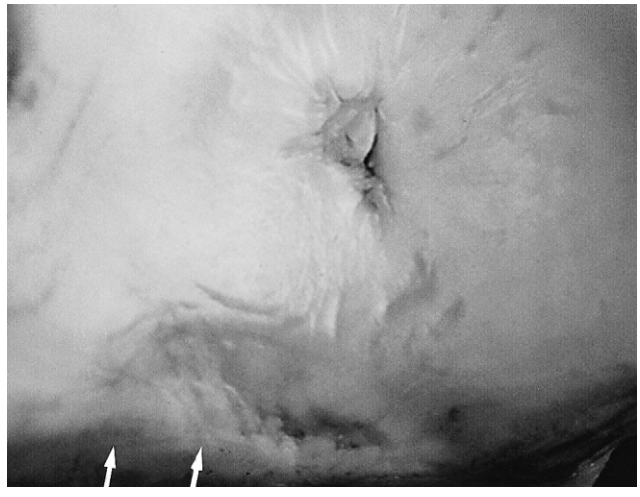

Fig. 41-16 Post-mortem appearance of the glenoid cavity of the scapula of 8-year-old Thoroughbred with no history of lameness. Modeling of the articular margin is apparent *(arrows)*, and the articular cartilage appears irregular. This was bilaterally symmetrical and is a typical finding in mature horses.

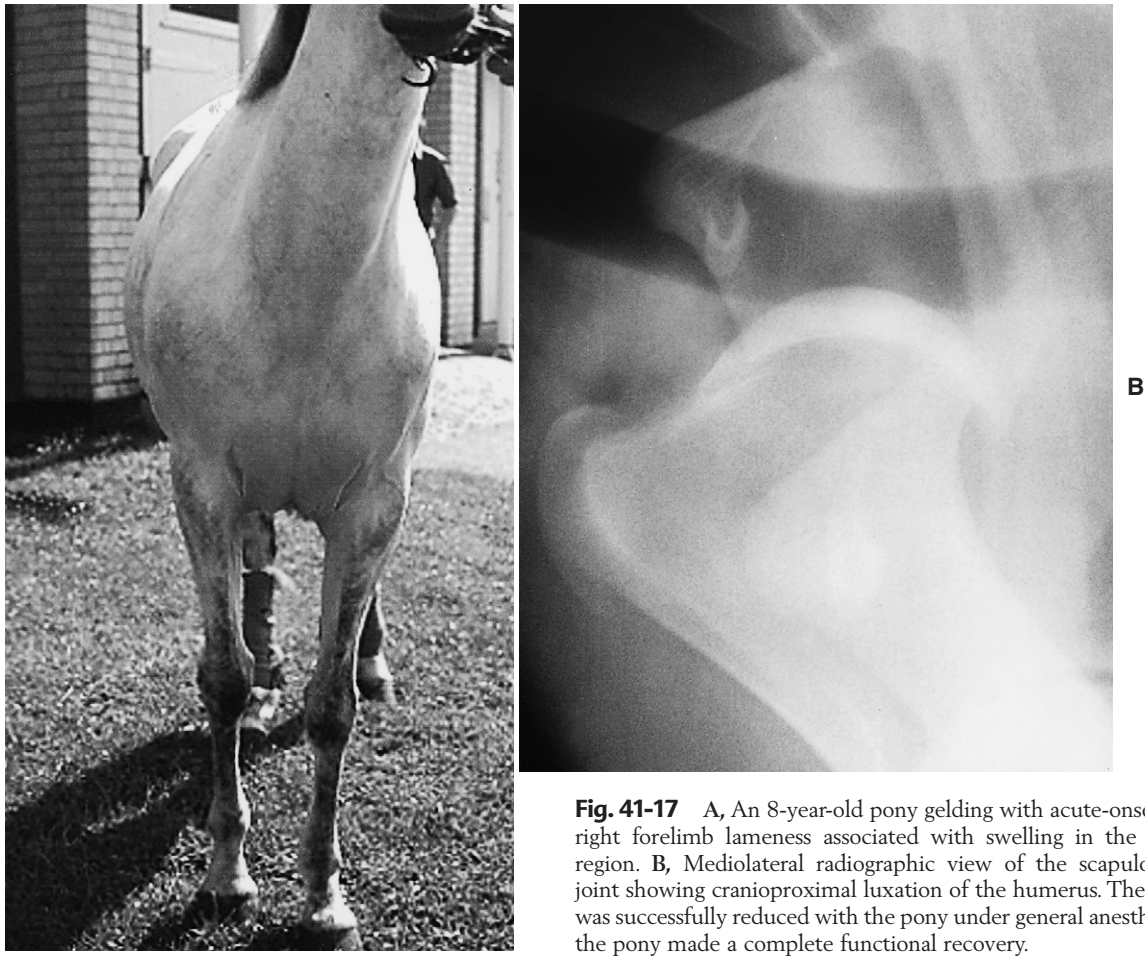

Fig. 41-17 **A,** An 8-year-old pony gelding with acute-onset, severe right forelimb lameness associated with swelling in the shoulder region. **B,** Mediolateral radiographic view of the scapulohumeral joint showing cranioproximal luxation of the humerus. The luxation was successfully reduced with the pony under general anesthesia, and the pony made a complete functional recovery.

tion with the horse under general anesthesia in dorsal recumbency. A hobble is placed around the distal aspect of the affected limb, and the limb is maximally extended vertically. Pressure is applied to the shoulder region to reduce the luxation. An assisted recovery from general anesthesia is recommended, followed by cross-tying to prevent the horse from lying down, minimize the risks of re-injury, and allow the traumatized joint capsule to heal. Periarticular fibrosis inevitably develops, and treating the horse with non-steroidal anti-inflammatory drugs and a controlled exercise program to restore normal joint mobility may be necessary. A complete functional recovery has been achieved in a small number of ponies. The presence of any concurrent fracture predisposes to recurrent luxation and warrants an extremely guarded prognosis. Persistent luxation results in the rapid development of a deep groove in the humeral head, extending from cranially to caudally; thus the prognosis is poor.[2]

Fracture of the Articular Surface of the Distal Scapula

Fracture of the articular surface of the distal scapula may result from a fall when the horse is jumping, resulting in acute-onset, severe lameness.[35] Manipulation of the joint produces pain, and sometimes crepitus can be elicited. Periarticular soft tissue swelling occurs in the acute stage, but this resolves relatively rapidly. Diagnosis requires high-quality radiographs, because the only detectable radiographic abnormality may be loss of clarity of the articular margins of the distal scapula. Mediolateral and craniomedial-caudolateral oblique views should be obtained. The prognosis for athletic function is hopeless.

Periarticular Trauma

Periarticular trauma—the result of a fall, collision between two horses, or collision between a horse and a solid object—may result in sudden onset, severe, unilateral forelimb lameness because of severe bruising. Extensive periarticular soft tissue swelling may develop rapidly, with pain on deep palpation. In the acute stage determining whether a concurrent fracture is present may be difficult, especially fracture of the supraglenoid tubercle of the scapula or the first rib, because history and clinical signs are so similar.

If damage is restricted to bruising, lameness generally rapidly improves over the following 7 days. However, if concurrent trauma to the suprascapular nerve or its branch to the infraspinatus muscle occurred, significant neurogenic atrophy of the supraspinatus or infraspinatus muscles may occur within 7 days (see page 413). If moderate to severe lameness persists, then radiographic examination is indicated. If damage is restricted to soft tissue structures, then treatment with non-steroidal anti-inflammatory drugs combined with restriction to box rest and controlled exercise usually results in a rapid and complete recovery.

Intertubercular Bursa

Tendonitis of Biceps Brachii

Injury of the tendon of biceps brachii is a relatively uncommon cause of forelimb lameness, with no typical history. Frequently no localizing signs suggest the source of pain. In some horses forced retraction of the limb induces discomfort, but this is an unreliable finding. Lameness varies from mild to

severe, and only if lameness is severe are the gait characteristics typical of proximal limb lameness. Lameness is improved by intrathecal analgesia of the intertubercular bursa, although it may take up to half an hour.

Diagnosis is based on ultrasonographic examination. The entire length of the tendon of biceps brachii should be examined carefully from its origin on the supraglenoid tubercle of the scapula to the musculotendonous junction. The horse should be standing fully load bearing on the limb to avoid hypoechogenic artifacts within the tendon. It is important to be aware of the anatomy of the tendon, which changes in shape from proximally to distally.[6] Examining the medial and lateral lobes independently is often necessary, because maintaining both lobes in focus simultaneously is difficult. The tendon should be examined in transverse and longitudinal planes and careful comparison made with the contralateral limb. Ultrasonographic abnormalities include enlargement of the tendon, loss of definition of one of its margins, hypoechogenic defects within the tendon, and loss of fiber pattern in longitudinal images. The humeral tubercles should be inspected carefully for evidence of any concurrent damage. Concurrent evidence of bursitis characterized by an abnormal amount of fluid within the sheath (bursa) may also be present and results in an increased anechogenic space between the tendon and the humerus. Horses with chronic lameness may show evidence of hyperechogenic foci within the tendon, representing fibrosis or mineralization. Adhesions may develop between the tendon and the wall of the bursa. Occasionally echogenic bodies are seen free within the bursa.

Treatment of horses with tendonitis of biceps brachii consists of box rest and controlled walking exercise.[36] Injection of hyaluronan may be beneficial. The tendon should be monitored by ultrasonography at up to 3-month intervals. At least 6 to 9 months of convalescent time is required for horses with acute lesions, which have a fair prognosis. The prognosis for horses with chronic injuries is poor. Permanent enlargement of the tendon within the confined space between the brachiocephalicus muscle and the humerus and loss of normal gliding function cause persistent pain.

Osteitis of the Humeral Tubercles

Osteitis of the humeral tubercles is a rare cause of forelimb lameness.[26] Horses show moderate to severe lameness and resent manipulation of the shoulder. Abnormalities of the humeral tubercles are seen radiographically as lucent areas or by ultrasonography as a roughened surface to the bone and overlying cartilage. The intertubercular bursa may contain an abnormal amount of fluid and the tendon of biceps brachii may be enlarged, with peritendonous reaction. Surgical exploration may reveal necrotic areas of bone that are readily debrided, resulting in improvement in lameness.

Fracture of the Humeral Tubercles

A discussion of fracture of the humeral tubercles is on page 405 (see Fig. 41-10).

Infection

Infection of the intertubercular bursa occasionally causes acute onset, moderate to severe forelimb lameness.[37-39] Infection may be a sequel to known trauma, a previous injection, and a penetrating wound, but it has been recognized with no history of trauma or evidence of a wound, presumably infection being hematogenous in origin. Infection occurs in immature athletic horses and older horses.

The horse may stand slightly favoring the lame limb. Deep palpation in the region of the bursa may elicit pain. Retraction of the limb is resented. Lameness is often evident at the walk. Synovial fluid withdrawn from the bursa is usually grossly brown discolored and turbid, and therefore intra-thecal analgesia is usually unnecessary. Diagnostic ultrasonography reveals an abnormal amount of fluid within the bursa; sometimes echogenic material is seen within the fluid, and the surface of the tendon of biceps brachii may be less well defined than normal because of fibrin deposition. Diagnosis is confirmed by measuring differential white blood cell count and total protein concentration and by cytological examination of the synovial fluid, with polymorphonuclear leukocytes dominating.

Treatment is by radical surgical debridement and thorough lavage of the bursa by open surgery[37] or endoscopy,[38] combined with long-term, broad-spectrum antimicrobial therapy (e.g., crystalline penicillin and gentamicin) and the use of nonsteroidal anti-inflammatory analgesic drugs. If a penetrating wound is identified, consideration should be given to using metronidazole. When the acute inflammatory response has subsided, controlled exercise is important to try to limit adhesion formation. If recognized and treated early and aggressively, a favorable outcome can be achieved, but prolonged therapy is often required.[37]

Non-Infectious Bursitis

Non-infectious bursitis does occur occasionally alone, together with tendonitis of biceps brachii (see page 411), or with osteitis of the humeral tubercles.[4,40] Lameness varies in degree and is usually substantially improved by intrathecal analgesia. Diagnosis is verified by ultrasonographic examination of the intertubercular bursa. The bursa has an abnormal amount of fluid but no abnormalities of the enclosed tendon or the humeral tubercles. Treatment by intrathecal administration of hyaluronan and triamcinolone, combined with controlled exercise, is usually successful.

Mineralization

Mineralization within the tendon of biceps brachii has been seen alone or as a sequel to a previous fracture of the supraglenoid tubercle. Ectopic mineralization within the bursa has been associated with significant proliferation of the synovial membrane of the intertubercular bursa.[9] No typical history is known. Lameness varies in degree and only if moderate to severe is typical of a proximal limb lameness. Lameness is improved by intrathecal analgesia of the intertubercular bursa. Mineralization may be identified radiographically, but it can be obscured by the humeral tubercles. Radiography is useful to identify any previous fracture. Diagnostic ultrasonography provides more accurate information about the precise site and extent of mineralization and any concurrent pathological condition of the tendon. The prognosis for return to full athletic function is guarded.

Scapula

Fracture of the Supraglenoid Tubercle

The scapula has four centers of ossification: the scapular cartilage, body of the scapula, cranial part of the glenoid cavity of the scapula, and supraglenoid tubercle. The cranial part of the glenoid cavity of the scapula fuses with the body by 5 months of age. The physis of the supraglenoid tubercle closes between 12 and 24 months of age. Fracture of the supraglenoid tubercle of the scapula is a relatively common injury, resulting from a collision with a solid object or fall. Fractures frequently occur through the original physes.[35] The fracture may be simple or comminuted, involving only the supraglenoid tubercle, without an articular component. Alternatively, the fracture may pass through the glenoid notch of the scapula, which may result in one large fracture or separation of both original physes.

Lameness is sudden in onset and moderate to severe. Over the first week the horse may show progressive improvement, but lameness persists. Neurogenic atrophy of the supraspinatus and infraspinatus muscles may develop within 7 days if a concurrent injury of the suprascapular nerve occurred. Disuse atrophy develops more slowly.

A palpable thickening in the region of the supraglenoid tubercle exists, but crepitus is rarely appreciated.

Diagnosis is confirmed radiographically (see Fig. 13-1). The fracture fragments are often displaced craniodistally, because

of the pull of biceps brachii, and if treated conservatively, a non-union develops. The radiographs should be inspected carefully to determine if the fracture has an articular component, which warrants a more guarded prognosis.

The prognosis with conservative treatment is poor for return to athletic function. Surgical treatment by removal of the fracture fragment(s) has been successful in some horses, although the level of work to which horses have returned has not been well documented. Various methods of internal fixation have been attempted, but the large distracting forces of biceps brachii have to be overcome. A small number of horses younger than 2 years of age and less than 400 kg body weight have been successfully treated by complete tenotomy of the biceps brachii and internal fixation using three 5.5-mm cortical bone screws.[41]

Stress Fractures

Stress fractures of the body of the scapula are an occasional cause of acute-onset forelimb lameness in young Thoroughbreds in training.[9] No localizing clinical signs are present, and lameness often frequently improves spontaneously with rest. A premature return to training may result in a catastrophic fracture. Diagnosis relies on nuclear scintigraphic examination. Treatment requires 6 to 8 weeks of box rest and controlled walking exercise, followed by a graduated return to full work.

Fracture of the Body of the Scapula

Fractures of the body of the scapula usually result from the horse falling at a fence when jumping at speed. Complete fractures result in severe lameness and extensive soft tissue swelling and merit destruction on humane grounds. Diagnosis is usually obvious based on clinical signs, and radiographic examination is not necessary. Radiography is required for the diagnosis of incomplete fractures (Fig. 41-18). High-quality radiographs are required, and this may be difficult because the horse may resent protraction of the limb because of pain. Horses with fractures that enter the scapulohumeral joint have a poor prognosis. However, horses with extra-articular, incomplete fractures of the body of the scapula have a good prognosis for return to full athletic function with conservative management.

Fig. 41-18 Mediolateral radiographic view of 7-year-old event horse with acute-onset, severe left forelimb lameness after a fall. There is an incomplete fracture of the body of the scapula. The horse was treated conservatively and made a complete recovery.

Fracture of the Scapular Spine

Fractures of the scapular spine result from a fall, collision with a solid object, or occasionally a kick. Acute-onset, moderate lameness occurs with associated localized soft tissue swelling and pain on palpation. Oblique radiographic skyline views of the scapular spine are necessary to identify a fracture. Diagnostic ultrasonography may be more helpful in identifying a fracture. Most fractures heal adequately with conservative management. Occasionally a sequestrum develops, necessitating surgical debridement. The prognosis for return to full athletic function is good.

Muscle

Triceps Myopathy

See Chapter 84 for a discussion on triceps myopathy (page 735).

Muscle Lesions: Braciocephalicus, Biceps Brachii, and Pectorals

Lesions of muscles in the shoulder region have not been well documented and probably occur more commonly than recognized. However, clinical signs are rather non-specific, and diagnosis is difficult. A number of dressage horses have been identified that have shown forelimb lameness only while performing lateral work. Palpation has revealed no detectable abnormality. Local analgesic techniques have not altered the lameness. Ultrasonographic examination has revealed hyperechoic areas of fibrosis or mineralization within braciocephalicus in the lame limb only.

A dressage horse showed lameness only at the walk. Local analgesic techniques were ineffective. Nuclear scintigraphic evaluation revealed increased radiopharmaceutical uptake in the musculature cranioproximal to the elbow. This correlated with a hyperechogenic region within biceps brachii.

Some horses have forelimb lameness associated with palpable soreness of the pectoral muscles, which responds well to physiotherapy. Soreness of the braciocephalicus muscles is often seen with lameness caused by distal limb pain. Lameness is sometimes seen associated with primary braciocephalicus muscle damage in event horses and horses that race over fences. In most horses with acute lameness, palpation reveals muscle soreness and induces muscle spasm. However, in chronic cases pain can be more difficult to identify.

Rupture of Serratus Ventralis

The serratus ventralis muscles arise from the third to seventh cervical vertebrae and the first eight to nine ribs and insert on the medial proximal aspect of each scapula. They sling the thorax between the forelimbs. Rupture of one or both of these muscles is a rare injury, caused by trauma. The proximal border of the scapula moves proximally. If rupture is bilateral, the scapulae become higher than the summits of the dorsal spinous processes in the withers region. Rupture of the serratus ventralis should be differentiated from neurological disease causing loss of function of the muscle.[31]

The horse tends to stand with the forelimbs close together. Palpation of the withers region or manipulation of the forelimbs causes pain. The horse is reluctant to move, takes small steps, and nods the neck stiffly.

Radiographic examination should be performed to rule out a fracture of the scapula or the dorsal spinous processes of the cranial thoracic vertebrae. The prognosis for athletic function is poor.

Nerve

Atrophy of Supraspinatus and Infraspinatus Muscles: Damage to the Suprascapular Nerve

The suprascapular nerve wraps around the cranial aspect of the neck of the scapula and in this position is vulnerable to trauma resulting in perineural edema, stretching, and neuroma formation. Neuroma formation usually results in permanent loss of

function and subsequent neurogenic atrophy of supraspinatus and infraspinatus muscles. This can occur within 7 days of injury. Atrophy results in abnormal prominence of the scapular spine, but damage to the suprascapular nerve alone does not result in any loss of stability of the scapulohumeral joint. Lameness may be due to trauma at the time of the injury but generally resolves rapidly, unless a concurrent fracture is present.

This condition has been called *sweeny*, but this can be confusing because this term has also been used to describe instability of the shoulder or shoulder slip resulting from loss of collateral support of the shoulder musculature. This latter condition is separate and should not be confused (see the following discussion). Experimental transection of the suprascapular nerve in two ponies and one adult horse resulted in rapid atrophy of the supraspinatus and infraspinatus muscles, which persisted over the long term but produced no gait abnormality.[2]

The injury usually results from a fall or collision with another horse or solid object. Permanent muscle atrophy may ensue, but this results only in a cosmetic defect, not a functional deficit. Electromyography can be used to determine whether any other muscles are affected, which would suggest an injury to the brachial plexus or to other nerves in addition to the suprascapular nerve. Patchy sweating indicates a lesion elsewhere.

Surgical treatment has been performed to decompress the suprascapular nerve by cutting out a notch on the craniodistal aspect of the scapula and removing fibrotic material from around the nerve.[42] Surgical treatment has resulted in restoration of more normal muscle mass. Care must be taken not to traumatize the scapula unduly, because this may predispose to fracture.

Instability of Shoulder: Damage to the Brachial Plexus

Lack of collateral support to the scapulohumeral joint by loss of function of the muscles on the medial (subscapularis) and lateral aspects of the joint results in so-called shoulder slip. As the horse starts to bear weight on the limb, the shoulder joint bulges abaxially (Fig. 41-19). Concurrently the heel of the foot tends to rotate outward. This gait abnormality is evaluated most easily viewing the horse walking toward the observer. The gait abnormality may be slight or severe.

Instability of the shoulder was formerly ascribed to atrophy of the supraspinatus and infraspinatus nerves secondary to suprascapular nerve damage, but profound atrophy of these muscles can be present with no detectable gait abnormality.[2,9] Experimental transection of the suprascapular nerve resulted in profound atrophy of supraspinatus and infraspinatus muscles but no detectable gait abnormality.[2] Seven horses with persistent instability of the shoulder that have been humanely destroyed and examined post mortem have had atrophy of at least the supraspinatus, infraspinatus, and subscapularis muscles. All horses had neuroma formation involving nerves of the brachial plexus or the ventral nerve roots of the contributing nerves. The suprascapular nerve appeared normal as it passed over the cranial aspect of the scapula.

Instability of the shoulder invariably results from trauma, usually the horse colliding with a solid object. Pain related lameness may also be present initially, but this generally resolves within 1 to 2 weeks provided that a concurrent fracture does not exist. Similar clinical signs occasionally occur transiently (for 1 to 3 hours) after intra-articular analgesia of the scapulohumeral joint, presumably because of extra-articular leakage of local anesthetic solution. Instability of the shoulder has also been seen in a Miniature horse with dysplasia of the scapulohumeral joint and advanced osteoarthritis.

After trauma, initially no muscle atrophy is detectable, but atrophy of several muscles is usually detectable within 7 to 10 days. Patchy sweating may develop in the caudal neck region or over the scapula, depending on which nerves have been damaged. Electromyography can be used to determine accurately which muscles are affected.

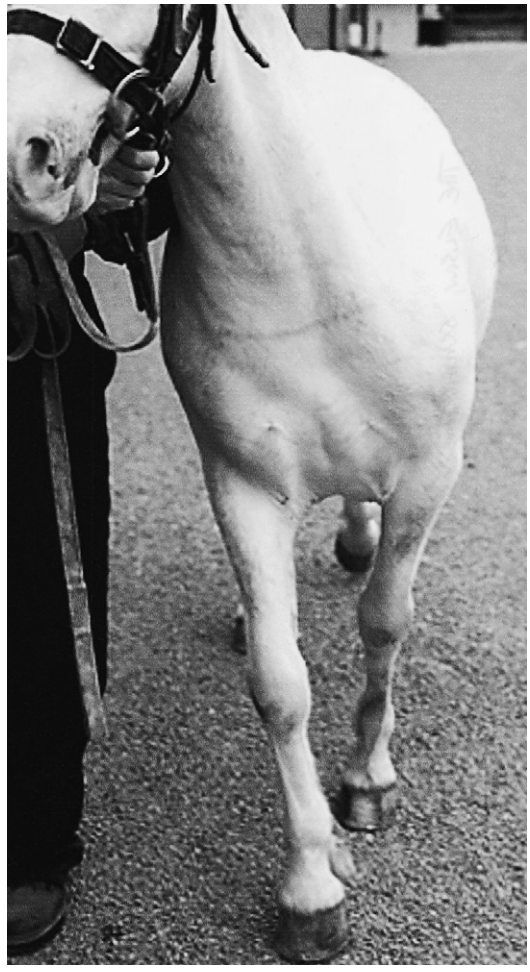

Fig. 41-19 A 7-year-old driving pony with acute onset instability of the left shoulder joint probably caused by a brachial plexus injury. The injury was of 12 days' duration. Note the medial placement of the left front foot. The heel rotated laterally as the foot broke over. There was moderate atrophy of the left infraspinatus, supraspinatus, and triceps muscles. The pony was treated conservatively, progressively improved, and made a complete functional recovery.

Prognosis depends on the nature of the nerve damage and the ability to achieve re-innervation of the affected muscles. Nerve regeneration occurs at approximately 1 mm per day. Progressive improvement in gait is a good prognostic sign. A normal gait may be restored despite persistence of atrophy of the supraspinatus and infraspinatus muscles.[2,43] However, a persistent gait abnormality 6 months after injury warrants a guarded prognosis. Surgical treatment is impractical because of the inaccessibility of the brachial plexus or the ventral nerve roots. Scapular notch resection is not indicated, because nerves in addition to or other than the suprascapular nerve are involved. This procedure also risks secondary fracture of the scapula.

Radial Nerve Paralysis

Radial nerve paralysis is an occasional cause of lameness. The clinical signs depend on the site or sites of damage. Complete radial nerve paralysis is most common, with loss of function of the extensor muscles of the elbow, carpus, and digits, and

results in inability to stand on the limb. The elbow is dropped, and the horse tends to stand with the affected limb forward, with the antebrachium at an angle of approximately 45° to the ground, with the carpus and fetlock semiflexed. Less commonly only the extensor muscles of the elbow are affected, so although the limb may be advanced forward, the elbow will drop during weight bearing. Occasionally only the extensor muscles of the carpus and digit are affected, so that the limb is advanced and placed normally, but then the carpus or fetlock may slightly knuckle forward. The horse has a tendency to stumble.

Lameness is usually sudden in onset. The horse may have a history of trauma. Paralysis occurs most commonly in young horses turned out together. Although damage to the radial nerve itself may be the cause of lameness,[44] many injuries are probably caused by compression of the brachial plexus between the scapula and the ribs.[4] An electromyogram may demonstrate involvement of more than the radial nerve. Equine protozoal myelitis should be considered in older horses, especially if evidence of other lower motor neuron pathological conditions exists (see page 129).

Many horses make a slow progressive recovery. Electrical stimulation of the affected muscles may help to maintain muscle mass. Problems may arise in young animals with overload of the contralateral limb, unless symptoms resolve quickly. An improvement within 2 to 4 weeks warrants an optimistic prognosis. Persistence of clinical signs for more than 6 months warrants a guarded prognosis.

First Rib

Occasionally acute-onset, severe lameness follows trauma from a fall or collision with a solid object associated with a fracture of the first rib. The lameness is typical of a proximal limb injury, but no other localizing signs are present. Atrophy of infraspinatus alone has also been recognized in some horses. Diagnosis is by radiographic examination. Nuclear scintigraphic examination may facilitate diagnosis. The prognosis is good after rest.

CHAPTER • 42

The Hind Foot and Pastern

Mike W. Ross

The contribution of the hind foot and pastern to hindlimb lameness is considerably less important than that of the digit to forelimb lameness. Extensive information regarding lameness of the foot and pastern in the forelimb is found in Chapters 26 to 36 and 83. This information is directly applicable to the hindlimb. During lameness examination, the hind foot and pastern are easily overlooked because they are in a potentially dangerous place to examine. Other regions of the hindlimb have been presumed to be more important and, historically, little has been taught about the distal part of the limb. Without a commitment to performing diagnostic analgesic techniques in the distal hindlimb, there is little way to discover whether the digit is the authentic source of pain unless the problem is severe or obvious. Subtle primary or compensatory lameness problems of this region are likely to go unnoticed daily. However, in certain sport horses, such as the draft horse, lameness of the hind foot and pastern is so common that this region cannot be overlooked.

ANATOMY AND INNERVATION OF THE HIND FOOT AND PASTERN

The bones are essentially the same as in the forelimb. The hind distal phalanx is narrower compared with the forelimb and has a steeper dorsal angle. The plantar surface is more concave, and the plantar processes are closer together.[1] The external appearance of the hind foot usually is more upright than the fore foot, but abnormal wear and shoeing practices can produce a common pathological condition of low, under-run heels (see Chapter 6). The hind middle phalanx is narrower and longer, and the hind proximal phalanx is slightly shorter than the corresponding bones in the forelimb.[1] The ligaments, tendons, digital flexor tendon sheath (DFTS), and distal interphalangeal and proximal interphalangeal joints are the same as in the forelimb. Innervation of the foot is derived primarily from the medial and lateral plantar nerves that originate from the tibial nerve (see Chapter 10). The medial and lateral plantar metatarsal nerves, which originate from the deep branch of the lateral plantar nerve, become superficial just distal to the "bell" of the second and fourth metatarsal bones. Unlike the palmar metacarpal nerves, the hindlimb medial and lateral plantar metatarsal nerves supply sensation to the pastern region and coronary band, a fact that can complicate interpretation of perineural analgesia in the hind digit.[2]

EXAMINATION, CLINICAL SIGNS, AND DIAGNOSIS

The clinical examination of the hind foot and pastern was described in Chapter 6, and a detailed description of the clinical investigation of the foot and shoeing is found in Chapters 26 to 28. A conscientious effort must be made during every lameness examination to evaluate the hind foot with the limb in both the standing and flexed positions. The type of shoeing and shoe wear are important in understanding potential lameness conditions of the foot, but perhaps more important, study of hind foot balance and shoeing can provide important clues in the diagnosis of lameness located more proximally in the limb. Dramatic abnormalities in balance and shoe additives, such as calks, grabs, trailers, and bars, can place added forces of shear and torsion on hindlimb bones and joints. Therapeutic recommendations cannot be made unless the clinician is aware of the type of shoes that are currently in place. Hoof imbalance has not been studied extensively in the hindlimb, but dorsal to plantar and medial to lateral hoof imbalance is a likely contributor to lameness in the proximal interphalangeal and metatarsophalangeal joints. Palpation for signs of inflammation, such as increased digital pulse amplitude, heat, swelling, and pain, must be performed but can be difficult in fractious horses. Palpation is difficult in the hindlimb because of the stay apparatus, which causes the digit to flex involuntarily. In Draft horses, signs of inflammation can be obscure (Fig. 42-1). Examination with hoof testers is important, but normally horses show considerable sensitivity across the heels (see Chapter 6). Because the foot is incorporated in the rigid hoof capsule and swelling may not be apparent, even severe lameness conditions, such as abscesses or fractures, can go unnoticed. Commonly lameness of the hind foot is misinterpreted as high up in the limb, because clinical signs are not prominent and easy to overlook.

Degree of lameness varies greatly. Most recognized problems of the hind foot cause obvious, often severe lameness, but occasionally subtle or insidious problems occur. Horses

Fig. 42-1 The defect in the coronary band of this draft horse was not detected until the long hair (or feathers) was shaved. Hoof tester examination yielded negative findings, but investigation of the foot was prompted by a positive response to perineural analgesia.

with the most common problems, such as hoof abscess and penetrating wounds, may not bear weight. If they are bearing weight, horses usually are severely lame at the trot. Horses with severe hind foot lameness, particularly of the toe region, may walk with a shortened caudal phase of the stride, similar to horses with pain in the coxofemoral region (see Chapter 7). The horse may bear weight only on the toe. Turning may accentuate pain. At the trot, horses with hind foot and pastern lameness have a shortened cranial phase of the stride and travel like horses with pain that originates anywhere distal to the distal crus. When the horse is viewed from behind, limb flight is characterized by moving the foot straight ahead or slightly medial to the line of expected limb flight and then stabbing laterally during the later portion of the stride, just before impact.

Many lameness conditions in this region worsen with a lower limb flexion test. Horses with osteoarthritis of the distal interphalangeal and proximal interphalangeal joints or tenosynovitis and tendonitis of the deep digital flexor tendon respond prominently. In general, hindlimb flexion tests have low specificity, and in horses that respond markedly to lower limb flexion, a source of pain located more proximal in the limb cannot be dismissed without using diagnostic analgesia.

Lameness must be localized using perineural or intra-articular analgesic techniques. Differentiation of sources of pain in the hind foot and pastern can be problematic because the same difficulties in interpretation of plantar digital and distal interphalangeal analgesic techniques occur as in the forelimb. When the plantar digital block is done with the limb elevated, it is difficult to inject the solution just above the cartilages of the foot, so this block is usually performed in a more proximal location than in the forelimb. It may be difficult to remove all pain in horses with severe lameness. Pain associated with the proximal aspect of the proximal phalanx, such as from mid-sagittal fractures, can easily be removed inadvertently during performance of plantar digital analgesia.[3] Careful interpretation of analgesic techniques is necessary, particularly in racehorses, in which metatarsophalangeal joint region lameness is common.

Imaging considerations are similar to those described in the forelimb. It may be preferable to obtain plantarodorsal rather than dorsoplantar radiographic views of the foot. Many horses are reluctant to stand on a block with the foot bearing weight for lateromedial views. Satisfactory images can readily be obtained with the foot bearing weight only on the toe provided that the foot is not rotated.[4]

SPECIFIC LAMENESS CONDITIONS

Overall the most common conditions of the hind foot and pastern involve hoof abscesses and bruises, penetrating wounds into the hoof capsule and soft tissues of the pastern region, and cellulitis. Scratches can cause horses to appear lame at a walk and when severe, lame also at the trot. Management of these conditions is well described elsewhere.

Distal Phalanx Fractures

Fractures of the distal phalanx occur in any type of sport horse as the result of direct trauma from kicking a wall or trailer. Occasionally horses step on a hard object while turned out or during competition. In racehorses, fractures of the distal phalanx can occur as a result of non-adaptive remodeling, but this is much less common than in the forelimb. Because many fractures are the result of direct trauma, the distribution varies. Articular plantar process fractures are most common, but incomplete (stress) fractures and mid-sagittal fractures also occur. Lameness is variable in degree, and it is important to recognize that lameness may be episodic in horses with a non-articular plantar process fracture. Fractures often can be seen in lateromedial radiographic views, but special oblique views may be required. Comminuted fractures are rare but develop as the result of direct trauma. Conservative management in most horses with fracture of the distal phalanx is quite successful. The decision to perform neurectomy is often made earlier than for injuries in a forelimb.

Laminitis

In horses with enterocolitis, pleuritis, metritis, or other systemic diseases, laminitis can develop in all four limbs, but rarely is the condition seen in only the hindlimbs. Even when hind feet are involved, clinical signs usually are most prominent in the front feet. Laminitis restricted to the hind feet only has been seen in overweight cob-type horses and ponies.[5] Traumatic laminitis can occur from intense exercise on hard ground in unshod horses, but it most commonly develops in the contralateral limb of horses with severe unilateral hindlimb lameness. In the latter form, called *orthopedic laminitis*, distal displacement or rotation of the distal phalanx generally takes considerable time to develop and can go unrecognized for several weeks. Often the first clinical sign that a problem is developing in the contralateral (laminitic) limb is that the lameness is observed to be inexplicably considerably improved in the original limb. Rarely, I have observed hindlimb laminitis as an apparently incidental finding in horses referred for scintigraphic examination for primary forelimb lameness or when whole-body scintigraphic examinations are performed. Marked increased radiopharmaceutical uptake (IRU) involving the distal or dorsal aspect of the distal phalanx and radiographic evidence of rotation were seen. Primary lameness is found elsewhere, but laminitis in these horses may represent an unusual form of compensatory lameness.

I have examined two pleasure horses with primary bilateral hindlimb laminitis (without forelimb involvement) in which an unusual hindlimb gait was observed. At the walk horses had a goose-stepping gait like that seen in horses with fibrotic myopathy. The horses appeared to be attempting to land with an exaggerated heel-to-toe hoof strike. Both horses had a marked shortening of the caudal phase of the stride. At the trot horses had a short, choppy gait, but because lameness was bilateral, overt unilateral signs could not be seen.

Keratoma

Keratoma involving the hind feet is rare. An unusual radiolucent defect thought to be a keratoma that caused lameness and poor racing performance, and associated with IRU was seen in the distal phalanx of a Thoroughbred racehorse (Fig. 42-2).

Navicular Syndrome

Navicular disease, osseous cyst-like lesions, and fractures of the navicular bone are unusual in the hindlimb but do occur in all types of horses and ponies (see Chapters 30 through 32). Lameness is variable in degree, usually unilateral, and improved by perineural analgesia of the plantar digital nerves. Lesions are usually readily detectable radiographically (Fig. 42-3). However, it is more difficult to obtain a skyline view of the navicular bone in a hindlimb than in a forelimb. Scintigraphy can be helpful in some horses.

Distal Interphalangeal Joint

Primary osteoarthritis of the hind distal interphalangeal joint is rare. Osteophytes involving the extensor process of the distal phalanx are commonly seen but are usually incidental radiographic findings. Osteoarthritis occurs as a result of instability or incongruity caused by articular fractures of the distal phalanx. Occasionally subchondral bone damage of the articular surface of the distal phalanx occurs and is recognized as radiolucent defects and secondary osteoarthritic changes;

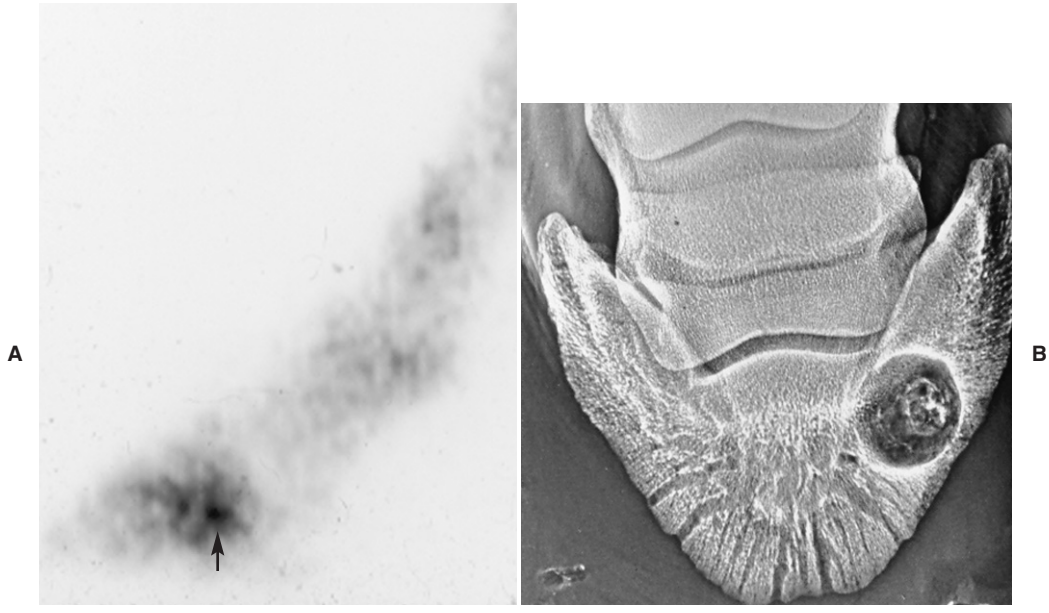

Fig. 42-2 **A,** Lateral delayed (bone) phase scintigraphic image. There is focal increased radiopharmaceutical uptake in the distal phalanx *(arrow)* of this Thoroughbred with undiagnosed right hindlimb lameness. **B,** Dorsoproximal-plantarodistal xeroradiographic view of a nearly circular radiolucent defect of the distal phalanx with either fragmentation or dystrophic mineralization within it. A tentative diagnosis of keratoma was made, but surgery was not performed.

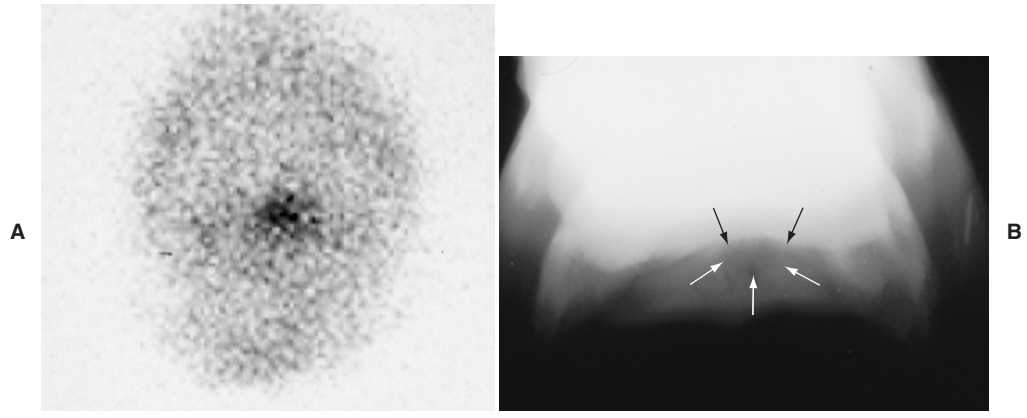

Fig. 42-3 **A,** Delayed (bone) phase scintigraphic image showing focal, moderately increased radiopharmaceutical uptake of the navicular bone (dorsal is to the top). **B,** Corresponding plantaroproximal-plantarodistal (skyline) radiographic view showing a distinct radiolucency *(arrows)* of the navicular bone in a 4-year-old Standardbred racehorse with left hindlimb lameness.

this damage usually is seen in older non-racehorse sport horses. Chronic, undiagnosed hindlimb lameness is followed by acute, prominent lameness. Diagnosis may be difficult, thus prompting scintigraphic examination. Focal areas of IRU in the subchondral bone of the distal phalanx should be differentiated from those in horses with incomplete fracture.

Extensor process fragments or fractures are rare. Osseous cyst-like lesions as a result of osteochondrosis of the distal phalanx are seen occasionally. Some small lesions restricted to the subchondral bone of the distal phalanx are difficult to identify radiographically, but usually result in intense, focal IRU scintigraphically. Definitive diagnosis may be possible only with magnetic resonance imaging or at post-mortem examination.[5] Other fractures involving the distal aspect of the middle phalanx and comminuted fractures of this bone occur. Involvement of the distal interphalangeal joint in horses with comminuted fractures of the middle phalanx is a negative prognostic finding.

The Hind Pastern

Lameness of the hind pastern region includes osteoarthritis of the proximal interphalangeal joint, osseous cyst-like lesions of the distal aspect of the proximal phalanx, osteochondral fragmentation of the proximal interphalangeal joint, fractures of the middle and proximal phalanges, subluxation of the proximal interphalangeal joint, tenosynovitis of the DFTS, tendonitis of the deep digital flexor tendon and the branches of the superficial digital flexor tendon, distal sesamoidean ligament desmitis, penetrating wounds, and cellulitis (see Chapters 36, 71, 75, and 83).

CHAPTER • 43

The Metatarsophalangeal Joint

Mike W. Ross

Lameness of the metatarsophalangeal joint is similar to that of the metacarpophalangeal joint, but historically it has largely been ignored and is mentioned only twice in a leading lameness textbook.[1] With fastidious use of both intra-articular and peri-neural analgesia, the metatarsophalangeal joint is now known to contribute substantially to hindlimb lameness.[2]

ANATOMY

The metatarsophalangeal joint is nearly identical to the metacarpophalangeal joint and is composed of the distal articular surface of the third metatarsal bone (MtIII), its sagittal ridge, and medial and lateral condyles; the medial and lateral proximal sesamoid bones (PSBs); and the proximal articular surface of the proximal phalanx, which has a prominent axially located sagittal groove (see Chapter 37). Minor differences exist in the shape and length of the proximal phalanx between the forelimbs and hindlimbs but are not clinically relevant. The metatarsophalangeal joint normally is more upright than the metacarpophalangeal joint and can achieve a greater degree of flexion. The lateral to medial width of the lateral condyle of the MtIII is less than that of the medial condyle. In racehorses, stress-related bone injury occurs predominantly in the lateral aspect of the hindlimb when based on scintigraphic examination. When combined with a smaller surface area, the lateral condyle may be prone to injury. The joint capsule, intersesamoidean and collateral sesamoidean ligaments, suspensory ligament (SL) attachments, and the flexor tendons all function to move and support the metatarsophalangeal joint. The dense collateral ligament has short, deep, and long superficial components. In the hindlimb the lateral digital extensor tendon joins with the long digital extensor tendon in the proximal dorsal metatarsal region. Therefore only the long digital extensor tendon is encountered during arthrocentesis or surgical procedures performed in the dorsal aspect of the metatarsophalangeal joint.

CONFORMATION

Fetlock valgus and varus deformities affect the metatarsophalangeal joint in foals, but fetlock varus deformity is of most concern and needs to be corrected early (see Chapter 60). Most normal horses are slightly toed out in the hindlimbs, but in some toed-out conformation may play a role in uneven load distribution and affect hindlimb gait. Horses with toed-out conformation tend to travel close behind and stab laterally during limb advancement, a gait that may cause excessive lateral shoe wear and hoof imbalance. Such gait and hoof imbalance may predispose the lateral aspect of the metatarsophalangeal joint to stress-related bone injury. Horses that are excessively straight behind have an abnormal degree of extension (or dorsiflexion) of the metatarsophalangeal joint. This conformation is undesirable because it places abnormal load on the SL and predisposes to suspensory desmitis, stifle joint lameness, and secondary osteoarthritis of the metatarsophalangeal joint.

CLINICAL CHARACTERISTICS AND DIAGNOSIS OF METATARSOPHALANGEAL JOINT LAMENESS

Lameness of the metatarsophalangeal joint occurs in most sport horses and is common in the racehorse. Both the Standardbred (STB) and Thoroughbred (TB) racehorse are prone to injury of this joint, but metatarsophalangeal joint lameness is more common in the STB, because gait and load distribution predispose to hindlimb lameness in this breed (see Chapter 2). Curiously, metatarsophalangeal joint lameness is apparently uncommon in Western performance horses despite the predominant use of the hindlimbs for many maneuvers and thus tremendous forces applied to the metatarsophalangeal joint (see Chapter 121). There is no pathognomonic historical information that incriminates the metatarsophalangeal joint more than other sources of hindlimb lameness, but racehorses are usually worse in turns. In horses with bilateral metatarsophalangeal joint lameness, poor performance may be the only historical finding and overt signs of lameness may not be present, but a short, choppy gait or intermittent, shifting hindlimb lameness is seen. A gait typical of bilateral stress-related bone injury of the distal aspect of the MtIII in TB racehorses being trotted in hand is described as an "exaggerated pelvic excursion" in a dorsal ventral direction (see Chapter 109).

Clinical signs of metatarsophalangeal joint lameness vary from subtle to overt and depend on the nature and severity of injury. Signs of inflammation may be absent in horses with stress-related bone injury but severe in horses with displaced or comminuted fractures. At the trot limb flight is similar to lameness originating from the metatarsal region and hock. As the limb moves forward, it deviates medially and is then stabbed laterally at the end of the cranial phase of the stride.

CHAPTER • 43

The Metatarsophalangeal Joint

Mike W. Ross

Lameness of the metatarsophalangeal joint is similar to that of the metacarpophalangeal joint, but historically it has largely been ignored and is mentioned only twice in a leading lameness textbook.[1] With fastidious use of both intra-articular and peri-neural analgesia, the metatarsophalangeal joint is now known to contribute substantially to hindlimb lameness.[2]

ANATOMY

The metatarsophalangeal joint is nearly identical to the metacarpophalangeal joint and is composed of the distal articular surface of the third metatarsal bone (MtIII), its sagittal ridge, and medial and lateral condyles; the medial and lateral proximal sesamoid bones (PSBs); and the proximal articular surface of the proximal phalanx, which has a prominent axially located sagittal groove (see Chapter 37). Minor differences exist in the shape and length of the proximal phalanx between the forelimbs and hindlimbs but are not clinically relevant. The metatarsophalangeal joint normally is more upright than the metacarpophalangeal joint and can achieve a greater degree of flexion. The lateral to medial width of the lateral condyle of the MtIII is less than that of the medial condyle. In racehorses, stress-related bone injury occurs predominantly in the lateral aspect of the hindlimb when based on scintigraphic examination. When combined with a smaller surface area, the lateral condyle may be prone to injury. The joint capsule, intersesamoidean and collateral sesamoidean ligaments, suspensory ligament (SL) attachments, and the flexor tendons all function to move and support the metatarsophalangeal joint. The dense collateral ligament has short, deep, and long superficial components. In the hindlimb the lateral digital extensor tendon joins with the long digital extensor tendon in the proximal dorsal metatarsal region. Therefore only the long digital extensor tendon is encountered during arthrocentesis or surgical procedures performed in the dorsal aspect of the metatarsophalangeal joint.

CONFORMATION

Fetlock valgus and varus deformities affect the metatarsophalangeal joint in foals, but fetlock varus deformity is of most concern and needs to be corrected early (see Chapter 60). Most normal horses are slightly toed out in the hindlimbs, but in some toed-out conformation may play a role in uneven load distribution and affect hindlimb gait. Horses with toed-out conformation tend to travel close behind and stab laterally during limb advancement, a gait that may cause excessive lateral shoe wear and hoof imbalance. Such gait and hoof imbalance may predispose the lateral aspect of the metatarsophalangeal joint to stress-related bone injury. Horses that are excessively straight behind have an abnormal degree of extension (or dorsiflexion) of the metatarsophalangeal joint. This conformation is undesirable because it places abnormal load on the SL and predisposes to suspensory desmitis, stifle joint lameness, and secondary osteoarthritis of the metatarsophalangeal joint.

CLINICAL CHARACTERISTICS AND DIAGNOSIS OF METATARSOPHALANGEAL JOINT LAMENESS

Lameness of the metatarsophalangeal joint occurs in most sport horses and is common in the racehorse. Both the Standardbred (STB) and Thoroughbred (TB) racehorse are prone to injury of this joint, but metatarsophalangeal joint lameness is more common in the STB, because gait and load distribution predispose to hindlimb lameness in this breed (see Chapter 2). Curiously, metatarsophalangeal joint lameness is apparently uncommon in Western performance horses despite the predominant use of the hindlimbs for many maneuvers and thus tremendous forces applied to the metatarsophalangeal joint (see Chapter 121). There is no pathognomonic historical information that incriminates the metatarsophalangeal joint more than other sources of hindlimb lameness, but racehorses are usually worse in turns. In horses with bilateral metatarsophalangeal joint lameness, poor performance may be the only historical finding and overt signs of lameness may not be present, but a short, choppy gait or intermittent, shifting hindlimb lameness is seen. A gait typical of bilateral stress-related bone injury of the distal aspect of the MtIII in TB racehorses being trotted in hand is described as an "exaggerated pelvic excursion" in a dorsal ventral direction (see Chapter 109).

Clinical signs of metatarsophalangeal joint lameness vary from subtle to overt and depend on the nature and severity of injury. Signs of inflammation may be absent in horses with stress-related bone injury but severe in horses with displaced or comminuted fractures. At the trot limb flight is similar to lameness originating from the metatarsal region and hock. As the limb moves forward, it deviates medially and is then stabbed laterally at the end of the cranial phase of the stride.

The cranial phase is shortened commensurate with the degree of pain. Lameness is more pronounced with the affected limb on the inside of a circle. I find it useful to characterize clinical signs into three categories: severe, unrelenting lameness; intermittent, severe lameness; and chronic, low-grade lameness.

Severe, Unrelenting Lameness

This form of metatarsophalangeal joint lameness is associated with intra-articular fractures or severe, end-stage osteoarthritis. Horses are obviously lame at the walk, cannot be trotted, and may be non–weight bearing. Deformity of the metatarsophalangeal joint may be obvious, as in horses with comminuted fractures of proximal phalanx. Effusion is obvious and diffuse, periarticular soft tissue swelling may be present. Horses with acute, displaced condylar fractures of the MtIII may have acute, progressive edema of the diaphyseal region, and those with comminuted fractures of the proximal phalanx often have severe soft tissue swelling. Palpation and flexion elicit severe pain and, in horses with comminuted or displaced fractures, crepitus. Radiographs are usually diagnostic. This category includes severe, complete, or comminuted fractures (e.g., spiral fractures of the MtIII), comminuted or complete fractures of the proximal phalanx, mid-body fractures of the PSBs, luxation or subluxation, and end-stage osteoarthritis. Horses with acute tendonitis of the deep digital flexor tendon (DDFT) with tenosynovitis can be severely lame, and intrathecal analgesia of the digital flexor tendon sheath (DFTS) may only partially remove pain. Ultrasonographic examination is required.

Intermittent, Severe Lameness

Horses with intermittent, severe lameness of the metatarsophalangeal joint may be able to train and perform at some level but develop severe lameness afterward. When exhibiting clinical signs, horses are lame at the walk, even toe-touching lame, and are obviously lame at the trot (grade 3 or 4 of 5), but after resting and receiving non-steroidal anti-inflammatory drugs (NSAIDs), horses are often able to gallop, jog, or train within 1 to 5 days. In some instances horses may be able to race, only to become lame once again. When walking in hand, horses often show marked lameness while turning, even if they are sound while walking in a straight line. Obvious signs of inflammation usually are not present, but horses generally respond positively to the lower limb flexion test and may show a painful response to deep palpation. Horses with incomplete mid-sagittal or dorsal frontal fractures of the proximal phalanx often manifest a painful response when firm digital pressure is placed on the proximal, dorsal aspect. Effusion may be present, but it is often absent or minimal even in horses with incomplete fractures. Because clinical signs may be difficult to detect, diagnostic analgesia is often necessary. Radiographs are usually diagnostic, but if findings are equivocal or the radiographs are obtained before radiographic changes develop, scintigraphic examination or follow-up radiographic examination in 10 to 14 days is required. Xeroradiographs and computed radiographs can be helpful. Conditions such as incomplete fractures of the MtIII, the proximal phalanx, and the PSBs and moderate osteoarthritis are in this category.

Chronic, Low-Grade Lameness

Diagnosis of chronic, low-grade metatarsophalangeal joint lameness is difficult. Specific signs that localize lameness to the metatarsophalangeal joint are lacking and lameness may only be subtle to mild (grade 1 of 5) at the trot in hand. Horses examined at the track and carrying a rider may only show mild lameness. Effusion and heat generally are absent and the response to lower limb flexion varies, but it usually is negative. Palpation may reveal mildly suspicious areas (e.g., pain over the abaxial aspect of the PSBs) in horses with sesamoiditis, but in most horses no abnormalities are noted. Concomitant lameness of the metatarsophalangeal joint and stifle region can occur in racehorses and clinical signs may not abate until both sites are treated. The association between the stifle and metatarsophalangeal joint is difficult to explain. In young horses with "loose stifles," knuckling of the metatarsophalangeal joint occurs when horses, particularly STBs, are jogged or worked slowly. Perhaps stretching of metatarsophalangeal joint capsule attachments or early subchondral bone trauma occurs during knuckling. Horses with "loose stifles" are thought to have patellar ligament and muscular instability and laxity and may benefit from counterirritant injection and simultaneous management of the metatarsophalangeal joint problem.

Diagnostic analgesia is required to localize pain causing lameness to the metatarsophalangeal joint, but in many horses lameness is difficult to accurately assess with the horse at a trot in hand. Often radiographic examination findings are normal and horses are referred for scintigraphic examination, which often reveals stress-related bone injury. Special radiographic projections may be needed to evaluate the distal aspect of the MtIII or for accurate identification of osteochondral fragments located in the dorsal and plantar aspects of the joint. In this category are conditions such as stress-related bone injury of the MtIII, early osteoarthritis, osteochondral fragments that occur traumatically or as the result of osteochondrosis, and sesamoiditis.

Diagnostic Analgesia

Articular pain originating from the metatarsophalangeal joint can usually be abolished or at least partially alleviated by intra-articular analgesia. Because only one injection is required, intra-articular analgesia is easier and safer to perform than perineural techniques, but pain originating from subchondral bone may not abate or may be only partially alleviated by intra-articular analgesia. Therefore the low plantar peri-neural technique or a variation must be used, because it is more effective in alleviating pain from all sources (see Chapter 10).

A variation of the low plantar block, the lateral plantar metatarsal block, can be performed in horses with stress-related bone injury of the distal plantarolateral aspect of the MtIII (see Chapter 109).[3] This block is particularly valuable in horses with bilateral lameness, because after one limb is blocked, the horse becomes obviously lame in the other.

In horses with chronic, low-grade lameness it may be necessary to perform analgesia and watch the horse train. Resolution of subtle signs, such as bearing in or out, not feeling right behind, performing dressage maneuvers, or in STB racehorses, being on a shaft or a line, may be the only sign of a positive response to diagnostic analgesia. Although peri-neural analgesia may result in slight loss of proprioception, it is generally preferable, because intra-articular analgesia may result in a false-negative response. If pain is elicited by firm palpation of the dorsoproximal aspect of the proximal phalanx, suspect a mid-sagittal fracture. Nerve blocks are contraindicated because of the risk of creating a complete or comminuted fracture.

The clinician should be aware that it is possible to inadvertently block pain associated with subchondral bone of the metatarsophalangeal joint when performing plantar digital or plantar peri-neural analgesia. This occurs most frequently in racehorses with mid-sagittal fracture of the proximal phalanx but can occur in horses with osteoarthritis or other conditions (see Chapters 10 and 42).

IMAGING CONSIDERATIONS

Radiographic Examination

Examination should include dorsoplantar (DPl), lateromedial (LM), dorsolateral-plantaromedial oblique (DL-PlMO), and dorsomedial-plantarolateral oblique (DM-PlLO) views. A

flexed LM view is useful to evaluate the sagittal ridge for the presence of osteochondrosis lesions and to see dorsal frontal fractures of the proximal phalanx. Vacuum phenomenon can occur because the metatarsophalangeal joint can be placed in extreme flexion. Sudden decompression of the joint during stress flexion is believed to cause what appears to be an air artifact in the distal plantar aspect of the MtIII.[4]

Horizontal oblique views are useful to evaluate the proximal-dorsal aspect of the proximal phalanx for the presence of osteochondral fragments, but overlap between the base of the PSBs and the proximal aspect of the proximal phalanx can hide lesions associated with the distal-plantar aspect of the joint. The x-ray beam should be angled down 15° to 20° to separate the PSBs and proximal phalanx (Fig. 43-1).

Using a horizontal x-ray beam in a DPl view, the PSBs are superimposed over the distal aspect of the MtIII and metatarsophalangeal joint. To better evaluate these areas, dorsal 15° proximal-plantarodistal oblique (D15° Pr-PlDiO), flexed DPl, and standing 125° DPl views should be used. Proximolateral (medial)-distolateral (medial) and proximoplantar-distoplantar tangential views of the PSBs are occasionally used to evaluate the abaxial and plantar surfaces of the PSBs, respectively.

Approximately 5% to 10% of normal horses have a small unilateral or bilateral radiolucent notch (1 mm in length) in the sagittal grove of the proximal phalanx that is seen in a DPl view and should not be confused with a mid-sagittal fracture. If clinical signs are consistent with mid-sagittal fracture, scintigraphic examination is recommended. Flattening of the plantar aspect of the distal MtIII condyles is not as common as in the metacarpophalangeal joint, but sclerosis of the plantar aspect of the MtIII can be seen in horses with stress-related bone injury and early osteoarthritis if well-exposed LM and flexed LM views are obtained. I question the significance of flattening of the condyle of MtIII in most horses. Xeroradiographs and computed radiographs are useful in the evaluation of horses with stress-related bone injury and incomplete fractures. Computed tomography and magnetic resonance imaging are also useful, but availability is limited.

Scintigraphic Examination

Scintigraphic examination is the best way to establish a diagnosis in many horses with intermittent, severe, or chronic low-grade lameness of the metatarsophalangeal joint. The most common scintigraphic findings in the metatarsophalangeal joint of STB and TB racehorses are focal areas of increased radiopharmaceutical uptake (IRU) that involve the distal plantarolateral aspect of the MtIII (Fig. 43-2).[5] This IRU is a form of stress-related bone injury and early osteoarthritis that is found in many racehorses with chronic, low-grade lameness; bilateral hindlimb lameness; and poor performance. Special radiographic views may then reveal sclerosis or radiolucent defects (Fig. 43-3). Similar scintigraphic findings are seen in horses with lateral MtIII condylar fractures. Focal areas of IRU are seen in horses with mid-sagittal or dorsal frontal fractures of the proximal phalanx (Fig. 43-4), sesamoiditis (Fig. 43-5), and osteochondrosis of the plantar process of the proximal phalanx (Fig. 43-6). Often areas of IRU are found in unusual sites, such as those associated with the medial PSB (osteochondral fragments of the abaxial border and sesamoiditis), intersesamoidean ligament injury with radiolucent defects in one or both PSBs, incomplete fractures of the PSBs, and medial condylar fractures of the MtIII. Any focal area of IRU located medially in the metatarsophalangeal joint should be investigated, because incidental findings are unusual in this location.

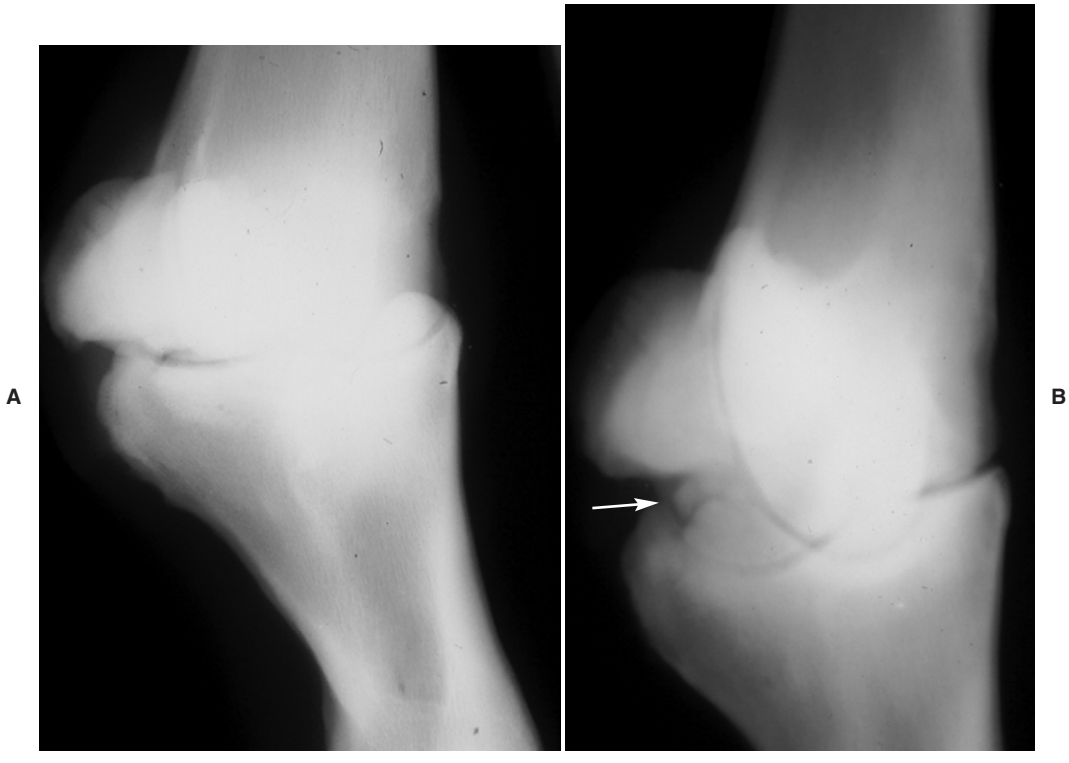

Fig. 43-1 **A,** Dorsomedial-plantarolateral oblique radiographic view obtained using a horizontal x-ray beam. Note the overlap of the distal aspect of the proximal sesamoid bones and the proximal aspect of the proximal phalanx. **B,** The proximal plantar aspect of the proximal phalanx can be clearly evaluated using a dorsomedial proximal-plantarolateral distal oblique view. An axial, intra-articular fragment is present *(arrow)*.

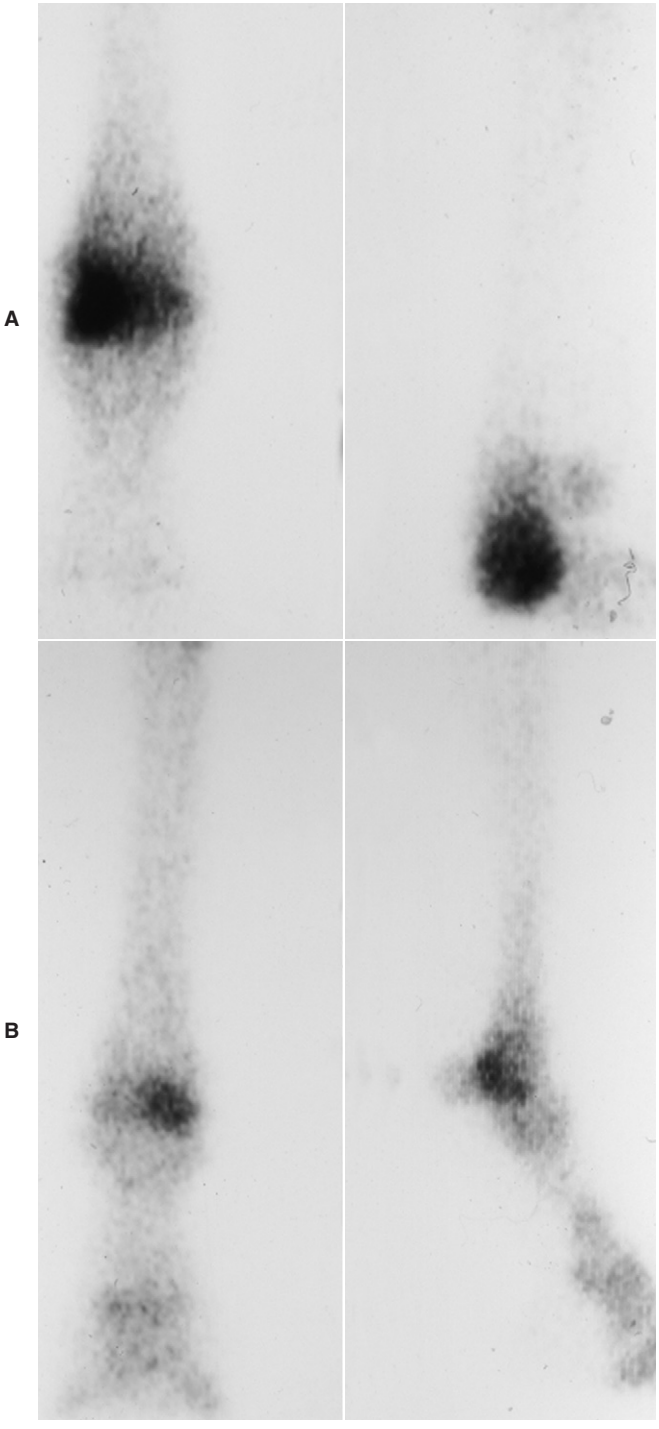

Fig. 43-2 **A,** Plantar (lateral to the left) and flexed lateral (on the right) right hindlimb and **B,** plantar (lateral to the right) and lateral (on the right) left hindlimb delayed (bone) phase scintigraphic images of the metatarsophalangeal joint in two Standardbred racehorses. All images show focal increased radiopharmaceutical uptake of the distal, plantarolateral aspect of the third metatarsal bone, which is the most common scintigraphic finding in the metatarsophalangeal joint of racehorses.

Scintigraphic changes are usually less pronounced in nonracehorses, and negative or equivocal results often occur. The most common scintigraphic findings in jumpers and dressage horses with metatarsophalangeal joint lameness are diffuse mild areas of IRU in all bones or focal mild or moderate IRU in the dorsal aspect of the joint that involves the distal MtIII

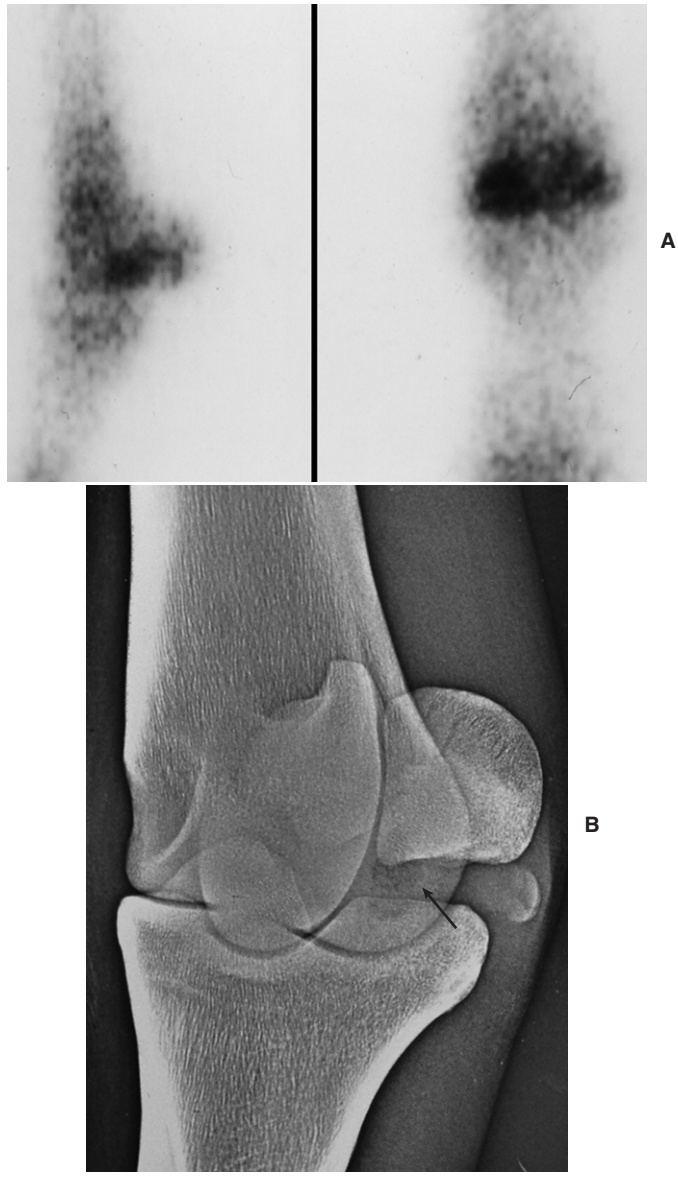

Fig. 43-3 **A,** Lateral (on the left) and plantar (lateral is to the left) bone phase scintigraphic images of a metatarsophalangeal joint. There is increased radiopharmaceutical uptake in the plantar aspect of the lateral condyle of the third metatarsal bone. **B,** Dorsolateral proximal-plantaromedial distal oblique xeroradiographic view showing a radiolucent defect *(arrow)* of the same area. This defect can easily be missed on routinely positioned views, but the increased radiopharmaceutical uptake seen in this area scintigraphically **(A)** prompted further investigation.

and proximal aspect of the proximal phalanx and is associated with marginal osteophytes and enthesophytes. In some horses arthroscopic examination has revealed full-thickness cartilage damage that primarily involves the distal MtIII and is consistent with osteoarthritis. Focal IRU in the proximal aspect of the plantar pouch is seen in horses with severe osteoarthritis (an ominous finding) (Fig. 43-7). I believe this finding is caused by accumulation of subchondral bone fragments in this location or modeling of the distal plantar aspect of the MtIII.

Ultrasonographic Examination

Ultrasonographic examination of the metatarsophalangeal joint region is indicated for suspensory branch desmitis (see Chapter 73). The abaxial aspect of the PSBs should be examined carefully to identify tearing and small avulsion fractures.

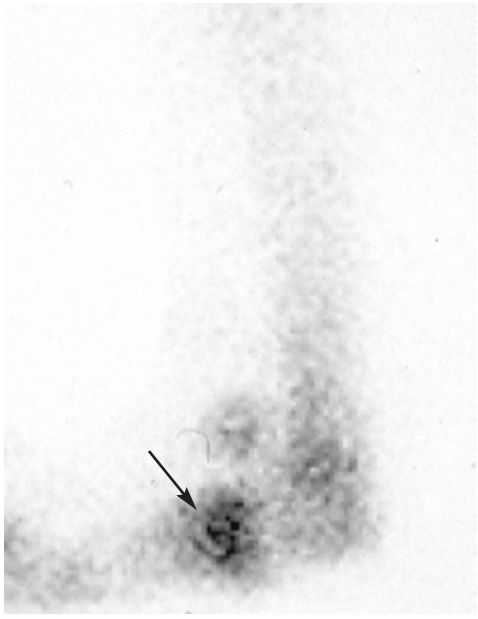

Fig. 43-4 Flexed lateral delayed (bone) phase scintigraphic image of a horse with incomplete mid-sagittal fracture of the proximal phalanx. Focal moderate increased radiopharmaceutical uptake in the proximal phalanx is somewhat more pronounced in the plantar aspect *(arrow)*. In most horses with mid-sagittal fracture of the proximal phalanx, increased radiopharmaceutical uptake is most prominent dorsally.

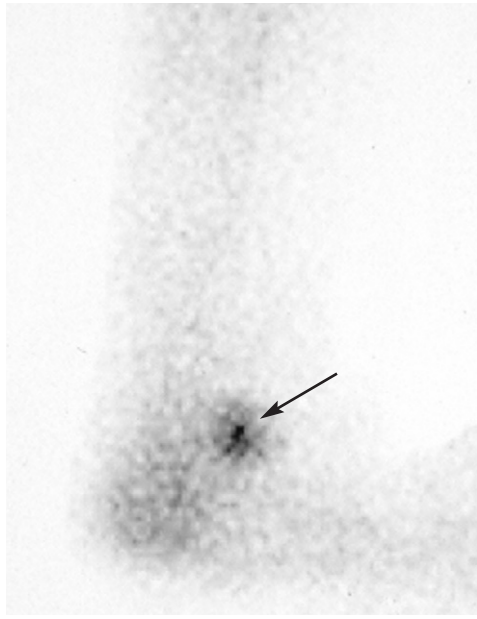

Fig. 43-5 Flexed lateral delayed (bone) phase scintigraphic image of a 2-year-old Standardbred racehorse with lateral sesamoiditis. There is focal moderate increased radiopharmaceutical uptake in the proximal sesamoid bones *(arrow)*. When these findings were combined with those of the plantar view, the increased radiopharmaceutical uptake was localized to the lateral proximal sesamoid bone.

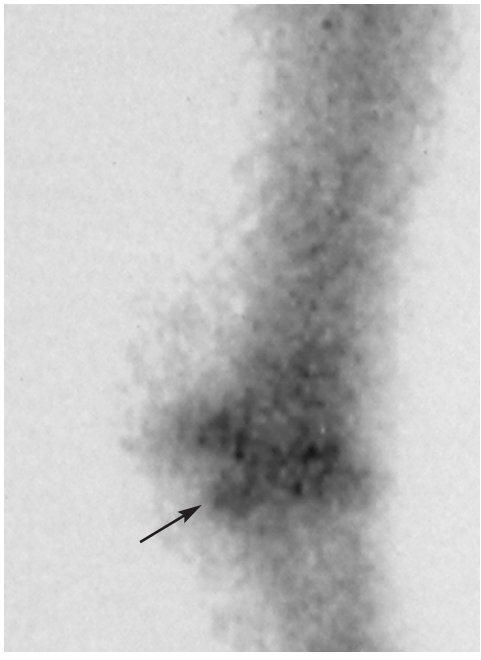

Fig. 43-6 Lateral delayed (bone) phase scintigraphic image. There is focal mild increased radiopharmaceutical uptake involving the proximal plantar process of the proximal phalanx *(arrow)* in a Standardbred racehorse with axial articular fragments of the plantar process.

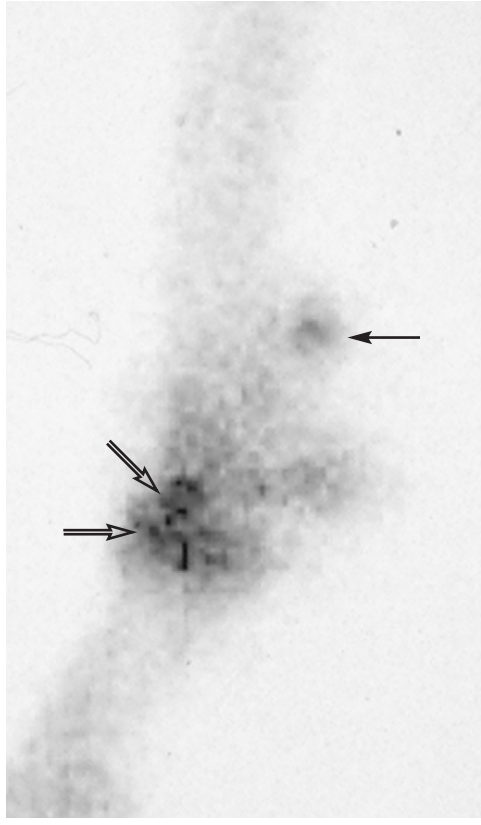

Fig. 43-7 An ominous finding in delayed (bone) phase scintigraphic images is increased radiopharmaceutical uptake in the region of the proximal plantar pouch *(arrow)*, which indicates the presence of severe osteoarthritis. There is increased radiopharmaceutical uptake involving the proximal aspect of the proximal phalanx and distal third metatarsal bone *(open arrows)*.

Proliferative synovitis (villonodular synovitis) is unusual in the metatarsophalangeal joint. The DDFT should be evaluated carefully if tenosynovitis of the DFTS is present[6] (see Chapter 71). Ultrasonographic examination is useful in horses with intersesamoidean and collateral ligament injuries or those with wounds and draining tracts to look for foreign material or communication with the articular surface.

Arthroscopic Examination

Arthroscopic surgery is used frequently for removal of osteochondral fragments and fractures of the PSBs, assistance in fracture reduction and screw placement in horses with condylar fractures of the distal MtIII and fractures of the proximal phalanx, and lavage and debridement in horses with infectious arthritis. Diagnostic arthroscopic examination is indicated if lameness is localized to the metatarsophalangeal joint, but radiographic findings are negative or suggestive of occult osteochondral fragments. Diagnostic arthoscopy is also indicated if scintigraphic images are abnormal, so that cartilage damage or osteochondral fragments are suspected, and to confirm the extent of cartilage damage in horses with osteoarthritis. Occult fragments involving the proximodorsal aspect of the proximal phalanx are occasionally found. Cartilage damage, sometimes full-thickness, is found on the distal-dorsal aspect of the MtIII and proximal aspect of the proximal phalanx in non-racehorses. In racehorses with osteoarthritis cartilage lesions are usually most pronounced in the plantar pouch, with extensive scoring or large areas of full-thickness damage and exposed subchondral bone on the PSBs. Although stress-related bone injury and later overlying cartilage damage is seen on the distal plantarolateral aspect of the MtIII, this area is difficult to evaluate during arthroscopic examination (Fig. 43-8).

SPECIFIC CONDITIONS OF THE METATARSOPHALANGEAL JOINT

Stress-Related Subchondral Bone Injury and Osteoarthritis

The term *osteoarthritis* implies disease of both the supporting bone and the articular surface of the metatarsophalangeal joint. The concept that the earliest lesion in osteoarthritis of the metatarsophalangeal joint in racehorses begins in subchondral bone is essential to understanding clinical signs, successful use of diagnostic analgesia, progression of bone and cartilage loss, and the horse's response (or lack thereof) to therapy. There are two syndromes of metatarsophalangeal joint osteoarthritis; one is seen in racehorses and the other in non-racehorse sport horses.

In racehorses osteoarthritis begins as a non-adaptive stress-related bone injury in subchondral bone. Although the overlying cartilage may be biomechanically and biochemically inferior, obvious clinical signs such as synovitis and a positive response to lower limb flexion are not seen until later. Low-grade unilateral or bilateral lameness is present, which is localized best by low plantar or lateral plantar metatarsal analgesia. Early stress-related bone injury is best substantiated using scintigraphic examination. Focal areas of IRU are present in the MtIII; the PSBs and the proximal aspect of the proximal phalanx also can be affected (see Fig. 43-2). Initial radiographic findings are either negative or reveal subtle sclerosis, but later radiolucent defects develop in subchondral bone, which is best revealed in a DPrL-PlDiMO view (see Fig. 43-3). Sclerosis is most obvious in the LM, flexed LM, and DPrL-PlDiMO views.

Later, overlying full-thickness cartilage damage develops (see Figs. 43-8 and 43-9). Stress-related bone injury can continue to the point where severe osteoarthritis or fracture of the MtIII develops; this type of severe injury is most common in racehorses between 4 and 6 years old. However, in some STBs the process causes lameness when horses are 2- or early 3-year-olds and then subsides or stabilizes. The condition is rarely seen in STBs until training speeds faster than 2 minutes, 20 seconds for a mile are achieved. In TB racehorses, this remodeling process is common in later 2- and 3-year-olds but can also be seen in older horses. Older horses given time off for undiagnosed lameness or other conditions are at risk to develop stress-related bone injury in the metatarsophalangeal joint 6 to 8 weeks after returning to training, when signs of poor gait or lameness develop and a focal area of IRU can be identified. In my experience, subchondral lucency occurs later in the TB than in the STB and is uncommon. Differences between the racing breeds related to gait, speed, and load distribution may account for this difference in progression of osteoarthritis. End-stage osteoarthritis develops in STB racehorses that have continued racing for many years and can be progressive in broodmares and breeding stallions.

In non-racehorse sport horses osteoarthritis is an insidious process without marked subchondral bone involvement. Bone and cartilage gradually deteriorate. Some horses affected may be ex-racehorses, but most are not. I have observed osteo-

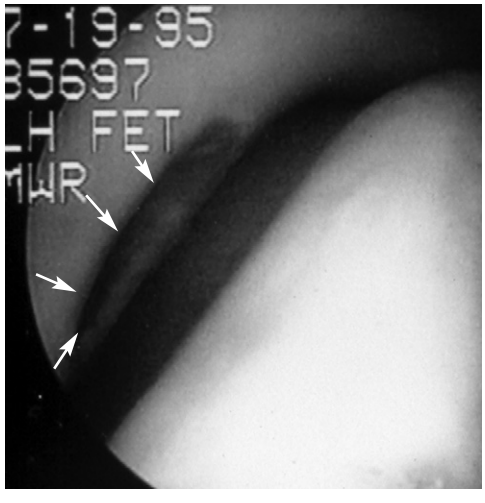

Fig. 43-8 Intraoperative photograph of a 5-year-old Standardbred trotter with severe stress-related bone injury of the distal plantarolateral aspect of the third metatarsal bone *(arrows)*. This area was debrided and the horse raced, but it dropped substantially in race class and was retired.

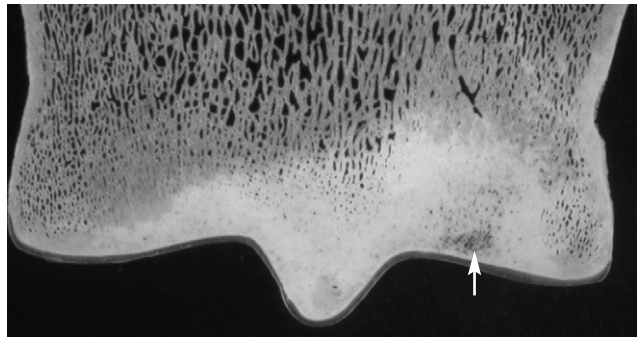

Fig. 43-9 Frontal plane microradiograph (100 μm) of the distal aspect of the third metatarsal bone (lateral is to the right) showing dense subchondral sclerosis and an area of intense resorption or necrosis of bone *(arrow)*. Cartilage overlying this area is intact. Severe subchondral modeling and remodeling and later osteoarthritis develop in the metatarsophalangeal joints of racehorses.

arthritis of the metatarsophalangeal joint mostly in upper-level jumpers and dressage horses. In these horses lameness is often chronic and low grade (grade 1 or 2 of 5), but it can progress to severe or intermittently severe. Effusion and a positive response to lower limb flexion are common findings. Concomitant tenosynovitis of the DFTS and previous lameness caused by suspensory desmitis and distal hock joint pain are common. Lameness is more consistently abolished using intra-articular analgesia in jumpers and dressage horses than in racehorses, but in some horses the low plantar block is required. Marginal osteophytes and entheseophytes may be detectable radiographically. Scintigraphy may reveal focal IRU in the dorsal aspect of the joint, diffuse IRU, or equivocal findings. Occasionally acute-onset lameness associated with focal IRU of the distal MtIII occurs that is similar to that found in racehorses. This lameness may indicate acute subchondral overload trauma from landing wrong after jumping a fence, stepping on uneven ground, or sustaining a fall or other accident in a paddock. In non-racehorse sport horses, arthroscopic examination often reveals cartilage damage most extensive in the dorsal aspect of the joint, marginal osteophytes on the apices of the PSBs, and occasionally osteochondral fragments of the proximal dorsal aspect of the proximal phalanx.

Shoeing and hoof balance may play a role in development or expression of clinical signs of osteoarthritis in all horses but may be more important in racehorses. In the STB racehorse clinical signs often develop within 2 to 3 weeks of a shoeing change, usually with the application of aluminum shoes with a low toe grab. Aluminum shoes are light and generally applied to pacers that are close to qualifying speed, but they are often used in trotters as well. Shear stress associated with these shoes may exacerbate existing disease or cause further trauma to subchondral bone. Aluminum shoeing is common in TB racehorses in North America, where these shoes are associated with other fetlock joint lameness and catastrophic breakdown. Abnormal hoof wear caused by gait, the presence of concomitant distal hock joint or metatarsal region pain, or hoof imbalance may cause asymmetrical loading of the metatarsophalangeal joint and add to subchondral bone trauma.

Management of Stress-Related Bone Injury and Osteoarthritis

Reducing bone stress is key to initial management in racehorses with early osteoarthritis characterized primarily by stress-related bone injury, because high-impact loading or high-strain cyclic fatigue of subchondral bone is the primary lesion. In STBs I previously recommended 4 to 6 weeks of light jogging (<2 miles per day), but results were poor even if recommendations were followed. I reassessed several horses after 6 weeks of light jogging, and although scintigraphic changes subsided, the horses were still as lame or slightly worse. I now recommend 3 weeks of walking and light jogging followed by re-evaluation. Although 3 weeks' reduction in training may allow healing or remodeling of damaged subchondral bone and microfractures, bone and muscle undergo detraining and horses need several (i.e., 3 to 6) weeks of slow return to normal exercise intensity. If lameness resolves, horses are returned to training, but if lameness persists I recommend 3 to 4 months of rest. In TBs, recurrence is quite high if horses are given only 6 to 8 weeks of rest. I recommend either 3 to 4 months of turn out or a program of 3 weeks of hand walking, followed by 3 weeks of walking with a rider up, followed by 3 weeks of trotting either with a rider up or using an exercise pony. A gradual return to normal exercise intensity is then recommended if horses are sound and moving well.

Hoof balance and shoeing characteristics should be evaluated and, in most instances, changed. A simple change in shoeing to an easier shoe, such as a flat steel or aluminum shoe, may reduce shear and torsion of the metatarsophalangeal joint. Toe grabs and any other shoe additives must be removed. If medial to lateral hoof imbalance is poor, it should be corrected.

Because the initial lesion is in subchondral bone, intra-articular injections appear to have limited therapeutic benefit but may make theoretical sense. Active treatment may help in persuading trainers to follow the recommended work program. A series of three intra-articular injections of polysulfated glycosaminoglycans (PSGAGs) are given every other week. Alternatively, if horses are currently racing but have mild unilateral or bilateral lameness or scintigraphic evidence of stress-related bone injury and poor performance, I recommend intra-articular injection with hyaluronan and methylprednisolone acetate (80 mg). Intramuscular administration of PSGAGs (once weekly for 8 weeks) is recommended, but therapeutic benefit is difficult to assess. NSAIDs such as phenylbutazone (2.2 to 4.4 mg/kg bid) are recommended. NSAIDs may help horses in modified exercise programs "get over the hump" when lameness persists after scintigraphic evidence of stress-related bone injury subsides. Because pathogenesis involves sclerotic subchondral bone, the roles of ischemia and increased intraosseous pressure in causing bone pain or necrosis and subsequent collapse of weakened areas of subchondral bone have been questioned. I used to recommend the administration of isoxsuprine (400 mg bid orally) in an attempt to improve peripheral blood flow. However, research evidence supports neither the achievement of adequate blood levels nor increased blood flow by use of the drug, and I do not currently recommend its use. Other drugs, such as aspirin (17 mg/kg bid orally), may be useful in improving blood flow, but half-life is short and therapeutic benefit has yet to be established. If increased intraosseous pressure and early ischemia lead to pain and subchondral bone damage, a procedure such as subchondral bone drilling, which is used to manage stress-related bone injury in cortical bone of the McIII, may be beneficial, but is currently only experimental. Topical counterirritation has historically been used and makes theoretical sense in horses with stress-related bone injury if increased blood flow occurs. The time-honored treatment of blistering and turning out may be the best method of management. We have used focused shock-wave therapy in some STB and TB racehorses with stress-related bone injury by aiming the shock waves at the plantarolateral aspect of MtIII (single treatment, 2000 shocks). Early results appear promising, but horses are given concurrent modified exercise programs and other therapy.

In racehorses with more advanced osteoarthritis the therapeutic value of intra-articular injections becomes greater, because overlying cartilage damage and synovitis become prominent. However, horses generally drop substantially in race class and eventually are retired. In TB racehorses, intra-articular injections have little benefit in horses in training but may have limited value in horses actively racing. The disease process appears to be self-limiting in TBs, because horses with continued chronic, low-grade lameness are often retired before the disease process advances or horses develop compensatory lameness in the forelimbs. In the TB racehorse subchondral radiolucency is unusual in my experience, but others have recognized progression of osteoarthritis and the development of changes similar to those seen in STBs (see Chapter 109). Why some horses are able to race with persistence of IRU, radiolucency, and sclerosis, whereas others cannot, is not easy to answer. Prognosis for both racing breeds appears to be guarded to fair at best. Of 19 STBs with lameness and IRU of the plantarolateral aspect of the MtIII, 18 raced, but only 13 remained at the same racing class or improved.[5] When radiolucent areas become prominent, arthroscopic examination and debridement may be an option, but it is difficult to manipulate instruments in the distal plantar pouch, because manipulation must be done with the joint in flexion (see Fig. 43-8). It is almost

impossible to reach these lesions using a dorsal approach, because they are located approximately 8 mm plantar to the middle of the condyle. In horses with end-stage osteoarthritis (i.e., loss of joint space, tilting of the sagittal ridge and groove, and severe proliferative and radiolucent changes), arthrodesis must be considered in broodmare or stallion prospects. Humane destruction may be required.

Non-racehorses often respond favorably to intra-articular injections of PSGAGs, hyaluronan, and short-acting corticosteroids (e.g., triamcinolone acetonide, isoflupredone acetate) or long-acting corticosteroids (e.g., methylprednisolone acetate). Exercise level is reduced for a period of 2 to 3 weeks and horses are given NSAIDs. Topical therapy using cold water hosing, poulticing, and bandaging is recommended. When lameness persists and scintigraphic examination reveals focal IRU in the dorsal aspect of the joint, or in horses with chronic lameness, long-term rest is necessary. Arthroscopic examination in these horses reveals areas of partial- or full-thickness cartilage damage that can be managed by debridement and microfracture into subchondral bone. However, the therapeutic value of arthroscopy is limited. If osteophytes are removed, they generally reform. If surgery is combined with rest, horses usually become sound, but lameness often returns when competition ensues. Prognosis for horses performing at the previous level of competition is guarded to poor. Rehabilitation of upper-level performance horses is quite difficult, because most have at least one compensatory lameness problem in addition to primary osteoarthritis of the metatarsophalangeal joint. Horses may be able to sustain a lower level of competition.

Plantar Process Osteochondral Fragments

Fragmentation of the proximal plantar processes of the proximal phalanx is a common finding in young STBs and Warmbloods but is also seen in TBs, Arabians, and Western performance horses. This condition is more frequently recognized since pre-sale and post-sale radiography has become common.

There are four distinct manifestations of decreasing frequency: axial articular fragments: abaxial, nonarticular fragments; nonarticular fragments originating from the base of the PSBs; and true acute fractures. (I prefer an anatomical description rather than reference to different types.[7]) The condition is much more common in the hindlimbs, except for non-articular fragments from the base of the PSBs, which occur almost exclusively in forelimbs (see Chapter 37). Combinations of axial and abaxial fragments often occur. The condition can be unilateral or bilateral and can be biaxial (involving both sides of the same joint).

Axial Articular Fragments

Axial articular fragments are most important and are most often medial, but can be lateral, biaxial, and bilateral. Of 119 horses with axial articular fragments, 92% were STBs; 95% of fragments were in the hindlimbs, most commonly the medial aspect of the left hindlimb (44%).[8] The incidence of axial articular fragments in 1- and 2-year-old STBs ranges from 5.6% to 28.8% but in TBs has been estimated at 2%.[9] The etiology remains controversial, but because STBs and the hindlimbs are clearly predisposed and fragments are recognized at an early age, osteochondrosis is the most likely explanation. Heritability estimates of axial articular fragments in STBs using a non-linear model were 0.21, and fragments were seen in 11.8% of foals.[10] I feel it is implausible that a large number of STB foals develop traumatic fractures at this site, whereas other breeds do not. I believe hereditary factors are most important. A traumatic etiology was suggested, because portions of the fragments were irregular, entrapped by mature fibrous tissue, and contained spicules of bone not covered by fibrocartilage, which gave the histological appearance of a fracture healed by fibrous union.[9,11,12] Evidence of short distal sesamoidean ligament insertions was not found and fragments were old.[9] Unfortunately, axial articular fragments examined were taken from horses with a mean age of 3.4 years and after horses had trained and raced, rather than from weanlings and yearlings, so degeneration and remodeling of fragments could have occurred. With only capsular attachments, how do alleged avulsion fractures occur? Etiology is most important when dispute or arbitration ensues after horses are sold at public auction (see Chapter 102).

There is chronic low-grade, high-speed metatarsophalangeal joint lameness. Horses often have a previous history of other ipsilateral hindlimb lameness, such as distal hock joint pain. Effusion and a positive response to lower limb flexion are lacking or inconsistent. Lameness is alleviated most consistently with low plantar analgesia, but differentiation from early stress-related bone injury and osteoarthritis can be difficult without scintigraphic examination. Stress-related bone injury or other bony abnormalities, such as mid-sagittal fracture of the proximal phalanx and occasionally condylar fractures of the MtIII, are commonly found simultaneously with axial articular fragments. Many horses with axial articular fragments never develop lameness and fragments are only detected on survey radiographs. If and how axial articular fragments cause lameness is not well understood. Axial articular fragments may vibrate at speed or become interposed in the joint surface during flexion, but synovitis does not play a role. These fragments may affect mechanics of the ipsilateral PSB or impinge on distal sesamoidean ligaments.[7] Nociceptive fibers were found in soft tissue attachments and stretching during full extension may cause pain.[9] In older horses, evidence of full-thickness cartilage damage on the MtIII and the PSBs suggests axial articular fragments may contribute to the development of osteoarthritis.

Radiographic examination reveals one or more fragments seen best in down-angled oblique views (see Fig. 43-1). If surgery is considered, both limbs should be examined radiographically. Scintigraphic examination may reveal mild abnormal bone modeling, but IRU is more commonly seen in horses with abaxial, nonarticular fragments (see Fig. 43-6).

Axial articular fragments should be removed using arthroscopic surgery. In recent years I have advised removal of fragments before horses begin training, because "down time" associated with arthroscopic surgery is less than if surgery is performed in the middle of a racing year. Subjectively it appears that horses that undergo surgery earlier have fewer problems with stress-related bone injury and osteoarthritis. In breeds such as the TB and Warmblood axial articular fragments may complicate sales and can be removed prophylactically. During arthroscopic surgery fragments are carefully trimmed free of capsular attachments using a specially designed intra-articular blade and removed.[13] If arthroscopic surgery is performed before training begins, horses are given 7 days of stall rest, followed by 7 days of stall rest with hand walking, then 7 to 14 days of walking in the jog cart (STBs) or walking and light trotting with an exercise pony (TB). If lameness develops when horses are in advanced stages of training or are racing, I recommend at least 2 to 3 months of rest before training resumes. The prognosis is good for future soundness if the fragment(s) caused the lameness. Sixty-three percent of racehorses and 100% of non-racehorses had performance similar to pre-injury levels after surgery, but the presence of cartilage damage or synovial proliferation was significantly associated with an adverse outcome.[7]

Abaxial, Non-Articular Fragments

Abaxial, non-articular fragments can be single or multiple and may occur in combination with axial articular fragments, either on the same side or opposite side of the joint. Abaxial, non-articular fragments usually are lateral and can be bilateral. Abaxial, non-articular fragments can be large and involve the

entire lateral, plantar process, including a small articular portion, but most are non-articular. These fragments resemble old fractures radiographically, but I believe they are manifestations of osteochondrosis.[11,14] Fragments are often seen in weanlings or yearlings without clinical signs of lameness, and when seen in older horses, lameness is rarely acute. Abaxial, non-articular fragments have been described as ununited proximoplantar tuberosities, and in some horses fragments identified at a young age subsequently reunited with the parent bone.[14] In my experience union of abaxial, non-articular fragments in older horses is rare.

Lameness is mild (grade 1 of 5 with the horse in hand), usually present at high speed, and worse around turns. Pain is abolished by low plantar analgesia. Palpation may reveal mild bony enlargement, but this enlargement is easily missed. Response to lower limb flexion is inconsistent. Occasionally a weanling or yearling develops acute lameness with obvious soft tissue swelling that involves the fetlock joint. Radiographs reveal an old abaxial, non-articular fragment, but generally lameness resolves quickly and is not related to the fragment.

Radiographs reveal one or more abaxial, non-articular fragments, which are occasionally accompanied by axial articular fragments (Fig. 43-10). Fragments are old and rounded, and radiolucent changes of the parent plantar process are common. A clear separation exists between the fragment and proximal phalanx that is filled by dense, fibrous tissue. Scintigraphic examination may reveal mild IRU.

Abaxial, non-articular fragments may or may not cause lameness and clear differentiation between sources of pain can be difficult. The decision of whether to perform surgery is often difficult, because conventional surgery is required to remove these non-articular pieces.[13] After surgery horses are given 4 weeks of stall rest, followed by 4 weeks of stall rest with hand walking, then 4 to 8 weeks of turn out in a small paddock or light jogging or galloping. Prognosis is excellent for future soundness, but within STB racehorses, pacers have a better prognosis than trotters. In yearlings with a combination of axial articular fragments and abaxial, non-articular fragments, I usually recommend arthroscopic surgery to remove axial articular fragments and leave abaxial, non-articular fragments in place unless clinical signs develop at a later date.

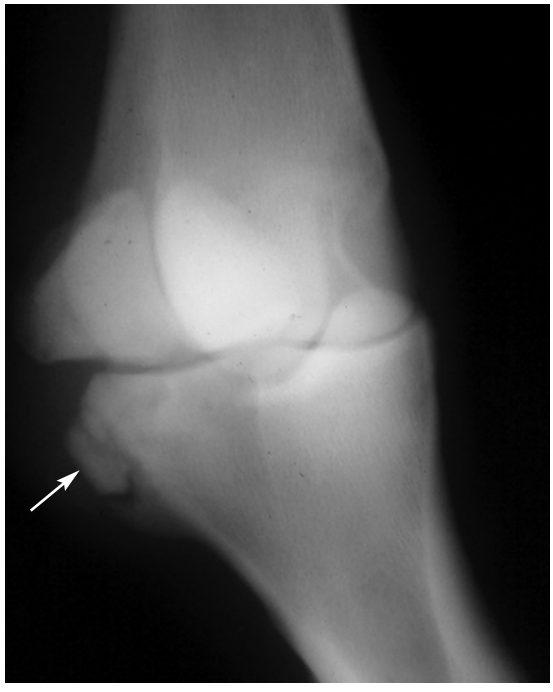

Fig. 43-10 Dorsolateral-plantaromedial radiographic view showing a large abaxial, non-articular fragment *(arrow)* of the proximal plantar process of the proximal phalanx. In this 3-year-old Standardbred racehorse lameness was not evident.

Although I strongly believe that axial articular fragments and abaxial, non-articular fragments cause lameness and I recommend surgery both therapeutically and prophylactically, others question the significance of these fragments. In a study evaluating radiographic findings in STBs before beginning training and subsequent race performance, there was no significant association between the presence of axial articular fragments, abaxial, non-articular fragments, and other forms of osteochondrosis and either race performance or racing longevity.[15]

Acute Fractures of the Proximal Plantar Process

True fractures of the proximal plantar process of the proximal phalanx occur, usually after known or suspected trauma, but are rare. Acute lameness and soft tissue swelling are present. Radiography reveals an acute fracture with a narrow, well-defined fracture line. The margins of the fracture are not rounded, nor are there radiolucent changes in the proximal phalanx. Internal fixation and fiberglass cast application is recommended. Prognosis depends on duration of the fracture before repair and fracture size (see Fig. 36-2). Osteoarthritis is a potential complication.

Osteochondrosis of the Sagittal Ridge of the Third Metatarsal Bone

A discussion of osteochondrosis of the sagittal ridge of the third metatarsal bone is presented in Chapter 58.

Osteochondral Fragments of the Dorsoproximal Aspect of the Proximal Phalanx

Osteochondral fragments of the dorsoproximal aspect of the proximal phalanx are common and occur in two forms. Well-rounded osteochondral fragments often occur in young horses, may be a manifestation of osteochondrosis, and are asymptomatic. Acute osteochondral fragments result in mild lameness or change in performance and are associated with an effusion and a positive response to lower limb flexion. Arthroscopic surgery and removal of these osteochondral fragments is recommended. In older STB and TB racehorses, osteochondral fragments can be large and multiple, and after surgery a minimum of 8 weeks' rest is given (Fig. 43-11). Cartilage damage on the opposing surface of the MtIII is common, and the amount is commensurate with size and duration of osteochondral fragments.

Other Osteochondral Fragments

Osteochondral fragments may be identified dorsal or plantar to the collateral ligaments, usually laterally. These osteochondral fragments are usually traumatically induced and may originate from the distal dorsal aspect of the MtIII, but they are not avulsion fractures. Proliferative changes often develop. Treatment is by surgical removal, but prognosis is guarded in racehorses.

A rare finding in the metatarsophalangeal joint is a loose fragment located in the distal aspect of the plantar pouch. In some horses, small defects in the dorsal sagittal ridge can be seen radiographically. A small fragment may have detached and migrated to the plantar pouch. Large, loose fragments may exist for some time in the plantar pouch without causing lameness.

Fractures of the Proximal Phalanx

The most common major fracture in the metatarsophalangeal joint is mid-sagittal fracture of the proximal phalanx or other fractures with a mid-sagittal component. These fractures occur most often in racehorses but also occur in other sport

Fig. 43-11 Intraoperative photograph of an osteochondral fragment *(arrow)* of the proximal dorsomedial aspect of the proximal phalanx. *MtIII*, Third metatarsal bone.

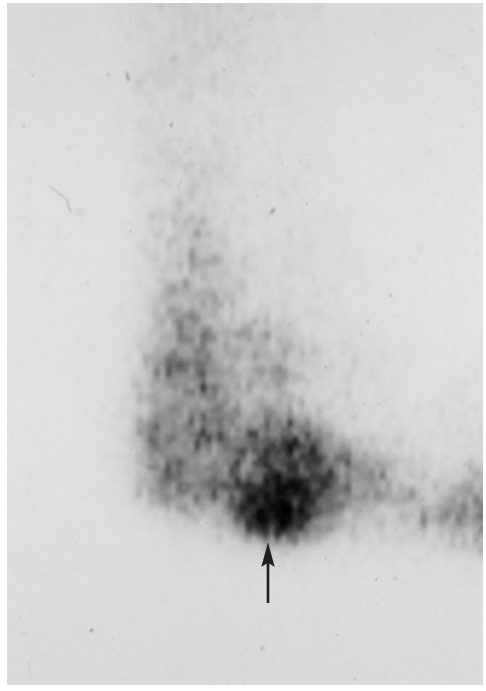

Fig. 43-12 Delayed (bone) phase flexed lateral scintigraphic image of a metatarsophalangeal joint showing focal increased radiopharmaceutical uptake associated with the proximal dorsal aspect of the proximal phalanx *(arrow)* in a Standardbred with dorsal frontal fracture of this bone. Mild increased radiopharmaceutical uptake was seen in the contralateral hindlimb.

horses. In racehorses, mid-sagittal fractures of the proximal phalanx occur in STBs equally in hindlimbs and forelimbs, but in TBs, forelimb fractures are most common. These fractures are discussed in Chapters 36 and 37.

Dorsal Frontal Fractures of the Proximal Phalanx

Dorsal frontal fractures of the proximal phalanx occur exclusively in hindlimbs, although large osteochondral fragments in the forelimb may cause similar clinical signs. They occur in both TB and STB racehorses. Although these fractures are reported to be more common in TBs,[16] in my experience the fracture is more common in STBs and can be unilateral or bilateral. If a dorsal frontal fracture of the proximal phalanx is diagnosed scintigraphically, contralateral IRU of the dorsal proximal aspect of the proximal phalanx is commonly seen (Fig. 43-12). IRU associated with a dorsal frontal fracture of the proximal phalanx must be differentiated from a mid-sagittal fracture. Mid-sagittal fractures are single-event injuries, but a dorsal frontal fracture of the proximal phalanx may be caused by stress-related bone injury, because gradations of IRU are seen in the proximal phalanx and concomitant contralateral IRU occurs. Although bilateral fracture or evidence of stress-related bone injury can be seen bilaterally simultaneously, horses may develop contralateral fracture the next year. TB racehorses can tolerate pain and race with this fracture; there may be chronic proliferative changes and a displaced fracture in a horse that raced within the last 10 days. Displaced fractures do not occur in STBs, and pacers are most likely to have an obvious fracture, whereas fractures in trotters may be scintigraphically active with only subtle radiographic changes.

A dorsal frontal fracture of the proximal phalanx usually results in intermittent, severe lameness, but bilateral fractures may cause poor performance without causing obvious signs of lameness. Effusion is present but may be only mild unless fractures are displaced. The response to lower limb flexion is positive. Intra-articular or low plantar analgesia abolishes lameness in horses with complete or displaced fractures, but the low plantar technique should be used in those with stress-related bone injury or incomplete fractures. Radiographs reveal a single fracture line that is best recognized in LM or flexed LM views. Fractures begin at the articular surface and course in a dorsodistal direction (Fig. 43-13). In TBs with displaced fractures an osteochondral fragment often is interposed between the main fracture fragment and the parent bone.

If fractures are non-displaced, conservative management provides a good to excellent prognosis in both TBs and STBs. Horses are given 4 weeks of stall rest, followed by 4 weeks of stall rest with hand walking, then 4 to 8 weeks of turn out in a small paddock. Two treatment options are available for horses with displaced fractures. In those with large fragments and interposed osteochondral fragments, arthroscopic surgery is recommended to remove small osteochondral fragments and to repair the dorsal frontal fracture using one or two 3.5-mm screws. If the fracture cannot be reduced or is broken or small, the fragment should be removed. Prognosis is good to excellent for future racing, but horses may drop in class, particularly those with compensatory or numerous lameness problems.

Fractures of the Proximal Sesamoid Bones

Overall, fractures of the PSBs are less common than in the metacarpophalangeal joint, but in STB racehorses there is nearly equal distribution of fractures. Apical fractures of the PSBs are more common in the hindlimb of STBs and most often involve the lateral PSB. Fractures of the PSBs can be traumatic or pathological. Young racehorses develop acute lameness and fracture without pre-existing disease of the PSB or SL. However, the PSB undergoes extensive remodeling similar to the MtIII, and it is possible, perhaps even likely, that these fractures represent a form of stress-related bone injury. In older racehorses and in some non-racehorse sport horses there is pre-existing lucent and proliferative sesamoiditis and suspensory branch desmitis, and fractures of the PSB appear to develop as a pathological, secondary, end-stage injury. In some non-racehorse sport horses fracture occurs as a single

Fig. 43-13 Flexed lateromedial xeroradiograph showing a typical dorsal frontal fracture *(arrow)* in a Standardbred. In the Thoroughbred, fractures are often displaced and have chronic proliferative changes, which indicate that horses have been training or racing with the injury.

event without pre-existing injury. Prognosis depends on the size of the fracture fragment and the degree of suspensory desmitis. In STB racehorses, prognosis is better in pacers than in trotters, and prognosis is poor in horses developing fractures early in training before racing begins (see Chapter 37). The prognosis is good in non-racehorse sports horses without pre-existing injury.

Fractures of the Distal Third Metatarsal Bone

Condylar fractures of the distal MtIII occur less frequently than those of the McIII (see Chapter 37). In a recent study of 135 horses with condylar fractures, 81% and 85% involved the forelimbs and lateral condyles, respectively.[17] Lateral and medial condylar fractures of the MtIII occur, but lateral fractures are most common. Lateral condylar fractures can be short and incomplete, long and incomplete, or long and complete. Bilateral fractures occasionally occur simultaneously. Condylar fractures are primarily racing injuries. In a recent study of TB, STB, and Arabian racehorses, TBs were over-represented and STBs under-represented; TBs had significantly more lateral and forelimb fractures than STBs.[18] Clinical signs are commensurate with the length and degree of displacement. Medial condylar fractures can be short, incomplete, and difficult to diagnose. However, most commonly lameness is severe and radiographs reveal that the fracture is long and incomplete but goes straight proximally to end abruptly in the diaphysis, forms a Y-shaped pattern, or spirals proximally to end near or at the tarsometatarsal joint. Occult fissure lines and spiraling should always be suspected, and it is critical to know the location of the fracture before horses are transported and prognosis is discussed. Horses with medial condylar fractures are at extreme risk for fracture propagation or comminution. Even after surgical repair, horses are at risk during anesthetic recovery and early in the postoperative period. Of 15 horses with medial condylar fractures of the MtIII, 12 were repaired, 2 suffered catastrophic fracture during recovery from general anesthesia, and 3 developed complete fracture within 4 days after surgery.[19] Recovery from anesthesia should be assisted and may best be performed using a pool recovery system.

Horses with short, incomplete lateral and medial condylar fractures can be managed conservatively or undergo surgical repair. Those with longer spiral or medial condylar fractures with a Y shape should undergo surgical repair. This repair can be accomplished by use of a combination of open observation of the fracture line and either screw fixation or a combination of screws and a dynamic compression plate (Fig. 43-14). Prognosis depends on whether fractures are medial or lateral, displaced or non-displaced, and whether a plate or numerous screws are used for repair. If fractures heal and plates (if used) are removed, prognosis for racing is favorable, but horses will drop in class.

Sesamoiditis

In the STB hindlimb sesamoiditis is most common in the lateral PSB but can occur medially and be a source of occult metatarsophalangeal joint lameness. In TBs sesamoiditis is most commonly observed in the forelimb. TBs can have obvious radiolucent lines in the PSBs in hindlimbs that are often asymptomatic. Disparity between limbs, rather than size or number of radiolucent lines, was found to be most important in determining clinical significance in TBs; horses with three or more channels were less likely to race as 2-year-olds and had decreased earnings per start.[20] In the STB racehorse the presence of one to three or more radiolucent defects less than or equal to 1 mm in width was not associated with lameness referable to the PSBs, but horses with wide, abnormally shaped defects developed lameness from sesamoiditis.[21] Conversely, of 753 young STBs that underwent radiographic examination before training, 21 horses had severe sesamoiditis, fractures, or enlarged PSBs, but a correlation between sesamoid pathology and lameness or decreased racing performance and earnings could not be made. In that study hindlimb PSBs were affected in only 6 horses and lameness developed in 14 horses.[22] Although lameness could not be directly attributed to changes in the PSBs, in some horses metatarsophalangeal joint lameness was diagnosed and perhaps compensatory lameness developed as a result of chronic, low-grade or high-speed lameness in these trotters. Seven of 21 horses had concomitant osteochondral fragments of the plantar palmar process of the proximal phalanx, although a clear relationship could not be established.[22]

Radiolucent Defects of the Axial Border of the Proximal Sesamoid Bones

See Chapters 73 and 75 for a discussion of radiolucent defects of the axial border of the proximal sesamoid bones.

Flexor Deformity of the Metatarsophalangeal Joint

Dorsal subluxation of the metatarsophalangeal joint (buckle or knuckle forward) occurs in horses with flexor deformity. Intermittent subluxation occurs in those with mild deformity, but some horses with more severe deformity maintain the metatarsophalangeal joint in partial flexion. Horses with chronic, severe tenosynovitis of the DFTS with extensive adhesions may develop progressive, severe flexor deformity. Desmitis of the accessory ligament of the DDFT may cause flexor deformity. In some horses, application of an extremely elevated heel shoe (e.g., 5 to 8 cm) may help alleviate pain (see Chapter 61).

Dropped fetlock or plantar subluxation (hyperextension) occurs in horses with severe chronic suspensory desmitis or those with severe, acute tearing of the superficial digital flexor tendon (SDFT), the DDFT, or both the SDFT and DDFT.

Soft Tissue Injuries of the Metatarsophalangeal Joint and Fetlock Region

Proliferative Synovitis

Proliferative synovitis (i.e., enlarged synovial pad or villonodular synovitis) occurs in the dorsal aspect of the metatarsophalangeal joint in horses with chronic osteoarthritis. However, it is much less common than in the metacarpophalangeal joint and is a rare primary cause of pain (see Chapter 37).

Fig. 43-14 Dorsoplantar radiographic views of the metatarsophalangeal joint and the entire metatarsal region. There is a spiral fracture of the third metatarsal bone *(arrows)* beginning at the medial condyle of the third metatarsal bone (medial is the left) in the metatarsophalangeal joint and extending to near the metatarsophalangeal joint (confirmed at surgery after subperiosteal dissection) before **(A)** and after **(B)** surgery.

Luxation and Subluxation: Tearing of the Collateral Ligament

Complete disruption of a collateral ligament causes luxation and results in severe, non–weight-bearing lameness and usually obvious valgus or varus deformity. This injury is more common in adult horses, because physeal fractures of the distal MtIII and proximal phalanx are more likely in foals. Initially little swelling occurs, but within a few hours soft tissue swelling can be prominent and manipulation of the joint reveals instability. Diagnosis is confirmed radiographically using DPl and stressed DPl views. Radiographs should be examined carefully for the presence of concurrent fractures on the contralateral or plantar aspects of the joint. Ultrasonography is used to identify the injured portion of the collateral ligament and extent of injury. After manual reduction with the horse under general anesthesia a fiberglass cast should be applied. The cast should be changed within 7 to 10 days, because swelling resolves and the cast loosens. Cast coaptation should be maintained for 8 to 10 weeks and then a heavy bandage should be applied. If crushing of the opposite side or plantar aspect of the joint did not occur, prognosis for soundness is guarded to fair. Osteoarthritis and chronic desmitis of the collateral ligament are possible.

Collateral Desmitis

Primary injury of the collateral ligament without luxation is rare in my experience. Clinical signs include firm soft tissue swelling and ultrasonographic evidence of desmitis in horses with lameness that is abolished by low plantar analgesia. Avulsion fractures may occur as a result of trauma.

Suspensory Desmitis

See Chapter 73 for a discussion of suspensory desmitis.

Tenosynovitis of the Digital Flexor Tendon Sheath

See Chapter 75 for a discussion of tenosynovitis of the digital flexor tendon sheath.

Deep Digital Flexor Tendonitis

See Chapters 71 and 75 for a discussion of deep digital flexor tendonitis.

CHAPTER • 44

The Metatarsal Region

Mike W. Ross

The metatarsal region, like most of the distal hindlimb, has received little attention in previous lameness textbooks. However, it is a common source of lameness problems and should not be overlooked, especially in view of the high incidence of suspensory desmitis in sport horses.

ANATOMY

The metatarsal region is bordered by the tarsometatarsal joint proximally and the metatarsophalangeal joint distally. The large third metatarsal bone (MtIII) provides all structural support and weight bearing and articulates predominantly with the third tarsal bone proximally and the proximal phalanx and proximal sesamoid bones (PSBs) distally. A prominent nutrient foramen in the MtIII should not be mistaken for a fracture and is usually located slightly higher than that of the third metacarpal bone (McIII).[1]

The second metatarsal bone (MtII) and fourth metatarsal bone (MtIV) are commonly referred to as the medial and lateral splint bones, respectively. The MtII articulates with the combined first and second tarsal bones proximally and ends distally with an enlarged "bell." The MtIV articulates with the fourth tarsal bone proximally but transmits less load than the MtII. The dorsal metatarsal artery runs obliquely, in a disto-plantar direction, in the proximal lateral aspect of the metatarsal region and then parallel and close to the dorsal aspect of the MtIV as it courses distally in the mid-metatarsal region. The dorsal metatarsal artery then courses deep to the MtIV and must be avoided during distal splint ostectomy. In one horse the dorsal metatarsal artery coursed through a bony and fibrous ring-like foramen in the distal MtIV and was inadvertently severed during ostectomy of the MtIV. Because the dorsal metatarsal artery is superficial, it can be lacerated from wounds in the lateral metatarsal region. Bleeding can be profound and the ends of a lacerated dorsal metatarsal artery should be ligated unless anastomosis is performed with the horse under general anesthesia. Collateral circulation develops if ligation is necessary. The long plantar ligament attaches to the proximal aspect of the MtIV.

The orientation of the metatarsal bones is clinically important. The proximal aspect of the MtIV is large and is located in a more plantar location than its counterpart, the fourth metacarpal bone (McIV). This orientation makes it impossible to palpate the normal proximal and mid-body portions of the suspensory ligament (SL). Therefore unless it is grossly enlarged, the SL cannot be palpated and conditions such as mild to moderate suspensory desmitis can easily be missed, particularly if lameness is chronic and signs of acute inflammation are not present.

Dense metatarsal fascia attaches to the abaxial margins of the MtII and IV and encircles the SL, deep digital flexor tendon (DDFT), and superficial digital flexor tendon (SDFT). Swelling of the SL within this dense fascial compartment can cause pain by compression of the adjacent metatarsal nerves.[2] The SL has a broad origin on the proximal, plantar surface of the MtIII and a small attachment to the distal tarsal bones. The hind SL is slightly longer and thinner than the front SL, and muscle content may be higher in hindlimbs compared with forelimbs, which can complicate ultrasonographic examination.[3] It was suggested that the higher incidence of suspensory desmitis in Standardbreds (STBs) than in Thoroughbreds (TBs) was related to higher muscle content, but this is unproven.[3]

The plantar surface of the MtIII and origin of SL are oblique and not parallel to the dorsal surface of MtIII. During ultrasonographic examination, care should be taken to account for obliquity and position the transducer perpendicular to SL fibers (see Chapter 73). The SL is bordered by the MtII and MtIV and is thus trapped within a bony and dense soft tissue encasement. In the mid-metatarsal region the body of the SL can be palpated as it emerges from this bony encasement and courses distally to divide into the medial and lateral branches that attach to the abaxial border of each PSB. The accessory ligament of the DDFT (ALDDFT) is thin and inconsistent. Although the ALDDFT is anatomically present in most horses, desmitis is rare (see Chapter 72). Desmotomy

CHAPTER • 44

The Metatarsal Region

Mike W. Ross

The metatarsal region, like most of the distal hindlimb, has received little attention in previous lameness textbooks. However, it is a common source of lameness problems and should not be overlooked, especially in view of the high incidence of suspensory desmitis in sport horses.

ANATOMY

The metatarsal region is bordered by the tarsometatarsal joint proximally and the metatarsophalangeal joint distally. The large third metatarsal bone (MtIII) provides all structural support and weight bearing and articulates predominantly with the third tarsal bone proximally and the proximal phalanx and proximal sesamoid bones (PSBs) distally. A prominent nutrient foramen in the MtIII should not be mistaken for a fracture and is usually located slightly higher than that of the third metacarpal bone (McIII).[1]

The second metatarsal bone (MtII) and fourth metatarsal bone (MtIV) are commonly referred to as the medial and lateral splint bones, respectively. The MtII articulates with the combined first and second tarsal bones proximally and ends distally with an enlarged "bell." The MtIV articulates with the fourth tarsal bone proximally but transmits less load than the MtII. The dorsal metatarsal artery runs obliquely, in a disto-plantar direction, in the proximal lateral aspect of the metatarsal region and then parallel and close to the dorsal aspect of the MtIV as it courses distally in the mid-metatarsal region. The dorsal metatarsal artery then courses deep to the MtIV and must be avoided during distal splint ostectomy. In one horse the dorsal metatarsal artery coursed through a bony and fibrous ring-like foramen in the distal MtIV and was inadvertently severed during ostectomy of the MtIV. Because the dorsal metatarsal artery is superficial, it can be lacerated from wounds in the lateral metatarsal region. Bleeding can be profound and the ends of a lacerated dorsal metatarsal artery should be ligated unless anastomosis is performed with the horse under general anesthesia. Collateral circulation develops if ligation is necessary. The long plantar ligament attaches to the proximal aspect of the MtIV.

The orientation of the metatarsal bones is clinically important. The proximal aspect of the MtIV is large and is located in a more plantar location than its counterpart, the fourth metacarpal bone (McIV). This orientation makes it impossible to palpate the normal proximal and mid-body portions of the suspensory ligament (SL). Therefore unless it is grossly enlarged, the SL cannot be palpated and conditions such as mild to moderate suspensory desmitis can easily be missed, particularly if lameness is chronic and signs of acute inflammation are not present.

Dense metatarsal fascia attaches to the abaxial margins of the MtII and IV and encircles the SL, deep digital flexor tendon (DDFT), and superficial digital flexor tendon (SDFT). Swelling of the SL within this dense fascial compartment can cause pain by compression of the adjacent metatarsal nerves.[2] The SL has a broad origin on the proximal, plantar surface of the MtIII and a small attachment to the distal tarsal bones. The hind SL is slightly longer and thinner than the front SL, and muscle content may be higher in hindlimbs compared with forelimbs, which can complicate ultrasonographic examination.[3] It was suggested that the higher incidence of suspensory desmitis in Standardbreds (STBs) than in Thoroughbreds (TBs) was related to higher muscle content, but this is unproven.[3]

The plantar surface of the MtIII and origin of SL are oblique and not parallel to the dorsal surface of MtIII. During ultrasonographic examination, care should be taken to account for obliquity and position the transducer perpendicular to SL fibers (see Chapter 73). The SL is bordered by the MtII and MtIV and is thus trapped within a bony and dense soft tissue encasement. In the mid-metatarsal region the body of the SL can be palpated as it emerges from this bony encasement and courses distally to divide into the medial and lateral branches that attach to the abaxial border of each PSB. The accessory ligament of the DDFT (ALDDFT) is thin and inconsistent. Although the ALDDFT is anatomically present in most horses, desmitis is rare (see Chapter 72). Desmotomy

to manage flexor deformity is not performed and would be ineffective because of the small size of the ALDDFT. The DDFT is located plantar to the SL for most of the metatarsal region, but in the proximal metatarsal region it is positioned plantaromedial. The SDFT is located plantar to both the SL and DDFT. Because the tarsal sheath ends in the proximal metatarsal region, distention can sometimes be palpated. The digital flexor tendon sheath (DFTS) begins in the plantar, distal third of the metatarsal region and encompasses the DDFT and SDFT (see Chapter 75).

In the proximal third of the metatarsal region the lateral digital extensor tendon joins with the long digital extensor tendon and the combined tendons course distally. The fibularis tertius and cranialis tibialis attach to the proximal, dorsal, and medial aspects of the MtIII. Proliferation and fracture can occur in these locations.

Distal continuation of the superficial fibular and saphenous nerves provides dorsal skin sensation. The tibial nerve divides to form the medial and lateral plantar nerves in the plantar tarsal region. The lateral plantar nerve, which courses plantar to the origin of the SL, gives off a deep branch that innervates the proximal aspect of the SL. Lateral plantar neurectomy performed just above this branch provides analgesia of the origin of the SL. The lateral plantar nerve gives off the medial and lateral plantar metatarsal nerves that run axial to each respective splint bone. The lateral plantar nerve and its counterpart, the medial plantar nerve, continue distally between the SL and DDFT.

Conformation

Sickle-hock, but most importantly straight hindlimb conformation predispose to metatarsal region lameness (see Chapter 4).

CLINICAL CHARACTERISTICS AND DIAGNOSIS OF LAMENESS IN THE METATARSAL REGION

There are no pathognomonic historical findings related to metatarsal region lameness. Palpation of the metatarsal region should be done with the horse in standing and non–weight-bearing positions. The metatarsal region cannot be adequately palpated when the horse is standing, because soft tissue structures in the proximal metatarsal region are not readily palpable in this position. Careful palpation for signs of inflammation and bony swelling should be performed with the limb in both positions. Even when the limb is flexed, it is still difficult to define the SL and DDFT proximally. However, it is possible to apply pressure over the proximal SL to check for a painful response. In some horses with proximal suspensory desmitis (PSD), edema may be present or the area feels full or slightly thickened, but dense fascia covering the SL and DDFT prevents expansion and swelling may go undetected. A painful response to deep palpation over the proximal medial splint bone and distal tarsus, referred to as the Churchill test, may indicate the presence of referred pain and primary distal hock joint lameness, but in my experience this is a non-specific test. Many horses with hindlimb lameness originating from sites other than the distal hock joints manifest a positive response to compression of both the medial and lateral splint bones. Palpation of the dorsal cortex of the MtIII may reveal pain in trotters or other horses that interfere and may be an important finding, but palpation may not necessarily localize the primary source of pain that is causing lameness. Careful palpation of the abaxial and axial aspects of both splint bones is necessary to uncover hidden splint exostoses. Even subtle enlargement of the SL body, as it emerges from the bony encasement of the splint bones, that is accompanied by a painful response can indicate early suspensory desmitis. Both branches of the SL and attachments to the PSBs should be carefully palpated. Horses with a history of curb may develop progressive SDF tendonitis in the proximal metatarsal region, but this can easily be overlooked unless the area is carefully palpated (see Chapters 6, 70, and 79).

Diagnostic Analgesia

The high plantar perineural block (see Chapter 10) should be used to localize pain to the metatarsal region. Plantar metatarsal nerves are blocked just distal (approximately 1.5 cm) to the tarsometatarsal joint (see Chapter 10).

Imaging Considerations

Routine radiographic examination includes the dorsoplantar (DPl), lateromedial (LM), dorsolateral-plantaromedial oblique (DL-PlMO), and dorsomedial-plantarolateral oblique (DM-PlLO) views. In a DPl view of the proximal MtIII, there is a normal area of mild sclerosis that should not be interpreted as modeling that is associated with stress reaction of the origin of the SL (Fig. 44-1). Accurate assessment of the proximal aspect of the MtIII for the presence of sclerosis or avulsion fracture requires that radiographic views be centered at this level.

Pool and delayed (bone) phase scintigraphic examination is quite useful to differentiate bone from soft tissue injury in horses with proximal plantar metatarsal pain and osteoarthritis. It is also useful to differentiate other conditions of the tarsometatarsal joint from those involving the proximal aspect of the MtIII. Focal increased radiopharmaceutical uptake (IRU)

Fig. 44-1 Dorsoplantar radiographic view showing the normal coarse trabecular pattern *(arrows)* seen in the proximal aspect of the third metatarsal bone, which can be mistaken for sclerosis associated with the suspensory attachment. This Standardbred racehorse had a sagittal fracture of the talus. Note the radiolucency of the talus *(open arrow)*.

seen in delayed (bone) phase images involving the proximal plantar aspect of the MtIII is the most important scintigraphic finding in the metatarsal region. Ultrasonographic evaluation should be performed to evaluate the plantar soft tissue structures (see Chapters 16, 73, and 79).

SPECIFIC CONDITIONS OF THE METATARSAL REGION

Bucked and Sore Shins: Dorsal Cortical Fractures of the Third Metatarsal Bone

Modeling and remodeling of the dorsal cortex of MtIII occurs similarly to that of the McIII, but differences in load distribution between forelimbs and hindlimbs account for the relative lack of clinical signs associated with this process in the hindlimbs. Scintigraphic examination often reveals mild, diffuse IRU of the dorsal cortex of MtIII in TB racehorses, but clinical signs of bucked shins are rare. In trotters common findings are pain on palpation, wounds and abrasions, and in some horses bony swelling that is associated with interference injury in the dorsal or dorsal, medial metatarsal region. Although these areas are painful to palpation, most sites are a sign rather than the cause of a high-speed gait deficit. Finding evidence of interference injury, however, is quite important because interference is often a sign of ipsilateral forelimb lameness and can be a cause of horses making breaks (going off stride). Dorsal cortical fractures are rare but can occur in TB and STB racehorses.

Medial and Lateral Condylar and Spiral Fractures of the Third Metatarsal Bone

Medial and lateral condylar and spiral fractures of MtIII are discussed in Chapter 43.

Mid-Shaft, Simple or Comminuted Fractures of the Third Metatarsal Bone

Diaphyseal fractures of the MtIII can result from propagation and displacement of medial condylar fractures. Direct trauma is the most common cause, often from kicks by other horses. Complete fracture of the MtIII occurs in foals and adult horses. Critical prognostic factors are degree of comminution; proximity of the fracture to the metatarsophalangeal joint and tarsometatarsal joints; integrity of the vascular supply; whether the fracture is open or closed; degree of contamination if open; and the horse's age, value, performance level, and intended use. Prognosis for adult horses with open, comminuted fractures of the MtIII is poor to grave, but in those with closed, mildly comminuted or oblique fractures, repair is possible and prognosis is guarded to fair. Horses with open fractures with gross contamination have a grave prognosis, regardless of age and degree of comminution, but those with small areas of skin loss and minor contamination can be successfully managed. Repair in horses with comminuted fractures involving the tarsometatarsal joint is difficult, but consideration of transfixation pin casts by using the distal tibia and distal aspect of MtIII could be given. In foals, vascular supply of the limb distal to fracture is a concern and should be assessed clinically or by using angiography or Doppler ultrasonography. Prognosis in foals with simple or mildly comminuted mid-shaft MtIII fractures repaired using one or two dynamic compression plates is fair to good (Fig. 44-2). In foals, external coaptation often causes profound flexor tendon laxity and should be avoided. External skeletal fixation by using pins and sidebars of casting material or acrylic is possible in the foal. In adult horses, methods of stabilization and repair include internal fixation using two dynamic compression plates, transfixation pin casts in combination with internal fixation, and casts alone.

In a recent study of 25 horses with MtIII or McIII fractures that were managed with internal fixation, external coaptation, or both, age, sex, weight, and the limb affected were not related to outcome, but affected horses were younger than the general hospital population. Seventeen horses had open fractures, and infection was the most common complication after surgery.[4] Non-union in an infected fracture was the most common reason for failure (seven horses). Of 24 horses in which outcome was determined, 16 (67%) had healed fractures and 12 (50%) horses were sound for the intended use.[4] Intended use was not defined; therefore prognosis in foals for future racing could not be determined.

Physeal Fractures of the Distal Third Metatarsal Bone

The most common fracture of the distal MtIII physis is a Salter-Harris type II fracture, but various other fractures can occur. These fractures are usually quite stable, but perfect reduction is difficult to achieve. Fracture reduction and external coaptation are usually successful, but insertion of one or two 3.5- or 4.5-mm bone screws in the metaphyseal component may help stabilize the fracture and reduce the time necessary for external coaptation. Even short periods of cast immobilization in foals can cause rapid onset of flexor tendon

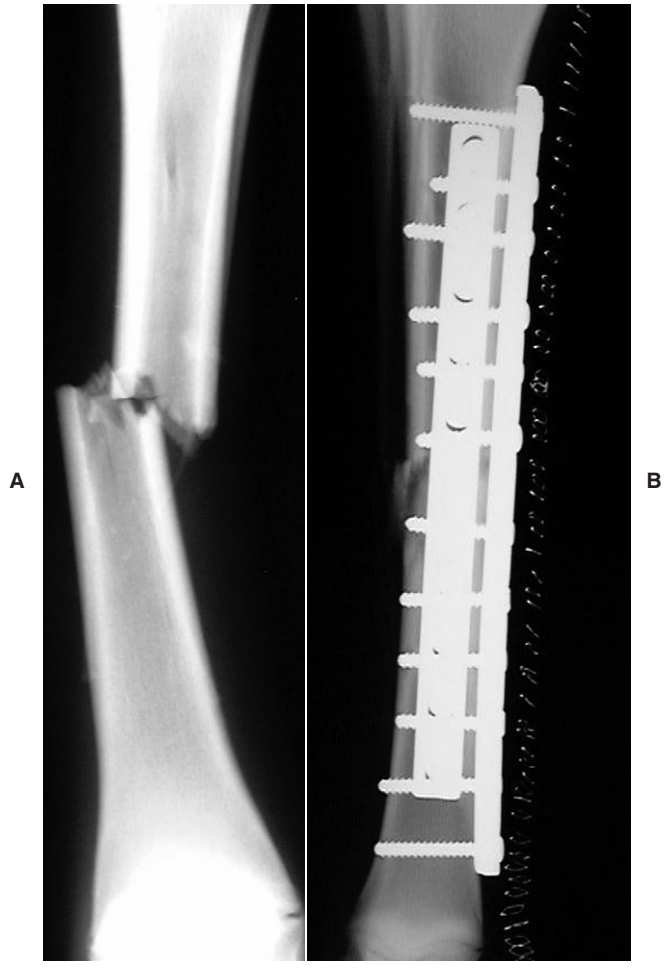

Fig. 44-2 This open (mildly contaminated) mid-shaft fracture of the third metatarsal bone in a 4-month-old Thoroughbred colt was successfully managed using two dynamic compression plates and a half limb bandage. **A,** The preoperative and **B,** postoperative appearance of the third metatarsal bone are shown. The plates were removed 4 months later.

laxity. Cast-bandage and bandage-splint combinations are preferred in young foals (i.e., several weeks old; see Chapters 38 and 73).

Incomplete Longitudinal Fractures of the Plantar Third Metatarsal Bone and Stress Reactions

Incomplete longitudinal fractures of the plantar cortex of MtIII occur considerably less frequently than those of the McIII. Stress reactions of the MtIII, defined as focal areas of IRU without radiographic confirmation of fracture, occur as part of a continuum of stress-related bone injury at the origin of the SL. Combined MtIII injury and PSD worsens prognosis, and it is important to establish whether injury involves bone, soft tissue, or both (see Chapter 38).

Transverse Stress Fractures of the Distal Aspect of the Third Metatarsal Bone

Transverse stress fractures of the distal aspect of the MtIII are described in Chapter 38. I have not recognized this specific fracture type in the MtIII.

Avulsion Fractures of the Third Metatarsal Bone Associated with the Origin of the Suspensory Ligament

Avulsion fractures of the MtIII that are associated with the origin of the SL are frequently seen and can be solitary injuries or associated with PSD. Horses can have acute-onset or chronic mild to moderate hindlimb lameness, depending on size and duration of fracture. Fractures occur most commonly in dressage horses, jumpers, and STB racehorses. Local signs of swelling are usually absent and diagnostic analgesia is essential for localization of pain. Focal areas of IRU are seen that are roughly triangular in shape and involve the proximal plantar aspect of MtIII (Fig. 44-3). It is important to differentiate IRU from that seen in the tarsometatarsal joint, but concomitant IRU in both areas is not unusual. In the MtIII it is unlikely to see a well-defined fracture radiographically, and usually only suspicious areas of radiolucency and sclerosis are seen. Bilateral avulsion fractures or stress reactions occur. Conservative management using a progressive increase in exercise without turn out is usually successful. Recurrence is common and most likely in horses that have associated proximal suspensory desmitis (see Chapter 38.)

Articular Fracture of the Dorsoproximolateral Aspect of the Third Metatarsal Bone

Articular fracture of the dorsoproximolateral aspect of the MtIII occurs primarily in STB and TB racehorses.[5,6] Acute onset of lameness is common, but a history of either chronic, undiagnosed hindlimb lameness or lameness referable to the distal hock joints is usually uncovered. Acute soft tissue swelling is rare. A small bony enlargement is often palpable but is easy to miss. Horses exhibit a positive response to upper limb flexion and to focal, deep pressure over the dorsolateral aspect of the MtIII. Lameness partially resolves after intra-articular analgesia of the tarsometatarsal joint or perineural analgesia of the fibular and tibial nerves. Initial radiographic examination reveals the presence of bony proliferation indicating that bone modeling preceded acute fracture (Fig. 44-4). Incomplete fractures are most common, but complete and mildly displaced fractures also occur. Scintigraphic examination is useful in differentiating this fracture from other conditions involving the tarsometatarsal joint and those involving

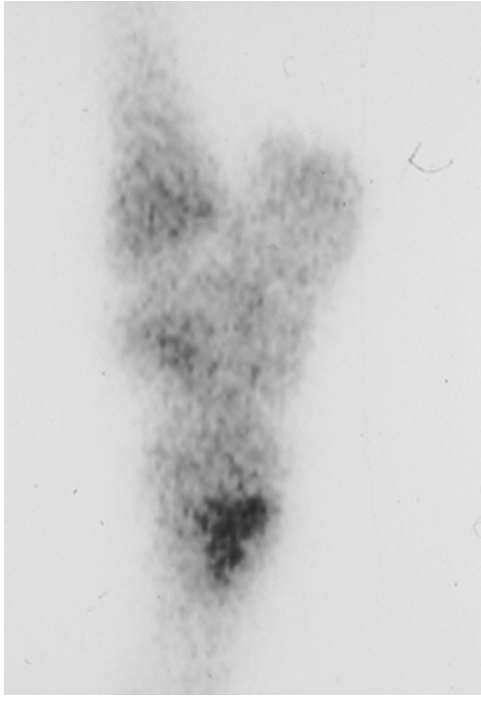

Fig. 44-3 Delayed (bone) phase, lateral scintigraphic image showing focal, triangular-shaped increased radiopharmaceutical uptake typical of an avulsion fracture of the third metatarsal bone that is associated with the origin of the suspensory ligament.

Fig. 44-4 Dorsomedial-plantarolateral xeroradiographic view of the hock and proximal metatarsal region of a Standardbred racehorse. There is an articular fracture of the dorsoproximolateral aspect of the third metatarsal bone *(arrows)*. Note the bone modeling of the proximal aspects of the MtIII and the third tarsal bone that preceded the fracture.

the proximal plantar aspect of the MtIII. Radiographs and scintigraphic images of the contralateral hindlimb often reveal similar but less pronounced changes.

Because proliferative changes precede fracture, it is presumed that the cause involves chronic fatigue and stress-related bone injury. Attachment of the tendons of the fibularis tertius and cranialis tibialis muscles likely contributes substantially to bone stress and may play a role. Horses with sickle-hock conformation appear predisposed to such injury. Concomitant radiographic evidence of osteoarthritis involving the dorsal aspect of the tarsometatarsal and centrodistal joints and dorsoproximolateral fracture of the MtIII is common.

Conservative management is advised in horses with incomplete fractures, but in those with displaced fractures, internal fixation using one or two 3.5-mm bone screws placed in lag fashion is advised. If horses have raced before fracture, the prognosis for future racing is good but only fair to guarded for returning to or sustaining racing in the same class. Horses that develop this fracture before actual racing begins have a poor prognosis. When horses return to training or racing, progressive osteoarthritis of the tarsometatarsal and centrodistal joints appears to be a limiting factor even when the fracture heals and proliferative changes associated with MtIII smooth.

Exostoses of the Second, Third, and Fourth Metatarsal Bones

Exostoses of the metatarsal bones (splint exostoses, splints) occur considerably less commonly than those involving the metacarpal bones, but they can cause lameness, or in racehorses, high-speed soreness. However, it is common to find large exostoses involving the proximal lateral aspect of MtIII or MtIV as an incidental finding that is never associated with lameness, although the lesion is scintigraphically active. Splint exostoses can be caused by direct trauma or instability between the metatarsal bones. There is a common misconception that splints arise from tearing of the interosseous ligaments between the MtII or IV and MtIII, but many splints do not involve the space between bones, and it is difficult to believe that instability and primary desmitis adequately explain the cause of splints. Many splints in the hindlimb involve the MtIII alone (and not MtII or MtIV), although the MtII and MtIV can be affected. Axially located exostoses (blind splints) do occur and are most important proximally, where bony proliferation could crowd or impinge on the proximal aspect of the SL and lateral and medial plantar metatarsal nerves. Direct trauma from interference injury is the most likely cause of most medially located splints. Faulty conformation does not appear to play a prominent role. Mature distal splint exostoses may predispose the MtII and MtIV to fracture in horses with progressive enlargement of the SL.

Lameness associated with splint exostoses is usually mild (grade 1 to 1½ of 5). Direct palpation elicits a painful withdrawal response and lameness is exacerbated. Infiltration of local anesthetic solution alleviates pain and a majority of observed lameness. Radiographs should be obtained when a fracture is suspected but otherwise yield little useful information unless there is drainage associated with bony proliferation.

Management of splint exostoses includes local cold therapy, including cold water hosing and icing, the application of a poultice and bandaging, and the administration of nonsteroidal anti-inflammatory drugs (NSAIDs). Injections of methylprednisolone acetate (80 mg) and Sarapin, an extract of the pitcher plant, (6 ml) subcutaneously and axially if needed for each exostosis reduces inflammation and pain. Repeat injections are often necessary. Cryotherapy is popular in racehorses, but clinicians should be aware that superficial skin pain persists for several weeks afterward, which leaves few ways to monitor improvement other than to monitor performance.

Fractures of the Second and Fourth Metatarsal Bones

Fractures of the MtII and MtIV occur primarily as a result of direct trauma from either a kick from another horse or kicking into or through a stationary object. The MtIV is injured most commonly. Simple, comminuted and displaced fractures occur and often wounds extend directly into the fracture site. The MtIV bears little load and appears to have remarkable recuperative ability. Diagnosis is usually straightforward, particularly if a wound is involved, but in some horses the presence of chronic lameness or drainage several weeks after injury prompts later radiographic examination, and only then is fracture diagnosed. Radiographs often reveal extensive comminution, but in many horses, basic axial alignment of fragments is maintained. When fractures of either the MtIV or MtII involve the tarsometatarsal joint, and particularly if fractures are open, infectious arthritis and osteoarthritis are possible but may be amenable to treatment.

The majority of MtIV fractures heal with conservative management, despite comminution and infectious osteitis, with appropriate antimicrobial administration and wound care. Loose subcutaneously located fragments can be removed with ease and deep tissue cultures should be taken. Although internal fixation[7] or total ostectomy of the MtIV[8] have been described, I have never found it necessary to contemplate surgery. Horses may need 4 to 6 months of rest. Impingement on SL function by callus from fracture healing is a possible complication but is unusual. Fractures of the mid and distal aspects of the MtII and MtIV are caused by chronic suspensory desmitis involving the body or branches. Suspensory desmitis is primary and MtII and MtIV fractures are secondary, resulting from a bowstring effect of the enlarging SL. Occasionally axially located callus from an old splint bone fracture may cause mild lameness from local irritation of the nearby SL. Local injections of anti-inflammatory agents resolve pain in most instances, but occasionally exostoses and the distal aspect of the splint bone are removed.

Ostectomy of distal fragments of the MtII and MtIV can be performed in combination with SL splitting and, in some horses, with ostectomy of apical or abaxial fracture fragments of the PSBs. A triad of clinical problems involving the *S*L, *s*plint bone, and PSBs (called the *three S's*) is often seen, and all three structures should be evaluated before management and prognostic recommendations are made.

Enostosis-like Lesions of the Third Metatarsal Bone

During scintigraphic examination, single or multifocal areas of IRU within the medullary cavity of the MtIII are occasionally seen, and intensity can range from mild to intense. Subsequent radiographic examination reveals one or more round to irregularly shaped radiopacities within the medullary cavity. Lameness in horses with enostosis-like lesions of the MtIII is unusual, particularly if there are small, focal areas of IRU involving only the area around the nutrient foramen. Of 17 enostosis-like lesions (in 10 horses), 4 lesions were identified in the MtIII, but in only 1 horse was lameness localized to the metatarsal region.[9] Lameness, if present, should abate with a high plantar block and resolves with rest and the administration of NSAIDs.

Hypertrophic Osteopathy

Hypertrophic osteopathy is discussed in Chapter 38.

Suspensory Desmitis

Suspensory desmitis, including proximal suspensory desmitis, suspensory body desmitis, and suspensory branch desmitis and associated bony injury, is the most important cause of lameness in the metatarsal region (see Chapter 73).

I have managed a small number of horses with confirmed proximal suspensory and body desmitis by using autogenous

bone marrow injection and proximal metatarsal fasciotomy.[10] Horses are placed under general anesthesia and a medial approach is used to gain access to the proximal aspect of the SL (Fig. 44-5). Thirty to 60 ml of liquid bone marrow should be harvested from the sternum and injected directly into the proximal SL and body as determined by ultrasonographic evaluation. The dense, overlying medial metatarsal fascia is transected from the level of just proximal to the tarsometatarsal joint to the mid-body region. The subcutaneous tissues and skin are closed. Horses should be given 4 to 6 months of progressive increase in exercise, including 4 weeks of stall rest, followed by 4 weeks of stall rest with hand walking, 4 weeks of walking with a rider up or in the jog cart, and then 4 weeks of walking and light trotting. Turn out exercise is forbidden. Of 15 horses with moderate to severe hindlimb proximal suspensory and body desmitis, 8 returned to full competition. However, lameness persisted or recurred in four horses, and three are still recovering. Whether improvement in some horses may result from reparative processes accelerated by the transfer of stem cells, the injection of growth factor–rich substrate into damaged SLs (see Chapter 74), fasciotomy and relief of compartment syndrome, or a combination of factors is unknown. We are currently evaluating the concentration of growth factors in bone marrow and platelet-rich plasma to evaluate possible future injections using this approach and others to augment healing of the SL.[11]

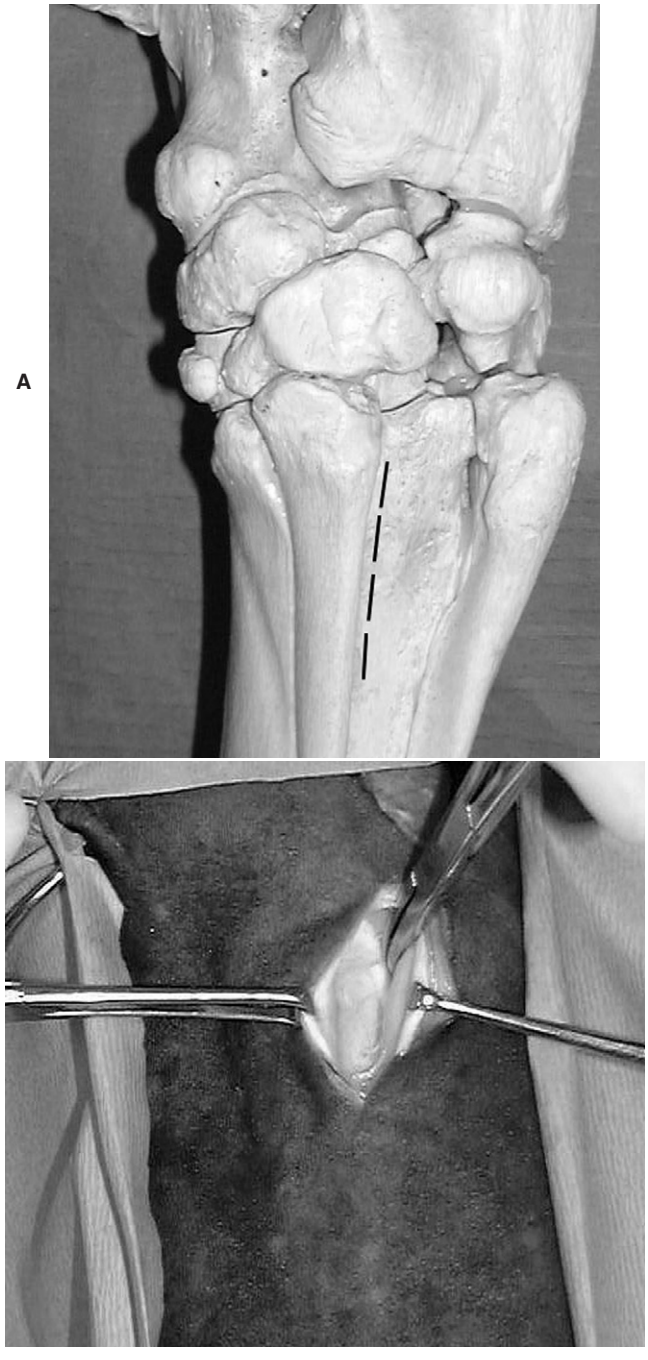

Fig. 44-5 **A,** Photograph of an anatomy specimen and **B,** a cadaver specimen showing the location and approach *(dotted line)* for bone marrow injection and fasciotomy used in management of horses with proximal suspensory and body desmitis. Dense metatarsal fascia is being retracted using Allis tissue forceps, exposing the origin of the suspensory ligament (curved Kelly forceps is positioned plantar to the suspensory ligament).

Tenosynovitis of the Digital Flexor Tendon Sheath

Tenosynovitis of the digital flexor tendon sheath is discussed in Chapter 75.

Desmitis of the Accessory Ligament of the DDFT

Desmitis of the ALDDFT is discussed in Chapter 72.

Deep Digital Flexor Tendonitis

Deep digital flexor tendonitis is discussed in Chapters 71, 77, and 79.

Superficial Digital Flexor Tendonitis

Tendonitis of the SDF is an unusual to rare cause of lameness, but it occurs in racehorses with chronic, progressive curb and in any type of sport horse as a result of direct trauma (see Chapter 79). SDF tendonitis may be obvious clinically or more subtle and requires careful palpation and ultrasonographic examination to confirm diagnosis. STB and TB racehorses with spontaneous SDF tendonitis invariably have sickle-hock conformation. The points of the hock should be compared, because in some horses loss of support accompanies SDF tendonitis and is a negative prognostic sign. Long-term rest has been successful in pacers, but trotters and TB racehorses have a poor prognosis for returning to racing. Most horses regardless of gait drop in race class.

Undiagnosed Metatarsal Region Lameness

In a small proportion of horses, lameness can be localized to the metatarsal region by high plantar analgesia, but comprehensive imaging fails to identify a source of pain. I believe most of these horses have proximal suspensory desmitis and pain from subtle swelling of the SL. Measurement of the cross-sectional area and comparison with the contralateral limb is useful. Horses with lameness inappropriate for the degree of injury confirmed using radiographic and ultrasonographic examinations should be referred for scintigraphic examination. Magnetic resonance imaging may be useful in the future to elucidate sources of plantar metatarsal pain.

Wounds of the Metatarsal Region

Wounds involving the metatarsal region are common and can be simple and involve the skin and subcutaneous tissues, but they are often complex and involve bone and deep soft tissue structures. Lacerations often involve the extensor and flexor tendons (see Chapter 82), and those involving the flexor tendons have serious implications for future performance and salvage. Laceration of the long digital extensor tendon often

delays healing of overlying wounds because movement of tendon ends exacerbates granulation tissue formation and delays wound contraction and epithelialization. Horses with long digital extensor tendon lacerations knuckle initially, but functional healing of the tendon most often results. A common wound is a distal-based flap wound that exposes the dorsal cortex of MtIII and often is associated with extensor tendon lacerations. Because the skin base is distal, much of the proximal, triangular-shaped section of skin becomes necrotic. The skin should not be removed prematurely. Osteitis of the MtIII from direct trauma, drying from exposure, superficial infection, and loss of blood supply may prolong healing. Occasionally, large areas of the dorsal cortex of MtIII have radiographic characteristics of sequestra, but in many horses surgical removal or curettage is not required. In my experience, many horses have received unnecessary surgery to remove damaged areas of MtIII cortex that if left in place would likely have healed uneventfully. However, horses that develop extensive proliferative changes of the MtIII usually have adhesions to the long digital extensor tendon and often have chronic lameness.

Small puncture wounds may result in localized osteitis of the MtII or MtIV. Removal and curettage should be reserved for those with purulent drainage refractory to management with antimicrobial therapy. Horses without drainage but with radiographic evidence of fragmentation within a radiolucent defect can be managed conservatively unless expedient resolution of the problem is mandatory. Horses with wounds and evidence of MtIII cortical crushing or obvious fractures should be managed with caution because catastrophic fracture could develop. Of substantial risk are those with acute, cortical fractures that resemble true saucer fractures. If horses are placed under general anesthesia to remove what is misinterpreted as devitalized pieces of cortex, there is a risk for catastrophic fracture during anesthetic recovery.

Acquired or secondary stringhalt is an unusual complication from metatarsal region wounds involving the long digital extensor tendon and sometimes the lateral digital extensor tendon. Horses at risk are those with extensive proliferation of the MtIII and adhesion formation with the overlying long digital extensor tendon. Mechanisms to account for the development of stringhalt include adhesion formation and interruption of the normal myotactic reflex.[12] Of 10 horses that developed stringhalt after dorsal metatarsal trauma, 6 horses developed stringhalt within 3 months, 3 developed stringhalt after 3 months, and in 1 horse time of injury to development of stringhalt was undetermined.[12] Of four horses managed with rest and progressive exercise, stringhalt resolved in one, improved in two, and remained the same in one horse.[12] Of five horses that received surgical management using lateral digital extensor myotenectomy, stringhalt resolved in two, improved in two, and remained the same in one horse.[12] In my limited experience with this condition, prognosis is guarded to poor for complete resolution of the gait deficit.

Diffuse Swelling in the Metatarsal Region

Diffuse swelling in the metacarpal region is discussed in Chapter 38, and this also applies to the metatarsal region.

Severe Cellulitis of the Metatarsal Region

Cellulitis of the hindlimb occurs frequently from kick wounds or other trauma. In many horses obvious signs of trauma are lacking, but severe lameness and signs of infection in the metatarsal region occur. A severe form of cellulitis occurs primarily in the TB racehorse in which severe lameness, swelling, and fever develop, apparently from a very small skin wound or excoriation, because an obvious wound is most difficult to find. This condition is similar to focal, peritarsal cellulitis (see Chapter 109). Initially it is difficult to differentiate cellulitis from infection of the tarsal sheath, SDFT, DDFT, and the DFTS, because swelling is diffuse and horses are severely lame. Within 48 to 72 hours, skin necrosis and sloughing can occur, which exposes underlying and sometimes infected SDFT. *Staphylococcus* and occasionally *Streptococcus* species are cultured. Laminitis in the contralateral limb is a risk initially. Skin sloughing can be pronounced and requires weeks to months of wound care and, in some horses, grafting. Involvement of underlying SDFT and other soft tissue structures is a poor prognostic sign.

CHAPTER • 45

The Tarsus

Robin M. Dabareiner, G. Kent Carter, and Sue J. Dyson

ANATOMY

The hock joint consists of numerous articulations, including the tarsocrural, talocalcaneal, talocalcaneal-centroquatral (proximal intertarsal), centrodistal (distal intertarsal), and tarsometatarsal joints. The bones consist of the talus and calcaneus and the central, first and second fused, third, and fourth tarsal bones.[1] The tarsocrural joint is a ginglymus joint based on the shape of deep grooves on the cochlear articular surface of the distal end of the tibia with the extensive surface of the trochlea of the talus. The articulation of these joints is at an angle of 12° to 15° dorsolateral to the sagittal plane of the limb. The proximal intertarsal, centrodistal, and tarsometatarsal joints are plane joints and are only capable of small amounts of gliding movement.

The fibrous part of the joint capsule attaches above the tibial articulation proximally and to the metatarsal bones distally. Distally the fibrous joint capsule attaches to the surfaces of the distal tarsal bones and blends in with the collateral ligaments.[2] The dorsomedial aspect of the joint capsule is thin and uncovered by any tendons or ligaments and forms a fluctuant swelling over the medial trochlea of the talus. The proximal aspect of the plantar fibrous joint capsule is also thin and extends proximally behind the distal end of the tibia for about 5 cm.[2] The plantar aspect of the distal joint capsule consists of the plantar and tarsometatarsal ligaments, which are thick and tightly adherent to the distal tarsal bones. The tarsus is composed of four synovial compartments. The tarsocrural compartment lubricates the tarsocrural joint and the cranial aspect of the proximal intertarsal joint. This is the largest compartment and is composed of four pouches: the dorsomedial, dorsolateral, plantaromedial, and plantarolateral. The proximal intertarsal synovial sac lines the talus and calcaneus proximally and the plantar aspect of the central and third tarsal bones distally and communicates cranially with the tarsocrural joint. The centrodistal joint lubricates the articulation between the central and third tarsal bones and the bones on each side, and the tarsometatarsal joint lubricates the third and fourth tarsal bones with the proximal metatarsal bones. There is communication between 8% and 30% of the centrodistal and tarsometatarsal joints, but not necessarily in both hocks of the same horse.[3-5] Communication between the distal tarsal joints and the tarsocrural joint occurs in about 3% of horses.[4]

Numerous ligaments surround the hock. The long collateral ligament is superficial and originates at the caudal aspect of the lateral malleolus of the distal tibia and attaches to the fourth tarsal and third (MtIII) and fourth metatarsal (MtIV) bones and forms a canal for the tendon of the lateral digital extensor muscle. The short lateral collateral ligament lies deep to the long lateral collateral ligament and originates from the cranial aspect of the lateral malleolus, passes caudally, and attaches to the lateral surface of the calcaneus. The long medial collateral ligament originates from the caudal aspect of the medial malleolus and attaches distally to MtII and MtIII and also attaches to the medial aspect of the distal tarsal bones. The short medial collateral ligament lies deep to the long medial collateral ligament and extends from the medial malleolus to the medial aspect of the calcaneus and sustentaculum tali. The plantar ligament is a strong, flat band that originates at the proximal plantar surface of the calcaneus and extends distally and attaches to the fourth tarsal bone and MtIV. The dorsal tarsal ligament spreads out distally from the distal tuberosity of the talus and attaches to the central and third tarsal bones and proximal aspect of the MtIII and MtIV bones. Numerous short ligaments connect adjacent bones of the tarsus and have connections between tarsal and metatarsal bones.

ARTICULAR DISEASES OF THE TARSUS

Osteoarthritis of the Distal Hock Joints

Distal hock joint pain is common in horses from all disciplines and is often associated with osteoarthritis. Distal hock joint pain is known colloquially as bone or jack spavin or occult or blind spavin in the absence of radiographic abnormalities. The term *juvenile spavin* has been used to describe early osteoarthritis that had a prevalence of 20% in a group of horses younger than 2 years of age.[6] Although it is usually seen in mature horses used for sport or pleasure, distal hock joint pain can occur in young Thoroughbred (TB) and Standardbred (STB) racehorses and Western performance horses (see Chapter 121). Distal hock joint pain may be a sequel to incomplete ossification of the central and third tarsal bones (see page 443). Certain conformational abnormalities (such as sickle-hock, in-at-the-hock, or cow-hock) or excessive straightness of the hindlimbs may predispose to distal hock joint pain, although this condition frequently occurs in normally conformed horses. Traditionally it has been proposed that osteoarthritis of the distal hock joints is caused by excessive compression and rotation of the distal tarsal joints as the horse jumps or stops, which results in abnormal tension on the intertarsal ligaments. However, this theory is not consistent with the common recognition of distal hock joint pain in pleasure horses or its high incidence in Icelandic horses, a breed in which osteoarthritis is thought to be a heritable condition.[7] Distal hock joint pain is classically thought to begin on the dorsomedial aspect of the joints and to progress dorsally. However, it is the Editors' experience that in early osteoarthritis, scintigraphic or radiographic abnormalities are frequently first identified only on the dorsolateral aspect of the joints. Nuclear scintigraphic studies of clinically normal mature athletes has shown mild increased uptake of radiopharmaceutical on the lateral aspect, which is consistent with increased modeling, presumably the result of a relative increased loading laterally compared with medially.[8]

The centrodistal and tarsometatarsal joints are most commonly affected, either individually or together, but osteoarthritis of the proximal intertarsal joint does occur, usually in association with osteoarthritis of the more distal joints. The condition may be unilateral but is often bilateral. Occasionally osteoarthritis of the talocalcaneal joint occurs in isolation[9] (see page 443).

History

Clinical signs of distal hock joint pain vary considerably among horses, ranging from a moderate to severe unilateral lameness to subtle changes in performance without overt lameness, (see Chapters 100 and 107 to 128). These signs include the horse becoming disunited in canter, an unwillingness to canter with a particular lead, and reluctance to turn or decelerate with proper engagement of the hindlimbs. The owner may comment that the farrier has experienced difficulties when shoeing the horse. Frequently a horse with bilateral distal hock joint pain has low-grade stiffness that wears off with work. Lameness frequently improves or resolves with rest but recurs when work is resumed. Treatment with non-steroidal anti-inflammatory drugs (NSAIDs) usually results in an improvement in lameness unless it is severe.

Clinical Signs

In many horses no abnormalities are detectable by visual inspection or palpation of the hock region. With more chronic distal hock joint pain there may be enlargement over the medial or dorsomedial aspects of the distal hock joints, which is the result of peri-articular soft tissue thickening. Distention of the tarsocrural joint capsule may occur either coincidentally or reflecting involvement of the proximal intertarsal joint. Frequently there is secondary soreness of the epaxial muscles in the lumbar region and sometimes caudal gluteal muscle soreness. The toe and branch of the shoe of the lame limb, or both, may wear abnormally. In the Editors' experience, shoe wear in this location, however, is not pathognomonic of distal hock joint pain. Some horses, if not properly trimmed, develop lateral flare of the hoof and mediolateral imbalance that is high medially. Flexion of the limb may be resisted slightly, but marked lifting of the limb during flexion is more likely to reflect stifle pain. The Churchill test (see Chapter 6) is helpful in identifying distal hock joint pain in some, but by no means all, horses. Soreness associated with specific acupuncture points (see Chapter 93) can also be suggestive of distal hock joint pain.

Lameness varies greatly in degree and is not necessarily correlated with the degree or type of osteoarthritic change detected radiographically. The horse should be assessed moving from the side, from behind, and from in front to appreciate all gait abnormalities. These abnormalities may include asymmetrical movement of the tubera coxae; reduced arc height of foot flight, with or without toe drag; shortening of the cranial phase of the stride; reduced extension of the fetlock; and a tendency for the limb to swing medially during protraction and slide laterally at ground contact. Lameness may be accentuated on a circle, in some horses with the lame or lamer limb on the outside, and in others with it on the inside. Gait abnormalities may be accentuated if the horse is ridden. However, none of these characteristics is pathognomonic for distal hock joint pain.

Kinematic gait measurements were recorded after endotoxin-induced lameness of the distal tarsal joints.[10] Both fetlock and tarsal joint extension during stance phase decreased, fetlock joint flexion and hoof height during swing phase increased, limb protraction decreased, and vertical excursion of the tuber coxae became more asymmetrical. These observations are not entirely consistent with the observations made in natural disease.

Proximal (upper) limb flexion tests (i.e., the so-called spavin test) are useful in accentuating lameness in some, but not all, horses with distal hock joint pain. The hindlimb should be held with the metatarsal region parallel to the ground for 60 to 90 seconds before the horse is trotted away. The limb may be held either by the toe of the foot or by cupping the hands behind the fetlock. Applying pressure to the flexor tendons should be avoided. The response to flexion should be interpreted in light of the discipline of the horse, the degree of accentuation of lameness, and its duration. Flexion of the non-lame or least lame limb should be performed first and the response compared with the contralateral limb. In some horses there is a paradoxical increase in lameness in the weight-bearing limb. Because of the reciprocal apparatus of the hindlimb, a positive response to proximal limb flexion is not specific for distal hock joint pain. The response to flexion may be recorded as none (0), mild (+1), moderate (+2), or severe (+3). A severe response is unusual in horses with distal hock joint pain.

Diagnostic Analgesia

Diagnostic analgesia is important to confirm the source(s) of pain. Although intra-articular analgesia is potentially more specific than perineural analgesia, the results can be misleading. A negative response to intra-articular analgesia does not preclude distal hock joint pain. Narrowing of the centrodistal joint space or peri-articular new bone can prohibit intra-articular injection. In the presence of extensive subchondral bone damage the response to intra-articular analgesia is very poor. Even in the absence of radiological change the response to intra-articular medication is sometimes substantially better than that to intra-articular analgesia, but the converse is also true in some horses.

However, intra-articular analgesia is very useful in many horses. The degree of communication between the centrodistal and tarsometatarsal joints is variable.[3,4] Therefore theoretically it is preferable to inject both the tarsometatarsal and centrodistal joints either separately or in combination. However, because it is considerably easier and safer to inject the tarsometatarsal joint, it is often preferable to block the tarsometatarsal joint first. Then if there is no response in lameness or only partial improvement, the centrodistal joint should be blocked. The techniques for intra-articular analgesia are described in Chapter 10. Improvement in lameness by 50% or more is considered a positive response. In the Editors' experience, lameness is often substantially improved within 10 minutes, although two authors (R.M.D. and G.K.C.) reassess lameness after 30 minutes. The Editors find reassessment of the response to flexion potentially misleading, although two authors (R.M.D. and G.K.C.) routinely repeat flexion tests. Perineural analgesia of the superficial and deep fibular and tibial nerves (see Chapter 10), although not specific for distal hock joint pain, can be very helpful in confirming hock pain, assuming that pain arising from the more distal aspects of the limb has already been excluded. With practice these blocks are reliable and safe and often result in a much greater degree of improvement in lameness than intra-articular analgesia. Improvement is generally seen within 20 minutes, but occasionally the response is delayed, and it is preferable not to proceed with further blocks until at least 1 hour has elapsed. Horses with specific performance problems associated with distal hock joint pain, rather than overt lameness, may respond better to intra-articular medication than either intra-articular or perineural analgesia.

Radiography and Radiology

Four radiographic views of the tarsus are required: lateromedial, dorsolateral-plantaromedial oblique, dorsomedial-plantarolateral oblique, and dorsoplantar.[11] Lesions may be detectable only in a single view, thus in the Editors' opinion, all four views should be obtained routinely. To cut through the centrodistal and tarsometatarsal joint spaces, it is important that the horse be standing with the metatarsal region vertically and bearing weight evenly on each hindlimb. Because the centrodistal and tarsometatarsal joints slope distally from laterally to medially, to reliably cut through the joint spaces in a lateromedial view, the x-ray beam should be angled 10° distally. Both hocks should be examined because the condition is often bilateral. If a horizontal x-ray beam is used, it can be difficult to cut through the entire centrodistal joint space in a

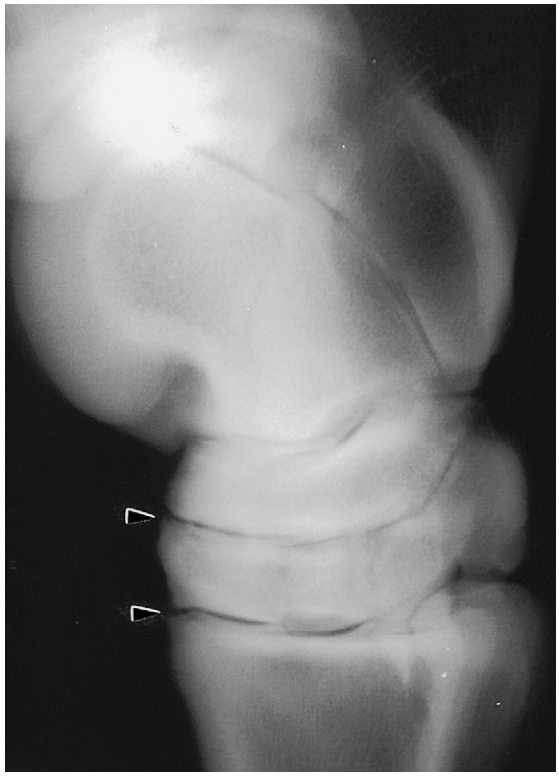

Fig. 45-1 Lateromedial radiographic view of the tarsus of a horse with mild peri-articular osteophyte formation *(arrows)* involving the centrodistal and tarsometatarsal joints.

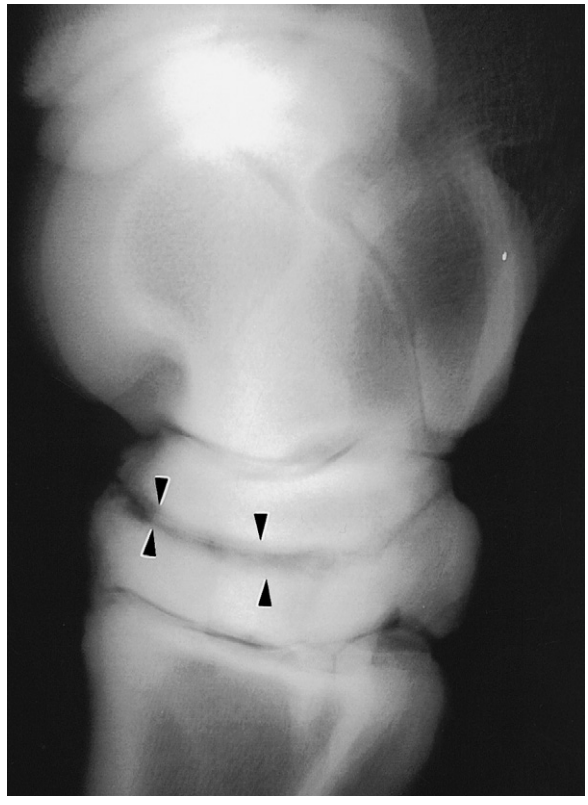

Fig. 45-2 Lateromedial radiographic view of the tarsus of a horse with osteoarthritis of the centrodistal and tarsometatarsal joints. There is modeling of central tarsal and third tarsal bones and irregularity of the centrodistal joint space *(arrows)* caused by subchondral lysis.

dorsoplantar projection, and it may appear that one side of the joint is narrowed. An additional dorsal 5° proximal-plantarodistal oblique view helps to determine whether there is genuine joint space narrowing. Involvement of the talocalcaneal-centroquatral joint merits a more guarded prognosis.

Radiographic abnormalities consistent with osteoarthritis include peri-articular osteophyte formation (Fig. 45-1), subchondral lucent areas (Fig. 45-2), subchondral sclerosis, periosteal new bone, and narrowing of joint spaces. The correlation between the degree of lameness and the extent of radiological abnormalities is poor.[12,13] Extensive changes may be present when lameness is first recognized. Some horses predominantly develop peri-articular changes, whereas others have abnormalities confined to the central and third tarsal bones and the proximal MtIII. The reason for these differences is currently unclear. Small osteophytes or entheseophytes on the dorsoproximal aspect of the MtIII can be incidental radiological abnormalities. Horses with severe subchondral lysis tend to be lamer and respond poorly to intra-articular analgesia and intra-articular medication.

Nuclear Scintigraphy

In many horses nuclear scintigraphy is unnecessary, but it can be very helpful in difficult horses and those with performance problems rather than overt lameness. A region of increased radiopharmaceutical uptake (IRU) may be focal or more diffuse. Very focal increased uptake may reflect intertarsal ligament enthesopathy rather than osteoarthritis. Intense IRU may be present in the absence of radiological abnormality, and these horses tend to respond poorly to intra-articular medication, despite a positive response to intra-articular analgesia. Because IRU may occur in association with primary lameness originating from pain elsewhere in the limb, results should be interpreted cautiously.

Treatment

The aim of treatment is to provide pain relief so that the horse can remain in work. Traditionally it has been suggested that by maintaining the horse in work, the affected joints will fuse. However, progressive radiological ankylosis is rarely observed, although radiography tends to underestimate the degree of joint fusion. Horses with involvement of the talocalcaneal-centroquatral joint and extensive subchondral bone lysis have a more guarded prognosis.

Treatment options include palliative therapy with NSAIDs; intra-articular medication with corticosteroids, hyaluronan, or polysulfated glycosaminoglycans (PSGAGs); with or without systemic treatment with PSGAGs, oral nutraceuticals, or both, combined with corrective trimming and shoeing[14]; and adaptation of the work program. Extracorporeal shock wave treatment has recently been described, but long-term results are lacking.[15] If medical therapy fails, surgical treatment, including cunean tenectomy, subchondral forage to reduce intra-osseous pressure,[16] drilling the affected joints to promote arthrodesis,[17] chemical induction of ankylosis using sodium monoiodoacetate,[18,19] or neurectomy[20] are options.

Selection of treatment depends on the degree of lameness, extent of radiological abnormalities, use of the horse, regulations for competition, response to previous treatment, time available, and financial constraints. Resting the horse usually is not beneficial. Palliative treatment with NSAIDs such as phenylbutazone is useful in pleasure horses; the lowest dose that alleviates lameness should be used. Long-term use of phenylbutazone, 1g twice daily for a 500-kg horse, is generally well tolerated. Any treatment should be combined with corrective trimming and shoeing to ensure correct mediolateral

balance and to facilitate breakover by shortening the toe, squaring and rolling the toe of the shoe, or setting the shoe back from the toe. A lateral trailer[14] or a lateral extension of the shoe provides symptomatic relief in some horses and tends to stop excessive twisting of the limb. However, these devices may be contraindicated in horses that have to stop and turn quickly, because the extension may dig into the footing and stop the distal limb abruptly, causing abnormal torque on the distal limb joints.

Intra-articular medication with corticosteroids, such as methylprednisolone acetate or triamcinolone, with or without hyaluronan, is extremely useful for management of horses with distal hock joint pain. However, horses with extensive radiological abnormalities often have a limited response. Horses with scintigraphic abnormalities in the absence of radiological change also respond poorly. Two authors (R.M.D. and G.K.C.) routinely treat both the centrodistal and tarsometatarsal joints of both hocks by using 60 to 80 mg of methylprednisolone acetate in each joint. If the competition schedule allows, the horse is turned out for 3 to 4 days, followed by 3 to 4 days of light riding before resuming normal activity. Phenylbutazone (2.2 mg/kg sid) is also recommended for 7 days to decrease the possibility of post-injection joint flare. Most horses are sound within 7 to 10 days and stay sound for 3 to 6 months, depending on severity of disease and level of horse use.

Similar results have been achieved using triamcinolone, 6 mg per joint (S.J.D.). There are no controlled clinical trials assessing the relative efficacy of different corticosteroids or the use of a combination of corticosteroids and hyaluronan, although some clinicians believe that combination therapy lasts longer. Hyaluronan alone is of dubious value. Corticosteroid injections can be repeated two or three times per year without promoting progressive radiological change. In some horses it is possible to predict when lameness will recur, and repeated treatment before this recurrence can maintain soundness. Although cunean bursitis is rarely recognized as a primary cause of lameness, some horses respond better if intra-articular treatment is combined with treatment of the bursa. A series of intra-articular injections of PSGAG (three injections given every 2 weeks) can be useful in competition and race horses with distal hock joint pain.

Systemic medication with PSGAG (500 mg IM once weekly for 6 weeks), hyaluronan (4 mg IV monthly), or oral nutraceuticals may be beneficial as adjunctive therapy. Treatment 3 to 4 days before an event may be useful. In some horses, increasing the dose of PSGAG to 1 g weekly gives better results.

Recently shock wave treatment that was performed with horses under general anesthesia, followed by 5 weeks of rest, resulted in an 80% improvement in lameness in horses 90 days later,[15] but long-term results are not available.

A variety of techniques for surgical arthrodesis of the distal hock joints[17,21,22] and subchondral forage[16] exist, and although subchondral forage can provide rapid pain relief in some horses, effective arthrodesis and resolution of lameness often takes up to 12 months. Careful surgical technique is essential to avoid the development of extensive peri-articular new bone, which can itself cause pain. Using the three-drill tract procedure,[17] a 66% success rate was reported.[21] However, the results in upper-level competition horses have been less favorable.[23] Cunean tenectomy alone may result in temporary improvement in clinical signs but is unlikely to restore soundness.[24] Chemical fusion with sodium monoiodoacetate has had excellent results in some horses,[18] but even if positive radiographic contrast studies do not show physical communication between the centrodistal and talocalcaneal-centroquatral joint, it is likely that in some horses, sodium monoiodoacetate can spread to these joints and result in progressive osteoarthritis. Arthrodesis of the centrodistal and tarsometatarsal joints can be followed by fracture of the central or third tarsal bone or the development of osteoarthritis in the talocalcaneal-centroquatral joint. Neurectomy of the deep fibular nerve and a partial neurectomy of the tibial nerves relieves the pain associated with osteoarthritis of the distal hock joints,[20] and approximately 60% of treated horses return to full athletic function.

Osteoarthritis of the Talocalcaneal Joint

Osteoarthritis of the talocalcaneal joint is unusual.[9] There are frequently no localizing signs. Lameness is resolved by perineural analgesia of the fibular and tibial nerves and may be improved by intra-articular analgesia of the tarsocrural joint. Radiographic abnormalities are confined to this joint and are best identified in lateromedial or dorsomedial-plantarolateral oblique views and include subchondral lucency or sclerosis and narrowing of the joint space. The prognosis is guarded to poor.

Osteoarthritis of the Tarsocrural Joint

Osteoarthritis of the tarsocrural joint may occur as a primary disease, develop secondary to osteochondrosis (see Chapter 58) or osteoarthritis of the distal hock joints (see page 440), or be a sequel to trauma. There may be distention of the tarsocrural joint capsule, but this is a variable feature. Lameness varies from mild to severe. Horses with longitudinal wear lines on the trochleas of the talus secondary to osteochondritis dissecans of the distal intermediate ridge of the tibia often have only mild lameness. However, horses with focal partial- or full-thickness cartilage erosions on weight-bearing parts of the trochleas of the talus may have severe lameness. Lameness usually is partially improved by intra-articular analgesia. In horses with primary osteoarthritis of the tarsocrural joint, usually there are no detectable radiological abnormalities and scintigraphic examination is generally negative. In racehorses, scintigraphic examination often reveals IRU involving the distal tibia and proximal talus and must be differentiated from subchondral trauma or fracture of the distal tibia and talus.[25] Definitive diagnosis is dependent on arthroscopic examination of the joint. The prognosis for resolution of lameness and return to full athletic function is generally guarded to poor. Response to intra-articular medication is often disappointing.

Incomplete Ossification of the Central and Third Tarsal Bones

Incomplete ossification of the central and third tarsal bones is most common in premature or twin foals, but it can occur in full-term singles and is characterized by a sickle hock appearance. It may occur unilaterally or bilaterally. Radiographically the bones are smaller and more rounded than usual. Early recognition and treatment are essential to avoid crushing of these bones with resultant progressive osteoarthritis. Cylinder tube casts can be used effectively with good results. In some horses the condition goes unrecognized until a young horse increases work intensity, although the horse may have a pre-existing curb-like appearance of the hock. Lameness may be sudden in onset despite the existence of advanced radiographic changes. Radiographic examination reveals a wedge shape of the central and third tarsal bones, which are narrower dorsally. One or more bones may be fractured. There is often advanced osteoarthritis. Although affected horses may be used for pleasure riding, the prognosis for competition use is guarded.

Distention of the Tarsocrural Joint Capsule

Among the many causes of acute or chronic synovitis of the tarsocrural joint (also known as *bog spavin*) are osteochondrosis, osteoarthritis, trauma, poor conformation, hemarthrosis, infection, and idiopathic causes. Signalment varies and

depends on origin. Clinical signs are excessive tarsocrural joint fluid, which is most easily recognized on the dorsomedial and plantarolateral aspects of the joint. Lameness may or may not be present and is dependent on etiology. Excessive distention of the joint capsule may result in mechanical lameness. Diagnosis is made on the basis of clinical appearance and the response to intra-articular analgesia if the horse is lame. Arthrocentesis may reveal hemorrhage. Radiographic examination should include four standard views, but if no radiological abnormality is detected, flexed lateromedial and flexed dorsoplantar (skyline) views may be helpful. Slightly oblique dorsoplantar views may be necessary to identify osteochondritic lesions of the medial malleolus of the tibia (see Chapter 58). In the absence of lameness or radiographic abnormalities, a diagnosis of idiopathic synovitis is made.

Treatment involves fluid drainage and intra-articular injection of either 80 mg of methylprednisolone acetate or 12 mg of triamcinolone. Combining hyaluronan with the corticosteroids may provide joint protection, but the strong anti-inflammatory effect of the corticosteroids seems most beneficial. Pressure bandages should be applied to help maintain joint decompression. Phenylbutazone (2.2 mg/kg) once daily for 7 days and confinement to a small area for 2 weeks is recommended. Approximately 50% of horses have resolution or decrease in effusion, although some horses may require retreatment. If joint effusion returns and the horse is not lame, the owner is advised that the horse has a cosmetic blemish that will probably not resolve completely. Horses that are lame and block to the tarsocrural joint but have no radiographic lesions are candidates for scintigraphic examination and diagnostic arthroscopy (see "Osteoarthritis of the Tarsocrural Joint," page 443). Hemarthrosis is discussed in Chapter 67.

Osteochondrosis of the Tarsocrural Joint

See Chapter 58 for a discussion of osteochondrosis of the tarsocrural joint (page 551).

Subchondral Trauma and Radiolucency of the Tibia and Talus

A relatively unusual lameness that is alleviated by intra-articular analgesia of the tarsocrural joint is associated scintigraphically with a focal region of IRU in the subchondral bone of either the distal tibia or the talus.[25] In some horses a progressive radiolucent defect may be identified radiographically, whereas in others no lesion could be identified radiographically but a lesion was recognized using computed tomography. These lesions are believed to be traumatic in origin. Conservative management has resulted in persistent lameness. Surgical curettage may offer a more favorable prognosis.

Fragments in the Talocalcaneal-Centroquatral Joint

The tarsocrural joint communicates directly with the proximal intertarsal joint in immature horses through a slit-like opening and in adult horses through a broad opening in the dorsal reflection of the synovium that is located at the distal dorsal aspect of the talus. The proximal intertarsal joint is approached through this synovial fenestration during arthroscopic exploration of the tarsocrural joint. A report describes 17 horses with either a free-floating fragment, which was suspected to have originated and dislodged from an associated osteochondritic lesion in the tarsocrural joint, or a fragment located at the distal end of the medial trochlear ridge with attachment to the synovial reflection that separates the tarsocrural and proximal intertarsal joints.[26] However, such fragments can be seen as incidental abnormalities and unassociated with lameness.[11] Fourteen of 17 horses returned to racing or intended performance activity after arthroscopic removal of the fragment.[26]

TARSAL BONE FRACTURES AND LUXATIONS

Fractures of the Distal Tarsal Bones

Fractures of the central and third tarsal bones occur most frequently in STB, cutting horses, or TB racehorses,[27-30] but they occasionally occur in other horses, sometimes secondary to previous fusion of the centrodistal and tarsometatarsal joints. These fractures cause an acute onset of a moderate to severe hindlimb lameness that is most noticeable when the affected limb is on the inside of a circle.[27-29] The lameness is exacerbated by hock flexion. The degree of lameness diminishes after 1 to 2 weeks of rest but returns if the horse returns to work. Some horses with incomplete fractures of the central tarsal and third tarsal bones can race a number of times before lameness becomes pronounced. On initial diagnosis, some fractures appear old in both the TB and STB racehorse. Horses with bilateral third tarsal bone fractures may be examined for poor performance rather than overt unilateral hindlimb lameness. Within STB racehorses, central and third tarsal bone fractures are more common than expected in pacers than in trotters, even if the normal 3:1 pacer/trotter ratio is considered. Heat, soft tissue swelling, and pain on digital palpation of the distal tarsal bones usually accompany the fracture. Synovial effusion of the tarsocrural joint may occur in horses with central tarsal bone fractures but is not usually seen in horses with third tarsal bone fractures.

Diagnosis is made by radiography, but a fracture may not be radiographically apparent until up to 10 days after injury, when demineralization of the fracture line occurs. Scintigraphy is useful in horses with mild or bilateral hindlimb lameness. Incomplete or bilateral fractures may be seen. Many fractures can be identified on a lateromedial radiographic view, but if no radiological abnormality is detectable in standard views, additional oblique views, including plantar 25° lateral-dorsomedial oblique, should be obtained (Fig. 45-3). However, the precise

Fig. 45-3 Plantar 25° lateral-dorsomedial oblique radiographic view of a tarsus. There is a complete sagittal fracture of the central tarsal bone.

location and orientation of fractures seems to vary between disciplines and between the central and third tarsal bones. Thus if a fracture is suspected, additional oblique views may be required. In many fractures in STBs the fracture does not appear to extend to the distal articular surface. In Western performance horses the fracture line is generally located in a more plantar region of the third and central tarsal bones than is seen in racehorses. Third tarsal bone fractures are most commonly dorsal or dorsolateral. In TB racehorses a wedge-shaped conformation of the dorsolateral aspect of the third tarsal bone may be a risk factor for fracture.[31] Comminuted fractures are more common in the central tarsal bone and may be difficult to identify radiographically.[28] Nuclear scintigraphy is invaluable for identifying the likely presence of a fracture if it cannot be determined radiographically.

Horses may be treated conservatively[30,32,33] or surgically.[28,29,33] Seven horses with fractures of the third tarsal bone that were treated conservatively remained lame for 12 months after injury,[28,29] whereas three horses treated by lag-screw compression returned to racing within 6 months.[28] Six racehorses with central tarsal bone fractures remained lame, whereas six Quarter Horses treated surgically made a complete recovery.[29] However, conservative management resulted in return to training within 8 months for 73% of 45 TB racehorses with fractures of the central or third tarsal bone,[30] and this corresponds with the Editors' experience. Ten (71%) of 14 STBs and 2 (33%) of 6 TBs returned to racing and started at least 5 races after injury, and 4 (80%) of 5 Quarter Horses returned to previous athletic function with conservative management.[32] If surgical treatment is performed, case selection is important, because many central tarsal bone fractures have hidden fracture lines that could be inadvertently displaced during screw placement. The large head of a 4.5-mm cortical bone screw may cause soft tissue inflammation and a periosteal reaction. For third and central tarsal bone fractures, 3.5-mm cortical bone screws are preferred. One or two screws should be placed through stab incisions by using radiographic or fluoroscopic guidance. The use of a Herbert cannulated compression screw has been reported.[29] Horses with fragments that are too small to allow lag-screw fixation, or those with chronic fractures of the third tarsal bone causing osteoarthritis of the centrodistal or tarsometatarsal joints, can be treated by surgical drilling to facilitate arthrodesis of the joints.

Sagittal Fracture of the Talus

Sagittal fractures of the talus are rare, usually non-displaced, can be difficult to diagnose, and have been recorded most frequently in STB and TB racehorses,[34,35] but they can occur in any type of horse. Twelve racehorses had a history of chronic, mild hindlimb lameness that became acutely severe during a race,[34,35] but lameness in other types of horses may be associated with trauma. Lameness is moderate to severe and usually associated with distention of the tarsocrural joint capsule. Intra-articular analgesia may improve lameness but rarely removes it completely. Fractures in racehorses usually originate at the proximal aspect of the sagittal groove of the talus and are often incomplete. Non-displaced fractures can be difficult to identify radiographically; extra views, including a dorsal 10° to 20° lateral-plantaromedial oblique and a flexed dorsoplantar (skyline) view, can be helpful. Fractures following trauma are frequently comminuted, and the degree of damage may not be apparent radiographically. Nuclear scintigraphy can be helpful in confirming the presence of a fracture; there is usually intense focal IRU in the proximal aspect of the talus.[14]

Eleven horses with incomplete sagittal fractures of the talus were treated conservatively with a minimum of 1 month of stall rest followed by small paddock turnout. Seven returned to racing performance within 7 to 8 months after injury; approximately 50% had the same or improved performance.[33] Horses with complete sagittal fractures have been treated by lag-screw compression using two 4.5-mm cortical bone screws.[35] Prognosis may be favorable in horses with simple acute fractures, but the prognosis for horses with comminuted fractures is poor.

Fractures of the Fibular Tarsal Bone

Fractures of the fibular tarsal bone (or calcaneus) are uncommon and usually the result of trauma. Physeal fractures in foals and fractures through the body of the bone are easily diagnosed because of the obvious loss of gastrocnemius muscle function, which results in a dropped-hock appearance. Chip fractures involving the plantar aspect of the calcaneus can be difficult to diagnose unless soft tissue swelling is present or a draining tract secondary to sequestra formation exists. Surgical removal of small fragments may be necessary, depending on size and location of the fragment (intra-articular or extra-articular). Diagnosis is confirmed radiographically. Flexed lateromedial and skyline views of the calcaneus are recommended in addition to standard views (Fig. 45-4). Complete body and physeal fractures can be difficult to reduce and stabilize, but horses can be treated successfully with bone plates and wires by using the tension-band principle. It is not possible to place a bone plate directly caudally because of the presence of the superficial digital flexor tendon, but the plantarolateral or lateral surface of the calcaneus has been used successfully.[35] Conservative therapy using casting methods alone has been unrewarding and is not recommended. Horses with open, comminuted fractures have a grave prognosis and humane destruction should be advised. Prognosis for future performance activity in horses with physeal or full-body fractures is considered poor.

Fracture of the Lateral Malleolus of the Tibia

The lateral malleolus is considered to be the distal end of the fibula and develops as a separate center of ossification that fuses to the distal tibial epiphysis by 1 year of age. The long

Fig. 45-4 Flexed lateromedial radiographic view of a tarsus. There is a complete, comminuted articular fracture through the calcaneus.

lateral and deeper short collateral ligaments originate on the lateral malleolus of the tibia, just plantar to the groove for the tendon of the lateral digital extensor muscle. Only a small portion of the lateral malleolus is intra-articular; therefore most fracture fragments are located within the joint capsule and collateral ligaments.

Lateral malleolar fractures are usually traumatic in origin. Small, well-rounded fragments, probably a manifestation of osteochondrosis, occur occasionally and should be differentiated because horses are often asymptomatic. Clinical and radiographic signs and results of surgical removal of the fragments were reported in 16 horses.[37] All were TBs with injuries incurred either during a fall in a race over fences or from being kicked. All horses had a moderate degree of lameness and tarsocrural effusion. Approximately 50% of the horses had periarticular swelling, thickening of the collateral ligament, and pain on digital palpation of the lateral malleolus. All fractures were visible on a dorsoplantar radiographic view (Fig. 45-5). Fourteen fractures were unilateral and two bilateral, with nine simple and nine comminuted. Thirteen of 16 fragments were displaced distally and rotated 90°.

Ultrasonographic evaluation is useful to determine the location of the fracture in a dorsoplantar plane and to identify a concurrent collateral desmitis. Small or minimally displaced fractures have been successfully managed conservatively. Surgical removal may result in a quicker recovery. The tarsocrural joint should be inspected arthroscopically to remove any debris, and surgical removal of some fragments is possible, but in some horses the fragment is removed via an incision through the lateral collateral ligament of the tarsocrural joint, depending on fragment orientation. If the fracture fragment is of adequate size, lag-screw fixation can be used. Thirteen of 16 horses treated by fragment removal returned to full athletic function.[37] With conservative or surgical management the prognosis is good.

Tarsal Joint Luxation

Complete luxation or subluxation of the tarsocrural, talocalcaneal-centroquatral, and tarsometatarsal joints may occur, with or without concurrent tarsal bone fractures.[38,39] Tarsal luxations are the result of severe trauma from kicks from other horses or limb entrapment in fixed objects, such as a fence or cattle guards. Proximal intertarsal and tarsometatarsal luxations are most common. Luxation causes severe, non–weight-bearing lameness, and there may be abnormal deviation of the limb at the tarsus. Crepitus may be present with a fracture, and palpation reveals tarsal joint instability. Diagnosis is confirmed by radiography. Dorsoplantar radiographic views obtained with medial or lateral limb traction are recommended to determine the extent of collateral ligament damage (Figs. 45-6, 45-7, and 45-8). Treatment consists of reduction of the luxation with the horse under general anesthesia and stabilization with the application of a full hindlimb cast extending from the foot to a point level with the tibial tuberosity. Internal fixation is rarely indicated but may be necessary with concurrent tarsal bone fracture. Tarsocrural or tarsal luxation with functionally intact collateral ligaments can be difficult to reduce, but manipulation of the tarsus with the limb in a flexed position may facilitate reduction. The limb should maintained in a cast for 4 to 6 weeks if the collateral ligaments are intact and 6 to 8 weeks if the collateral ligaments are ruptured.[38,39] After the cast is removed, the hindlimb is placed in a heavy cotton bandage with rigid splints for an additional 4 to 6 weeks before turnout in a small area is allowed. Of the seven reported horses with tarsal joint luxation (three proximal intertarsal, three tarsometatarsal, and one tarsocrural), all were treated with closed reduction and external coaptation, and all returned to either light riding, pasture soundness, or breeding activity. The presence of tarsal bone fractures did not affect outcome. All horses had a reduction in range of motion of the tarsus and osteoarthritis that

Fig. 45-5 Dorsoplantar radiographic view of a tarsus. There is a fracture of the lateral malleolus *(arrows)*.

Fig. 45-6 Flexed lateromedial view of a hock. There is widening of the plantar aspect of the talocalcaneal-centroquatral joint *(arrows)*, which is indicative of luxation.

prevented the return to athletic soundness. Prognosis for horses with proximal intertarsal and tarsometatarsal joint luxations is reasonably good for pasture soundness.[38] A guarded prognosis is warranted for tarsocrural joint luxation because of the difficulty in reducing the luxation.

Fig. 45-7 Stressed dorsoplantar view of a hock. There is luxation of the tarsometatarsal joint, which is associated with fracture of the third and fourth tarsal bones.

Fig. 45-8 Stressed dorsoplantar view of a hock. There is luxation of the tarsocrural joint.

SOFT TISSUE INJURY OF THE TARSUS

Various soft tissue injuries of the tarsus are discussed elsewhere: calcanean bursitis (see Chapter 80), cunean tendon bursitis-tarsitis (see Chapter 109), curb (see Chapter 79), subcutaneous calcaneal bursitis (capped hock; see Chapter 80), distention of the tarsal sheath (thoroughpin; see Chapter 77), luxation of the superficial flexor tendon from the tuber calcanei (see Chapter 81).

Collateral Ligament Damage

Complete extension of the tarsocrural joint is prevented by tension in the collateral ligaments. Collateral ligament injury is usually the result of trauma or a fall. Lameness varies from mild to severe, depending on the degree of damage. There is often distention of the tarsocrural joint capsule and peri-articular soft tissue swelling. Flexion is usually resented. Analgesic techniques are usually not required, but lameness may be improved in some horses by intra-articular analgesia of the tarsocrural joint. In an acute injury there often are no radiographic abnormalities; however, 4 to 6 weeks after injury, entheseophytes develop at the origin or insertions of the injured collateral ligaments. Nuclear scintigraphy is helpful in horses with mild injuries, because it demonstrates intense, focal IRU at the ligament attachment sites.[40] Ultrasonographic evaluation is used to identify the injured structure(s) and assess the severity of the injury (see Chapter 17). Initial treatment involves stall rest, cold water therapy, topical dimethylsulfoxide with or without corticosteroids, and NSAIDs. Long periods of rest (e.g., 6 months) followed by a controlled exercise program have been recommended.[40] Prognosis depends on the severity of injury, but horses with very extensive periosteal new bone have been able to return to full athletic function, although some residual enlargement of the hock has persisted.[23]

Entheseopathy of the Lateral Collateral Ligaments of the Tarsocrural Joint

Entheseopathy of the long, and less commonly, the short lateral collateral ligaments is a rare condition that is recognized most often in STB racehorses, especially pacers, and results in lameness that is improved by analgesia of the tarsocrural joint. There may be distention of the tarsocrural joint capsule, and subtle, localized soft tissue swelling may be present. Diagnosis usually depends on scintigraphic findings[41] that show focal, intense IRU on the lateral aspect of the calcaneus. Entheseous new bone is usually detectable radiographically. Local injections with methylprednisolone acetate and Sarapin, an extract of the pitcher plant, may result in improvement, but rest is the treatment of choice.

Rupture of the Fibularis Tertius

See Chapter 85 for a discussion of rupture of the fibularis (peroneus) tertius.

Stringhalt

See Chapter 49 for a discussion of stringhalt.

MISCELLANEOUS TARSAL INJURIES

Osteitis of the Calcaneus

Osteitis of the tarsal bones is uncommon. However, the enlarged end of the tuber calcanei has minimal soft tissue protection and is at risk of traumatic injury and subsequent infection. Management of these injuries can be complicated if the tarsocrural joint, calcaneal bursa, or tarsal sheath is involved. Most horses sustain a traumatic injury from kicking a fixed object or being kicked by another horse.[42] Osteitis usually

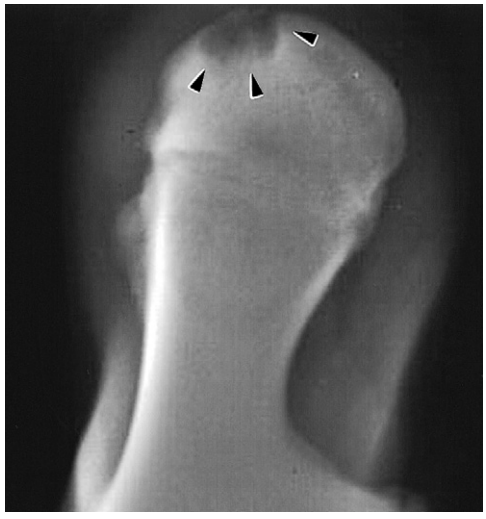

Fig. 45-9 Flexed plantaroproximal-plantarodistal radiographic view of the calcaneus. There is a osteolytic lesion in the tuber calcanei *(arrows)*. There is also new bone on the lateral aspect (to the left) of the calcaneus.

causes moderate to severe lameness, cellulitis, and tarsal tenosynovitis. The severity of lameness often decreases once drainage is established. Twenty-two of 28 horses had a wound or draining tract over the plantar aspect of the calcaneus.[42] Lateromedial, flexed lateromedial, and plantaroproximal-plantarodistal (skyline) radiographic views are the most helpful (Fig. 45-9). Radiographic signs of calcaneal osteitis or sequestra formation may take several days or weeks to appear, and thus sequential radiographic evaluation is recommended. Rarely is the medullary cavity of the calcaneus involved; hence the term *osteitis* rather than *osteomyelitis* is preferred. Ultrasonography is useful to assess calcanean bursa or tarsal sheath involvement. If tarsal sheath involvement is suspected, cytological evaluation of the tendon sheath fluid with aerobic and anaerobic microbial culture and susceptibility is recommended (see Chapter 77). Treatment is based on resolving the infection and debridement of any bony lesions. Broad-spectrum antimicrobials such as penicillin (22,000 IU/kg q12h IM) and gentamicin sulfate (6.6 mg/kg q24h IV) are recommended until culture results are known. Pure bacterial cultures were isolated in 14 of 28 horses in one report,[42] but mixed bacterial isolates do occur. The most common pure bacteria colonies isolated were *Escherichia coli*, *Streptococcus zooepidemicus, Staphylococcus aureus,* and *Enterobacter cloacae.* All isolates were susceptible to penicillin, gentamicin, or trimethoprim sulfamethoxazole. With acute infection, antimicrobial medication alone may be satisfactory, but surgical intervention to remove infected soft tissue and damaged bone or sequestra is usually required. Resection of the infected soft tissues and curettage of the bony lesion can resolve calcaneal lesions that do not involve the tarsal sheath. Infections involving the tarsal sheath require flushing the sheath and establishing drainage (see Chapters 24 and 77). Duration of antimicrobial therapy depends on clinical response, but should continue for at least 7 days after resolution of the lameness and wound drainage. Phenylbutazone (2.2 mg/kg PO) should be used as needed for pain relief.

The prognosis for horses with calcaneal osteitis depends on the structures involved and duration of infection before treatment. Quick and aggressive medical and surgical treatment improve the chances of horses returning to athletic function. In one study, 9 of 18 horses were used as broodmares and 9 returned to athletic function.[42]

Osteitis of the Sustentaculum Tali

The sustentaculum tali is on the plantaromedial aspect of the calcaneus. Injuries involving the medial aspect of the hock often involve the sustentaculum tali and adjacent tarsal sheath. Injury usually occurs from direct trauma, most commonly from a kick wound. Lameness is often severe. Diagnosis can be difficult because of the severe soft tissue swelling that accompanies this injury, especially when acute. Although unusual there can be communication of the site of infection or fragmentation of the sustentaculum tali with the tarsocrural joint. Radiographic examination should include dorsomedial-plantarolateral oblique, dorsoplantar, and plantaroproximal-plantarodistal views. Ultrasonography is useful to assess the deep digital flexor tendon (DDFT) and tarsal sheath. Infection of the tarsal sheath as a result of sustentaculum tali fragmentation (see Fig. 77-3) or lysis requires surgical curettage of the sustentaculum tali and lavage and flushing of the tarsal sheath. Horses with bony irregularities in the tarsal groove of the sustentaculum tali can be severely lame, even without infection, because of motion of the DDFT against the roughened bone, which results in severe tendonitis. The tarsal retinaculum can become constrictive if the tendon is inflamed and swollen, which causes further tendon damage and pain. Surgery with the horse under general anesthesia is recommended to transect the tarsal retinaculum, explore and curette necrotic bone involving the sustentaculum tali, and drain and flush the tarsal sheath.[43] The tarsal groove should be smoothed with a curette to avoid abrasion to the DDFT after surgery. Endoscopic examination of the tarsal sheath may be difficult in horses with severe swelling from concomitant infection. In horses with mild swelling, drainage localized to the region of the sustentaculum tali and without substantial tarsal tenosynovitis, a small incision should be made directly over the fragments. The fragments should be removed and the site curetted; the incision is closed primarily. In these horses, prognosis for future soundness is favorable. Horses should be treated with systemic antibiotics based on culture and susceptibility results. Antimicrobial therapy is continued for 7 days after resolution of clinical signs and may require 4 to 6 weeks of treatment. After surgery, horses should be confined to a stall or small run for 8 weeks with daily hand walking, followed by 6 more weeks of pasture turnout before returning to normal activity. Prognosis is good for returning to athletic activity. Seven of nine horses returned to previous use (three barrel racing, one cutting, and three pleasure riding) after surgery.[43]

Infectious Arthritis

See Chapter 66 for a discussion of infectious arthritis.

Peri-Articular Cellulitis

Peri-tarsal infection results in acute-onset, very severe non–weight-bearing lameness associated with localized swelling that is usually but not invariably on the dorsal aspects of the hock. The swelling is hot and exquisitely painful to palpation. These signs are associated with an elevated rectal temperature, neutrophilia, and hyperfibrinogenemia. In some horses, skin abrasions can be identified somewhere in the more distal part of the limb.

Prompt, aggressive treatment with oxytetracycline (5 mg/kg IV sid) or other antimicrobial agents and phenylbutazone (4.4 mg/kg) for at least 5 days, combined with forced walking exercise for as much as possible daily, usually results in rapid resolution of lameness. Horses can often start trotting within 3 days of the onset of clinical signs and should be trotted for 10- to 15-minute periods repeatedly through the day. The prognosis is usually favorable; 1 of 10 horses developed osteomyelitis of the third tarsal and fourth tarsal bones, although this horse ultimately made a complete recovery.[44]

CHAPTER • 46

The Crus

Mike W. Ross

ANATOMY

In the horse the crus is located between the stifle and hock joints. Anatomy of the hock and stifle are discussed in Chapters 45 and 47. The medial tibia lacks muscle covering and is easily palpated, but muscles and tendons cover the cranial, lateral, and caudal aspects. The tibia has proximal and distal physes and a separate center of ossification for the tibial tuberosity.

The fibula is lateral, does not share axial load, and fuses with the tibia to form the lateral malleolus. The proximal fibula may develop from two or more separate centers of ossification, and fibrous union may persist throughout life. The result of this union is transverse radiolucent lines that are evident radiographically and should not be confused as fractures.[1,2]

Muscles and tendons of the crus are important in locomotion and support of the hindlimb. The long digital extensor muscle originates from a common tendon with the fibularis tertius from the extensor fossa of the femur and is located cranially and laterally in the crus. The fibularis tertius courses distally to divide into dorsal and dorsolateral tendons of attachment. Avulsion injury of the tendon of origin of the fibularis tertius and long digital extensor causes a classic disruption of the hindlimb reciprocal apparatus. The cranialis tibialis muscle is deep to the long digital extensor muscle and distally splits into two parts, the medial of which is called the *cunean tendon* (jack tendon) and may play a minor role in horses with distal hock joint pain. The lateral digital extensor muscle originates proximally and its tendon courses laterally over the tarsus and joins the long digital extensor muscle in the proximal metatarsal region. Myotenectomy of the lateral digital extensor tendon and muscle is performed for management of stringhalt.

The paired gastrocnemius muscles originate from the distal, caudal femur and share a single, strong tendon that courses distally and inserts on the calcaneus. The superficial digital flexor and deep digital flexor muscles and tendons arise caudally. The superficial digital flexor tendon (SDFT) begins medial to the gastrocnemius tendon and courses from medial to caudal to attach to the calcaneus before continuing distally. The deep digital flexor tendon (DDFT) is deep to both the SDF and gastrocnemius tendons and courses distally over the plantaromedial aspect of the calcaneus, the sustentaculum tali. The combined SDFT and gastrocnemius tendons form the common calcaneal tendon, the major extensor of the hock, and injuries can cause partial or complete loss of hock support. The tarsal sheath begins in the distal, caudal aspect of the crus and surrounds the DDFT.

The fibular (peroneal) nerve originates from the sciatic nerve and branches in the proximal crus to become the superficial and deep fibular nerves that run between the long digital extensor and lateral digital extensor muscles and tendons. The tibial nerve is palpable in the distal, caudal aspect of the crus, cranial to the common calcaneal tendon.

CLINICAL CHARACTERISTICS AND DIAGNOSIS OF LAMENESS OF THE CRUS

Degree of lameness can vary from the subtle, high-speed lameness seen in horses with early stress-related bone injury to acute, non–weight-bearing lameness, swelling, and deformity seen in horses with complete tibial fractures. Horses with tearing of the gastrocnemius tendon, musculotendonous junction, origin, and insertion have varying degrees of hyperflexion of the tarsocrural joint and partial loss of the reciprocal apparatus. Because the hock drops during weight bearing, the degree of pelvic hike is less than expected and the degree of lameness may be underestimated. Foals with fibularis tertius and long digital extensor avulsion injury lose integrity of the reciprocal apparatus and have swelling on the lateral, proximal aspect of the crus. Fibularis tertius injury in adult horses may cause swelling of the distal, cranial aspect of the crus near the tarsocrural joint, but lesions in the mid-crus are not associated with swelling. Calcinosis circumscripta, which are round to oblong, non-painful mineralized masses, are attached to the distal aspect of the lateral patellar ligament and lateral femorotibial joint capsule or collateral ligament.

No gait characteristics are pathognomonic of pain associated with the crus. Horses with tibial stress fractures have a shortened cranial phase of the stride and, most often, a stabbing type of hindlimb gait when viewed from behind. Injuries of the crus are suspected when lameness is pronounced, but sites in the rest of the limb are eliminated by using diagnostic analgesia. In Thoroughbreds (TBs), in which the risk of tibial stress fractures is high, a tentative diagnosis of stress fracture is made when lameness is pronounced and recurrent after work.

Palpation of the crus should be done with the limb in both the standing and flexed positions, but this often yields no information. The medial side of the tibia is most easily felt, and occasionally in horses with tibial stress fractures there is mild swelling and pain is elicited by deep compression. Unfortunately, most tibial stress fractures involve the caudolateral cortex, and it is difficult to compress this area during palpation. Digital tibial percussion sometimes elicits a painful response in horses with tibial stress fractures, but there are many false-positive and false-negative responses.

Diagnostic Analgesia

There is no practical method to use diagnostic analgesia in the entire crus. The distal portion is blocked when fibular and tibial nerve block is performed, and pain from injuries involving the distal tibia and caudal soft tissues may be abolished, but this block is unreliable. Lameness of the crus becomes more likely in horses in which perineural and intra-articular techniques for the rest of the limb have been exhausted. In at least three TB racehorses, pain associated with tibial stress fractures has been abolished or diminished by intra-articular analgesia of the femorotibial joint. An explanation is not readily apparent.

Imaging Considerations

Large cassettes and film (35 × 43 cm) should be used to obtain radiographs of the entire length of the tibia. There are normal areas of modeling involving the cranial cortex of the tibia that appear as layers or a mound of bone, but stress fractures do not occur here. Occasionally, an obvious bony proliferation is seen involving the caudal or caudolateral tibial cortex, under the fibula in normal horses. Periosteal and endosteal proliferation of the caudal and lateral (rarely medial cortex) and oblique linear radiolucency are changes that may be seen in horses with tibial stress fractures. Enostosis-like lesions appear as single or numerous medullary radiopacities. In some horses the fibula has one or more transverse radiolucent lines through the proximal one third of the bone that should not be mistaken for fractures. Stress-related bone injury of the tibia is most easily imaged and diagnosed using scintigraphic examination. Without scintigraphy the diagnosis can be easily missed radiographically. Enostosis-like lesions may be associated with single to numerous areas of increased radiopharmaceutical uptake (IRU) in the medullary cavity and should be differentiated from the cortical uptake associated with tibial stress fractures.

Ultrasonographic examination is useful in evaluating the gastrocnemius muscle and tendon. Patellar desmitis at the attachments can be diagnosed by using ultrasonographic and scintigraphic examinations. Ultrasonographic examination is useful in horses with fibularis tertius injury, thoroughpin or "false" thoroughpin, and to evaluate the tarsal sheath (see Chapter 6).

SPECIFIC CONDITIONS OF THE CRUS

Tibial Stress Fractures

Tibial stress fractures are the most common lameness condition of the crus and occur most commonly in TB racehorses. In my experience, tibial stress fractures are rare in other sport horses, including the Standardbred (STB) racehorse. In an 8-year period, of 1020 STBs in which scintigraphic examination was performed, only 3 horses (2 of which were trotters) had tibial stress fractures.[3] Thirteen STB racehorses, 11 pacers and 2 trotters, with tibial stress fractures were reported in one study,[4] but based on my experience, this is a highly unusual clustering of horses. Pacers were over-represented and factors such as breeding, track size, training methods, and referral bias may have played a role. The caudal tibial cortex appears prone to stress-related bone injury because it is under compressive forces when loaded. The highest compressive forces were recorded in the mid-diaphysis at the walk, but loading at the gallop, pace, and trot was not determined.[4-6]

Tibial stress fractures usually occur in 2- and 3-year-old racehorses. Tibial stress fractures occur later in training than stress fractures of the humerus, can occur when horses are racing, and also occur in older horses. Usually lameness is unilateral. Stress-related bone injury is more advanced in the lame limb, but scintigraphic evidence of stress-related bone injury can be bilateral. Typically TB racehorses with tibial stress fractures usually become acutely lame after training or racing, only to become reasonably sound within 3 to 5 days. Lameness recurs after another work session or race, but overt clinical signs other than lameness are subtle or lacking. Horses with pelvic stress fractures and those with stress-related bone injury of the distal third metatarsal bone manifest similar signs. Lameness may be severe initially, but within a few days horses can be trotted and show grade 2 to 4 lameness (of 5). Occasionally, severe non–weight-bearing lameness is present, which usually indicates the presence of a spiral fracture.

Tibial stress fractures are seen as focal areas of IRU of the caudal or caudal lateral tibial cortex and are usually singular, but can be multiple and bilateral (see Chapter 19). Caudomedial tibial stress fractures occur rarely. In horses in North America, tibial stress fractures are usually located from mid-diaphysis to the distal tibia, but occasionally a fracture is seen in the proximal, caudal metaphyseal region. In TBs racing in Europe the proximal caudal site is affected more commonly.[7] Occasionally a spiral fracture of the distal tibial cortex is seen. In general, intensity of IRU is inversely proportional to the amount of radiographic change. In horses with stress-related bone injury a continuum of bone changes occur that precede and eventually lead to fracture. If radiographs show proliferative changes and an oblique fracture line, IRU is usually mild to moderate. In horses that develop sudden, severe lameness, focal or spiral intense IRU is seen, but radiographic changes are equivocal or mild. Authentic tibial stress fractures do not occur in the cranial cortex, but IRU from a previous fibular nerve block can produce an artifact resembling fracture (see Fig. 19-15).

Most horses are given 4 weeks of stall rest, followed by 4 weeks of stall rest with hand walking, then 8 weeks of turn out in a small paddock before returning to race training. Earlier return to race training predisposes to recurrence of stress-related bone injury and fracture. Fracture of the contralateral limb the next racing year is possible, but recurrence of ipsilateral fracture is unusual, unlike recurrence seen early in training in horses with humeral stress fractures. Horses with severe lameness may have difficulty rising in the stall and should be bedded on good footing or kept in the standing position for several weeks by the use of cross ties or other suitable restraints.

Tibial Diaphyseal Fractures in Adult Horses

Tibial fractures in adult horses occur from trauma from falling, a spill sustained while performing, being kicked, or while attempting to rise after general anesthesia. Horses with tibial stress fractures, usually those with severe initial lameness or spiral fracture, can develop comminuted fractures if turn-out exercise is given too soon, or if a horse struggles to rise in a stall. One of the only reported successful repairs of an adult horse with a displaced tibial fracture was performed after the horse was anesthetized for radiographs of the pelvis and coxofemoral joint only to develop a displaced, closed tibial fracture as a result of displacement from a tibial stress fracture. The injury was repaired using two dynamic compression plates and bone screws.[8] In general, however, prognosis is grave for adult horses with displaced, comminuted tibial fractures, because comminution is severe, additional fracture lines often propagate proximal and distal from the fracture site, fractures are often open, and implant failures are common (Fig. 46-1). Prognosis for horses with comminuted fractures involving the distal tibia and tarsocrural joint is hopeless. A horse with a closed, simple, or mildly comminuted mid-shaft oblique or transverse fracture may be a candidate for an attempt at internal fixation. However, prognosis is poor to grave, because even with double-plating or triple-plating techniques, implant failure is common and fixation usually fails during anesthetic recovery even with a pool recovery system. Given the extremely poor prognosis, transportation of a horse with a flail leg should be avoided. Most horses should be immediately destroyed.

Tibial Fractures in Foals

Suckling and weanling foals with displaced, comminuted tibial fractures have a reasonable prognosis for salvage and some become performance horses and racehorses. The size of the foal is critical, and complications in those heavier than 225 to 325 kg may be similar to adult horses. Most foals with tibial fractures sustain kick trauma from mares or have other accidents.

Fig. 46-1 Lateromedial radiographic view of an adult tibia. There is a typical comminuted tibial fracture. The prognosis is grave and the horse should be humanely destroyed.

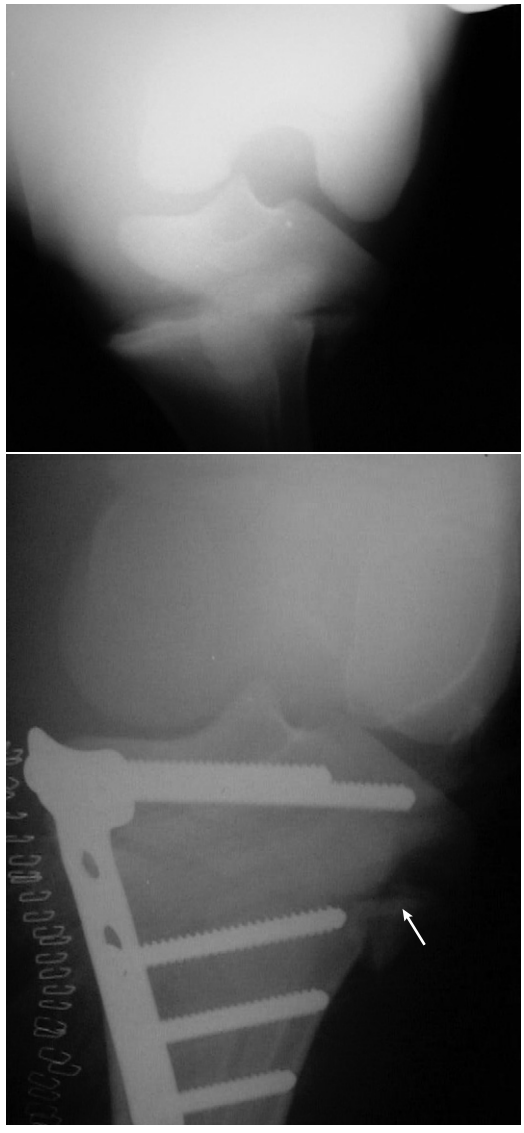

Fig. 46-2 Caudocranial radiographic projection of a foal with a Salter-Harris type II fracture of the proximal tibial physis before **(A)** and after **(B)** surgery. Note the lateral metaphyseal component *(arrow)*.

Proximal Physeal Tibial Fractures

Salter-Harris type II fractures occur in sucklings, weanlings, and rarely in yearlings. These fractures result in acute-onset lameness and swelling of the proximal, medial aspect of the crus and stifle. Within 1 to 3 days, foals are often weight-bearing and may be surprisingly comfortable. Radiographs reveal a simple Salter-Harris type II fracture with a lateral metaphyseal component (Fig. 46-2). Occasionally mild comminution exists laterally. Foals with minimal displacement can be managed conservatively, but progressive displacement, as evidenced by valgus deformity, usually occurs. Foals should be treated surgically. Many methods have been used, but the most stable repair is a medial approach, in which either a T plate or two short dynamic compression plates should be applied by using 5.5-mm bone screws in the epiphyseal component. A long metaphyseal component can be engaged using screws placed in lag fashion. The tension side of the proximal tibia is medial and the T plate should be applied in this location. Because the soft tissue covering is minimal, chronic drainage from the wound is common until the plate(s) is removed. Prognosis for life is good to excellent and for soundness is fair to good. Prognosis for racing is not established and sequelae from differences in limb length are unknown, but racing is not out of the question.

Mid-diaphyseal Tibial Fractures

Similar considerations for degree of comminution, location of fracture, and whether the site is open or closed apply to foals and adult horses, but in foals prognosis associated with repair is considerably better than in adults. Foals with closed, mid-shaft, transverse, or oblique fractures with minimal comminution are the best surgical candidates, but successful repair of those with comminution has been achieved (Fig. 46-3). Foals with open fractures that are associated with a small wound and minimal contamination are also surgical candidates. A cranial approach is used to place two dynamic compression plates on the craniolateral and craniomedial aspects and additional screws to repair loose fragments. In nine foals whose injuries were repaired in this manner, results were considered excellent in six, and good or fair in two.[9] If fractures heal, implants should be removed, and if contralateral angular deformity does not develop, prognosis for racing should be fair to good.

Distal Physeal Fractures of the Tibia

Distal physeal fractures of the tibia do occur but are rare. There is acute severe lameness, swelling, and angular and rotational deformity of the limb. Salter-Harris type II fractures are most common, but the small size of the epiphysis complicates surgical repair. Substantial tibial shortening can be expected and prognosis is poor.

Tibial Malleolar Fractures

Medial malleolar fractures are rare but occasionally occur from trauma and may be associated with substantial collateral ligament injury. When collateral ligament injury is minimal, fragments can be removed arthroscopically, but visibility can be difficult without proper instrumentation. After fragments are removed, the arthroscope can usually be advanced to the plantar pouch. Prognosis is good in horses without substantial collateral ligament damage and tarsocrural instability. However,

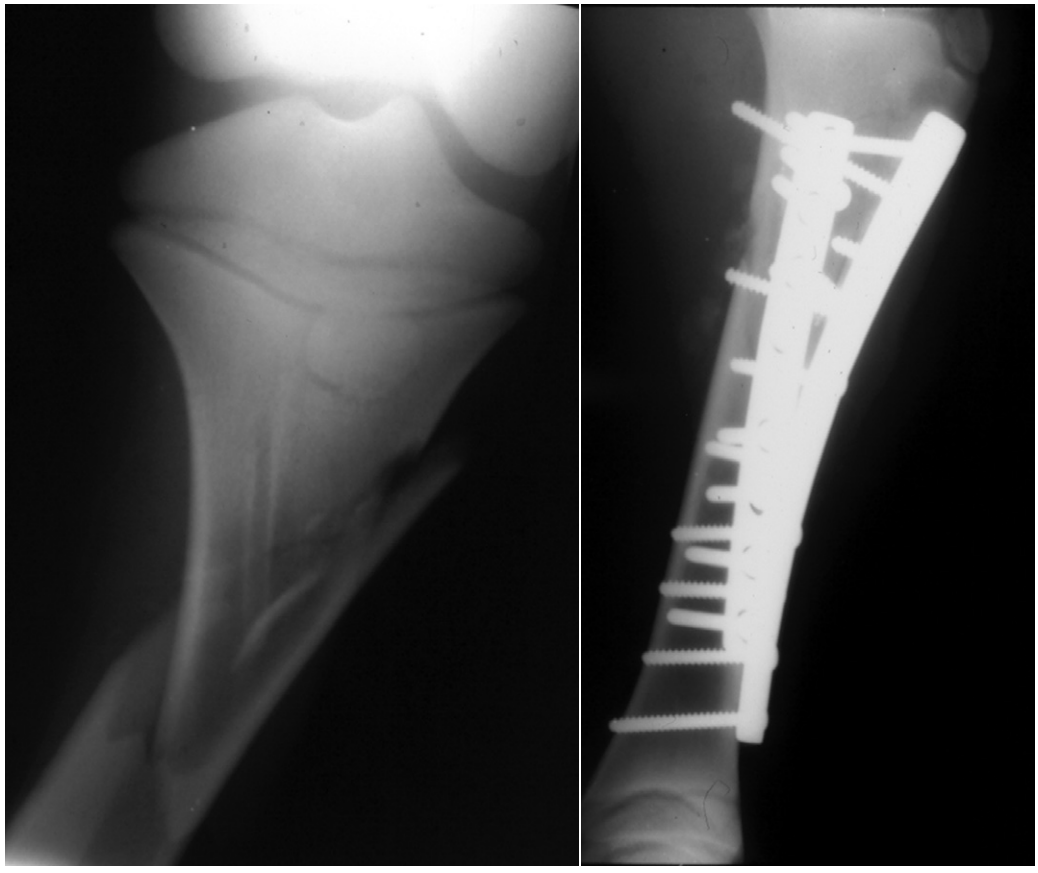

Fig. 46-3 A, Preoperative and B, postoperative craniocaudal radiographic views of a 2-month-old Standardbred foal with a diaphyseal tibial fracture.

if there are additional loose fragments within the joint, this may indicate further damage of the tarsocrural joint.

See Chapter 45 for a discussion of lateral malleolar fractures.

Tibial Tuberosity Fractures

Direct trauma causes tibial tuberosity fractures, which occur most often in field hunters and jumpers. Fractures are usually non-articular and can vary in length, width, and depth. In most horses with injuries that are managed conservatively, fractures heal functionally but without radiographic evidence of union. Surgical repair of non-articular fractures in six horses resulted in a successful outcome.[10] Large fractures involving the femorotibial joint surfaces can be repaired, but surgical repair is not necessary in most horses and can be associated with catastrophic fracture of the tibia if occult fracture lines are not recognized and implant failure occurs[11] (see Fig. 47-12). In one study, 10 of 14 horses with non-articular tibial tuberosity fractures that were managed conservatively were sound and horses performed at the expected level[12] (Fig. 46-4).

Fig. 46-4 Lateromedial radiographic view of the proximal tibia in a horse with chronic lameness and fracture of the tibial tuberosity. Conservative management of this horse resulted in a successful outcome, although radiographic evidence of fracture union was never achieved.

Enostosis-like Lesions of the Tibia

Enostosis-like lesions of the tibia are diagnosed by scintigraphic and radiographic examinations and can be a cause of chronic, mild hindlimb lameness.

Osteochondroma of the Tibia

Osteochondroma of the tibia is a rare radiographic finding in the distal, caudal tibia and may be incidental or cause tarsal tenosynovitis. I have seen one adult horse with osteochondroma that as a foal had repair of a tibial fracture. The condition has rarely been reported.[13]

Osseous Cyst-like Lesions of the Proximal Tibia

Osseous cyst-like lesions of the proximal tibia are unusual, may be the result of osteochondrosis, and frequently communicate with the lateral femorotibial joint. Some adult horses

develop radiolucent changes caused by osteoarthritis, but in these horses osseous cyst-like lesions are acquired, not developmental. Some adult horses develop sudden-onset lameness associated with a well-established osseous cyst-like lesion that was previously asymptomatic with no evidence of primary osteoarthritis. Clinical signs are similar to those in horses with other subchondral bone cysts or osseous cyst-like lesions of the femorotibial joint, but lameness is often pronounced in adult horses with osteoarthritis. In most horses with osseous cyst-like lesions involving the lateral femorotibial joint, curettage is difficult or impossible without elevating or severing the lateral meniscus. Some of these horses respond to conservative management and intra-articular injections of hyaluronan and corticosteroids. Intralesional injection with corticosteroids has also been reported. In horses with acquired osseous cyst-like lesions related to osteoarthritis, the lesion is usually medial and prognosis is poor because cartilage damage of the proximal tibial condyle and distal medial femoral condyle is usually severe. Of 12 horses with osseous cyst-like lesions, 6 were believed to be the result of osteochondrosis and 3 of the 6 horses that received surgical debridement became athletes. Only 2 of 6 in which osseous cyst-like lesions were caused by osteoarthritis returned to work after surgery.[14]

Osseous Cyst-like Lesions of the Distal Tibia

Osseous cyst-like lesions of the distal tibia are rare injuries and appear to be acquired as the result of trauma or stress-related bone injury. I have seen osseous cyst-like lesions in this location in a jumper and a STB racehorse. In both horses, there was acute-onset lameness and tarsocrural effusion. Scintigraphic examination revealed focal, moderate to intense IRU of the distal tibia. Horses were rested and later performed at a level similar to pre-injury level. Computed tomography was useful in elucidating the lesion in other horses (see Chapter 20).

Physitis of the Distal Tibia

A discussion of physitis of the distal tibia is in Chapters 59 and 129.

Fibular Fractures

Authentic fibular fractures occur rarely and are often fortuitously diagnosed scintigraphically or radiographically when images are obtained in horses with undiagnosed hindlimb lameness or in those with suspected tibial stress fractures. Fractures occur either proximally or in the mid-diaphyseal region and can appear as chronic non-unions with bulbous proliferation on each side of the fracture. Rest is recommended. The entire limb should be evaluated carefully to exclude another site of pain causing lameness. Six horses with proximal fibular fractures made complete functional recoveries; horses were sound within 3 months, but a fracture line persisted radiographically until 4 to 6 months after the injury.[7]

Soft Tissue Injuries of the Crus

Fibularis tertius injury in foals and adult horses is discussed in Chapter 81, and gastrocnemius tendonitis is discussed in Chapter 81. Stringhalt is discussed in Chapter 49.

CHAPTER • 47

The Stifle

John P. Walmsley

ANATOMY

Developmental Anatomy

The seven centers of ossification in the stifle of the foal are the metaphyses of the femur and tibia, distal femoral epiphysis, proximal tibial epiphysis, patella, tibial tuberosity (the apophysis), and fibula. The proximal tibial physis closes at about 2½ years of age. The tibial apophyseal-epiphyseal physis closes by 1 year of age. The apophysis does not fuse with the metaphysis until 3 years of age. This apophysis is an important radiographic feature in a young horse and can be mistaken for a fracture. The distal femoral physis closes by about 2½ years of age. In young foals the margins of the femoral trochleas and the patella are irregular for the first 3 months of life because of incomplete ossification. The fibula is not evident radiographically until about 2 months of age, and a high percentage of adult horses have one and occasionally up to three horizontal radiolucent lines in the fibula distal to its head. These should not be confused with fracture lines.[1]

Reciprocal Apparatus

The reciprocal apparatus has a significant influence on the action of the stifle. Extension of the joint exerts a pull on the superficial digital flexor tendon, which originates in the supracondyloid fossa of the femur and is mostly tendonous. Because this flexor tendon has an insertion on the calcaneus, the hock must extend simultaneously with the stifle. On the cranial aspect of the stifle the fibularis (peroneus) tertius, also a tendonous structure, originates in common with the long digital extensor tendon between the lateral trochlea and the lateral condyle of the distal femur.[2] The fibularis tertius passes through the extensor sulcus in the lateral part of the tibial head, associates closely with the deeper tibialis cranialis, and inserts on the third tarsal and third metatarsal bones and the fourth tarsal bone and calcaneus. Flexion of the stifle necessitates hock flexion because of the action of the fibularis tertius.[3] Weight bearing is achieved without muscular effort by the parapatellar fibrocartilage of the medial patellar ligament hooking over the medial femoral trochlea by contraction of the quadriceps femoris. The patella is released by contraction of the quadriceps femoris, combined with the lateral pull of the tensor fascia latae and biceps femoris.

Femoropatellar Joint

The articulation between the patella and the trochleas of the femur forms the femoropatellar articulation. The patella has three straight ligaments. The medial patellar ligament attaches to the medial border and the base of the patella through the parapatellar fibrocartilage. Arthroscopically the ligament can be viewed beneath the joint capsule. Distally the medial patellar ligament attaches medial to the groove on the cranial aspect of the tibial tuberosity. The middle patellar ligament originates on the cranial part of the patella just proximal to the apex and inserts in the distal part of the groove of the tibial tuberosity. The lateral patellar ligament extends from the lateral aspect of the patella to the lateral part of the tibial crest. The biceps femoris has a tendon of insertion on this ligament.[3] Femoropatellar ligaments also reinforce the joint capsule medially and laterally, the lateral ligament being the more distinct.

The medial trochlear ridge of the femur is larger and more rounded than the lateral trochlear ridge and articulates with the medial part of the patella and the fibrocartilage of the medial patellar ligament. The joint capsule has a large suprapatellar pouch and inserts abaxially on the trochlear ridges forming lateral and medial recesses, the lateral being the smaller. A large fat pad is cranial to the joint capsule, proximal and distal to the patella. In my experience, most horses have a slit-like opening into the femorotibial joint at the distal end of the medial trochlear ridge and frequently the lateral trochlear ridge as well. Latex passes from the femoropatellar to the medial femorotibial joint in 60% to 65% of horses and in the reverse direction in 80% of horses.[3] Diffusion of mepivacaine between all the compartments may occur in about 75% of horses.[4]

Femorotibial Joints

The medial and lateral femorotibial joints are separate compartments, which are divided by an intact median septum in a healthy joint but which may communicate after trauma.[5] The crescent shaped, fibrocartilaginous medial and lateral menisci lie between the respective femoral and tibial condyles to form a congruent articulation.[2] Both are attached to the tibia, cranial to the intercondylar eminences, by cranial ligaments. The medial ligament wraps around the cranial aspect of the medial intercondylar eminence before inserting on the tibia. The medial meniscus is also attached caudally to the medial intercondylar eminence by the caudal ligament, which can be seen arthroscopically in the caudal part of the femorotibial joint. The lateral meniscus attaches caudally to the popliteal notch of the tibia and through the strong meniscofemoral ligament to the caudal part of the intercondylar notch of the femur. Only the cranial and caudal poles of the menisci can be viewed arthroscopically because of the close apposition of the tibia and femur, but the respective cranial ligaments are clearly visible. During flexion the menisci slide caudally, and during extension they slide cranially.

The cranial cruciate ligament has its tibial attachment cranial to the medial intercondylar eminence, and its femoral attachment in the lateral part of the intercondylar notch. The cranial cruciate ligament lies beneath the median septum and usually cannot be directly viewed arthroscopically without removing the septum. A better view is often gained from the lateral compartment. The caudal cruciate ligament originates in the popliteal notch of the caudal tibia and runs proximally, medial to the cranial cruciate ligament, to insert cranially in the intercondylar notch of the femur.[7] The ligament can be viewed beneath the septum in the cranial and caudal medial compartment of the femorotibial joint. In the dog the cranial cruciate ligament is under tension during extension of the femorotibial joint,[8] and this may be so in the horse.

The collateral ligaments both originate proximally on the respective epicondyles of the femur. The medial collateral ligament inserts distally on the tibia distal to the medial condyle and has attachments to the medial meniscus. The lateral collateral ligament lies over the popliteal tendon and inserts distally on the head of the fibula. The popliteal tendon originates close to the lateral collateral ligament on the femur and courses distally and caudally, in close apposition to the femoral condyle, to the triangular insertion of the muscle on the caudal aspect of the proximal tibia. The tendon is viewed arthroscopically in the cranial aspect of the lateral femorotibial joint and also in the caudal part, which it effectively divides, limiting the arthroscopic accessibility. The tendon of origin of the long digital extensor muscle can be followed arthroscopically from its origin to the extensor notch of the femur and is usually invested within the joint capsule, although in some traumatized joints, the tendon appears separate.[5]

DIAGNOSIS

General Considerations

The history may give an important lead to diagnosing the cause of lameness. For example, a young horse is a candidate for osteochondrosis or subchondral cystic lesions. Acute-onset stifle lameness in a horse at pasture or during work is more likely to be a traumatic injury involving ligaments or bone. Sudden reduction of work or poor condition may predispose to upward fixation of the patella. Palpation of the patellar ligaments and the outline of the patella, collateral ligaments, long digital extensor tendon, tibial crest, and medial and lateral tibial condyles should be possible. Many horses with stifle injuries manifest no abnormalities on physical examination of the joint. If severe trauma has occurred, the whole region may be swollen, making appreciation of the individual structures difficult. The horse may guard the limb so strongly that instability may not be obvious. Because of the ligamentous structures around the joint, distention is only readily palpable over the cranial aspect of the femoropatellar joint and over the medial femorotibial joint cranial to the medial collateral ligament.

Gait and Manipulative Tests

Differentiating stifle lameness in the horse by studying the gait is difficult, because the reciprocal apparatus coordinates the movement of the whole limb. In my view attributing the cause of certain gait changes to stifle pain is not possible. Some horses with stifle pain may carry the stifle slightly abducted, but this is not specific. A careful analysis of the whole limb is required to establish the site of pain. Other gait changes that may be seen with stifle lameness, but which are also not specific, are a reduced cranial phase of the stride and a reduced flexion of the limb in flight. Many horses with stifle pain dislike going downhill. Horses with delayed release or upward fixation of the patella tend to avoid fully extending the limb and appear to have a crouching gait. Flexion of the upper limb exacerbates lameness in horses with stifle lameness and abduction of the limb may be painful. When performing proximal limb flexion tests, holding the limb at mid-metatarsal level, rather than by the foot, helps to differentiate between upper and lower limb pain.

Three specific manipulative tests have been described for the stifle. These are the cruciate test, collateral ligament test,[9] and patellar displacement test. Most horses with significant stifle pain resent these tests, which makes the tests difficult to perform and interpret. All manipulation or flexion tests should be done on the contralateral limb first. For the cruciate test the affected limb should be weight bearing. The head of the tibia is pushed caudally and then released 5 to 10 times before trotting the horse. Laxity is supposed to be appreciated and lameness exacerbated if severe cruciate injury exists. I have never found this test effective. Pain in the affected joint provokes strong guarding by the horse so that the procedure is impossible to perform. The medial collateral ligament test involves abducting the distal limb against shoulder pressure exerted on the femorotibial joint 5 to 10 times before trotting the horse. Horses with ruptured medial collateral ligaments are so painful and instability is so great that this test is inappropriate, but it can be useful for a sprain of the ligament. The lateral collateral ligament is less often affected, but it can be tested by pulling the distal limb medially. Lameness associated with problems with patella release may be worsened by pushing the patella proximally several times with the horse weight bearing, before trotting, but again this is an unrewarding test.

DIAGNOSTIC ANALGESIA

In many horses with low-grade stifle lameness, positive diagnostic analgesia is the only way to localize the site of pain, so it is an important test. Because diffusion of local anesthetic solution between the three joint compartments is so variable,[4] all three must be blocked to ensure a valid test. Alleviation of lameness after analgesia of one compartment does not necessarily infer that that compartment is definitely the source of pain.

I use a 5-cm, 19-gauge needle for each joint compartment and up to 30 ml of local anesthetic solution, because experience has shown that 20 ml in each compartment might be incompletely effective in a 600-kg horse. Strict aseptic procedure should be followed. Arthrocentesis of the femoropatellar joint is well tolerated and performed first. An intradermal bleb is usually unnecessary. However, an inexperienced veterinarian may find one helpful for the medial femorotibial compartment, because some horses are sensitive about injection at this site. My preferred approach for the femoropatellar joint is between the middle and medial patellar ligaments. Synovial fluid is infrequently retrieved from this site unless the joint capsule is distended. If a synovial fluid sample is required, it may be retrieved more easily through a lateral approach.[10] The lateral cul-de-sac is entered caudal to the caudal edge of the lateral patellar ligament and 5 cm proximal to the tibial condyle. The medial femorotibial compartment is entered over the medial tibial condyle between the medial patellar ligament and the medial collateral ligament. A small outpouching of the joint capsule may be palpated. The lateral femorotibial compartment is best approached just cranial or caudal to the long digital extensor tendon, and close to the tibial plateau. Less space is available between the meniscus and the joint capsule in the latter approach, so the former is preferred. An improvement in lameness can be expected in 30 minutes, but the clinician is wise to allow at least 1 hour for the final assessment.

A number of conditions causing lameness in the stifle respond incompletely or not at all to intra-articular analgesia. Horses with medial collateral ligament injuries may be unaffected. Horses with subchondral bone cysts in the medial femoral condyle show a variable response, ranging from resolution of lameness to little change, and analgesia can take much longer to take effect. Horses with conditions that cause severe lameness are often only partially improved by analgesia; these conditions include infections; fractures, particularly patellar and tibial crest fractures; advanced osteoarthritis; and severe cruciate and meniscal tears.

IMAGING CONSIDERATIONS

Radiography

Although many stifle injuries are not associated with detectable radiographic changes, radiography is usually the first imaging mode to be employed once the site of lameness has been established. An x-ray machine capable of producing

at least 90 kV and 20 mAs is required. In larger horses adequate definition will only be achieved with even higher-powered x-ray generators. Fast-screen film combinations can be used particularly for caudocranial views. Using as slow a combination as possible is always worthwhile, commensurate with safe practice, to achieve the best definition on the radiograph. Large cassettes are necessary and should preferably be held in a cassette holder with a long handle. Because of the difficulty of aligning the cassette perfectly in the standing horse, using a grid is impractical, although one can be used if the horse is anesthetized. Many horses dislike having cassettes placed close to the stifles, so great care must be taken with this procedure. If any doubt exists about the horse's temperament, the horse should be sedated.

Five standard views are most commonly used: lateromedial, flexed lateromedial, caudocranial, caudolateral-craniomedial oblique, and cranioproximal-craniodistal oblique (skyline).[1]

Lateromedial View

The horse should be standing naturally for this view. The x-ray beam is directed perpendicular to the stifle. The stifle is naturally rotated slightly laterally in most horses, which predisposes to the beam being directed from too far cranially. The x-ray beam should pass just proximal to and parallel to the tibial plateau. The landmark on which to target the x-ray beam is the lateral condyle of the tibia. The cassette has to be pushed as proximal as possible, which can be difficult in a well-muscled horse. In a well-positioned x-ray the femoral condyles are superimposed on each other.

Flexed Lateromedial View

The limb is held in the farrier's position with the tibia parallel to the ground. If the stifle is held with its axial plane vertical, directing the x-ray beam perpendicular to the joint is easier. The same landmarks are used as for the standing lateromedial view. When the x-ray beam is correctly positioned, the femoral condyles are superimposed. The flexed view reveals a greater area of the medial intercondylar eminence of the tibia and the cranial part of the femoral condyles and also allows more complete imaging of the patella.

Caudocranial View

The caudocranial view requires relatively high exposure factors. A key feature for correct positioning is the angle of the tibia, because the x-ray beam should be perpendicular to the tibia. Placing the horse in its natural stance or with the limb slightly caudal to the contralateral limb facilitates correct alignment. The x-ray beam should divide the limb in the caudocranial plane and pass just proximal to the level of the lateral tibial condyle. The natural lateral rotation of the stifle should also be taken into account. Thus the x-ray beam is usually aimed craniodistally and craniolaterally and meets the caudal musculature of the thigh surprisingly proximally. The correct view defines the femorotibial joint spaces and clearly images the intercondylar eminence of the tibia within the supracondylar fossa of the femur.

Caudal 30° Lateral-Craniomedial Oblique View

For the caudal 30° lateral-craniomedial oblique view the x-ray beam is directed 30° from the caudocranial plane and slightly from proximal to distal, so that it crosses parallel to the tibial plateau, which it should bisect. The main value of the view is imaging the lateral femoral trochlea, with the advantage of highlighting the medial femoral condyle, and it can be used to screen for osteochondrosis lesions and subchondral cystic lesions.

Cranioproximal-Craniodistal Oblique View

The cranioproximal-craniodistal oblique view is a skyline view of the patella and femoral trochlear ridges and may be the only view on which a patellar fracture may be seen. In a standing horse the limb is held in the farrier's position with the tibia horizontal. The x-ray beam is aimed along the articular surface of the patella, but it may be impeded by the horse's flank. Twisting the metatarsal region medially, which rotates the stifle laterally, sometimes allows better access to the patella. The cassette is held along the cranial proximal aspect of the tibia, and the x-ray beam is directed almost vertically. Checking the position of the patella on a previous flexed lateromedial view helps to decide on the correct beam angle. In an anesthetized horse the leg is flexed with the horse in dorsal recumbency and the x-ray beam is directed from distal.

The contours of the femoral trochlear ridges and the patella are irregular in young foals. In most foals this irregularity is present up to 11 weeks of age, and in 45% of foals, up to 25 weeks.[11] In foals older than 5 months of age, irregularity of the femoral trochleas is abnormal. Irregularity of the femoral or tibial condyles is abnormal at any age.

Ultrasonography

A significant proportion of stifle lameness is caused by soft tissue damage, so ultrasonography has a potential diagnostic role in defining the injury and has several advantages over other imaging diagnostic techniques. At present ultrasonography is the only method of assessing soft tissue injury in the stifle in a standing horse. The disadvantages are that ultrasonography requires experience to be used effectively and a good-quality ultrasound scanner with a sector and a linear array transducer is necessary. Transducer frequencies of 7.5 and 5 MHz are needed to image the cranial aspect of the stifle, but a 3-MHz transducer is required to image the caudal part of the stifle.[12-14] When it becomes available, magnetic resonance imaging is likely to be a superior imaging technique for soft tissues of the equine stifle.[15]

Ultrasonography can be valuable for differentiating joint capsule distention from extra-articular swelling. Soft tissue structures that can be imaged include the patellar ligaments, the menisci and the respective cranial ligaments, the collateral ligaments, the cranial and caudal cruciate ligaments, the meniscofemoral ligaments, the long digital extensor tendon of origin, and the popliteal tendon. The articular cartilage and bony outline of the femoral trochlear ridges and the cranial and caudal one third of the femoral condyles may also be imaged.[12-14]

The patellar ligaments and the collateral ligaments can be imaged longitudinally and transversely with a 7.5- to 10-MHz linear array transducer with the horse weight bearing. The middle patellar ligament is the most obvious of the three and is a useful landmark. The menisci can also be imaged with this transducer from caudal to the medial and the lateral patellar ligaments. They appear as wedge-shaped structures of moderate echogenicity with the base of the wedge closer to the transducer. The cranial ligaments of the menisci are more easily imaged with a small convex array or sector transducer, which can be aimed more perpendicular to the meniscal ligaments and which can be more easily positioned between the patellar ligaments. The cruciate ligaments are difficult to image, because aligning the transducer perpendicular to the fibers of the ligament is difficult. Only a small length of ligament can be imaged at a time, which can make interpretation equivocal. Cruciate ligaments can only be viewed with the stifle flexed, using a convex array or sector scanner. From caudal a sector transducer is preferable for imaging the caudal cruciate ligament and the meniscofemoral ligaments and in large horses a 3-MHz transducer is necessary.[13]

Scintigraphy

Scintigraphy has been used on horses for more than 20 years, but little published evidence assesses its specificity and sensitivity for conditions of the stifle. For most stifle conditions scintigraphic findings are variable, and although positive findings are obviously helpful, negative findings can also add useful information. The significance of any scintigraphic result should be confirmed as exhaustively as possible by other tests, particularly diagnostic analgesia, because false-positive results

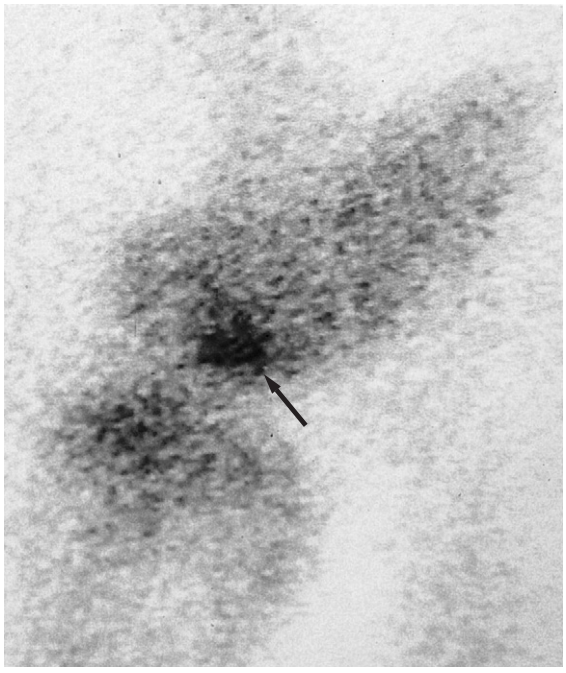

Fig. 47-1 Lateral delayed (bone) phase scintigraphic image of the left stifle of 9-year-old Thoroughbred cross gelding. There is focal increased radiopharmaceutical uptake in the distal femoral condyle *(arrow)*. A subchondral bone cyst in the medial femoral condyle thought to be causing lameness was seen radiographically.

also occur. In the normal adult stifle the caudal tibial epiphysis often has highest uptake of radiopharmaceutical.

Nuclear scintigraphy is most consistently valuable in diagnosing incomplete fractures or avulsions associated with the stifle.[16] However, although positive results may be obtained within 24 hours of injury, in some horses at least 3 days must elapse before significant increased radiopharmaceutical uptake occurs. Subchondral cystic lesions that are causing lameness may be scintigraphically positive or negative (Fig. 47-1). The lesions are more likely to be detected in older horses, using a caudal view, than in an immature horse with high background activity. Absence of radiopharmaceutical uptake was thought to be due to osteoclasts being the dominant cells in certain stages of the condition.[17,18] Although scintigraphy has been used to assess osteochondrosis in people,[19] bone scan findings are not well documented in horses. I have had positive and negative scintigraphic results associated with clinically significant osteochondrosis of the lateral femoral trochlea. Soft tissue injuries of the stifle are often scintigraphically negative, but in my experience increased radiopharmaceutical uptake can occasionally be encountered in these horses, especially in association with enthesopathy.

Scintigraphy is certainly a useful tool as a diagnostic aid for lameness in the stifle and can be useful for evaluating the bone activity of lesions. Occasionally horses may respond positively to intra-articular analgesia, but no significant abnormalities are found on radiography, ultrasonography, and arthroscopy. Increased radiopharmaceutical uptake in the stifle may be the only finding. Making a definitive diagnosis in these horses is difficult, although conceivably subchondral bone pain may be a possible cause of the lameness. One should bear in mind that many stifle conditions are negative scintigraphically. Conversely the joint may be scintigraphically positive when the cause of lameness is elsewhere in the limb.

ARTICULAR DISEASES

Femoropatellar Joint

Osteochondrosis

Osteochondrosis has been recognized in horses for 50 years and is an important cause of stifle lameness in young horses. The exact cause of the disease is still not well defined, but several factors are known to influence its development. Adequate dietary copper is important. Mare's milk is relatively low in copper, and because the foal relies on copper stored in its liver during late pregnancy, it will be deficient if the mare's diet contains insufficient copper. The zinc/copper ratio is also important, because zinc inhibits the absorption of copper.[20] Foals on high-energy diets are more prone to the disease.[21] Insufficient or excessive exercise and trauma may be factors that influence the development of the disease. Genetic factors may predispose to osteochondrosis in the hock of Swedish Standardbreds.[22] Large, fast-growing males are more susceptible. Osteochondrosis is most frequently seen in Thoroughbreds and Warmbloods. The lesions probably develop in the first 7 months of life,[23] but sometimes clinical signs may not be manifest until the horse is brought into work. In the sports horse this may be as late as 5 years of age or even older, when a mild to moderate lameness may develop as the horse begins more serious work. In my experience, surprisingly severe lesions can remain undetected until this time. Lesions are most commonly seen on the lateral trochlear ridge of the femur[24] but do occur on the medial trochlea, the intertrochlear groove, and the patella and are often bilateral.

Signs and diagnosis Osteochondrosis may be present asymptomatically. Lameness is often acute in onset and varies from a subtle gait deficit to marked lameness. Lameness is often more acute in onset and more severe in foals and young yearlings than in older horses. Distention of the femoropatellar joint capsule is often present and can be severe, especially in foals and yearlings. Gluteal muscle atrophy is seen in horses with severe lesions. Flexion tests are mostly positive. Synovial fluid may be hemorrhagic, but it is often normal. Intra-articular analgesia of the femoropatellar joint should improve lameness.

Radiographic changes include the following: no detectable signs; slight loss of contour or loss of outline of the lateral trochlear ridge; irregular defects in the trochlear ridge; radiopaque fragments within the defect (Fig. 47-2); round radiopaque bodies loose in the joint; and more rarely, irregularities on the patellar apex or the medial trochlear ridge.[1,25,26] Lateromedial and caudolateral-craniomedial oblique views are the most useful projections. Horses with radiographic lesions do not always show lameness.[25,27] Some horses have no detectable radiographic abnormalities, but osteochondrosis lesions are diagnosed on arthroscopic examination. Lesions without fragmentation in young foals may resolve with time[25] but many progress.[26]

Treatment Conservative management, with confinement and correction of dietary imbalances, or arthroscopic debridement of the lesions are the main treatment options. Conservative management is appropriate for horses with mild lesions. Because of the insensitivity of radiographic evaluation of osteochondrosis lesions, an argument can be made for arthroscopic examination of most horses with radiographic lesions or persistent femoropatellar effusion and lameness that fails to respond to conservative treatment.[27] Arthroscopic examination would ensure that radiographically silent cartilage lesions are treated effectively. Osteoarthritis can also be evaluated. For horses with fragmentation and significant subchondral bone lysis, arthroscopic surgery is probably the treatment of choice.[24] In my opinion more caution is required when treating foals arthroscopically, because some foals with large radiographic lesions are found to have intact cartilage at arthroscopy. Debridement of such lesion can leave a large

Fig. 47-2 Lateromedial radiographic view of the femoropatellar joint of a yearling Thoroughbred colt. There is a large irregular defect in the subchondral bone of the lateral trochlear ridge containing several radiopaque fragments.

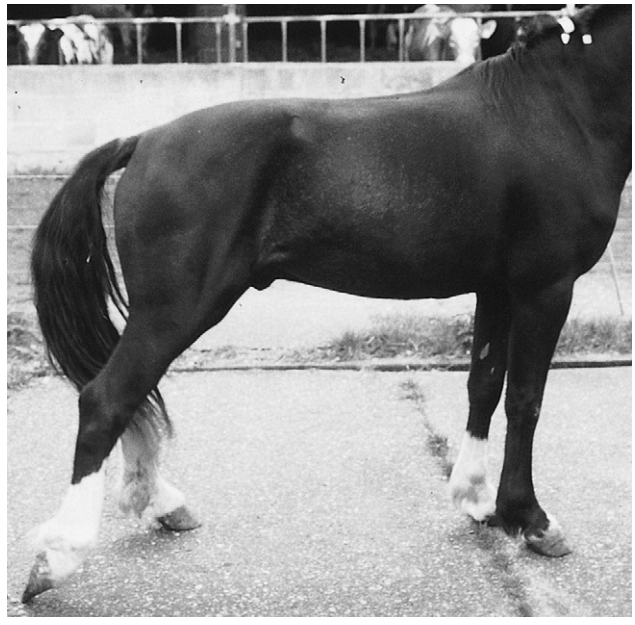

Fig. 47-3 Three-year-old Welsh Cob gelding with the typical stance of upward fixation of the patella in the right hindlimb.

deficit in the lateral trochlear ridge. Leaving the lesions intact may be preferable, because some healing may take place. If the clinical signs are persistent, these horses should be re-examined arthroscopically at a later date.

A variety of lesions are seen arthroscopically. The articular cartilage may appear intact, but if probed, large flaps may lift from the subchondral bone. Large defects on the lateral trochlear ridge may contain nodules of mineralized cartilage, which are readily removed, and often large tufts of fibrillated cartilage are associated with the lesion. The exposed subchondral bone is frequently soft and crumbly. Extensive areas of fibrillated cartilage over the adjacent lateral trochlear ridge and the opposing patella are often present in older horses.[5] Loose cartilage should be removed and the lesion should be curetted to healthy subchondral bone, which is a source of pluripotential cells. The cartilage perimeter should be vertical to allow better attachment of tissue regrowth.[28] A thorough lavage to remove all debris at the completion of surgery is essential. Postoperatively 6 weeks of stable rest with daily hand walking after 2 weeks is recommended. The horse should then be left for another 4 to 5 months at pasture before returning to work.

Prognosis Mild lesions in foals have been shown to heal with conservative management.[25] For more severe lesions better results have been reported with arthroscopic debridement.[24] Sixty-four percent of 161 horses were able to perform athletically. In this series, treatment of horses with mild to moderate lesions and treatment of older horses was most successful, which has also been the experience in my practice. The presence of extensive secondary articular cartilage fibrillation did not have a significant effect on the outcome in horses more than 2 years of age.[5]

Upward Fixation of the Patella and Delayed Patellar Release

Upward fixation of the patella occurs when the stifle subtends an angle of approximately 145° and the medial patellar ligament hooks over the medial trochlea of the femur, thus locking the reciprocal apparatus with the limb in extension. The condition is more common in horses with a straight hindlimb conformation with a stifle angle nearer 140° (in the normal horse the angle is about 135°), so that only a small degree of extension is required for upward fixation to occur.[29] Upward fixation is not a luxation of the patella, despite being commonly described as such. Predisposing straight hindlimb conformation or the condition itself may be hereditary.[30] Upward fixation of the patella is more commonly seen in young horses and ponies, especially if they are in poor condition, when weak thigh musculature fails to release the patella. Upward fixation can occur in older animals after trauma to the stifle region, is most frequently manifest when the affected horse is stabled, and sometimes occurs in fit horses that are suddenly given box rest. Lameness may develop in horses with more severe or long-standing lesions. I recognize delayed patellar release as a condition in which delayed release of the patella occurs, without complete upward fixation, and which presumably is a less severe form of the disease.

Signs and diagnosis A horse with upward fixation of the patella stands with the hindlimb locked in extension with the fetlock flexed (Fig. 47-3). The leg releases with a snap, usually unaided, but occasionally the horse needs assistance. Some horses merely show intermittent delayed release of the patella, especially when turned toward the affected limb. This can be mistaken for stringhalt. Delayed patellar release is manifested by a catching of the patella as the limb is protracted, usually as the horse moves off. Delayed release of the patella may be evident as a rather jerky movement of the patella when the horse moves over in the stable or as it decelerates from canter to trot or trot to walk. Horses in which the condition is chronic develop stifle soreness and may be resistant to work, especially in deep going. If the condition is more serious, horses try to avoid extending the hindlimbs while walking uphill or downhill. Femoropatellar joint distention may be present. Diagnosis may depend on the history and the owner's description if the horse does not lock the patella during the examination. Locking the patella manually may be possible by pushing it proximally, although this can be difficult and is resented by many horses. A careful search should be made for concurrent stifle disease such as osteochondrosis or soft tissue injury, and the site of any lameness should be confirmed by diagnostic analgesia. X-ray examination of both stifles is prudent, because any pathological condition caused by upward fixation or concurrent with it affects treatment and prognosis.

Treatment For a horse that has the patella locked, pushing the patella medially and distally and backing the animal is recommended but difficult to do. Pulling the limb forward with a side line may provide relief. If the upward fixation of the patella is intermittent and not causing lameness, a conditioning program should be undertaken. This includes an exercise regimen, the administration of anthelmintics, an increased plane of nutrition, and dentistry as appropriate for each horse. The exercise regimen depends on the specific circumstances for each horse. Daily lunging should be instituted to a level that is appropriate for the age and type of horse. Stable rest is usually contraindicated, and turning the horse out to pasture as much as possible is preferable. Immature horses should be allowed time to outgrow the problem. Injection of counter-irritants containing iodine into the medial and middle patellar ligaments has been used at this stage of the disease.[31] Delayed patellar release requires the same management.

Because of potential complications, which include fragmentation of the patella and lameness, surgery is only indicated when the following criteria have been fulfilled:

1. Upward fixation of the patella persists despite an appropriate conditioning program.
2. Lameness has developed because of the disease.
3. The condition in an immature horse does not resolve as the animal matures.

The surgery can be performed under local anesthesia in the standing horse.[32] A small incision is made over the distal part of the medial patellar ligament. I find that minimizing the incision length seems to reduce the incidence of postoperative swelling. A curved Kelly forceps is then advanced caudally under the ligament, developing a path for a blunt-ended bistoury. The bistoury is passed until its end can be palpated caudal to the medial patellar ligament, before the ligament is severed close to its tibial insertion. Stringent asepsis should be observed. Once the ligament is severed, the border of the tendon of the sartorius muscle is palpable caudally. Some surgeons prefer to perform this surgery with the horse under general anesthesia, which allows for complete asepsis: the ligament can be exteriorized before severing, and the fascia overlying the ligament can be sutured before skin closure.

Postoperatively I prefer to confine the horse for 2 months to allow the patella to settle in its new position in the intertrochlear groove. Hand walking can be introduced during the second month.

Prognosis A substantial number of horses respond to conservative treatment. Occasional recurrences happen if the horse has enforced stable rest, but many grow out of the condition. After surgery and in the absence of degenerative changes in the joint, the horse should return to normal use, although some appear to have a slightly restricted gait. Recurrence of the condition is unusual. Some fibrous thickening is palpable at the surgical site for many years in most horses and indefinitely in some horses. Significant complications including lameness, local swelling, fragmentation of the patella, and even fracture of the patella have been reported[33-36] and have also been produced experimentally. If fragmentation causes lameness, it can be treated arthroscopically with good results.[33] In my experience up to 30% of horses have minor fragmentation of the patella, without clinical signs, after medial patellar desmotomy.

Fragmentation of the Patella

This condition is generally considered to be a sequel to medial patellar desmotomy or to be associated with upward fixation of the patella, and it is manifested by fragmentation of cartilage and bone off the apex of the patella.[33,36] This condition is not chondromalacia of the patella, which could be a form of osteochondrosis, and has not been specifically reported in horses. If the condition follows desmotomy, clinical signs can appear from 3 weeks to more than 12 months postoperatively. Horses can develop fragmentation within a few weeks of surgery without clinical signs.[5] A medial patellar desmotomy has been performed experimentally in 12 horses, and eight of these developed fragmentation.[36] The lesions may be caused by instability of the patella after medial patellar desmotomy.

Signs and diagnosis Lameness varies from a stiff hindlimb action to an obvious lameness. Flexion is resented and worsens the lameness. Synovial effusion is common and excessive fibrous tissue reaction may be present at the surgical site. Radiographically, small bone fragments are present close to the apex of the patella (Fig. 47-4), often combined with subchondral bone lysis and roughening or spurring of the cranial surface of the patellar apex.

Treatment Arthroscopic debridement is indicated. The lesions are most commonly on the lateral surface of the apex and may be partly obscured by synovial villi, so a careful arthroscopic examination should be performed before deciding on the site of the instrument portal. Debridement of the lesion to healthy subchondral bone is required.

Prognosis The prognosis for athletic function is reasonable, although some horses anyway appear to have a slightly stiff hindlimb action after medial patellar desmotomy. Ten of 15 horses returned to athletic use.[33] In my experience the incidence of the condition has decreased in the last 8 years, which may be because fewer patellar desmotomies are being performed or because more care is taken during convalescence.[5]

Luxation of the Patella

Lateral luxation of the patella in the foal is considered to be an inherited condition caused by a recessive gene.[37] Luxation in the adult is likely to be traumatic in origin.[38] Because the medial trochlear ridge is larger, only severe trauma induces medial displacement. Hypoplasia of the lateral trochlea is often present,[39] but the condition also occurs in foals with apparently normal conformation.[37] Luxation is most common in miniature breeds but has been reported in Standardbreds, Thoroughbreds, and an Arabian foal,[38-40] and I have seen it in a Welsh Cob.[5]

Signs and diagnosis The condition may be unilateral or bilateral and has been graded as follows:

- Grade 1: The patella can be manually luxated but readily reduces itself.
- Grade 2: The patella is usually in place but luxates intermittently.

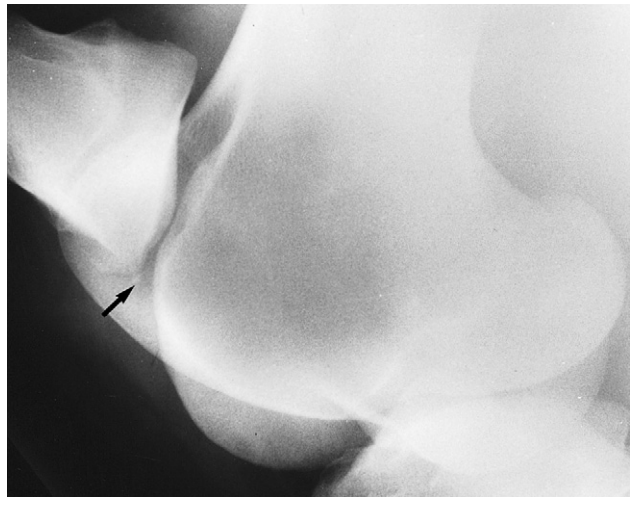

Fig. 47-4 Lateromedial radiographic view of the stifle of a 7-year-old Thoroughbred cross gelding that had previously had a medial patellar desmotomy to treat intermittent upward fixation of the patella. The apex of the patella is fragmented (*arrow*).

- Grade 3: The patella is usually luxated but can be manually relocated.
- Grade 4: The patella is continuously luxated and cannot be relocated.[39]

Severely affected foals are unable to extend the stifle and stand in a characteristic crouching position. If less severe, the condition may not be obvious clinically, but horses are usually reluctant to flex the stifle and have a stiff gait in the affected limb. Some horses show little evidence of the disease until degenerative changes provoke lameness. I have seen a Thoroughbred yearling with severe osteochondrosis of the lateral trochlear ridge, which led to a diminution of the ridge and allowed the patella to luxate laterally. Lateromedial, cranioproximal-craniodistal oblique, and caudocranial radiographic views are the most useful to ascertain the position of the patella and to evaluate the trochlear ridges.

Treatment Lateral release and medial imbrication of the femoropatellar compartment are necessary to maintain the patella in the intertrochlear groove.[38-40] Both lateral release and medial imbrication appear to be important. Recession sulcoplasty is valuable in the presence of hypoplasia of the lateral trochlear ridge of the femur.[40]

Prognosis Poor success can be expected with surgery in the presence of osteoarthritis and in larger horses. In foals there is a moderate prospect of achieving athletic function. Aggregating the results from the 3 case series mentioned, the patella maintained its position postoperatively in 8 out of 11 foals.[3,4] Breeding from affected animals should be discouraged.

Osteoarthritis

Any injury to the femoropatellar joint can potentially cause osteoarthritis. The injury could be simple trauma or result from any of the previously mentioned conditions if they have caused irreversible changes.

Signs and diagnosis The clinical signs depend on the cause and severity of the condition. Lameness is usually persistent, and chronic joint distention may be present. If osteochondrosis is responsible for osteoarthritis, radiographic changes typical of chronic osteochondrosis are likely to be present (see page 458). Cartilage fibrillation, ranging from focal tufting to widespread involvement of the trochlear or patellar articular cartilage, may be seen arthroscopically and full-thickness defects of the articular cartilage may be present in more severely affected horses.

Treatment Initially treatment depends on the inciting condition and is described in the appropriate sections. However, once chronic osteoarthritic changes have developed, realistically therapy is likely only to be palliative. Intra-articular medication with small doses of corticosteroids, such as 10 mg of triamcinolone acetonide combined with hyaluronan, may give temporary relief. A controlled exercise regimen may help, and in some horses an arthroscopic debridement prolongs working life.

Prognosis The femoropatellar joint is more forgiving than the femorotibial joints, and although osteoarthritis will not resolve, if mild it may be tolerated enough for a horse to perform useful work. More severely affected horses are unlikely to return to athletic use.

Distal Luxation of the Patella

One report of distal luxation of the patella has been made.[41] The horse had the affected limb flexed and non–weight-bearing. The patella was relocated with the horse under general anesthesia, and when the horse was re-examined 3 months later, no lameness was seen.

Patellar Ligament Injuries

Patellar ligament injuries are rare. Sprain of the middle patellar ligament is the most common, although lateral patellar ligament injuries also occur.[42] There may be an association between middle patellar desmitis and previous medial patellar desmotomy. Jumping horses are most commonly affected.

Signs and diagnosis Lameness can be severe in the acute phase but varies. Sometimes no localizing signs are apparent, but in some horses femoropatellar effusion, periarticular thickening, or edema are seen. Intra-articular analgesia of the femoropatellar joint may not affect the lameness. The diagnosis is confirmed by ultrasonography. Proximal, mid-body, and distal lesions have been identified. Radiographic changes are unusual and one should bear in mind that entheseous change on the cranial aspect of the patella may be seen as an incidental finding during radiography of the stifle. Scintigraphy may show increased radiopharmaceutical uptake in the patella or proximal tibia in association with proximal or distal lesions.

Treatment Horses with severe injuries may require rest for up to 6 months.

Prognosis Lameness is often slow to resolve and is recurrent in some horses.

Femorotibial Joint

Subchondral Cystic Lesions

The cause of subchondral bone cysts and other osseous cyst-like lesions is still unknown. The distal weight-bearing aspect of the medial femoral condyle is the most frequent site for subchondral bone cysts.[43] Osseous cyst-like lesions have been identified in the caudal femoral condyles in foals.[44] Osseous cyst-like lesions also occur in the proximal tibia. Lesions thought to result from osteochondrosis were in the lateral aspect of the tibia, and those associated with osteoarthritis were more common medially in a report of 12 horses.[45] Subchondral bone cysts and osseous cyst-like lesions may be a form of osteochondrosis,[46] but trauma is also probably an important factor. Subchondral bone cysts in the medial femoral condyle have been produced experimentally after development of full-thickness defects in cartilage and subchondral bone.[17] Lesions did not form if the defects were made only in cartilage. The lining of these lesions has been shown to contain active inflammatory enzymes that cause bone resorption.[47] In the literature the syndrome in the young horse is emphasized, but in my experience subchondral bone cysts and osseous cyst-like lesions occur in any age group, mostly apparent as a primary lesion but sometimes as a sequel to osteoarthritis.

Signs and diagnosis The condition is reported to be more common in horses under 4 years old,[43] but in my practice is encountered in horses of all ages.[5] Lameness is mild to moderate but can be severe at first and acute in onset. Lameness may be intermittent, especially in older horses. Affected horses seem to be lamer when turning. Occasionally mild medial femorotibial effusion occurs, but often no signs are obvious on physical examination. Intra-articular analgesia of the medial femorotibial joint may be required to diagnose the site of pain causing lameness. Because the subchondral bone is probably the site of pain, local anesthetic solution must diffuse into the lesion and may not be completely effective. A 50% improvement in lameness justifies radiography.

The caudocranial, caudolateral-craniomedial oblique, and flexed lateromedial radiographic views are the most useful for demonstrating the lesion. Subchondral bone cysts in the medial femoral condyle are relatively round or oval, with a variably sized base and communication with the joint (Fig. 47-5). A sclerotic rim is usually seen only in horses with older lesions. Radiographic signs of osteoarthritis may also be apparent in some horses. The osseous cyst-like lesions in the tibia have a similar morphology. Subchondral bone cysts can also occur as incidental radiographic findings in sound horses. Lesions in the caudal femoral condyles in foals may appear as localized or extensive osseous defects on radiography. Scintigraphic findings in horses with subchondral bone cysts are inconsistent,[17] but in some horses the lesions are clearly depicted. Flattening or indentation of the distal medial femoral condyle is sometimes seen radiographically and may be a precursor of a

Fig. 47-5 A caudocranial radiographic view of the right stifle of a yearling Thoroughbred colt. Medial is to the left. There is a subchondral bone cyst in the medial femoral condyle with a sclerotic rim and a wide base that communicates with the medial femorotibial joint.

subchondral bone cyst. These lesions are relatively common and frequently do not cause lameness. Occasionally increased radiopharmaceutical uptake is seen in these defects.[5] In my experience positive scintigraphic findings, together with a positive response to diagnostic analgesia, are good indications that the defect is a cause of lameness, but some scintigraphically positive lesions do not result in clinical signs, although the Editors consider this unusual.

Treatment Conservative treatment involves stable or pasture rest, with or without non-steroidal anti-inflammatory medication or intra-articular corticosteroids.[48,49] Horses with non-articular osseous cyst-like lesions or small articular defects are probably best treated conservatively. If the horse does not respond to conservative treatment, and for articular lesions, arthroscopic debridement is indicated.[43,46,50] Debridement of the cyst lining and removal of all debris from the joint is the goal. Experimentally the use of cancellous bone grafts did not improve the outcome.[51] Postoperative intralesional corticosteroid has been advocated to suppress the inflammatory mediators.[47] Subchondral bone forage is contraindicated, because reports indicate that it may worsen the lesion.[43] Debridement of small medial condylar defects should be approached with caution, because this may provoke a worsening of the lesion. Tibial osseous cyst-like lesions can be debrided arthroscopically, but many of them lie beneath the cranial meniscal ligament, which must be divided to gain access.

Prognosis A 50% success rate has been reported with conservative treatment of horses with medial femoral condylar subchondral bone cysts, but remodeling of bone may be more prolonged than with surgical treatment.[48] Arthroscopic treatment carries a 70% to 75% success rate in horses under 3 years old.[43,50] An assessment of the results in older horses is required. Improvement of clinical signs after surgery frequently occurs without radiological resolution. Limited reports of surgical treatment of tibial osseous cyst-like lesions[45] suggests that the lateral osteochondrosis associated lesions may respond best, and this is also my experience.

Meniscal and Meniscal Ligament Injuries

The cause of meniscal injuries in horses is not well documented, but in dogs meniscal injuries are considered to be caused by crushing forces combined with tibial rotation and flexion or extension of the stifle.[8] A few reports of the condition in horses have been published.[52-55] At my hospital 55 meniscal injuries in 52 horses have been diagnosed arthroscopically as the primary cause of lameness. The medial meniscus was affected in 75% of horses. The cranial ligaments of the menisci were involved in nearly all horses.[56] Concurrent injury to other structures in the stifle was diagnosed in 44 of 55 horses and included articular cartilage damage on the femoral condyles in 26 horses, cruciate injury in 9 horses, cartilage lesions on the medial intercondylar eminence of the tibia in 7 horses, and disruption of the long digital extensor tendon of origin in 4 horses. Secondary medial collateral ligament injury was not diagnosed. Primary medial collateral ligament rupture with secondary meniscal injury was not included in the series. Twenty-seven of 79 other horses that were examined arthroscopically and that had other stifle injuries, but no evidence of meniscal damage, did have fibrillation of the axial borders of the cranial ligaments of the menisci.[52] The significance of this is uncertain.

Signs and diagnosis Lameness is often acute and severe in onset after trauma but mostly becomes low grade and persistent. Distention of the femoropatellar or medial femorotibial joints can be expected in 66% of horses. Lameness is exacerbated by flexion of the limb in about 90% of horses.[55] Diagnostic analgesia is usually necessary to confirm the site of pain causing lameness but may not render the horse completely sound. Radiographic signs occur in about 55% of horses. New bone formation on the cranial aspect of the medial intercondylar eminence of the tibia is the most frequent finding (33%)[56] and appears to be more common with meniscal than cruciate ligament disease[55] (Fig. 47-6). Dystrophic mineralization and osteoarthritic changes may be seen in severe lesions. Ultrasonography demonstrates some of the more severe lesions.[57]

Arthroscopy offers the best chance of a definitive diagnosis and an assessment of concurrent damage. Because only the cranial and caudal poles of the menisci can be seen, assessment of meniscal injury is limited. Owing to these limitations, I graded changes visible from cranially as follows:

1. Tears extending longitudinally from the cranial ligament into the meniscus, with minimal separation
2. Tears involving the cranial pole in which the extent of the injury is visible (Fig. 47-7)
3. Severe tears that extend beneath the femoral condyle and that cannot be completely assessed or debrided.[55]

An injury of a caudal meniscal pole would require further classification but has not been reported.

Treatment Horses with acute stifle injuries that have no definitive diagnosis should be managed with rest and anti-inflammatory medication, followed by controlled exercise. Arthroscopy is indicated if conservative therapy is unsuccessful or for severely lame horses. Grade 1 meniscal tears can only be superficially debrided. Intra-articular suturing for some horses may be a way forward. Grade 2 and 3 tears are debrided as effectively as possible by removing all loose tissue. A careful assessment of visible concurrent damage should be made. Postoperatively controlled exercise begins at 2 to 3 weeks and can gradually be increased over 3 months, depending on progress and the extent of the injury. Free exercise at pasture should be avoided for 6 months.

Prognosis Return to full athletic use can be expected in about 50% of horses overall, though improvement may be seen in another 10%.[55,56] Full function was regained in 54% of 28 horses with grade 1 tears, 50% of 14 horses with grade 2 tears, 25% of 8 horses with grade 3 tears, and neither of

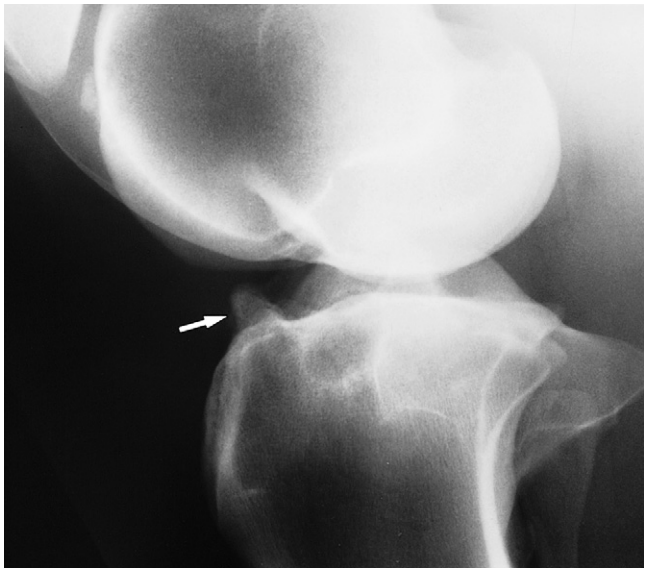

Fig. 47-6 Lateromedial radiographic view of the left stifle of a 7-year-old Thoroughbred cross gelding. There is new bone on the cranial aspect of the intercondylar eminences of the tibia (*arrow*). Note also the large lucent zone in the proximal tibia. There is an old osteochondrosis lesion involving the lateral trochlear ridge of the femur. Arthroscopic examination revealed a tear of the medial meniscus.

Fig. 47-7 Arthroscopic view of the left lateral femorotibial joint of 6-year-old eventer gelding. The lateral meniscus has a grade 2 tear *(arrow)*.

2 horses with two menisci affected. Concurrent articular cartilage damage appeared to worsen the prognosis, and only 3 of 8 horses with concurrent cruciate ligament injury became sound. Horses treated arthroscopically within 2 months of injury fared 25% better than those treated later than 2 months.[56] If radiographic signs of osteoarthritis were present, the prognosis was poor and only 1 of 4 horses with dystrophic mineralization improved after arthroscopy.

Cranial and Caudal Cruciate Ligament Injuries

In the dog the cranial cruciate ligament can be injured when the stifle is in hyperextension, or after sudden rotation with the stifle in flexion,[8] and this is likely to pertain to the horse. Direct trauma to the joint or degenerative change in the ligament can also lead to cruciate injury in the horse.[5,58] Experimentally[59] and in my clinical experience[5] the cranial cruciate ligament fails most frequently at mid-body level, but avulsions of its tibial and less often of its femoral attachments have been reported.[58,60] Caudal cruciate ligament injuries occur less frequently.[61] Concurrent injuries, including damage to the medial collateral ligament, the menisci, and articular cartilage, are often associated with cruciate tears.[58,62]

Signs and diagnosis Lameness is often associated with a history of trauma and is usually acute in onset and severe at first. Distention of the femoropatellar or the femorotibial joints is sometimes present. In severe injuries crepitus may be detectable. The cruciate draw test appears to be valueless in the conscious horse, but the flexion test is usually positive, especially with severe injury. With mild injuries diagnostic analgesia is required to confirm the site of pain causing lameness. In my series of 48 horses with cranial and caudal cruciate ligament injuries diagnosed at arthroscopy, radiographic signs included the following[5]:

- No changes in at least 50% of horses.
- Fracture of the intercondylar eminence of the tibia; however, this can occur without significant cruciate injury.
- New bone formation cranial to the intercondylar eminence of the tibia. This finding was three times more common in horses with meniscal injuries than those with cruciate ligament injuries in my series.
- Bony resorption or fragmentation at the femoral attachment of the cruciate ligaments.
- Cranial displacement of the tibia with cranial cruciate ligament rupture.
- Osteoarthritis, or mineralization of the ligament, associated with chronic lesions.

Ultrasonographic evaluation of the cruciate ligaments is difficult. Arthroscopy offers the best evaluation of the cruciate ligaments. The cranial cruciate ligament is covered by the median septum, which may make the ligament difficult to assess, but the septum is often disrupted in cranial cruciate ligament injury. Motorized debridement of the septum may be required to see the ligament. The caudal cruciate ligament is viewed from the cranial and caudal aspects of the medial femorotibial joint. Mild cranial cruciate ligament changes are difficult to quantify because of inflammatory changes in the median septum, but fiber disruption is seen in moderate injuries (Fig. 47-8). With acute, severe injuries of the cranial cruciate ligament, inflammatory debris must be removed before the torn ends of the ligament can be seen. Concurrent articular cartilage or meniscal damage within the joint is common.

Treatment With acute injuries the same treatment criteria apply as for meniscal injuries. The indications for arthroscopy and for postoperative management are also similar. Arthroscopic debridement is best performed with a motorized synovial resector. Repair of complete cruciate ligament rupture has not been reported in horses, and the best treatment that can be offered is good debridement of loose tissue to allow less severe injuries the best chance to heal.

Prognosis Prognosis is poor in horses with moderate to severe injuries. In one report, 2 of 10 horses were pasture sound and 1 raced,[58] and in another report 2 of 6 were pasture sound.[62] In my series lameness persisted in 4 horses with severe injuries; 6 of 17 horses with moderate injuries became sound and 21 of 27 with minor superficial changes became sound.[5]

Collateral Ligament Injuries

Injury of the medial collateral ligament is more frequently diagnosed than injury of the lateral collateral ligament. Such injury is associated with acute trauma, which, as in the dog, probably involves a medial or lateral force on the joint or distal limb.[62] Concurrent injury of the menisci or cruciate lig-

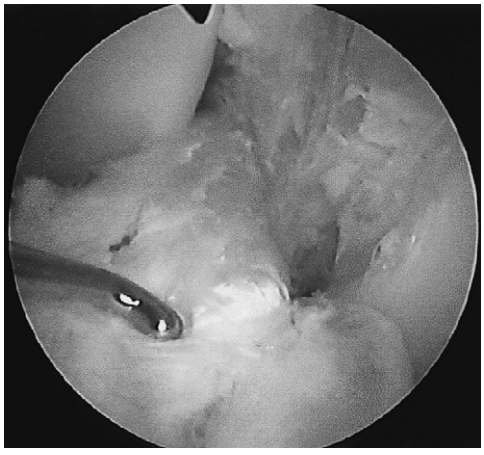

Fig. 47-8 An arthroscopic view of the right femorotibial joint of an 8-year-old Warmblood gelding. The median septum has been removed with the motorized synovial resector to reveal a chronic, low-grade fiber disruption of the cranial cruciate ligament.

aments commonly occurs in horses with severe injuries,[62,63] but not necessarily in those with more moderate injuries.

Signs and diagnosis The most easily diagnosed collateral ligament injuries are complete ruptures of the medial collateral ligament, which manifest as an acute, severe lameness after trauma. Instability of the stifle occurs with swelling and pain over the ligament. Sprains of the collateral ligaments are less obvious. Heat and pain may be palpable and chronic thickening develops in some horses. The collateral ligament test can be useful but is not specific. Flexion of the limb is usually painful, but intra-articular analgesia of the medial femorotibial joint may be negative. If complete rupture of the ligament has occurred, stressed caudocranial radiographs are diagnostic. Widening of the joint space occurs on the affected side (Fig. 47-9). Entheseophyte formation at the origin and insertion may be seen in chronic injuries. Ultrasonography can be helpful in diagnosing and assessing the injury.

Treatment Horses with mild sprains, in which no instability occurs, are treated with stall rest for 6 weeks and anti-inflammatory medication until the inflammation subsides, followed by controlled exercise for another 6 weeks. One report describes the repair of a complete rupture of the medial collateral ligament using braided polyester material attached to two 6.5-mm cancellous screws in the femur and tibia to stabilize the joint.[64] Orthopedic wire was originally used, but it dislodged postoperatively. The surgery is a salvage procedure and is not well documented, and concurrent injury and patient compliance should be carefully assessed before undertaking surgery.

Prognosis Horses with mild sprains have a moderate chance of returning to athletic use, depending on the extent of any concurrent injury. Results are not well documented, and in my view the prognosis is probably poor if entheseous change develops at the medial collateral ligament attachments. The prognosis for complete ruptures is grave. The horse described above that was treated surgically became lame after falling 9 months postoperatively, but it had been comfortable at pasture until then. Because associated meniscal or cruciate injury is common, a high chance exists of osteoarthritis in the long term, even if the medial collateral ligament heals.

Articular Cartilage Trauma

Articular cartilage defects on the medial or lateral femoral condyles or on the axial part of the tibial plateau are frequently encountered during arthroscopic examination. Usually they accompany other femorotibial injuries, but occasionally they are the only finding, in which case they may be considered the primary cause of lameness.[65] Cartilage lesions were diagnosed as the primary cause of lameness in approximately 25% of horses undergoing diagnostic arthroscopy of the stifle in my series.[5] Primary lesions may be seen on both the medial and lateral femoral condyles.

Fig. 47-9 Stressed caudocranial radiographic view of the left stifle of 10-year-old riding horse with rupture of the medial collateral ligament of the femorotibial joint. Medial is to the right. There is widening of the medial joint space. Note also the osseous opacity proximal to the intercondylar eminences (*arrows*).

Signs and diagnosis Horses in which articular cartilage lesions are a primary cause of lameness usually have mild to moderate lameness. Diagnostic analgesia is required to define the site of pain. Abnormalities are rarely seen radiographically. At arthroscopy a variety of lesions may be present. These include thickening, softening, and creasing of the cartilage, widespread fibrillation, focal tufts of fibrillated cartilage, circumscribed nodules of cartilage, apparent tears of the articular surface, and areas of exposed subchondral bone.[56,65,66]

Treatment Doubt about the long-term effect of debridement of cartilage lesions still exists.[67] Small, full-thickness lesions are probably best debrided to subchondral bone; micropicking the bone appears to improve healing to a degree.[68] The effect of smoothing partial thickness defects is still controversial and may provoke the development of an osseous cyst-like lesion.[43,67] Debris should be thoroughly lavaged from the joint.

Prognosis The prognosis for return to soundness for horses with cartilage defects is generally guarded. Six of 7 horses with focal defects returned to racing, but 5 horses with larger lesions remained lame.[65] In my practice a full-thickness articular cartilage defect was diagnosed arthroscopically in 17 horses as being the primary cause of lameness. Five of 8 horses for which follow-up information was available became sound.[5] Of 16 horses in which generalized articular cartilage fibrillation was the cause of lameness, 7 of 8 horses for which follow-up information was available became sound.

Osteoarthritis

Osteoarthritis of the femorotibial joint can be a sequel to any injury described in this chapter that has the potential to damage the articular cartilage. Osteoarthritis is likely to develop when the initial tissue damage is severe, is not treated, or is treated ineffectively.

Signs and diagnosis Many horses have a history of lameness that has already been treated or chronic lameness of varying intensity. Diagnostic analgesia may be required to identify the site of pain, but in many horses joint effusion and thickening are palpable on the medial aspect of the joint. Flexion of the limb is painful and some horses resent holding up the limb for shoeing. Radiography reveals typical changes associated with osteoarthritis, including osteophytosis, flattening of the articular surfaces of the femoral condyles, sclerosis and lucent zones in the subchondral bone, narrowing of the joint space, and dystrophic mineralization of soft tissues.

Treatment Management of osteoarthritis is at best palliative. If possible, the inciting lesion should be treated appropriately in an attempt to prevent worsening of the changes. Intra-articular corticosteroids or glycosaminoglycans, and in some horses arthroscopy, may give temporary relief.

Prognosis Once radiographic changes of osteoarthritis are manifest, the prognosis for athletic soundness is poor. With careful management less severely affected horses may be able to perform light work or be kept at pasture.

Fractures Involving the Stifle

Fractures of the Patella

External trauma is the commonest cause of patellar fracture in the horse.[69] Contraction of the quadriceps muscles may be the cause of some avulsion fractures. The majority of horses have a history of direct trauma, such as a kick, or an impact on the stifle by hitting a fixed fence while jumping. If the trauma occurs while the stifle is in flexion, the patella is fixed against the trochlear ridge of the femur, which is thought to render it more vulnerable to fracture.[70]

A variety of fracture morphology is seen.[70,71] Sagittal fractures of the medial aspect of the patella are probably the most frequent. These are usually articular and the fragment often involves a significant area of the attachment of the parapatellar fibrocartilage of the medial patellar ligament. Fragmentation of the base of the patella sometimes accompanies these fractures[69] or may be seen separately. Non-articular fractures are mostly seen as mildly displaced fragments on the cranial aspect. Complete horizontal fractures are severe injuries, and the massive forces exerted by the extensor muscles have a significant bearing on their management. Complete sagittal fractures are less catastrophic because the distracting forces are not as strong. Comminuted fractures of the whole body of the patella occasionally occur after severe trauma.

Signs and diagnosis The history and clinical signs often strongly suggest the possibility of patellar fracture. Initially lameness may be severe and remains so in horses with midsagittal and horizontal fractures. In horses with many of the smaller avulsion fractures, or fractures of the medial aspect, lameness becomes moderate to mild after a few days. Often evidence of trauma and local swelling are apparent in the stifle region. Crepitus is occasionally present, and pain may be elicited on palpation of the patella. The femoropatellar joint is usually distended. Horses with chronic, less severe fractures often have surprisingly little direct evidence of the injury. Flexion of the limb is usually painful.

Radiography is essential to confirm the diagnosis and to evaluate the fracture. Lateromedial views may give no indication of the fracture, so a cranioproximal-craniodistal view is essential (Fig. 47-10). Severely injured horses greatly resent positioning for this radiographic view and may require analgesia. Occasionally general anesthesia is required, but it should not be attempted without treatment options being in place.

Treatment Horses with open wounds must be treated with debridement and antibiotics, and it is vital to establish if joint infection exists and treat it appropriately. Horses with small non-displaced, non-articular fractures may be treated conservatively with stable rest. Most heal by fibrous union only. Horses may return to work in 8 weeks. Fragments off the base of the patella need arthroscopic debridement if debris is loose in the joint. Small fragments at the base of the patella, which are embedded in the soft tissue attachments, may not require removal.[72] Articular fractures of the medial aspect are best removed.[69] This can be done by arthrotomy or arthroscopy (Fig. 47-11) and requires careful dissection of the fragment from the medial patellar ligament. The distal end of the fracture is clearly seen arthroscopically. Concurrent joint damage should be evaluated and can have an important bearing on the outcome. Complete horizontal fractures must be treated by internal fixation.[70,73,74] Lag screw fixation with 5.5-mm cortical screws or partially threaded 6-mm cancellous screws, possibly with reinforcement with tension band wiring, is necessary to combat the huge distraction forces of the extensor muscles. Anesthetic recovery has to be carefully controlled by delaying attempts of the horse to stand by use of sedation, to avoid breakdown of the repair. Sagittal fractures can also be fixed using the lag screw principle.[75]

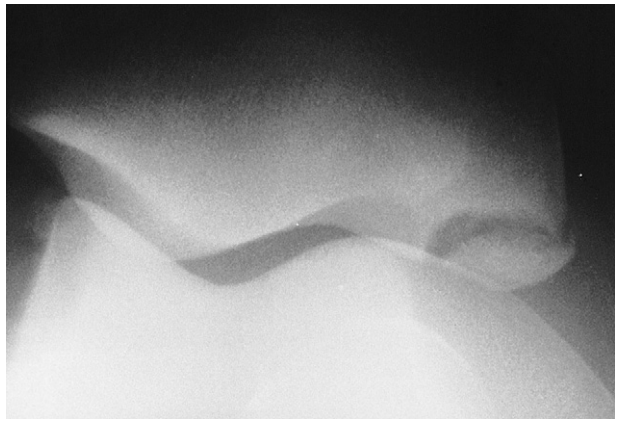

Fig. 47-10 Craniopoximal-craniodistal radiographic view of the right patella of 10-year-old eventer gelding that hit a cross-country fence with the right stifle. Medial is to the right and cranial is to the top. There is a displaced fracture of the medial pole of the patella.

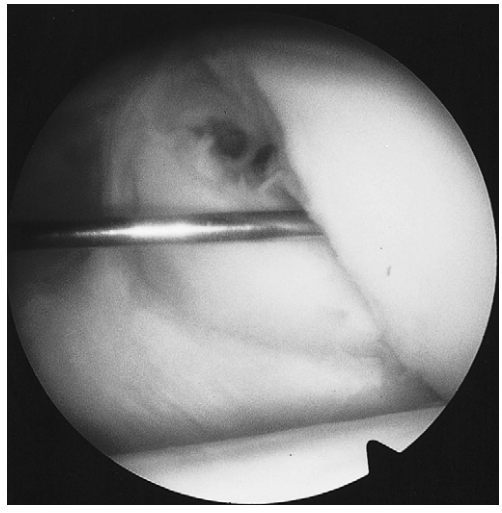

Fig. 47-11 Arthroscopic view of the left patella of the horse in Fig. 47-10 showing the fracture line (*with probe inserted*) in the medial aspect of the patella.

Prognosis Horses with small, non-articular fractures usually have a good prognosis with conservative management.[72] Ten out of 12 horses with medial fractures without concurrent joint disease treated by partial patellectomy returned to athletic use.[69] My experience has been similar. Internal fixation of horizontal and mid-body vertical fractures can be rewarding, but the risk of breakdown during anesthetic recovery is significant, especially in the horizontal fractures. Severely comminuted fractures have a poor prognosis.

Fracture of the Intercondylar Eminence of the Tibia

These fractures have been described as avulsion fractures of the insertion of the cranial cruciate ligament.[58,76,77] However, because the insertion of the cranial cruciate ligament is cranial to the eminence, they are probably not avulsions but may be caused by trauma to the joint involving a lateral force from the medial femoral condyle on the intercondylar eminence.[78]

Signs and diagnosis The history and presenting signs are similar to other acute, severe stifle injuries, and confirmation of the fracture is made radiographically. The caudocranial and flexed lateromedial views are the most useful. Once the acute inflammation has subsided, lameness can be mild to moderate in horses that do not have significant injuries to vital soft tissue structures.

Treatment An arthroscopic assessment is essential for evaluating the fracture and concurrent soft tissue damage in the joint, which is extensive in some horses. If accompanying soft tissue injuries have a reasonable prognosis, treatment of the fracture can be rewarding. Small fragments should be removed. Horses with large fragments can be treated by internal fixation.[78] Alternatively, large fragments can be removed, but this depends on fragment configuration and the involvement of soft tissue structures, such as the cranial cruciate ligament or the cranial ligament of the medial meniscus that wraps around the cranial surface of the eminence.[76,77]

Prognosis If soft tissue damage is reparable, the prognosis for fracture treatment can be good. The possibility always exists of articular cartilage or soft tissue damage that is not detected at arthroscopic examination[78] but that may ultimately cause chronic lameness.

Fracture Fragments off the Femoral Trochlear Ridges or Femoral Condyles in Adult Horses

These injuries usually result from direct external trauma, such as hitting a fence while jumping, a penetrating wound, or a kick.[72,79]

Signs and diagnosis Characteristically there is a sudden-onset, moderate to severe lameness, with a history of acute trauma. Effusion of the femoropatellar joint is usually present. With condylar fractures there is also effusion of the medial femorotibial joint. Crepitus may be present and flexion of the joint causes pain. In the femoropatellar joint fragments arise most commonly from the distal lateral trochlea and are best seen on flexed and standing lateromedial radiographic views. Caudocranial views are also important for identifying the position of fragments in the cranial or caudal femorotibial joints, and cranioproximal-craniodistal oblique views are necessary to rule out concurrent patellar fractures. The fracture site may not be obvious. Because these fractures are often caused by direct trauma, often the stifle region has a wound, and in these circumstances a strong chance of infection in the joint exists. Infection should be ruled out by examining the synovial fluid. Infection can also occur by extension into the joint, hours or even days after the injury. If a sudden increase in lameness occurs, synoviocentesis must be repeated.

Treatment Fragments should be removed to prevent the development of osteoarthritis. Most can be removed arthroscopically,[72,79] but arthrotomy may be necessary for excision of large slabs.[80] In many horses I prefer to wait a few days before examining the joints arthroscopically, because the initial intra-articular hemorrhage hinders surgery. Many horses have a severely inflamed synovium in which fragments may be embedded and difficult to find. Fragments in the femoropatellar joints are often loose, whereas in the femorotibial joints they more often have soft tissue attachments, but conditions vary greatly, and intra-operative radiography to ensure removal of all fragments can be useful. Evaluation of the remainder of the stifle joint for concurrent injuries is important.

Prognosis Horses with trochlear ridge fractures have a good prognosis after fragment removal.[72,79] If no significant soft tissue damage occurred, the prognosis is also favorable after removal of fracture fragments in the femorotibial joint. One should bear in mind on the initial assessment that some of these injuries are not as catastrophic as the radiographic changes suggest.

Salter-Harris Fractures of the Femur, Types III and IV

Type III and IV Salter-Harris fractures of the femur tend to occur in older foals and usually result from a fall with the limb in adduction or from an external trauma. From limited reports, type II fractures, which are not discussed in this section, are the most common physeal fracture; but of the articular fractures, type IV fractures appear to be more common.[81-83] Type IV fractures often have a characteristic configuration in which the fracture begins in the trochlear ridges in the horizontal plane and exits through the caudal lateral diaphyseal cortex.[81]

Signs and diagnosis Foals with minimally displaced fractures may be weight bearing, but the others usually have acute, severe lameness, swelling, pain, and often crepitus in the affected joint. Radiography confirms the fracture and should include enough views to establish its configuration.

Treatment Conservative treatment may be appropriate for horses with stable, minimally displaced fractures.[81] Internal fixation is indicated for horses with displaced or unstable fractures. Repairs using lag screw fixation, cobra head bone plates, and angle blade plates have been reported.[81-84] Implanting screws through the articular cartilage of the femoral trochlea is sometimes necessary, and crossing the physis with an implant does not seem to have affected growth in the distal femoral physis in older foals.[81] The dynamic condylar screw plate may be of value.

Prognosis From the few published reports[81] comes evidence that foals with minimally displaced fractures have a good chance of achieving athletic use with conservative treatment. If surgery is required, the outcome is more equivocal, but good success has been achieved in some horses.

Fractures of the Tibial Tuberosity

The tibial tuberosity is a relatively exposed structure and is susceptible to fracture after direct trauma, such as a kick, or a collision with a fence. These fractures do not seem to be associated with the growth plate of the tibial tuberosity or with avulsions of the insertions of the patellar ligaments, though the lateral patellar ligament is often involved. They may not be true avulsion fractures, but because of the patellar ligaments, some do displace proximally.[85] Traction apophysitis similar to Osgood-Schlatter disease in people has been reported in horses[86] but is rare. In the horse reported, lameness was mild and small fragments detached from the cranial aspect of the tibial tuberosity were visible radiographically. A variety of fracture configurations occur, from small fragments on the cranial proximal aspect, to large fractures extending from distal to the tibial crest to proximally into the femorotibial joint.

Signs and diagnosis Most horses are acutely, severely lame immediately after sustaining the fracture, but in some this may settle into a milder lameness if left untreated. Swelling and crepitus are common. A wound on the lateral tibia may be present and intra-articular fractures may be associated with joint effusion. Care should be taken to rule out other injuries

in the stifle, such as fracture of the patella, or joint infection if an open wound exists. Infection can even develop by extension into the joint through a skin graze. Because of the lateral curvature of the tibial tuberosity, several radiographic views are often required to identify the contour of the fracture, the caudolateral-craniomedial oblique view being the most useful. The tibial tuberosity does not fuse until at least 3 years of age,[87] and its physis should not be confused with a fracture.

Treatment Non-displaced fractures may heal with stable rest, but one should bear in mind that displacement can occur some time after the injury because of the pull of the quadriceps muscles on the patellar ligaments. Because of this, preventing the horse from lying down for 2 weeks is wise. Small fragments can be removed if they do not involve disruption of the middle patellar ligament. Horses with large fractures heal satisfactorily if treated conservatively in the Editors' experience, provided they are not displaced. Large fractures can also be treated by internal fixation. Lag screw fixation does not provide a secure enough repair, so tension band wiring,[88] a lateral narrow dynamic compression plate,[89] and a cranial narrow dynamic compression plate[85] have been used. I believe that the most secure repair is achieved with the latter (Fig. 47-12). The plate should extend well distal to the distal extremity of the fracture to withstand the distraction forces of the quadriceps muscles. Because of the shape of the cranial proximal tibia, contouring of the plate demands considerable twisting and bending, but this does not seem to affect its efficacy. A technique for preoperative plate bending has been reported as a way of saving surgery time,[90] but in my experience this is not especially time consuming. Most horses are substantially more comfortable postoperatively, but they should be prevented from lying down for 2 weeks.

Prognosis Conservative treatment of horses with non-displaced, small fragments results in a good prognosis. Horses with larger fractures may respond to conservative treatment with complete return to soundness, but convalescence is often prolonged. Good results for return to full athletic function have been reported after repair with a cranially applied plate,[85] and in my view this is the treatment of choice. A potential risk exists for failure of the repair during anesthetic recovery, or the early postoperative period,[89] or for tibial fracture. This emphasizes the importance of adequate fixation and restriction of the horse during early convalescence.

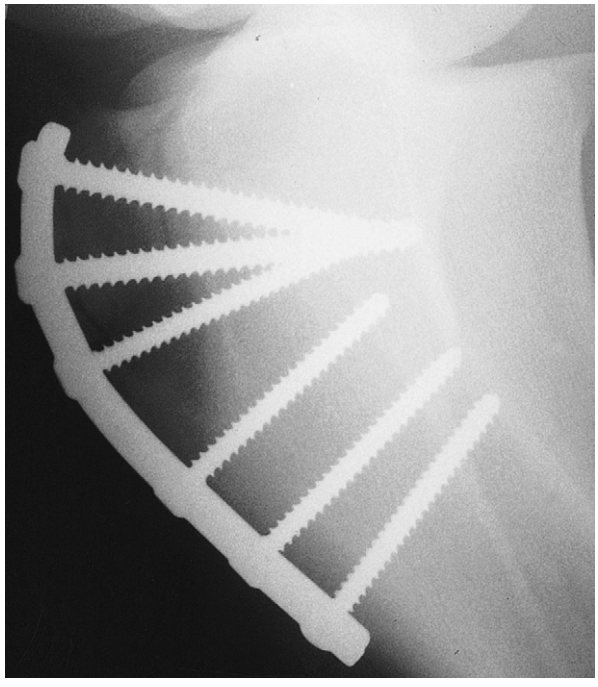

Fig. 47-12 Postoperative lateromedial radiographic view of the right tibia of 13-year-old pony gelding that had sustained a fracture of the tibial tuberosity. The fracture had been treated by internal fixation with a narrow dynamic compression plate.

Fractures of the Fibula

Fracture of the fibula is usually caused by direct trauma and is a rare injury. Lameness is often moderate to severe at first. Palpation of the region may not elicit obvious pain, but radiography should be diagnostic. The caudocranial view is the most useful, but great care must be taken to differentiate a fracture from persistent radiolucent lines that result from separate ossification centers in the fibula. As many as three of these lines can be present, and they may be irregular. Scintigraphy is a useful aid to diagnosis in the absence of localizing clinical signs or if one has difficulty interpreting the x-ray films. From limited experience, confinement of the horse for 2 to 4 months is usually long enough for reasonable healing to take place, and the prognosis is good.

Other Diseases

Avulsion of the Origin of the Fibularis (Peroneus) Tertius and Long Digital Extensor Tendon

Avulsion of the origin of the fibularis tertius and long digital extensor tendon is a relatively rare condition in horses and is usually caused by sudden, forceful hyperextension of the hindlimb. Mid-substance tears are probably more common than avulsions of the common tendon of origin of the fibularis tertius and long digital extensor muscles, but the latter have been reported in foals.[91-93] Avulsions of the origin of the fibularis tertius and long digital extensor muscle occasionally occur in adult horses,[5] although more distal injuries are commoner. Foals may be more likely to suffer avulsions because of weaker bone.[92] Minor disruption of the common tendon of origin may be seen at arthroscopy.[5]

Signs and diagnosis The classical sign of rupture of fibularis tertius and avulsion of its origin is the ability to extend the hock while the stifle is flexed, resulting in a dimpling of the Achilles tendon. Synchronous flexion of the hock and stifle has been reported with avulsions of the origin, presumably because the avulsed bone is held by the joint capsule.[92] Horses may bear weight normally, but during the protraction phase of a stride, the distal limb appears flaccid. Lameness can be severe at first and distention of the femorotibial and femoropatellar joints may be present. Radiography is necessary for diagnosing avulsion fractures. Minor disruptions of the tendon of origin manifest as a non-specific lameness associated with pain in the stifle and can be diagnosed by arthroscopic examination; they may accompany other stifle injuries.[5]

Treatment Horses with injuries to the tendon of origin are usually best evaluated arthroscopically, which also offers the opportunity to check for concurrent injury. Small bone fragments can be removed, but large fragments embedded in the joint capsule may be better left.[92] Six weeks of stable rest followed by controlled exercise for 3 months is recommended after surgery.

Prognosis Horses with avulsion injuries have a guarded prognosis for full soundness, but successful outcome has been reported.[92] Minor disruptions of the origin may heal, but much depends on concurrent injuries.

Calcinosis Circumscripta

Calcinosis circumscripta lesions are described as calcified, granular, amorphous deposits that induce fibrous reaction.[94] They usually lie in the subcutaneous tissue close to joints or tendon sheaths. The lateral aspect of the stifle adjacent to the fibula is the predilection site for these lesions,[94-96] but they have been reported on the dorsolateral surface of the hock,[94]

the neck, and the shoulder.[94,95] Calcinosis circumscripta is an uncommon condition, more often seen in young horses. The cause is unknown.

Signs and diagnosis The usual reason for presentation is an unsightly lesion that has been slowly increasing in size. Occasionally the lesion appears to affect the horse's gait. Lesions are usually hard, well circumscribed, and firmly attached to underlying tissue. The overlying skin is not involved. Caudocranial radiographs show a circumscribed, roughly oval lesion of mineralized tissue (Fig. 47-13) lying close to the lateral aspect of the femorotibial joint, with the bulk of the lesion distal to this. These lesions may be seen incidentally on scintigraphic examination as focal areas of intense increased radiopharmaceutical uptake on the lateral aspect of the proximal tibia. The lesion is clearly visible in a caudal view in a subcutaneous location, superficial to the tibial cortex, but in a lateral view could be confused with a proximal tibial stress fracture.

Treatment Treatment is only indicated if the lesion is causing clinical complications or for cosmetic reasons. Surgical excision is necessary to remove the mass. Care should be taken when embarking on excision because some lesions are attached to the femorotibial joint capsule, which may be entered inadvertently. Steps should be taken to prevent postoperative seroma formation by closing dead space, suturing a stent bandage over the wound, and preventing the horse from lying down for several days postoperatively. The mass usually has a thick fibrous capsule and contains deposits of gritty material.

Prognosis In horses that are not treated, the mass remains but may not cause complications. A good result can be expected after surgical excision. Regrowth has not been reported, but postoperative problems with wound healing could be serious if the femorotibial joint is involved.

Hematoma in the Stifle Region

The stifle region is vulnerable to external trauma, particularly when horses are jumping. Profound injuries to vital structures may result, but frequently external trauma causes only superficial bruising or a subcutaneous hematoma. The clinician's task is to differentiate between a swollen stifle that has a potentially career-threatening injury and one that has a superficial lesion such as a hematoma.

Fig. 47-13 Caudocranial radiographic view of the stifle of an 8-year-old riding horse with an oval mass of mineralized tissue lateral to the head of the left tibia. The lesion is typical of calcinosis circumscripta.

Signs and diagnosis A hematoma is manifested as a variably sized swelling, usually on the cranial aspect of the stifle, and may take several hours to reach maximum size. Smaller swellings may be difficult to differentiate from femoropatellar joint effusion. A hematoma is only painful on palpation until the initial bruising and swelling has settled. An uncomplicated hematoma does not usually cause lameness once the discomfort associated with the initial bleeding has passed. Other concurrent injury should be suspected if the horse is significantly lame, especially if lameness persists for several days. A hematoma may occasionally involve only the stifle initially but appear to spread to the inguinal and ventral abdominal areas. Huge swellings can cause oozing from the skin and skin loss. A careful search should be made for open wounds, which could lead to infection in the hemotoma or cellulitis. Cellulitis usually takes at least 24 hours to form, the swelling is firmer than a hematoma, hot, and painful. Lameness worsens as infection progresses.

Ultrasonography is a helpful tool for diagnosing hemotoma, which can be confirmed by aseptic centesis of the swelling. In the early stages, frank blood is retrieved, but as the blood clots, the fluid collected will be serum. Radiographic examination is indicated if lameness is severe or persists.

Treatment In the initial phase, when hemorrhage is likely, the horse should be confined and cold applied to help to slow hemorrhage. Phenylbutazone can be given for its anti-inflammatory effect. Antibiotics should be administered if the horse has an open wound. Although some clinicians feel that draining these hematomas is contraindicated, in my experience hematomas resolve better after effective drainage. Drainage should not be attempted until the hemorrhage has stopped and the free blood has clotted, usually 3 to 4 days after the injury. A 2- to 4-cm scalpel incision at the most dependent point of the hematoma ensures that drainage continues until the cavity has filled in.

Prognosis In the absence of concurrent injury or infection and once the hematoma has resolved and is free of fluid, the prognosis for athletic use is good.

CHAPTER • 48

The Thigh

Dan L. Hawkins

THE GLUTEAL SYNDROME

Pain that can be demonstrated with digital pressure along a line between the wing of the ilium and the greater trochanter of the femur was first recognized as a cause of lameness 45 years ago.[1-3] Various aspects of the origin, diagnosis, and management of the syndrome have been appreciated since its initial recognition by Dr. Churchill and myself.[1-5] The condition has also been referred to as *sacrosciatic lameness* or *pelvic myositis*. We have preferred to use the term *gluteal syndrome* because we believe that there may be more than one abnormality that will result in this type of pain.

Gluteal syndrome has been diagnosed in most breeds and uses of horses. Standardbred (STB) racehorses seem to have the highest incidence, but it is not uncommonly seen in Thoroughbred (TB) racehorses. One risk factor for STBs is related to the more recent harness and race bike designs that tend to decrease the weight borne by the forelimbs while transferring weight to the hindlimbs. Gluteal syndrome has been diagnosed in horses that are used for hunting, jumping, eventing, and endurance racing.

Based on dissections of cadavers, the accessory head of the middle gluteal muscle was identified as the deep structure that best corresponds anatomically to the characteristic pattern of pain. This muscle originates on the concave surface of the wing of the ilium near the tuber coxae. At its caudal extent, the accessory head of the middle gluteal muscle forms a flat tendon that passes over the cranial aspect of the greater trochanter of the femur and inserts on the crest below it. The accessory head is directly related to other aspects of the middle gluteal and superficial gluteal muscles superficially and is important in propulsion of the hindlimbs[6] (Fig. 48-1).

The pathological process associated with the accessory head of the middle gluteal muscle is uncertain. It is known that in horses with some acute injuries a hematoma may form in the area between the ilium and greater trochanter. Small, hypoechogenic areas may be demonstrated ultrasonographically in muscle tissue in the same area. In other horses the muscle may become partially detached from the ilium. Horses with the latter condition develop a depression in the musculature caudal to the tuber coxae after the acute stage. In horses with chronic pain the affected muscle mass may become very firm, presumably as a result of fibrosis. Post-mortem evaluation of two horses with chronic refractory gluteal syndrome did not provide any conclusive information. Other potential changes such as fasciitis, gluteal tendonitis, or injury to one or more adjacent muscles have been considered. Whatever the cause, the source of pain is consistently confined to the area described.

To date, the most reliable, practical method of diagnosis is by careful, systematic physical examination of the area between the wing of the ilium and the greater trochanter of the femur with the horse standing on the limb. More specifically, the musculature should be palpated and examined for changes in resilience, swelling, or fibrosis. The position and outline of the tuber coxae should be evaluated. Next, gentle, deep pressure should be applied along the entire area

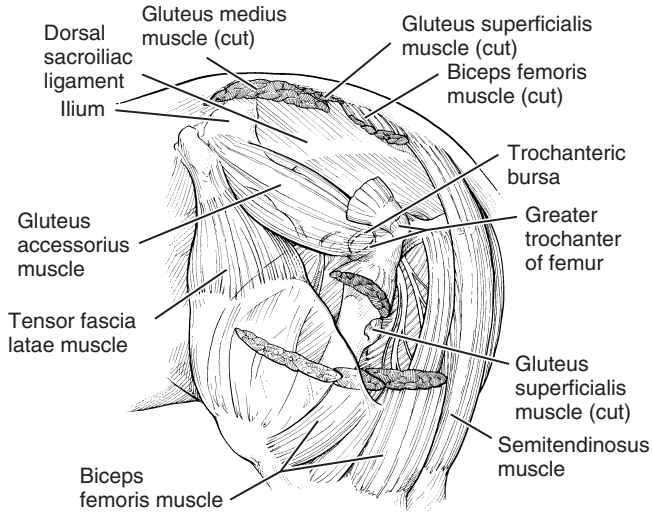

Fig. 48-1 Drawing of the anatomy of the lateral pelvic and proximal thigh regions showing the accessory head of the middle gluteal muscle, the most likely source of pain associated with gluteal syndrome. The tendon of the accessory head of the middle gluteal passes over the cranial portion of the greater trochanter where there is a bursa. Inflammation in this region causes trochanteric bursitis.

Fig. 48-2 Careful palpation for pain is the only way to establish the clinical diagnosis of gluteal syndrome.

described with the tips of eight digits (Fig. 48-2). Initially, light digital pressure should be applied, but then the pressure is gradually increased to firm, deep pressure. The pressure is maintained briefly to evaluate the horse's response. Finally the area caudal to the ilium, the central portion, and the caudal part of the accessory head of the middle gluteal muscle should be examined similarly. Each one third of the area should be considered separately to determine whether the area is affected generally or if the injury is confined to one or more

sections. A sound horse will not respond to the examination of any of the areas. An affected horse leans away from the pressure while showing a reluctance to voluntarily bear full weight on the limb as long as the pressure is maintained. A positive response for this syndrome as described is specific and should not be confused with that for trochanteric bursitis (see section entitled "Trochanteric Bursitis").

Most horses with acute gluteal syndrome tend to drag the toe of the affected limb on the ground at a walk. Horses with chronic gluteal syndrome do not drag the toe at a walk, but at a slow trot they break over on the inside of the toe and swing the leg medially and then laterally, finally landing on the outside branch or toe of the shoe. At this gait the lameness produced appears identical to that caused by trochanteric bursitis or tarsitis. When the horse trots, paces, or runs at high speed, the abnormality starts off as described, then the limb appears to tire and is carried more in abduction the further in the race or competition the horse proceeds. It appears that early in the race the horse is able to tolerate the gluteal pain and continue to use the limb for propulsion. However, with sustained speed or intensity of effort over distance, compensatory mechanisms within the limb fatigue as pain from the gluteal injury becomes overwhelming. At this point a trotter or pacer may make a break or freeze on a line, a TB may bolt or stop trying in the race, and a show horse may refuse to jump or crash when it tries. Many of these horses are believed to have a stifle problem because the quadriceps muscles fasciculate when they pull up. Others are believed to have exercise-induced pulmonary hemorrhage because they stopped like a bleeder, but no blood is seen endoscopically. Regardless, speed, intensity of work, and distance are key factors in how this problem affects an athletic horse. Some horses that accommodate to the injury, or are treated and do not recover to total soundness, can perform reasonably well at slower speeds or less intense work.

There is not a specific cause for gluteal syndrome. The onset is frequently directly associated with being cast in a stall, slipping or falling while playing in a paddock, or going down in a trailer or van and struggling to get up while the head is tied. Gluteal syndrome also develops when there is a chronic, pre-existing problem in the distal aspect of the same limb, such as hock lameness, suspensory desmitis, or other problem that causes the horse to carry its weight on the toe at high speed. Slipping or losing footing on a soft racetrack or other muddy surface is also associated with development of the clinical signs.

Horses with this injury are best treated while in moderate, controlled exercise, regardless of the treatment approach. Rest alone, even for extended periods of time, has not been successful as a treatment. Several weeks of careful exercise management with repeated evaluations provide the best chance for a favorable response to treatment. Horses with acute injury, hemorrhage, and severe lameness should be rested until they are walking well and the seroma has resorbed before resuming exercise and treatment. Intramuscular injections of a counterirritant, acupuncture, or therapeutic ultrasound are the best treatment options. At present, I still believe that injections of a counterirritant into the area of sensitivity yield the best results. The injection site is prepared with a surgical scrub followed by rinsing with 70% isopropyl alcohol. An injection grid is marked on the horse by drawing three lines in the wet hair over the accessory head of the middle gluteal muscle (Fig. 48-3). One hundred milliliters of a 2% iodine diluted in sesame oil solution is injected intramuscularly into 20 sites (5 ml per site) on and between the grid lines with a 4-cm, 19-gauge needle. If the pain is concentrated in the cranial or caudal one third of the area between the tuber coxae and the greater trochanter of the femur, the injection sites can be limited to the cranial or caudal half of the area, respectfully. After injection moderate, controlled exercise is recommended on a daily basis beginning the day after injection for all horses. After injection horses with acute or recent gluteal syndrome are walked and jogged for 3 weeks and then re-examined. If the lameness is improved, but the area is still sensitive or if there has been no improvement, the injection is repeated in the same manner. Horses with chronic gluteal syndrome are walked and jogged for only 1 week before light training is resumed. Some horses respond dramatically to the treatment and appear to be pain-free within less than a week. The injury cannot heal within that time frame; therefore the temptation to resume full training too quickly must be resisted. When the treatment is successful and horses return to full work and racing, 10% to 20% may experience a recurrence of the problem. These horses generally respond well to treatment as they did previously.

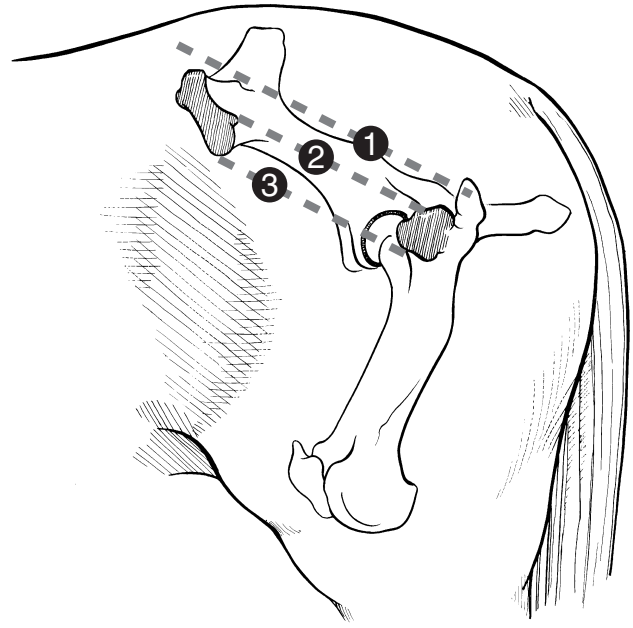

Fig. 48-3 Diagrammatic representation of the injection pattern for intramuscular injections of counterirritant solution to manage gluteal syndrome.

Lameness that fails to improve after two or three injections at 3-week intervals is considered refractory to this mode of treatment. For these horses, I suggest that the trainer or owner try another form of treatment, such as therapeutic ultrasound or acupuncture. Approximately 10% to 15% of horses do not respond to any mode of treatment and never recover from the injury. The prognosis is guarded initially for unilateral injury and poor if the problem is bilateral or if there is a chronic condition more distally in the same leg. In these more complicated cases, failure is related to the aggravating effect of each injury on the other.

Shoeing can be a factor in the management of the gluteal syndrome. Slipping on the racetrack, cross-country course, or show jumping arena is a major factor in development and recurrence of the injury. I recommend that TB racehorses that have or have had this condition be shod with block heels on both branches of each hind shoe. Calks applied near the end of both branches of the hind shoes during training and competition can be used in other types of horses.

TROCHANTERIC BURSITIS

Pain elicited by firm digital pressure over the greater trochanter of the femur and the musculature immediately caudal to it is attributed to inflammation of the trochanteric bursa and is a cause of lameness in horses.[1,2] Historically this condition has

been referred to as trochanteric bursitis, trochanteric lameness, and whorl bone lameness.[7] Anatomically the bursa is interposed between the flat tendon of the accessory head of the middle gluteal muscle and the cranial portion of the greater trochanter, which is covered with cartilage at this point. The tendon inserts on the crest below the greater trochanter (see Fig. 48-1).[7]

Although confident, positive diagnosis is achieved by physical examination in almost all horses, a technique of injection of local anesthetic solution into the bursa has been described.[8] The condition is relatively common for all breeds and uses of athletic horses and is generally considered to be a secondary problem. Trochanteric bursitis often is associated with tarsitis or other problems in the affected limb in which the horse lands on the toe. An additional cause that has been overlooked is that associated with over-reaching with the hindlimbs to compensate for a chronic problem in the forelimbs. A horse that is chronically sore in front (e.g., navicular disease) will try to carry more of its weight on the hindlimbs by over-extending the ipsilateral limb, which results in excessive strain on the tendon of the middle gluteal muscle. Wet, cold weather conditions appear to have a positive association with the incidence and response to treatment.

Trochanteric bursitis causes a gait abnormality that is similar to that produced by tarsitis. A horse with purely trochanteric lameness breaks over on the medial aspect of the toe; carries the leg medially, even crossing the midline; and then the leg moves laterally to land on the lateral aspect of the toe and branch of the shoe. The length of stride is shortened and the hindquarters are carried toward the opposite side, which is sometimes described as "dog trotting" at a slow gait. Trochanteric lameness especially affects horses when they are racing around turns, jumping, circling, or performing precision dressage movements.

Trochanteric bursitis is generally a chronic condition that is diagnosed at the same time as a primary condition in the lower limb or ipsilateral forelimb. The more distal condition (e.g., tarsitis) should be addressed before the bursitis is treated. Occasionally trochanteric bursitis is identified without an associated primary condition, or it may spontaneously resolve after correction of the associated primary lameness.

Rest is of no value in treating trochanteric bursitis and may intensify the lameness when the horse returns to training. The most effective, practical treatment of trochanteric bursitis is injection of the soft tissues over and around the bursa with a counterirritant solution. The area for injection is prepared with a surgical scrub followed by rinsing with 70% isopropyl alcohol. Approximately 6 ml of a 2% iodine diluted in sesame oil solution should be injected into 8 sites with a 4-cm, 19-gauge needle (Fig. 48-4). The horse should be maintained in mild, controlled exercise for 1 week before resuming normal work. Normally within 5 to 7 days after treatment the horse should become sound behind and no longer resent palpation over the bursa. Horses that require reinjection are more commonly encountered during cold, wet climatic conditions. The prognosis is good for obtaining a cure for trochanteric bursitis provided the associated primary lameness is corrected. Alternatively, solutions of a corticosteroid can be injected in the same manner. In my experience injection of corticosteroids directly into the bursa is not necessary to alleviate the lameness.

Trochanteric bursitis has been addressed here as a performance-limiting condition in the athletic horse. Trochanteric bursitis that results from external trauma, infection associated with a wound, or a fracture of the greater trochanter of the femur is not discussed.

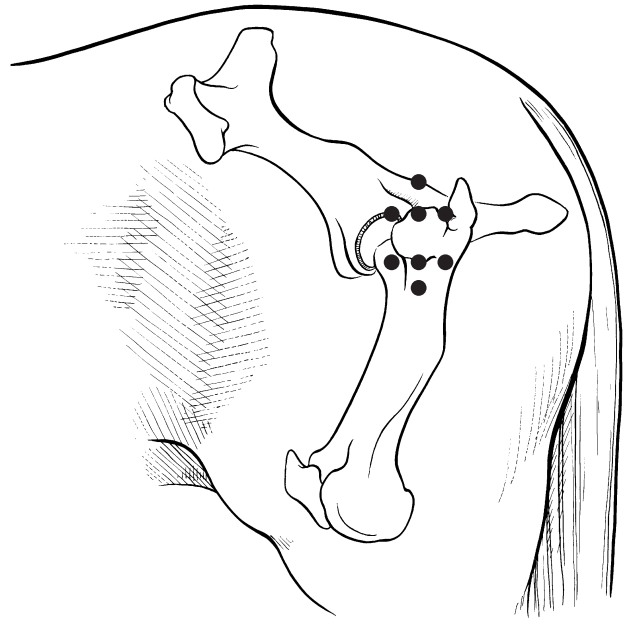

Fig. 48-4 Diagrammatic representation of the injection pattern to manage horses with trochanteric bursitis.

FRACTURES OF THE FEMUR

Fractures of the femur occur most commonly in foals and weanlings, although they may be seen in older horses. Most femoral fractures result from external trauma, such as a kick or fall with the limb in adduction or abduction. In young foals fractures may be associated with breaking to lead. In most horses the traumatic incident is not witnessed, but the horse is found with an unstable, non–weight-bearing lameness in the affected hindlimb. Because of the energy required to fracture the femur of an adult horse, the fracture generally has a severely comminuted configuration. Although foals and weanlings most commonly acquire diaphyseal femur fractures, fractures involving the proximal or distal femoral physis are not uncommon. Salter-Harris type II distal femur fractures are most commonly seen in older weanlings and yearlings.

Diagnosis

In most horses the diagnosis can be made after a brief physical examination. Femur fractures result in an acute onset of severe lameness, with swelling in the area of the femur. Rotational instability is elicited when internal or external rotation is applied by grasping the proximal tibia and calcaneal tuber. Crepitation may be appreciated with manipulation of the limb. However, swelling and hemorrhage in the large muscle mass of the thigh may keep the fracture ends separated and make it difficult to elicit crepitus. The large muscle mass also makes open fractures uncommon. Swelling is most consistent with diaphyseal fractures, but it is often less obvious with proximal physeal fractures and minimally displaced distal physeal fractures. In most horses the distance between reference points, such as the patella and the greater trochanter of the femur, is shortened because of the overriding of the fracture fragments that is caused by contraction of the quadriceps muscles. Foals with proximal physeal fractures may be able to bear some weight on the affected limb.

Radiographic evaluation is required to obtain a definitive diagnosis and determine the severity of a femoral fracture. Radiography of horses larger than young foals requires use of general anesthesia unless the fracture is located in the distal femur. Many small foals can undergo radiography safely when recumbent under heavy tranquilization or anesthesia. Because induction and recovery of large yearlings and adults cannot be assisted sufficiently to prevent complications and discomfort, anesthesia is contraindicated for assessment of unstable femur fractures. Ultrasonography can be used to confirm a displaced femoral fracture in a standing horse.

Once the horse is in lateral recumbency with the affected limb down against the cassette and the opposite limb abducted, the x-ray beam should be directed from medial to lateral. Radiography of the diaphysis and proximal femur requires a grid and high-capacity radiographic generator except for examination of small foals and the distal femur of larger horses. Two exposures are generally required for the mediolateral images because of the variation in soft tissue mass around the distal and proximal femur. Craniocaudal views are also required to assess the severity of the fracture and the degree of overriding. Evaluation of the proximal physis requires that the horse be positioned in dorsal recumbency with the cassette and grid under the coxofemoral area.

Case Selection for Treatment and Prognosis

The decision to treat horses with femoral fractures by surgical intervention depends on several variables. The size of the patient is the single most important consideration, regardless of fracture type. Successful surgical treatment of diaphyseal or proximal physeal fractures has been accomplished only in foals and small ponies.[9] Distal physeal fractures have been successfully repaired in yearlings.[10,11] However, adult horses or young horses weighing more than 200 kg (440 lb) with displaced diaphyseal fractures warrant humane destruction.[12] Fracture location and configuration, soft tissue injury, temperament of the horse, client expectations, and economic considerations are other important determinants for case selection. Compromise of the vascular supply to the distal limb that is caused by the fracture, damaged major vessels, and swelling can result in failure due to necrosis of the distal limb.[13]

Surgical techniques, complications, and the prognosis for horses with diaphyseal and proximal and distal physeal femur fractures have been reviewed.[9,12,14] Of foals with diaphyseal fractures that were repaired with double plating, 50% of the fractures healed and 75% of the horses were able to perform the intended use.[15] The most common complications were seroma formation and infection. Foals with a successful outcome were younger than 3 months of age. Additionally, an intact caudal cortex was considered necessary for a successful outcome. Conservative management of horses with diaphyseal fractures can result in fracture healing. However, limb shortening, rotational deformity, and serious varus deformity in the contralateral limb are common complications of this approach. The prognosis of horses with distal fractures was more guarded than that for diaphyseal fractures because of the limited amount of bone for implant purchase. Conservative management of horses with distal fractures can result in a satisfactory outcome if the fracture is minimally displaced and stable.[15]

Although proximal femoral physeal fractures account for 16% of physeal fractures in the horse,[16] sufficient reported results of surgical treatment to establish good prognostic information are lacking. Currently the prognosis for successful repair is guarded at best. Conservative management is unlikely to result in a comfortable horse. Unstable fixation, necrosis of the femoral head, and osteoarthritis of the coxofemoral joint are the more common complications associated with failure of surgical or conservative approaches.

Other less common types of proximal femoral fractures that cause less severe lameness in older horses include the third trochanter (see Chapter 52) and greater trochanter. Ultrasonography is helpful in confirming these fractures. Unless these fractures are associated with a wound or become sequestrated, they should be managed with stall rest.[9] Stress fractures of the femur are rare but occasionally occur in the proximal cranial femoral cortex (Editors).

OSSIFYING MYOSITIS

See Chapter 81 for a discussion of ossifying myositis.

CHAPTER • 49

Mechanical Lameness in the Hindlimb

Beth A. Valentine

GENERAL CONSIDERATIONS

Mechanical lameness reflects altered biomechanical forces affecting limb function. The biomechanics of limb function depend on normal functioning of peripheral nerves, muscles, tendons, and ligaments. Appropriate muscle contraction and relaxation are important factors in limb biomechanics. A muscle that cannot contract with sufficient force, or a muscle that cannot relax and stretch, can result in a significantly altered gait. Mechanical lamenesses are typically most obvious at the walk and often become less evident or disappear at the trot. Gait alterations are usually not evident at the canter, although a horse with a mechanical lameness may not be capable of generating a smooth canter and may appear to be hopping or "off" behind at the canter. Mechanical lamenesses include altered gaits caused by decreased and increased joint flexion.

The importance of proper functioning of the neuromuscular system for a normal hindlimb gait is exemplified by horses with chronic motor neuron disease and myopathy from equine polysaccharide storage myopathy (EPSSM). Both of these relatively recently recognized neuromuscular disorders can cause a fibrotic myopathy type or a stringhalt type of gait. Horses with EPSSM may develop prolonged or intermittent upward fixation of the stifle. Underlying myopathy was found in horses with shivers (shiverers).[1,2] Neuropathy is known to be a cause of stringhalt[3,4] and was found in horses with fibrotic myopathy.[5] Trauma to peripheral nerves may also cause a mechanical lameness. The possible role of altered proprioceptive input to the affected limb is an intriguing one and is discussed under appropriate headings.

Equine protozoal myelitis or myeloencephalitis (EPM) with involvement of motor neurons causing selective denervation may also cause a mechanical lameness. Horses with lameness from EPM should, however, also exhibit proprioceptive deficits and ataxia. EPM is unlikely to cause an obvious mechanical lameness without accompanying ataxia. I have difficulty accepting that EPM could cause selective damage to motor neurons sufficient to cause a mechanical lameness without also causing concurrent spinal cord white matter damage and ataxia. However, neurological deficits may be subtle early in the disease. Careful neurological evaluation by a clinician with expertise in equine neurological evaluation is an important part of examining a horse with a mechanical lameness, because distinguishing between gait abnormality caused by mechanical lameness and gait abnormality caused by neurological disease may be difficult.

Electromyography and muscle biopsy may aid in determining the cause of a mechanical lameness. Concentric needle electromyography of denervated muscle often reveals abnormal spontaneous activity such as positive sharp waves, fibrillations, and myotonic bursts. Abnormal spontaneous activity may also be present in muscles of horses with myopathy, but these findings are generally mild and may be absent. Biopsy of the semimembranosus or semitendinosus muscle is useful for evaluating evidence of denervation atrophy and of EPSSM. However, if denervation of a single muscle or part of a muscle causes the gait alteration, sampling error may result in a false-negative result.

Mechanical lameness does not usually cause pain and horses usually do not respond to anti-inflammatory therapy. Methocarbamol therapy is indicated only when muscle cramping from central nervous system disease is suspected. Phenytoin therapy has proved to be useful in some horses with mechanical lameness, particularly those with stringhalt.

Mechanical lameness in the horse is from abnormal structure or function of the musculoskeletal system, or more commonly, of the neuromuscular system. Possibly a variety of underlying problems can result in the same type of mechanical lameness.

ANATOMICAL CONSIDERATIONS

A number of unique anatomical features in the equine hindlimb contribute to mechanical lameness. The configuration of the patellar ligaments in the stifle joint allows locking of the stifle into an extended position. The stay apparatus minimizes the muscular effort required for a horse to stand for long periods of time. The reciprocal apparatus links the actions of the stifle and hock, primarily through the fibularis (peroneus) tertius and superficial digital flexor tendons, such that an abnormal action in either joint affects the action of both.

Innervation patterns to the muscles of the hindlimbs may also contribute to mechanical lameness. The semitendinosus muscle, for example, receives innervation from two different nerves, the caudal gluteal and sciatic nerves. Often more than one muscular branch innervates long muscles such as the semitendinosus and possibly the semimembranosus. Damage to one nerve or to a muscular branch can result in partial denervation of a large muscle, with resultant altered biomechanical forces leading to abnormal limb action.

UPWARD FIXATION OF THE PATELLA (LOCKING STIFLE OR FIXATION OF THE PATELLA)

Clinical Characteristics

Horses with upward fixation of the patella are periodically unable to flex the stifle or the hock and drag the extended limb behind them on the toe (Fig. 49-1). The condition occurs most commonly after a period of standing still and tends to decrease with continued exercise. An intermittent form of patellar fixation, called *delayed release of the patella*, also occurs, in which the patella appears occasionally to catch briefly, followed by exaggerated flexion of the stifle and hock. This gait resembles the abnormal gait of stringhalt and shivers and may occasionally occur at the trot and canter, in addition to at the walk. Affected horses may appear to be in some discomfort, particularly if the joint is locked for an extended time, and can become somewhat irritable.

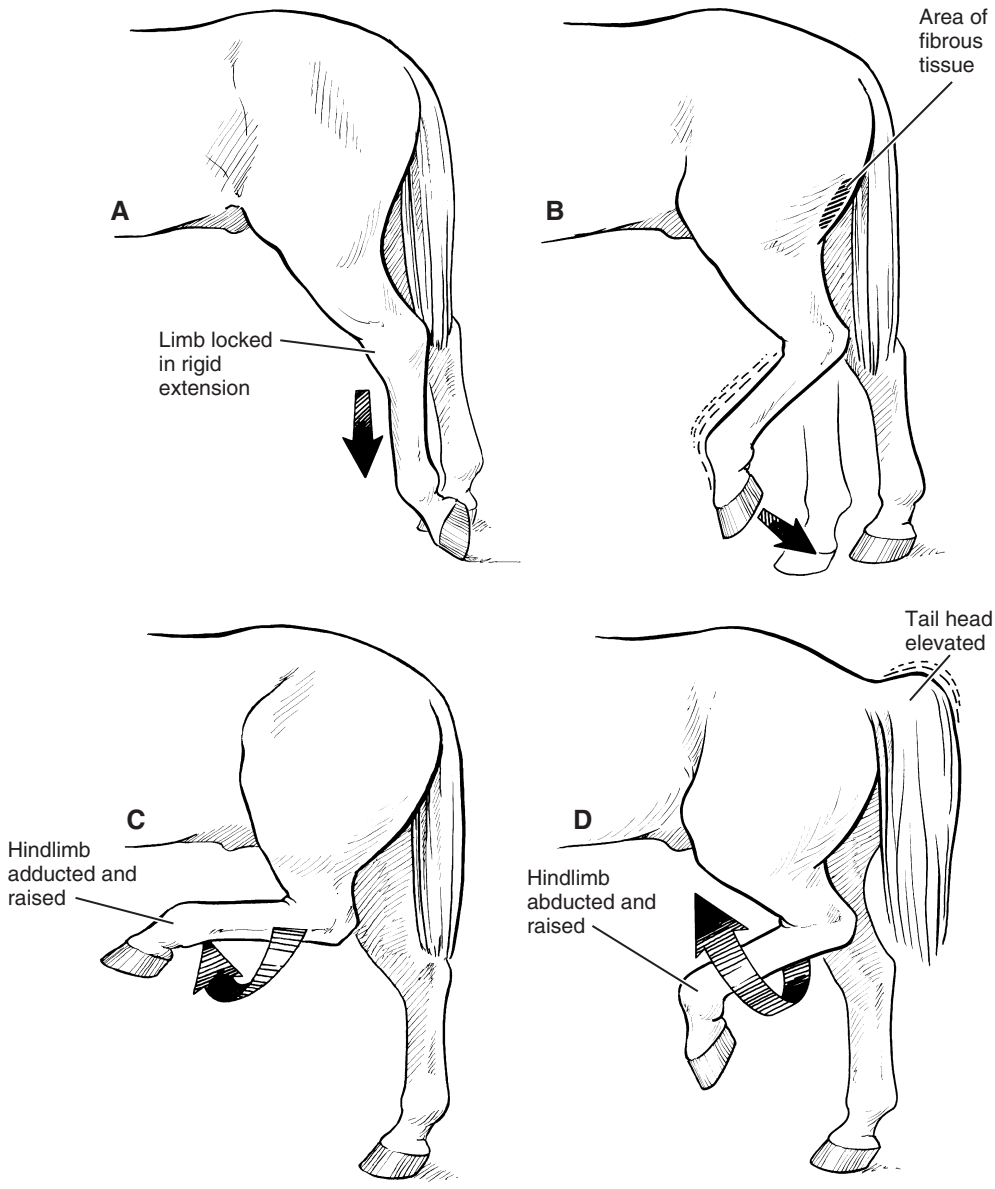

Fig. 49-1 Diagrammatic representation of the common mechanical hindlimb gait abnormalities. **A,** In horses with upward fixation of the patella the hindlimb is periodically held in rigid extension. The fetlock joint is flexed, and the horse walks on the toe. Horses with intermittent upward fixation can have a gait similar to shivers (see **D**). **B,** Horses with fibrotic myopathy show slapping of the affected hindlimb downward just before the end of the cranial phase of every walk stride. Hock flexion is near normal, but fibrous tissue in the caudal thigh region limits the cranial phase of the stride. **C,** Horses with stringhalt exaggerate flexion of the hock with the hindlimb in a normal (adducted) position. This gait occurs at every walk stride. Excessive hock flexion causes some horses to hit the ventral abdomen with the dorsum of the hindlimb. **D,** Horses with shivers often have abnormal tail head elevation and hold the affected hindlimb in a flexed and raised position away from the midline (abducted). This abnormal gait occurs sporadically, not at every walk step, which helps to distinguish it from stringhalt.

Low-grade intermittent upward fixation or delayed release of the patella is relatively common, but it is often difficult to detect. Affected horses have a slightly jerky movement of the hindlimb that may be most apparent during deceleration from trot to walk and when the horse is working in deep footing, especially on turns. Warmbloods, Thoroughbreds, and Standardbreds may be predisposed to upward fixation of the patella. The episodic nature of intermittent upward fixation of the patella adds to the difficulty of detecting a horse with low-grade signs. Careful observation while moving the horse over from side to side, or walking down an incline, can be particularly useful.

Cause

Upward fixation of the patella has been attributed to abnormal laxity and to increased tenseness of patellar ligaments. Decreased force of muscle contraction of the thigh muscles (quadriceps and biceps femoris) that move the patella out of

the locked position may also cause upward fixation of the patella. This may be the explanation for upward fixation of the patella occurring in horses with underlying myopathy, causing weak or stiff muscles. Horses and ponies with overly straight hindlimbs may be prone to upward fixation of the patella, because such conformation can result in overextension of the stifle joint, leading to patellar locking.[6] Permanent upward fixation of the patella rarely occurs secondary to luxation or subluxation of the ipsilateral coxofemoral joint.

Biomechanical Basis

Upward fixation of the patella is caused by failure of the medial patellar ligament to unhook from the medial ridge of the femoral trochlea, causing the stifle to lock in extension. Abnormalities of the fibrocartilage at the medial aspect of the patella also possibly make the joint prone to locking. Once the stifle is locked in extension, the hock is also fixed in extension through the action of the reciprocal apparatus. The biomechanical basis for stifle hyperflexion after the brief period of patellar catching in intermittent upward fixation of the patella (or delayed release of the patella) is not entirely clear and may be from increased force of contraction of the biceps and quadriceps muscles during the transient locking phase. Clearly, therapy for this disorder should be directed at correcting the underlying cause. Unfortunately, for many horses an exact cause is never determined.

Medical Therapy

Exercise is an important part of therapy for patellar fixation. Conditioning exercise, including work on hills, may result in complete resolution of the problem in some horses. Uphill work may be more beneficial than downhill exercise. Horses that respond to conditioning exercise indicate that muscle dysfunction can play an important role in the development of upward fixation of the patella. If underlying myopathy such as EPSSM is the cause, diet change to one that is high in fat and low in starches and sugars[7] and continued exercise conditioning may be beneficial. The most effective diets are those that provide at least 20% to 25% of total daily energy from fat and less than 20% of total daily energy from starches and sugars.

Another medical therapy is administration of estrogenic compounds. The rationale is presumably that estrogens can cause tendon and ligament relaxation. Whether horses with upward fixation of the patella have overly tense patellar ligaments and whether estrogen has any effect on patellar ligaments and tendons is unclear. Estrogen effects on muscle cell metabolism and muscle tone are possible. Anecdotal evidence suggests that some horses may benefit from this type of therapy. Intramuscular injection of 1 mg estradiol cypionate per 45 kg of body weight (i.e., 11 mg/500 kg) once weekly for 3 to 5 weeks has been recommended.

Injection of iodine-containing counterirritants into and around the medial and middle patellar ligaments has also been advocated. The rationale is also unclear; presumably the sclerosing action of these compounds acts to tighten loose ligaments. Injection of a 2% solution of iodine in oil or of ethanolamine oleate has been advocated. Injection of 1 to 1.25 ml of these compounds into multiple sites in and around the distal aspect of the medial and middle patellar ligaments is recommended.

Surgical Therapy

Medial patellar desmotomy may be necessary, although this should be considered only in horses with severe upward fixation of the patella that are unresponsive to conditioning exercise or medical therapy or for horses that are persistently locked for several days. Because the transected ligament often eventually heals with a fibrous union, the main benefit of surgery may be temporarily to alter the action of the stifle joint such that the horse is capable of conditioning exercise. Development of fragmentation of the apex of the patella (sometimes referred to as patellar chondromalacia) is possible after medial patellar desmotomy (see Fig. 47-4). Middle patellar desmitis is also a potential untoward sequela.

FIBROTIC MYOPATHY

Clinical Characteristics

The abnormal gait of fibrotic myopathy is characterized by a shortened cranial swing phase of the affected limb while walking, with an abrupt catching of the forward swing, a slight caudal swing, and slapping of the hoof onto the ground (see Fig. 49-1). This abnormal gait is present at every walk stride, but it is often much less apparent at the trot and canter. Affected horses may have a palpable thickening behind the stifle in the area of the insertion of the semitendinosus and semimembranosus muscles or farther distally, but this is not a consistent finding. Osseous metaplasia may accompany fibrosis in some horses. Affected muscles may exhibit some degree of atrophy. Some horses have an obvious dimple or depression in the affected muscle. Ultrasonographic evaluation of the caudal thigh musculature can be useful[8] and may detect focal hyperechoic areas of fibrosis when none are palpable or hyperechoic areas with underlying acoustic shadowing associated with mineralization.

Fibrotic myopathy is most often a unilateral problem but can occur bilaterally. Fibrotic myopathy may occur first in one hindlimb, followed by development of a similar abnormal gait in the other hindlimb months to years later. This gait abnormality does not appear to be painful or distressing to the horse, and signs do not increase from anxiety or decreased ambient temperature. Fibrotic myopathy occurs most often in adult horses but has also been described in neonates. Fibrotic myopathy in foals does not appear to be associated with palpable fibrosis of the distal semitendinosus.

Cause

Fibrotic myopathy has been attributed to tearing at the insertion of the semitendinosus muscle during activities that result in extreme tension, such as sliding stops in reining horses and struggling from catching a leg in a halter or tether. Traumatic injuries to the semitendinosus, or inflammatory processes such as abscesses at injection sites, can cause fibrotic myopathy. Less commonly, damage to the semimembranosus or gracilis is a cause.[9] Fibrotic myopathy present at birth has been speculated to be caused by trauma at or soon after birth.[10] Adhesions between the semitendinosus and the semimembranosus or biceps femoris muscles causing restriction of muscle action have been proposed.[11] Careful study of a small series of horses with fibrotic myopathy found that underlying traumatic or degenerative neuropathy causing denervation of the distal semitendinosus can result in fibrotic myopathy.[5] Two horses with minimal fibrosis had bilateral fibrotic myopathy from degenerative neuropathy of unknown cause. One horse had unilateral fibrotic myopathy caused by nerve damage after fracture and scarring of the caudal aspect of the greater trochanter. This horse had characteristic fibrosis of the distal aspect of semitendinosus. Underlying neuropathy is the most likely cause in horses in which fibrotic myopathy develops in one hindlimb and progresses to involve the other hindlimb.

Biomechanical Basis

Functional shortening caused by denervation, muscle scarring, or adhesions to adjacent muscles results in increased muscle tension that does not allow full extension of the stifle, and secondarily the hock, during the cranial swing phase.

Medical Therapy
No medical therapy has been shown to be useful in treating fibrotic myopathy. Exercise does not appear to alleviate or exacerbate the abnormal gait.

Surgical Therapy
Surgical resection of the affected distal semitendinosus muscle (semitendinosus myotomy),[12] affected muscle and tendon of insertion (semitendinosus myotenectomy),[9,11] or semitendinosus tenotomy at the tibial insertion[10] have all resulted in some degree of immediate gait improvement. Myotomy and myotenectomy have been associated with a relatively high degree of postoperative complications compared with simple tenectomy. Semitendinosus tenectomy may result in satisfactory results in many horses, although others may require myotenectomy or myotomy. If portions of muscle are excised, submission of these samples to a histopathologist with expertise in the pathology of neuromuscular disease may aid in determining the cause. At least partial recurrence of fibrotic myopathy after surgery occurs in about one third of horses, although the resultant gait deficit may not interfere with full return to function.[12] If progressive neuropathy is the cause, recurrence of signs after any type of surgery is likely.

STRINGHALT

Clinical Characteristics
The abnormal gait of a horse with stringhalt is an exaggerated upward flexion that occurs at every walk stride (see Fig. 49-1). The affected leg is brought up and in (adducted) underneath the horse, such that the fetlock may contact the ventral abdominal wall. This abnormal gait often lessens considerably during the trot and usually, but not always, disappears at the canter. Affected horses may have difficulty backing and in horses with mild disease the gait abnormality may only be apparent while backing. In such horses a diagnosis of mild shivers should also be considered. Stringhalt may affect one or both hindlimbs. The Australian form of stringhalt is bilateral and occurs in groups of horses on pasture containing dandelions known as flatweed (*Hypochoeris radica*).[3] The toxic principle is as yet unknown. Forelimbs may also be affected in horses with Australian stringhalt. A similar syndrome has been seen in the Pacific Northwest and in Europe. Horses with stringhalt may or may not appear distressed by the gait abnormality. Similar to shivers (see the following discussion), anxiety and cold weather are reported to increase the severity of clinical signs in horses with stringhalt.[4,11]

Cause
True stringhalt, or sporadic, or pasture-associated, stringhalt are most likely caused by underlying neuropathy. The Australian form of stringhalt has been clearly shown to be from underlying neuropathy.[3] All horses with sporadic stringhalt in which I examined muscle or peripheral nerve have had evidence of neuropathy and denervation atrophy, although the cause has not been apparent. Histopathological evaluation of the lateral digital extensor muscle after lateral digital extensor myotenectomy has been particularly useful in detecting evidence of denervation atrophy. Horses with equine motor neuron disease have generalized denervation atrophy and can develop stringhalt that may be bilateral. Denervation atrophy of multiple muscles of the affected hindlimb is seen in horses with stringhalt from EPM. Careful examination of multiple nerves from horses with sporadic[13] or pasture-associated stringhalt[3] has revealed widespread neuropathy. Laryngeal hemiplegia associated with stringhalt is common, indicating a predisposition for abnormalities of long nerves. The condition is similar to peripheral neuropathies in dogs, in which long nerves such as the recurrent laryngeal and sciatic nerves can be preferentially involved, and the cause is often not known. Lesions occur in the left recurrent laryngeal nerve in about 60% of horses of Australian stringhalt.[3] Clinical signs of laryngeal dysfunction may or may not be apparent. Development of stringhalt has been reported in horses after trauma to the dorsal hock and metatarsal regions in the area of the extensor tendons.[14] If proprioceptive deficits and ataxia are detected in a horse with stringhalt, peripheral neuropathy caused by EPM should be considered likely.

Biomechanical Basis
Although underlying neuropathy is well established as a cause of stringhalt, the biomechanical basis for the exaggerated flexion is still somewhat perplexing. Altered proprioception from neuropathy was suggested[6] and this hypothesis is appealing. Neuropathy may lead to paresthesia or to altered input to or activity of muscle spindles. Given the exaggerated flexion of the hindlimbs of most horses after placement of hind limb shipping (traveling) boots, altered sensation leading to limb hyperflexion is plausible. Other proposed causes include tendon adhesions around the tarsocrural joint or altered tendon reflexes after trauma[14] and hyperexcitability of motor neurons.[4]

Medical Therapy
For horses with stringhalt associated with plant toxicity, removal from the pasture may be curative, although recovery may take months to years and may not be complete.[4] Trauma-induced stringhalt may resolve with exercise therapy.[14] Oral phenytoin at 15 to 25 mg/kg once or twice daily may also be effective in some horses. The beneficial actions of phenytoin may include stabilization of neuronal, peripheral nerve, or skeletal muscle membrane electrical activity or decreased anxiety from sedation.[4]

Surgical Therapy
Horses with residual gait abnormality after plant toxicity or traumatic neuropathy and horses with stringhalt caused by degenerative peripheral neuropathy may benefit from lateral digital extensor myotenectomy. Although some affected horses may return to full and high-level athletic performance after surgery, for many this should be considered a salvage type of operation to allow a more normal gait for breeding horses, pasture pets, and horses in which the owner's expectations of performance are limited to light hacking.

SHIVERS (SHIVERERS)

Clinical Characteristics
First described in Draft breeds, this disorder also occurs with some frequency in Warmbloods. Anecdotal evidence suggests a heritable predisposition. Shivers also occurs sporadically in other breeds, including Thoroughbreds, Quarter Horses, Arabians, and Morgans. In my experience with 25 shiverers approximately 80% were stallions or geldings.

The clinical features of shivers, particularly in horses with early or mild disease, may resemble stringhalt or intermittent upward fixation of the patella. Affected horses may be described as stringy, especially by Draft horse owners. Affected horses exhibit an episodic hyperflexion of the hindlimb and often abduct the limb before placing the hoof on the ground (see Fig. 49-1). The affected limb may be held up in a flexed and abducted position for several seconds. Frequently the tail is simultaneously raised (Fig. 49-2). The horse may stretch its head up or forward during these episodes and flickering of the eyelids and ears may occur. The muscles of the affected limb may tremble, but more commonly the tail quivers. As opposed to stringhalt, this abnormal gait is sporadic rather than occur-

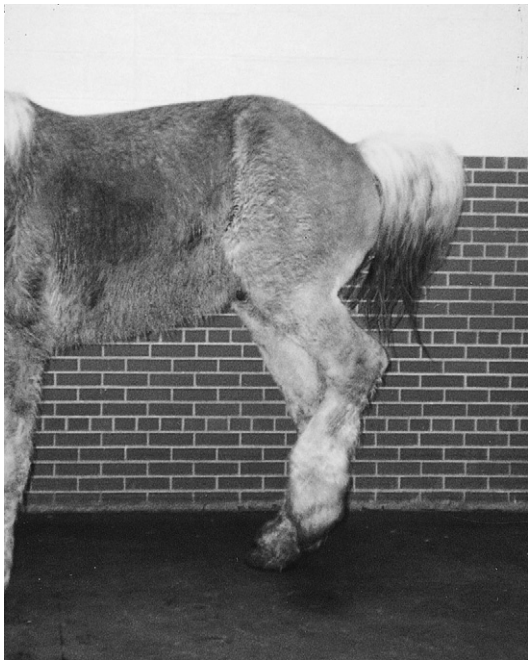

Fig. 49-2 Belgian Draft horse exhibiting the raised tail and hindlimb overflexion characteristic of severe shivers.

ring at every stride and is not apparent at the trot or canter. The abnormal gait is most often seen when backing, turning tight circles, in the first walk stride after standing, and in the last walk stride before halting. The clinical signs may also be seen periodically while the horse is standing still. The abnormal gait is exacerbated by lack of exercise, cold ambient temperature, and increased anxiety in the horse. Neurological examination does not reveal evidence of postural reflex abnormalities or of ataxia.

The farrier may first diagnose shivers, because trimming and shoeing the hindlimbs is often difficult in these horses. They may be reluctant or appear unable to hold the affected limb up, or to stand on three limbs, for any length of time. When asked to lift a hind foot, the horse often hesitates, followed by an exaggerated flexion.

Shivers most often starts as a hitch in one hind limb. Shivers is a progressive disorder that eventually involves both hindlimbs and may progress to involve forelimbs. Severely affected horses develop generalized muscle atrophy and weakness and may exhibit periodic cramping of each leg in succession, with occasional leaning of the body such that the horse appears ready to fall. Onset is often between 2 and 4 years of age, but this varies extremely, as does the rate of progression. The most severe form of progressive shivers occurs in Draft horses. A somewhat milder form occurs in Warmbloods, in which sporadic abnormal hindlimb action is seen, but Warmbloods with shivers rarely exhibit a raised and quivering tail. Clinical signs in such horses are often mistaken for stringhalt or intermittent upward fixation of the patella. Affected horses may appear unaware of the problem and continue to compete in harness or at high levels in dressage or jumping for many years. Prepurchase evaluation of these high-performing shiverers can be particularly vexing, because the expected progression of signs is completely unpredictable.

A recently recognized and poorly understood syndrome known as "stiff-horse syndrome" may resemble shivers. Affected horses have a stiff gait and muscle spasms in the epaxial muscles of the lower back and in the muscles of the hindlimbs. Spasms may be precipitated by voluntary movements or by someone picking up a limb. Increased levels of antibodies to glutamic acid decarboxylase have been reported.[15]

Cause

Although an underlying neuropathy was proposed, careful study of two Draft horses with shivers failed to reveal evidence of peripheral or central nervous system disease. Examination of muscle from these and a small but growing number of shivers horses of various breeds has revealed underlying EPSSM. Contiguous groups of glycogen-depleted skeletal muscle fibers in muscles of the proximal thigh and back have been seen in a small number of horses studied and indicate that this disorder may involve episodic muscle contracture (cramping).[1]

Biomechanical Basis

As with the exaggerated gait of stringhalt and of intermittent upward fixation of the patella, explaining the abnormal gait of shivers is difficult. The possible role of episodic muscle cramp or abnormal sensations within the affected leg is worthy of further study. Horses with an abscess in a hind hoof may show an abnormal flexing of the limb while standing that resembles shivers, and hind hoof abscesses often increase the abnormal action of the affected hindlimb in horses with shivers.

Medical Therapy

Regular exercise may help alleviate some of the signs of shivers and may even slow the progression. To date, the only medical therapy that appears to reverse the signs of shivers has been a change to a high-fat and low starch and sugar diet.[2,7] Whether this therapy acts by decreasing muscle cramping, decreasing anxiety in the horse, a combination of these effects, or some other mechanism is still unknown. In my experience approximately 80% of horses diagnosed with shivers (and many misdiagnosed as stringhalt) have responded to some degree after 4 to 6 months of diet change. These horses include those in which muscle biopsy revealed characteristic changes of EPSSM and horses with no apparent abnormalities in the muscle samples examined. Improvement is often only partial, but most owners have been pleased with results, and dietary therapy may help to slow the progression of the disease.

Surgical Therapy

No surgical therapy is available for shivers.

OTHER MECHANICAL LAMENESSES

The biomechanical basis of mechanical lameness resulting in decreased flexion of the stifle and hock, such as fibrotic myopathy and upward fixation of the patella, are readily understood. These gaits are also characteristic and readily distinguished from other mechanical lamenesses. The mechanical lamenesses resulting in hyperflexion—that is, intermittent upward fixation of the patella, stringhalt, and shivers—however, have clinical similarities that can make them difficult to distinguish. One may also safely say that altered gaits from abnormal muscle or nerve function may not fall into one of the previously defined categories. A horse may appear stringy, locked up, have a goose waddle or stiff, stabbing hindlimb gait, or just appear off in a hindlimb because of mechanical lameness. A slight reduction in hock flexion at the walk may be considered normal for the horse, but this gait may also reflect a mechanical lameness.

In all horses with perplexing hindlimb lameness, the possibility of a form of mechanical lameness should be considered. This is especially true in breeds such as Draft, Quarter Horse, and Warmblood-related breeds that are recognized to have a predilection for underlying myopathy. Because underlying myopathy or neuropathy is likely to be the most common cause of mechanical lameness, electromyography and muscle biopsy should be considered in all horses with mechanical lameness of the pelvic limbs.

CHAPTER • 50

Estrous Cycle and Performance in Athletic Mares

Joan S. Jorgensen and Richard A. Mansmann

Some fillies and mares periodically suffer from a variety of problems that may be linked to the estrous cycle and can have serious consequences on performance,[1,2] including alterations in behavior that affect training or riding, lameness, back pain, abdominal pain, or an increased propensity for muscle spasms and exertional rhabdomyolysis (ER) (tying up).[3] These conditions have been associated with the estrus (heat) or diestrus phases of the cycle, but in some horses the problems cannot be linked to any stage of the estrous cycle.[2]

The estrous cycle has two phases: estrus and diestrus. Typical behavioral signs of estrous include the adoption of a urination stance and passage of intermittent spurts of urine, tail raising, and allowance of stallion contact.[4-6] Concentrations of estrogen and luteinizing hormone increase, and serum progesterone levels decrease.[6,7] In contrast, mares in diestrus kick at stallions and do not allow contact.[4,6] Serum estrogen and luteinizing hormone concentrations are low, and progesterone dominates the hormonal profile. Progesterone suppresses the manifestation of estrus behavior and is considered to dominate the behavioral effect of estrogen.[4,8-10] Thus most treatments for abnormalities associated with the reproductive cycle include some form of progestin.[3]

PROBLEMS ASSOCIATED WITH THE REPRODUCTIVE CYCLE

A recent survey of the American Association of Equine Practitioners revealed that the most frequently reported clinical sign of a change in performance caused by the estrous cycle was a change in attitude.[11] Other signs included tail swishing, difficulty in training, squealing, horsing, urinating excessively, kicking, and a general decrease in performance. Anecdotal reports from Thoroughbred racehorse practitioners suggested that some young nervous fillies were predisposed to ER. Furthermore, anxious mares may be at an increased risk for orthopedic problems because they are often worked for longer to reduce the anxiety and improve performance.

Difficulty in training or riding, lameness, back pain, or ER are most commonly associated with musculoskeletal or neurological disorders. Similarly, abdominal pain is usually linked to gastrointestinal disease. Thus these problems should be ruled out before incriminating the reproductive system. Mares with colic-like discomfort, hindlimb lameness, or back pain when the rider is in the saddle may have painful ovaries, especially in the peri-ovulatory period.[2,12] Indeed, pressure applied

CHAPTER • 50

Estrous Cycle and Performance in Athletic Mares

Joan S. Jorgensen and Richard A. Mansmann

Some fillies and mares periodically suffer from a variety of problems that may be linked to the estrous cycle and can have serious consequences on performance,[1,2] including alterations in behavior that affect training or riding, lameness, back pain, abdominal pain, or an increased propensity for muscle spasms and exertional rhabdomyolysis (ER) (tying up).[3] These conditions have been associated with the estrus (heat) or diestrus phases of the cycle, but in some horses the problems cannot be linked to any stage of the estrous cycle.[2]

The estrous cycle has two phases: estrus and diestrus. Typical behavioral signs of estrous include the adoption of a urination stance and passage of intermittent spurts of urine, tail raising, and allowance of stallion contact.[4-6] Concentrations of estrogen and luteinizing hormone increase, and serum progesterone levels decrease.[6,7] In contrast, mares in diestrus kick at stallions and do not allow contact.[4,6] Serum estrogen and luteinizing hormone concentrations are low, and progesterone dominates the hormonal profile. Progesterone suppresses the manifestation of estrus behavior and is considered to dominate the behavioral effect of estrogen.[4,8-10] Thus most treatments for abnormalities associated with the reproductive cycle include some form of progestin.[3]

PROBLEMS ASSOCIATED WITH THE REPRODUCTIVE CYCLE

A recent survey of the American Association of Equine Practitioners revealed that the most frequently reported clinical sign of a change in performance caused by the estrous cycle was a change in attitude.[11] Other signs included tail swishing, difficulty in training, squealing, horsing, urinating excessively, kicking, and a general decrease in performance. Anecdotal reports from Thoroughbred racehorse practitioners suggested that some young nervous fillies were predisposed to ER. Furthermore, anxious mares may be at an increased risk for orthopedic problems because they are often worked for longer to reduce the anxiety and improve performance.

Difficulty in training or riding, lameness, back pain, or ER are most commonly associated with musculoskeletal or neurological disorders. Similarly, abdominal pain is usually linked to gastrointestinal disease. Thus these problems should be ruled out before incriminating the reproductive system. Mares with colic-like discomfort, hindlimb lameness, or back pain when the rider is in the saddle may have painful ovaries, especially in the peri-ovulatory period.[2,12] Indeed, pressure applied

to the ovaries per rectum can elicit a pain response.[13] Palpation of a large ovulatory follicle or a follicle that has recently ovulated, other genital tract characteristics of estrus, and concomitant behavioral signs of estrus may support this diagnosis. The discomfort should subside shortly after ovulation, but it may recur with future cycles.[12]

Peri-ovulatory discomfort is thought to be caused by a combination of extremely enlarged follicles that affect neighboring tissues and the release of follicular fluid during ovulation, some of which may leak into the peritoneal cavity and cause localized inflammation. These factors may result in localized pain that lasts approximately 24 to 48 hours.

The estrous cycle is also characterized by changes in the hormonal profile. Specific balances between gonadotropins and sex steroids are necessary for smooth transitions between phases of the reproductive cycle. We propose that any alteration in the ratios between luteinizing hormone and follicle-stimulating hormone; androgens, estrogens, and progestins; or both results in erratic behavior that leads to poor performance. Ongoing studies of behavior and performance in athletic mares are intended to test this hypothesis.

TREATMENT

Treatment of performance problems related to the estrous cycle is directed toward stabilizing the hormonal profile by medical, physiological, or surgical means.

Medical

The most common form of medical therapy is some form of progestin: oral, injectable, or pellet implant (Table 50-1). Progestin therapy has long been the standard for preventing ovulation. However, treatment for performance problems in mares does not necessarily require suppression of estrus. Altrenogest (Regu-Mate) is given orally, once daily (0.044 mg/kg), and is the only drug that is approved for use in mares. Administering all other forms of progestins is considered extra-label usage. Care must be taken in handling this drug because it can be absorbed through the skin and may potentially affect the menstrual cycle of women. Pelleted implants for use in cattle containing either 100 mg progesterone and 10 mg estradiol benzoate (Synovex C), or double those dosages (Synovex S), have been used successfully for performance problems for up to 3 months. The implants are placed subcutaneously in the side of the neck beneath the mane. A potential complication is development of implant site reactions or abscesses.[3]

Other steroidal medications have been used successfully but much less frequently. Glucocorticoids (dexamethasone) interfere with ovulation in many species, including mares.[14] Dexamethasone can be administered orally or by injection. However, dexamethasone must be given at least once daily and has been associated with serious complications, such as an increased susceptibility to infection and laminitis.[15] Dexamethasone (15 mg IM bid) has suppressed estrus signs in ovariectomized pony mares.[16,17] Mares that have a predisposition to ER have been treated successfully with anabolic steroids such as testosterone and boldenon undecylenate (Equipoise).

Physiological

Progesterone levels obtained during pregnancy are generally sufficient to suppress sexual behavior in mares,[18] thus breeding a problem mare may temporarily resolve performance problems. Most mares can train and continue to perform until the eighth month of pregnancy. However, the undesirable behavior may be passed on to female offspring, and several risks are associated with breeding, pregnancy, parturition, and foal management.

Table • **50-1**

Drugs Used to Treat Hormone-Related Performance Problems in Mares

Form of Drug	Progestins	Glucocorticoids
Oral	Altrenogest (Regu-Mate) 0.044 mg/kg PO q24h Hoechst-Roussel Agri-Vet Co.	Dexamethasone (Azium) 10 mg/500 kg PO bid Schering-Plough Animal Health Corp.
	Megestrol acetate (Ovaban) 65-85 mg/500 kg PO q24h Schering-Plough Animal Health Corp.	
Injectable	Medroxyprogesterone acetate (Depo-Provera) 200-250 mg/500 kg IM q8-14d Pharmacia	Dexamethasone solution 15 mg/500 kg IM bid Vedco, Inc.
	Progesterone impregnated microspheres (Lutamate Plus) 1.25 g progesterone + 100 mg estradiol-17β/500 kg IM q12-14d Unavailable in United States	
Pellet implant	Synovex C 6-8 pellets (100 mg progesterone, 10 mg estradiol benzoate) Synovex S 3-4 pellets (200 mg progesterone, 20 mg estradiol benzoate) Implant subcutaneously q3mo Fort Dodge Laboratories	

Surgical

Ovariectomy is irreversible and considered a therapy of last resort. The surgery may be successful in treating hormone-related performance problems, but many reports indicate that mares continue to exhibit undesirable traits after surgery.[3,16,17,19,20] These findings suggest that other systems may play an important and as yet uncharacterized role in erratic performance problems. For example, the adrenal gland is an important source of sex steroid production. Further investigation into performance problems related to the reproductive cycle and the associated hormone producing organs is necessary to fully understand this problem.

Diagnosis and Management of Pelvic Fractures in the Thoroughbred Racehorse

Robert C. Pilsworth

Injuries to the pelvis of the horse have in the past been considered uncommon.[1-3] They have also previously been described as invariably resulting from external trauma.[4] Only recently have pelvic fractures been recognized as a common cause of lameness in the racing Thoroughbred (TB). Stover et al.[5] confirmed a high incidence of stress fractures in the pelvis of American racing TBs examined at post mortem. Similarly in a clinical study performed in Newmarket, England, pelvic fractures were found to be common in the young racing TB.[6,7] We are gradually realizing that pelvic fractures in the TB are most often the end stage of a cycle of bone fatigue and injury, commonly called stress-related bone injury. This has focused attention on early detection, before the development of a full-blown displaced fracture. This section outlines steps to aid in early detection and management strategies subsequent to diagnosis.

PELVIC ANATOMY

The pelvis comprises the symmetrical halves and the sacrum in the midline. The left and right halves of the pelvis are joined in the ventral midline at the pubic symphysis. Although technically a joint, this becomes mineralized with age and is in most horses a firm bony union. A second joint occurs on each side between the pelvis and the head of the femur forming the coxofemoral joint. The third joint is that between the ventral surface of the pelvis and the sacrum, the sacroiliac joint. Only the coxofemoral joint has any significant degree of movement. The sacroiliac joint does have a synovial membrane, but in many horses it is largely immobile. In most horses the sacroiliac joint is spanned by dense bands of fibrous connective tissue and, despite having a cartilage surface, little or no movement takes place in the normal sacroiliac joint. Each half of the pelvis comprises three bones, which meet at the acetabulum, the ilium cranially, the ischium caudally, and the pubis medially. The ilium has a large wing of bone extending from the tuber sacrale in the midline to the tuber coxae at the lateral extremity. The blade of the ilium narrows to form the shaft, which extends back to form the cranial segment of the coxofemoral joint. Caudal to the coxofemoral joint, and forming its caudal margin, is the ischium. Joining the two acetabula, forming the floor of the pelvis with its contralateral counterpart, is the pubis. The bones of the pelvis form a large fulcrum on which most of the gluteal muscle mass originates, to exert considerable propulsive forces on the hindlimbs. Although the pelvis can fracture anywhere as a result of external trauma or a fall, as is common with many other stress injuries, the forces involved in locomotion create predilection sites for stress fractures. These sites are associated with the concentration of forces involved in load bearing at speed and the biomechanics, innate structure, and form of the bone.

DIAGNOSTIC TECHNIQUES

Clinical Examination

A thorough working knowledge of the anatomy of the equine pelvis is essential for clinical examination to be useful. Because of the large muscle mass over the horse's hindquarters only the bony extremities of the pelvis can be palpated. However, it is often possible to gain information about horses with pelvic injuries by studying the position of these bony landmarks. For instance, the normal position and angle of the tuber coxae in the racehorse is often disturbed in horses with fracture or sacroiliac joint instability. The position of the tubera coxae can be assessed by viewing the horse from behind, with an assistant placing fingertips on the craniodorsal extremity of the tubera coxae (Fig. 51-1). It is important that the horse stands completely level, with both hind feet together, for this test to be meaningful. Some horses, however, show asymmetry viewed in this way that is not linked to lameness. Similarly, careful palpation of the tubera sacrale can give information about the possible involvement of the sacral wing of the ilium or disruption of the sacroiliac joint.

Ventral displacement of one tuber sacrale is commonly encountered in ilial wing fractures, where the overlap of the fracture fragments seems to allow the tuber sacrale to move ventrally. Often a pain response is associated with palpation of a horse with tuber sacrale displacement, and sometimes movement of the bone itself may be felt if the fracture is complete. Fracture of a tuber coxae is often produced by external trauma, usually after a fall, but can also occur as a stress-related athletic injury. This usually results in a cranioventral displacement of the fracture fragment, because of the distrac-

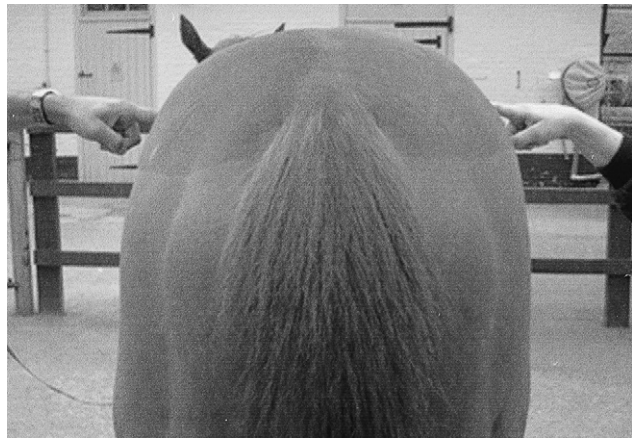

Fig. 51-1 Assessment of the position of the bony pelvis by fingertip levels placed on the dorsal extremity of the tubera coxae on either side.

tive forces of associated musculature. The tuber coxae in these horses can often be felt situated in the sub-lumbar fossa, and the remnant fracture bed can be palpated at the original site. Fractures of the ischium can sometimes be felt by manual palpation, although the extensive muscle spasm and protective boarding which is associated with these fractures often precludes this examination. Finally, muscle tone in the tail and anus should be evaluated, because fractures involving the sacrum can involve neural elements that supply these structures and cause flaccid paralysis of the rectum and anal ring and of the vulva in the filly, the cauda equinum syndrome (Fig. 51-2). Bilateral ilial wing fractures can produce the same neurological appearance associated with severe nerve root damage consequent on movement of the pelvis in relation to the sacrum.

Rectal examination allows direct manual assessment of the integrity of the pubis, internal surface of the wing of the ilium, and ventral border of the sacroiliac joint. Sometimes an obvious, sharp discontinuity in the bone surface can be felt, particularly in horses with fracture of the pubis. Gentle rocking of the horse by an assistant, while the clinician maintains digital contact with the bone surface of the pelvis per rectum, sometimes allows an appreciation of relative movement of adjacent bones, or more commonly, a sensation of crepitus. In horses with fracture of the ilial wing, a soft asymmetrical swelling can often be felt at the fracture site, representing a sub-fascial hematoma. The more serious hemorrhage that occurs when the iliac artery is severed by the sharp dorsal edge of the fractured ilium and that can be fatal often cannot be detected per rectum. If not immediately fatal, this free blood often percolates ventrally to cause massive swelling and edema of the thigh musculature.

Some horses have several stress fractures identified scintigraphically, only one of which may have initially collapsed, leading to overt lameness. Progressive collapse of the pelvis may then occur during the convalescent period, as incomplete fractures become complete and displaced because of bone resorption and weakening of the fracture site. The degree of lameness seen in these horses varies enormously, depending on the type and extent of the fracture, and is considered separately in the after discussions of each class of fracture.

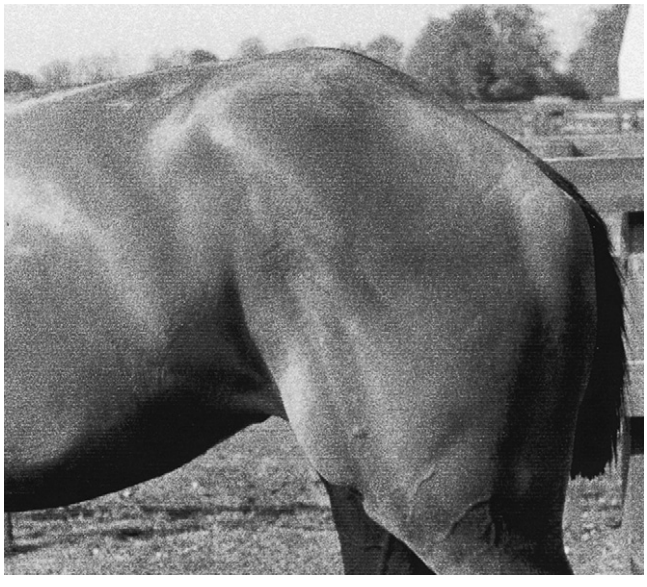

Fig. 51-2 A horse with a sacral fracture. Note the abrupt angle change just behind the tubera sacrale, where the sacrum and coccyx have moved ventrally. The tail has complete flaccid paralysis. This filly had urine and fecal retention.

Diagnostic Ultrasonography

Ultrasonography is useful for diagnosing pelvic fractures and has proved especially useful in demonstrating fractures to the ilial wing, ilial shaft, and tuber coxae. Ultrasonography is quick, easy, and within the capability of clinicians with a suitable ultrasound machine. Ultrasonography may eliminate the requirement for a horse to travel to a referral center for diagnosis, and the risk associated with radiography under general anesthesia can be avoided. Ultrasonography has obvious limitations. For example, adequate imaging of the sacral wing, sacroiliac joint, and the femoral head is not possible. Fractures with minimal displacement or poorly developed callus are also difficult to image, as are incomplete fractures involving the ventral surface of the ilium. For this reason ultrasonography should not be regarded as a stand-alone imaging modality for identifying a fracture of the pelvis but should be used with a thorough clinical examination and, if available, scintigraphy. In many horses the exact site and extent of the fracture can be determined, which allows improved prognostic and management advice to be given. The healing process can be monitored by serial examinations, allowing the management program to be tailored to the individual horse. A longitudinal- or sector-array ultrasound transducer can be used, provided it has a deep enough penetration to see the bone surface (i.e., a 3.5- or 5-MHz transducer). The muscle mass lying above the bone structures acts as a natural "standoff," bringing the bone surfaces into the focal zone of the ultrasound beam. A separate standoff may be required to evaluate the position of the tubera sacrale and to detect any displacement. In thin-coated horses no clipping is required, provided adequate saturation of the coat is achieved by degreasing with a detergent solution (chlorhexidine), or by soaking in surgical spirit, followed by application of a coupling gel before scanning. Horses with thicker hair coats must be clipped to obtain images of adequate quality. Images can be difficult to produce in horses with large amounts of subcutaneous fat because of the attenuating properties of this tissue. Numerous blood vessels running through the musculature can create acoustic shadows, which may be confused with a discontinuity of the bone surface. Identifying the bony landmarks such as the tubera sacrale, tubera coxae, cranial and caudal margins of the ilial wing, and greater trochanters of the femur allow anatomical orientation. A dry pelvic specimen is also useful in orientation. Both sides of the pelvis should be evaluated, because the normal side can be used for comparison. However, keep in mind that bilateral ilial wing stress fractures occur and both sides may be abnormal. For recording and reference purposes the area of the ilial wing imaged is referred to as line A, B, or C and the distance from the tuber sacrale is measured. Scans aligned longitudinally along the ilial shaft are referred to as line D. This simple system is useful, especially in follow-up examinations. A systematic method for recording ultrasonographic findings has been published elsewhere.[8]

Radiography

Radiography of the pelvis is easily carried out in a foal when it can be performed under heavy sedation, for instance, with a combination of detomidine and butorphanol, with the foal allowed to stand again shortly after the procedure. Standard projections include a ventrodorsal view with the foal lying on its back and a lateral view with the foal lying on its side on top of the cassette. A grid is mandatory to reduce scattered radiation produced by the large mass of soft tissue covering the pelvis. Radiography in the adult horses is considerably more difficult. General anesthesia is required for thorough radiographic examination of the pelvis for numerous reasons, including the safety of the horse, personnel, and radiographic equipment. Administering general anesthesia to a horse suspected of having a pelvic fracture is contraindicated because

of the possibility of the horse displacing the fracture on recovery. Fracture displacement can lead to fatal hemorrhage or worsening of clinical signs, which is particularly true in horses with an incomplete fracture of the wing and shaft of the ilium. It is also difficult to get high-quality radiographs of the pelvic bones without extensive prior starvation of the horse to allow emptying of the gastrointestinal tract. Small, incomplete, pelvic stress fractures are extremely difficult to see radiographically. Standing radiography in the horse has been described.[9] However, in our hands this has proved difficult, presents real risks of damage to the equipment, and is a significant radiation hazard to attending personnel. The standing examination is also limited to examination of the acetabulum and ilial shaft, and images of the ilial wing are obscured by the sub-lumbar and overlying dorsal lumbar musculature. Image quality obtained in this way is also often poor. Although radiography used to be the imaging technique of choice for assessing horses with pelvic fractures, in our hospital it has been replaced by ultrasonographic and scintigraphic evaluation.

Scintigraphy

Scintigraphy is considered the most sensitive method of assessing acute bone damage in the horse.[3,10-12] A full review of veterinary nuclear medical techniques applicable to the horse has recently been published (see Chapter 19).[13] Special techniques for examining the pelvis have also been described, including an oblique projection of the ilium, which is useful in diagnosing incomplete stress fracture in this site.[14] Sacroiliac joint luxation has also been described as a scintigraphic diagnosis, the appearance of which is extremely similar to the ilial wing fractures observed by others.[3] To examine the equine pelvis fully using a gamma camera, dorsal projections of the entire pelvis are mandatory. The lateral projection of the pelvis tends to be difficult to interpret because of the apparent focal increased radiopharmaceutical uptake (IRU) observed at the tuber coxae and the coxofemoral joint in a normal horse. The massive muscle mass interposed between the slender bones of the ilial shaft and the gamma camera result in extensive shielding and poor images. Radioactive urine in the underlying bladder contributes to extensive background radiation, further decreasing image quality. Movement is a key factor in limiting image quality, but motion correction software can be used to minimize this complication. However, the lateral oblique projection described by Hornof et al.[14] usually gives better images of the ilial wing and shaft. A caudal oblique projection is also employed by some to give better images of the coxofemoral joint and acetabulum. A method for scintigraphic examination of the pelvis using a handheld probe has also been described.[15] If a pelvic fracture is strongly suspected and initial scintigraphic examination is performed within 3 to 5 days of injury and is negative, a follow-up examination should be performed at least 10 days from the time of injury. Early fractures, even those with associated displacement, may not be evident scintigraphically for several days after injury.

FRACTURES OF THE TUBER COXAE

Fractures of the tuber coxae are often described as a knocked-down hip. They are relatively common and fairly straightforward to diagnose by clinical examination of the bony landmarks of the pelvis. They may occur after direct trauma or a fall but also as an athletic injury in training or racing.

Clinical Signs

On the first day of injury, the horse is moderately to severely lame, even at the walk. Often the horse shows intense muscle spasm and guarding of the affected hindquarter. The horse may sweat and scrape the ground, which can mimic the signs of colic. The affected tuber coxae is often displaced cranioventrally and is palpable in the region of the sub-lumbar fossa. The parent bed from which the fragment originated is often palpable in the original site of the tuber coxae. Lameness rapidly resolves, and after only 24 to 48 hours many horses are walking sound, but they will still trot lame. Hemorrhaging often occurs, which may present as a subcutaneous hematoma. Occasionally the sharp spiculated end of the ilium wears through the overlying skin, leading to development of a compound fracture, which can be extremely difficult to treat, because the skin overlying the sharp fragment will not heal and infection becomes a problem.

Scintigraphic Examination

Scintigraphic examination is probably not indicated in most horses, because the clinical diagnosis is straightforward. If performed, scintigraphic examination reveals significant focal IRU associated with the displaced tuber coxae and also a fairly obvious distortion of the normal anatomy of the pelvis on the dorsal image. In the Editors' experience, photopenic regions associated with ventral displacement of the fracture fragments may be present.

Ultrasonographic Examination

Directly after injury, horses with tuber coxae fracture have clinical signs similar to those with other fractures of the pelvis, and an ultrasonographic examination helps to confirm the diagnosis and to define better the limits of the fracture. The fracture is easily seen as a disruption to the normally smooth and continuous contour of the ilial wing as it approaches the tuber coxae. A standoff may be required for better imaging of the bone immediately beneath the skin. It is important to perform a thorough examination of all the bony structures to eliminate fractures in other regions of the pelvis.

FRACTURES OF THE ILIAL WING

Fractures of the ilial wing appear to be among the most commonly encountered type of athletic stress fractures in the skeletally immature TB racehorse.[16]

Clinical Signs

A horse with a complete ilial wing fracture often shows lameness, but the initial lameness varies from lame at the walk to grade 1 to 4 out of 5 at the trot. Lameness often resolves rapidly within 24 to 48 hours, and the horse then has a slight gait abnormality, walking with the back hunched up, but with no overt lameness. A horse with an ilial wing fracture often plaits with the hindlimbs at the trot and has a shortened stride. Although a complete fracture may be present on only one side, evidence of a sub-clinical stress fracture in the same site on the contralateral limb is common, and this may contribute to the peculiar gait shown by the horse. Obviously, pain from both sacroiliac joints considerably affects the freedom of movement of the hindlimbs. A horse with bilateral lesions may appear to have signs of exertional rhabdomyolysis, but plasma creatine kinase levels are often normal or only slightly raised (500 to 1500 IU/L).

Incomplete fractures may occur on one or both sides, and this can often show as poor propulsion and a poor hindlimb action in the absence of clinical lameness. In a horse with a complete fracture, ventral displacement of the ipsilateral tuber sacrale is often apparent and can be detected by careful digital examination of the midline of the spine and both tubera sacrale. Firm pressure in the previous site of the tuber sacrale often evinces a marked pain response, with associated

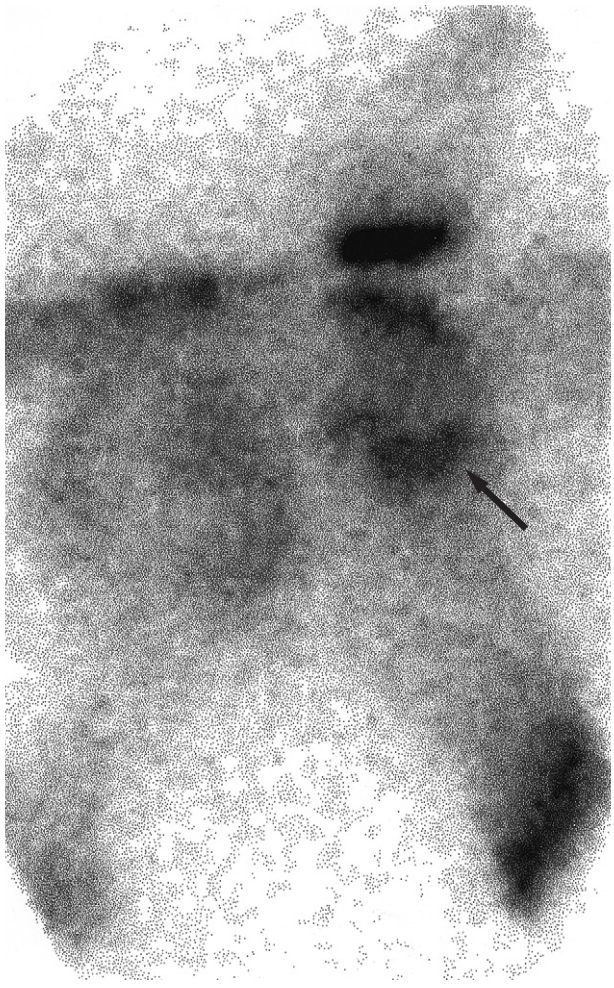

Fig. 51-3 Dorsal lateral oblique delayed (bone) phase scintigraphic image over the left side of the pelvis of a horse with a stress fracture of the ilial wing. Cranial is to the right. Focal increased radiopharmaceutical uptake *(arrow)* appears about a fourth of the way between the tuber sacrale and tuber coxae, the most common predilection site for stress fractures of the ilial wing.

muscle spasm over the sacroiliac joint region. Palpating the tip of the tuber sacrale in its ventrally displaced position is sometimes possible. Often fairly profound muscle wastage is associated with this injury in the first 2 weeks, and this contributes significantly to the apparent asymmetry of the horse when viewed from behind. Bilateral complete fractures lead to profound stiffness, unwillingness to walk, and boarding of the muscles of the pelvis in response to digital manipulation. They can lead to collapse and inability to rise, with significant neurological deficits in severe injuries.

Scintigraphic Examination

Scintigraphy usually reveals marked focal IRU associated with the ilial wing, usually 10 to 15 cm from the midline (Fig. 51-3). Increased radiopharmaceutical uptake may be bilateral or unilateral. A clear fracture line and the displacement of the ilial wing are sometimes clearly visible. The lateral oblique projection[14] is particularly useful in determining whether the fracture extends to the cranial and caudal cortices of the ilial wing.

Ultrasonographic Examination

The normal ultrasonographic appearance of the ilial wing is a smooth and regular concave hyperechoic line, extending between the tuber sacrale and the ipsilateral tuber coxae. Acoustic shadowing and refraction artifacts can be created by the many blood vessels within the musculature and must not be confused with disruption to the bone contour. Ilial wing fractures appear as a disruption to the ilial wing contour, with changes ranging from a clear fracture gap to small irregular echogenic areas on the dorsal surface, representing prodromal periosteal new bone formation. The fractures normally run sagitally and involve the bone dorsal to or in close proximity to the sacroiliac joint. The bone abnormalities often appear more severe toward the caudal margin of the fracture. Sometimes hemorrhage at the site of fracture appears as an anechogenic defect in the normal granular texture of skeletal muscle (Fig. 51-4).

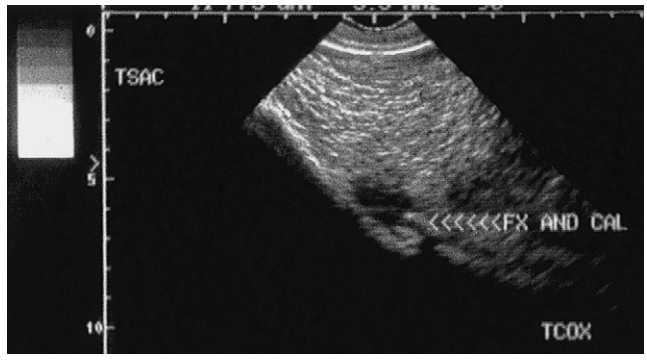

Fig. 51-4 Ultrasonographic image of the left ilial wing obtained using a 3.5-MHz sector transducer. There is a stress fracture of the ilial wing *(FX AND CAL)*. The fracture appears as a discontinuity in the pelvis surface. Adjacent to the fracture is irregular echogenic material (callus), and just dorsal to the fracture is a large anechogenic defect in the muscle (hemorrhage).

FRACTURES OF THE ILIAL SHAFT

The ilial shaft is a common site for fracture after a fall or as a spontaneous athletically induced injury.

Clinical Signs

Fracture of the ilial shaft is extremely painful, producing non–weight-bearing lameness, and is often associated with shock from extreme pain and rapid blood loss. The two tubera coxae often show marked asymmetry when viewed from behind, although encouraging the horse to bear weight equally to allow this examination to be carried out can be difficult. Sometimes with incomplete or minimally displaced fractures, no displacement of the tuber coxae is apparent initially, but in these horses the pelvis often collapses early in convalescence, at which time asymmetry becomes obvious. Collapse of the pelvis can often make the fracture less painful for the horse for reasons that are unclear. Rectal examination is often useful, and gentle rocking of the horse while the arm is inserted in the rectum often allows clear crepitus to be felt with the fingertips on the ilial shaft of the affected side. A hematoma next to the fractured ilium can also be easily palpated in many horses. Not uncommonly horses damage the iliac arteries with the sharp edges of the comminuted fracture fragments, and this can result in severe and sometimes fatal hemorrhage.

Horses usually do not resent palpation and flexion of the distal limb, although forced abduction of the limb including the hock and stifle may elicit a painful response. Palpation of the hindquarters usually results in intense muscle spasm and guarding on the affected side. Bizarre consequences of the

severe lameness and change in functional anatomy after some of these fractures include permanent upward fixation of the patella, contracture of the hamstring group of muscles and spastic hyperextension of the tarsus, and are not uncommon. These complications invariably result in a grave prognosis.

Scintigraphic Examination

Many horses are too lame to allow transport to an equine clinic for scintigraphic examination, and a combination of clinical signs and ultrasonographic findings can establish the diagnosis. Probe point-counting techniques usually show a fairly massive and widespread IRU on the affected side of the pelvis, and seeing clearly from the plot exactly where the fracture has taken place is difficult. Gamma camera studies give much more detail than do probe point-counting techniques, and a caudal oblique projection is often extremely useful in illustrating the extent and nature of the fracture. Because pelvic anatomy is directly visible on a gamma camera scan, the displacement of the fracture fragments and of the ilial wing is often easily appreciated.

Ultrasonographic Examination

The ilial shaft is examined by aligning the ultrasound beam in a craniocaudal direction and following the ilial shaft from the flat surface of the ilial wing toward the greater trochanter of the femur. With ultrasonography a displaced ilial shaft fracture is easily detected as a discontinuity to the bone surface. Passive movement of the limb may show independent movement of the fracture margins in real time scanning. Hypoechogenic areas may be present around the fracture line, which represent hemorrhage into the musculature. As with other fractures, if displacement is minimal, an ultrasonographic examination may fail to detect any pathological condition.

FRACTURES OF THE PUBIS AND ISCHIUM

Discrete fractures of the ischium are relatively uncommon. The horse usually has unilateral lameness with obvious swelling over the caudal thigh. A fall, falling backward, or rearing over are often noted in the history. Often palpable crepitus and a marked pain response on firm digital pressure to the site are apparent. The tail may be held to one side, because of muscle spasm associated with the painful lesion. Often focal sweating occurs on a patch of skin on the back of the thigh, presumably resulting from nerve damage. Fractures of the pubis are only encountered with other multiple pelvic fractures, or after a fall, and are uncommon.

Scintigraphic Examination

Scintigraphy shows focal IRU associated with the ischium and sometimes clear displacement of a segment of bone. Isolated fractures of the pubis can be difficult to see because of the mass of bone and muscle interposed between the fracture site and the gamma camera. For this reason a handheld probe, used per rectum, can give useful information. A bladder artifact produced by delayed excretion of urine may give the appearance of an IRU in this site.

Ultrasonographic Examination

The pubis is the least rewarding of the pelvic bones to examine by ultrasonography. A rectal probe is required, and only marked changes are detectable. The ultrasonographic examination is limited by the small degree of probe movement that is possible within the rectum, coupled with the irregular normal contour of the bone at this site.

Part of the ischium is also examined internally using a rectal transducer. This approach may be the only way to detect any ultrasonographic changes associated with an acetabular fracture. The caudal-most portion of the ischium and the ischiatic tuberosity can be examined percutaneously. Normally a smooth concave contour extends caudally from the greater trochanter of the femur. Ultrasonographic changes similar to those described in other sites where bone damage has taken place can be seen in this area. Comparing the contralateral ischium to the fractured one is useful.

FRACTURES INVOLVING THE ACETABULUM

Horses with fractures of the ilial shaft and ischium that involve the acetabulum have the poorest prognosis of all for return to athletic function as a racehorse and normally develop osteoarthritis of the coxofemoral joint, which results in permanent and progressive lameness. Acetabular fractures commonly result from trauma, often subsequent to slipping over or being cast. This is one of the more frequent causes of lameness in a horse found not bearing weight on a hindlimb in the stable or paddock, with no obvious inciting cause.

Clinical Examination

The horse is extremely lame and is often unwilling to move. The horse has extremely short protraction of the hindlimbs at the walk and often hops rather than attempting to bear weight. Pain occurs on abduction of the limb, and often firm palpation of the muscle mass around the coxofemoral joint causes muscle spasm and pain. Crepitus may be felt with displaced fractures if the hand is applied to the greater trochanter of the femur while the horse is walked, although commonly these fractures are incomplete and crepitus is not apparent. In horses younger than 2 years of age separation of the femoral head can occur from trauma and produces similar clinical signs to a comminuted acetabular fracture.

Scintigraphic Examination

Scintigraphic examination reveals focal IRU associated with the coxofemoral joint, greater trochanter of the femur, and ilial shaft on the affected side. The IRU is particularly visible on a caudal oblique view in which both coxofemoral joints can usually be seen using a large field of view gamma camera. Osteoarthritis of the coxofemoral joint contributes significantly to IRU in horses with a chronic fracture. These fractures are not associated with intense focal IRU initially and early examination may give false-negative results (Fig. 51-5, *A*). At least a week is required before scintigraphic abnormalities are detectable and often this time period is necessary anyway to allow humane transport of the horse. If the clinician is doubtful, the scan should be repeated 14 days later, when bone uptake will be maximal[17] (Fig. 51-5, *B*). Separation of the femoral head, which occurs infrequently in yearlings usually after a fall, produces similar scintigraphic changes, with significant IRU associated with the coxofemoral joint.

Ultrasonographic Examination

Because of the great depth of the acetabulum and the many changing bone contours, the acetabulum is probably the most difficult area of the pelvis to image by ultrasonography. Subtle pathological conditions may well be missed. The greater trochanter of the femur provides a good landmark by which to orient the image. The normal acetabular region is represented as a smooth and regular hyperechoic line of the acetabular rim. The greater trochanter of the femur is close to the skin surface as a hyperechoic line extending down and toward the acetabular rim. In some horses a hypoechogenic region represents the joint space. In foals and immature animals a hyperechoic convex line extends from the greater trochanter and represents the femoral head.

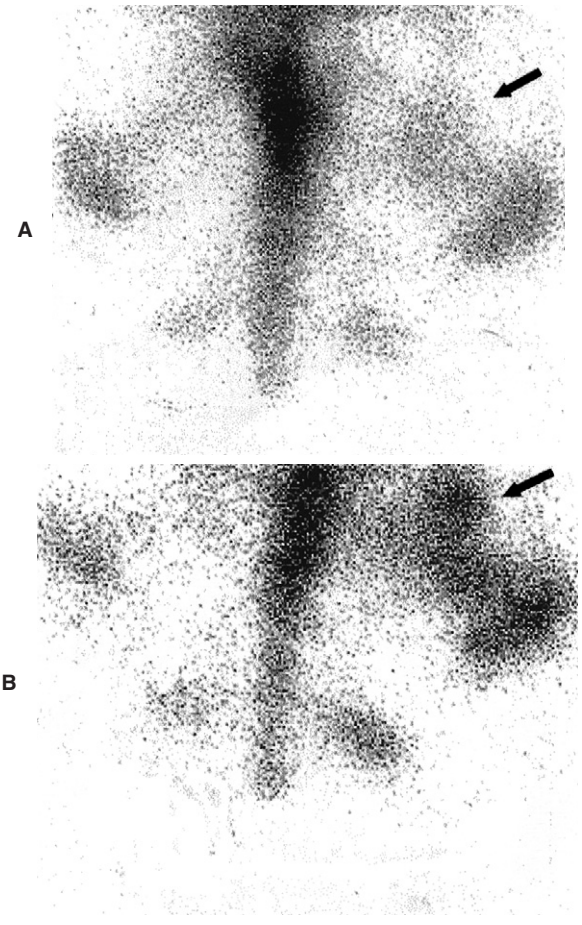

Fig. 51-5 Caudal-dorsal oblique delayed (bone) phase scintigraphic image of the pelvis of a horse with a fracture of the right acetabulum. **A,** An image acquired about 5 days after injury. **B,** An image acquired 3 weeks later. There is poor radiopharmaceutical uptake of this fracture *(arrow)* in the acute stage compared with that at the second examination.

A fracture can appear as a discontinuity or irregular roughening of the acetabular rim and will be particularly obvious if greater degrees of callus are present.

PRINCIPLES OF TREATMENT OF HORSES WITH PELVIC FRACTURES

Surgical repair of pelvic fractures is not currently a realistic option in the adult horse. The period of box rest required for bony union ranges from 2 to 3 months, judged by monitoring fracture healing with ultrasonography. The end result in terms of the functional anatomy of the pelvis depends on the degree of displacement in the initial insult and the extent of subsequent distraction of the fracture fragments by subsequent muscle contracture. For instance, tuber coxae fracture fragments heal by becoming adherent to the cranial wing of the pelvis through fibrous union. Despite the fact that the position of the tuber coxae often changes by several centimeters and the tuber coxae comes to rest in the sub-lumbar fossa, many horses make a full return to athletic function and race with success. Fractures of the sacral wing of the ilium are often non-displaced and can make an extremely good, smooth bone union after healing. Often an abnormal angle is apparent on the ilial surface, because of distraction of the fragments by muscle contraction before healing. Although the abnormal angulation of the pelvic blade cannot help the stability of the sacroiliac joint immediately beneath the fracture, many affected horses do go on to train and race successfully. In a review of 20 horses with ilial fractures, 15 horses made a full recovery to advanced race training and 11 of these raced successfully.[6] Involvement of the ilial shaft considerably worsens the prognosis for racing, though many heal adequately to allow retirement to stud. Some general principles of the care and management of horses apply equally to the different types of pelvic fractures and can be outlined as follows:

- Pain should be controlled during the initial phase by administration of non-steroidal anti-inflammatory drugs (NSAIDs), such as phenylbutazone, until the horse appears comfortable walking around the stable.
- The risk that normal recumbency in the box will result in displacement of an already fractured pelvis is always present. Unfortunately the proximity of the sharp edge of the fractured ilium to the iliac arteries makes this a potentially life-threatening complication. Therefore a horse suspected of major pelvic bone injury should be tied up by the head during the initial convalescent period. When doing so, it is important that the horse has enough rope to move around comfortably, without a sufficient length to encourage it to attempt to lie down. A "break string" should always be between the rope and the head collar, so that if a horse tries to lie down, it can do so without risk. Tying the horse in a position where it can see outside events is best, so that the horse is not alarmed by things happening behind it, to avoid the horse being startled and the risk of displacement of a lesion.

  Horses should remain tied up for no more than 1 month. Many horses cope with being tied up without problems, but while they are tied up, horses should be fed from the floor several times a day and be held by an attendant while they eat. This encourages drainage of bronchial secretions down the trachea and may help to prevent pleuritis and pleuropneumonia, which can develop with prolonged periods of being tied up.[18] During the period that NSAIDs are being administered by mouth, any rise in rectal temperature will be masked. For this reason it is vital to take regular (every 48 hours) blood samples to assess changes in white blood cell count, plasma viscosity, and fibrinogen level, which may signal an early onset of pneumonia or pleuritis. Subsequent to NSAID therapy, rectal temperature should be monitored twice daily. When a horse is untied after a month, the fracture fragments possibly still can displace, leading to fatal hemorrhage. However, displacement is rare, and the clinician must balance the potential risk to the horse against the humanitarian aspects of keeping a horse tied up continuously for more than a month. Although I feel strongly about tying up horses with pelvic fractures, others feel differently, and many horses with pelvic fractures have been managed successfully without being tied up.
- Once untied, a horse requires a minimum of another 2 months of stable rest, combined with daily walking exercise to encourage normal blood flow to the feet, before turnout is safe. Pasture rest for another 2 months is then advisable for horses with a severe, displaced fracture, even before contemplating covering. Pregnancy and parturition can severely test fracture healing, therefore a prolonged convalescent period is required. Often questions arise about the suitability of mares undergoing pregnancy and parturition after pelvic fractures. In my experience the main concerns are lameness, the ability to get up and down, and

maintaining weight, rather than callus formation and the physical inability to deliver a foal.

- If a pelvic fracture has led to an extreme unilateral lameness, the contralateral foot is at real risk of developing laminitis. Many horses will not allow the contralateral limb to be raised long enough to fit a frog support. It is therefore vital that the horse is bedded on deep litter (bedding), so that the bedding can pack up under the foot to give some support. A frog support should be placed as soon as possible and the shoes should be removed. Once the horse is able to bear weight on the affected limb, short periods of walking exercise help prevent vascular stasis and lymphangitis that often accompany weight bearing on one limb for prolonged periods of time. Walking may also help prevent supporting limb laminitis, but only if the horse is not profoundly lame in the affected limb. Support bandaging of the contralateral limb in horses with severe unilateral lameness is probably worthwhile and certainly helps to prevent the occurrence of lymphedema.
- Administration of acetylpromazine in small doses (25 to 50 mg PO bid or 0.02 to 0.04 mg/kg injected IM bid, judged on degree of tranquilization by the first dose) to a lame horse helps for three reasons: preventing laminitis; relieving some anxiety and allowing the horse to rest, which is important for recovery; and preventing upward fixation of the patella, to which the horses are prone, presumably by causing mild muscle relaxation.
- Most horses with incomplete or minimally displaced complete ilial wing stress fractures become sound rapidly. I do not normally keep these horses tied up, but nonetheless a small but real risk of fatal hemorrhage exists in these horses, even when they are apparently sound. Displacement is rare, but from the outset the risk should be explained to and understood by all involved in the management decisions.
- Adult horses with fractures involving the acetabulum have the poorest prognosis for return to athletic function, although horses often become sound enough to be retired to pasture. Compromise of the diameter of the pelvic canal diameter can be a complication, especially if the ilial shaft is involved and the fracture has healed with abundant callus. Even for experienced clinicians, being categorical about the ability of a mare with a narrowed pelvic canal to breed can be difficult. Often a trial mating to an inexpensive stallion is the most pragmatic management choice, if the clinician has doubts.

  Careful thought should be given to each individual horse to make sure that the horse's future is worthwhile, in terms of quality of life for the horse and the economic realities of the situation, before subjecting a horse to a prolonged and by necessity, painful convalescent period.

  Prognosis in foals with acetabulur fractures is considerably better than in adult horses. Treating a foal with an acetabular fracture is definitely worthwhile, because at this age the pelvis appears capable of healing with little chance of developing osteoarthritis in the coxofemoral joint. Foals are treated with 12 weeks of box rest initially and progressive turnout in a nursery paddock.

  Separation of the femoral head in a young horse carries a hopeless prognosis and, if confirmed, should lead to immediate euthanasia.
- As with any horse that has had a prolonged period of box rest, the clinician must remember that although the pelvic fracture may have healed, the rest of the horse's skeleton will have decalcified significantly because of disuse. It is therefore vital that horses are treated as "naive skeletal specimens" when training is resumed. The exercise program should increase gradually, beginning with walking only for the first 2 weeks and building up gradually through walking and trotting to slow speed cantering, eventually re-attaining race speed training. Clinicians should remember that the skeleton takes approximately 1 month at each gait to adapt to the loads placed on it. Bringing a horse back from injury often takes as long as the period of box rest itself, if further orthopedic problems are to be avoided.

CHAPTER • 52

Pelvic Injuries in the Non-Racehorse

Sue J. Dyson

ANATOMICAL CONSIDERATIONS

Detailed anatomy of the ilium, ischium, pubis, sacrum, coxofemoral joint, sacroiliac joint, nerves, and major vessels is described elsewhere (see Chapter 53, page 501).

CLINICAL SIGNS

History

Pelvic injury in a mature athletic horse is a comparatively unusual cause of lameness, except as the result of trauma from a fall, rearing and falling over backward, becoming cast in the stable, or sustaining an injury during transport. When the horse has no history of trauma, diagnosis can be difficult, and excluding all possible sources of pain in the distal limb is frequently necessary before focusing on the pelvic region.

Horses with significant pathological conditions of the sacroiliac joints frequently have a history of progressive reduction in performance, difficulty in engaging the hindlimbs, and poor hindlimb impulsion, especially when ridden.

Clinical Examination

Clinical assessment of individual structures of the pelvic region by visual examination and palpation is not easy, especially in Warmblood and draft breeds, because of the large muscle mass of the hindquarters. Frequently, only the tubera coxae and tubera sacrale can be palpated. Large muscle mass may prohibit palpation of the greater trochanter of the femur. Atrophy of the hindquarter musculature is non-specific and can reflect disuse because of pain arising anywhere in the limb, although atrophy of the muscles around the tail head often reflects injury to the tuber ischium, or local nerve damage. Asymmetry of the height of the tubera sacrale is a common finding in horses in full work, free from lameness, although it may be seen along with poor performance or alterations in hindlimb gait. Apparent asymmetry may actually reflect differences in size of the dorsal sacroiliac ligaments. Alteration in muscle mass in the proximity of the tubera sacrale superficially can give a false impression of asymmetry of the tubera sacrale. Asymmetry of the tubera coxae may reflect a previous injury unassociated with ongoing pain. Poor muscle development in the lumbar region and over the hindquarters may make the tubera sacrale and the summits of the dorsal spinous processes of the lumbar vertebrae appear abnormally prominent. This should alert the clinician to the possibility of thoracolumbar or pelvic pain; however, this finding is non-specific and may reflect the horse's work history.

The pelvic region should be appraised visually and palpated systematically, and although preliminary assessment is usually best performed in the stable, for accurate evaluation of symmetry of the musculature and bony elements of the pelvic region the horse should be standing completely squarely behind on a firm, level surface with the horse looking straight ahead. In a horse with severe lameness this may not be possible, because the horse may be unwilling to load the lame limb fully. Careful differentiation should be made between muscular and bony asymmetry. Significant muscular atrophy can make accurate assessment of symmetry of the pelvic bones difficult. To evaluate accurately the levelness of the tubera coxae, two assistants each must place an index finger on the craniodorsal aspect of each tuber coxae and extend the finger horizontally, or the tubera coxae should be marked using tape. Elevation of the tail may be necessary to identify muscle atrophy around the tail head, which may be seen along with nerve damage, or injuries of the ipsilateral tuber ischium.

Assessment of symmetry when the horse is unwilling to bear weight evenly on both hindlimbs is not easy, but particular attention should be paid to the way in which the limb is positioned. An abnormally straight limb may reflect luxation of the coxofemoral joint and secondary upward fixation of the patella. The greater trochanter of the femur of the lame limb may appear higher than that of the contralateral limb.

The muscles of the lumbar and pelvic regions should be assessed carefully to identify any area of abnormal muscle tension, pain on palpation, or unusual firmness. Firm stroking of the muscles first with a finger and then with a blunt-ended object (e.g., artery forceps) is useful to determine whether muscle spasm or muscle fasciculation are induced. Palpation of the caudal muscles of the crus is also important, because abnormal pain or tension can reflect primary muscle injury or an injury of the ipsilateral tuber ischium.

Firm pressure should be applied to the bony prominences to see if pain or an abnormal reaction, such as sinking on the hindlimbs when pressure is applied to the tubera sacrale, can be induced. Both tubera coxae should be grasped simultaneously, and the horse rocked from side to side to determine whether crepitus can be detected by palpation or auscultation, bearing in mind that the absence of crepitus does not preclude a fracture.

Careful, systematic examination of the pelvic canal region per rectum is also indicated to assess the aorta and iliac arteries, psoas musculature, the caudal aspect of the ilial shaft, and the pubis and ischium.

Pelvic injuries should also be considered when a clinician examines a recumbent horse that has fallen over a fence. Palpation of the pelvic region is even more difficult in these circumstances. Even with a severe fracture, palpating any abnormality may be impossible. The clinician should bear in mind that in the acute phase, local reflexes such as the patella reflex and the withdrawal reflex may be suppressed, which does not necessarily reflect a spinal cord injury. Major fractures may be associated with rupture of one or more large vessels, resulting in potentially fatal internal hemorrhage. Thus it is important to assess the recumbent horse as a whole, monitoring pulse rate, color of mucous membranes, and capillary refill time. Increased pulse rate and progressive pallor of the mucous membranes is a good indicator of major vessel rupture, such as laceration of the iliac artery after fracture of the ilial shaft.

Manipulation of the limb may be resented if pain is associated with the coxofemoral joint, but generally the responses

to flexion of the limb, protraction, retraction, or abduction are rather non-specific. A horse with pain associated with the sacroiliac joints or a coxofemoral joint may be reluctant to stand on one limb, with the other limb raised, and may behave awkwardly in anticipation of discomfort. However, the reaction is non-specific, and one must bear in mind that some horses present difficulties in picking up the hindlimbs in the absence of any sign of lameness or poor performance. Difficulties in picking up hindlimbs may be caused by reluctance to accentuate weight bearing on the lamest limb, reluctance to flex the lame limb, or may be psychological. If the horse is a shiverer, unilaterally or bilaterally, the response to hindlimb flexion can be difficult to assess.

The degree and character of lameness depends on the underlying cause. Fractures or luxation of the coxofemoral joint results in acute onset, severe lameness. Lameness associated with other lesions in the pelvic region may vary in degree, not only among horses with similar lesions, but also within and between examination periods. Pain from the coxofemoral joint frequently results in the horse moving on three tracks, with the non-lame limb being placed between the two forelimbs. On the lunge the horse may be inclined to break to canter, rather than move with adequate hindlimb impulsion, but this is not specific for pelvic pain and is typical of many horses with hindlimb lameness. Pain associated with the coxofemoral joint or the greater trochanter of the femur sometimes results in the horse carrying the lame limb in canter. Lesions associated with the sacroiliac joints frequently result in the horse crossing over each hindlimb at the trot (i.e., plaiting), but this is not pathognomonic and some horses move with a base wide hindlimb gait.[1] The horse may move with reduced hindlimb impulsion rather than overt lameness. Although acute fractures of the tuber ischium invariably cause lameness, chronic injuries may result in loss of performance (e.g., jumping to the right) rather than overt lameness.

The response to flexion tests is non-specific. The clinician should bear in mind that increased weight bearing on one limb, caused by flexing the contralateral limb, may accentuate lameness in the weight-bearing limb. Turning the horse in small circles, inducing rotational forces on the coxofemoral joint, may accentuate lameness associated with the coxofemoral joint.

Ridden exercise is invaluable in horses with a history of poor performance, reduced hindlimb impulsion, or low-grade lameness, because frequently the lameness is accentuated. Some horses with sacroiliac pain or pain associated with new bone on the caudal aspects of the wings of the sacrum (see pages 495 and 497) show extreme reluctance to go forward freely. However, care must be taken to differentiate these horses from those with bilateral hindlimb lameness, thoracolumbar pain, or recurrent low-grade exertional rhabdomyolysis and those performing poorly because of the rider (see Chapter 100), previous poor schooling, or a combination of boredom and an unwilling temperament.

Analgesic Techniques

In horses with chronic lameness, reduced hindlimb impulsion, or poor performance, excluding the distal limb as a source of pain by performing perineural analgesia of the fibular and tibial nerves and intra-articular analgesia of the three compartments of the stifle joint may first be necessary. If the response is negative, intra-articular analgesia of the coxofemoral joint may be indicated. This is relatively straightforward to perform if the horse is not well muscled and the greater trochanter of the femur is readily palpable. However, in the majority of heavily muscled, mature competition horses, needle placement must be guided by ultrasonography. Even if the needle is accurately positioned, retrieval of synovial fluid may be difficult. Extra-articular deposition of local anesthetic solution may result in transient paralysis of the obturator nerve and instability of the limb. The technique is described in Chapter 10 (page 120).

Clinicians have anecdotally described positive responses to infiltration of local anesthetic solution in the region of the sacroiliac joints, but I do not believe that intra-articular injection can be achieved reliably. However, generalized infiltration of local anesthetic solution around the sacroiliac joint region in part may alleviate pain associated with the joint and periarticular structures and has been useful in some horses. The techniques are described on page 506. Infiltration of local anesthetic solution around the sacroiliac joint regions resulted in significant improvement in all 34 horses in which it was performed. These horses had clinical signs suggestive of sacroiliac joint pain, and the majority also had abnormal radiopharmaceutical uptake in the sacroiliac joint region.[1]

Serum Muscle Enzyme Concentration

Measuring serum concentration of creatine kinase (CK) and aspartate aminotransferase (AST) is invaluable for diagnosing horses with acute and chronic rhabdomyolysis (tying up). In horses with chronic tying up, comparing resting levels with concentrations reached after maximum exercise may be necessary. Peak levels of CK are likely to occur 3 hours after exercise. If a horse has had a tying-up episode within the last 4 to 5 days, AST levels almost invariably will be raised. Some horses with chronic recurrent problems have constantly elevated levels of CK and AST. The degree of elevation of muscle enzyme concentrations may show a poor correlation with the severity of clinical signs.

DIAGNOSTIC IMAGING

Radiography

Radiographic examination of the pelvic region of a horse, anesthetized and positioned in dorsal recumbency or in the standing position, is described in depth elsewhere.[2] Since the advent of nuclear scintigraphy and diagnostic ultrasonography the indications for radiographic examination have decreased. If the source of pain has been localized to the coxofemoral joint, radiographic examination is indicated to determine the nature of the pathological condition and hence prognosis. High-quality radiographs can only be obtained with the horse positioned in dorsal recumbency under general anesthesia. Evaluation of the sacroiliac joints can be difficult because of the superimposition of abdominal viscera. Identification of new bone formation on the caudal aspect of the joint and irregular joint space width are poor prognostic indicators. Nuclear scintigraphic examination gives accurate information about bone turnover, but anatomical detail is less well defined. Therefore radiography of a horse with a suspected acetabular fracture may be indicated at least 6 weeks after the onset of lameness to determine whether a suspected fracture involves the coxofemoral joint, which merits an extremely guarded prognosis for return to full athletic function in a mature horse.

Radiographs of the coxofemoral joint obtained in the standing position may be satisfactory for confirmation of luxation or major fractures of the joint.

Ultrasonography

Diagnostic ultrasonography of the pelvic region can be performed transcutaneously or per rectum. The choice of transducer frequency depends on the structures to be imaged. Transcutaneous evaluation of the bony elements of the pelvis and the deep musculature requires a 5- or 3.5-MHz transducer, depending on the size of the horse, whereas evaluation of the dorsal sacroiliac ligaments, sub-lumbar musculature, ventral aspect of the lumbar and sacral vertebrae, and aorta and iliac arteries is better performed using a 5- or 7.5-MHz

transducer. Evaluation of nerve roots per rectum may be best achieved using a 10-MHz transducer.

Diagnostic ultrasonography is useful in evaluating fractures (see Chapter 51, page 485), assessing muscles (see Chapter 84) and the sacroiliac ligaments (see page 497), determining blood vessel patency (see page 497), assessing the lumbar vertebrae and articulations (see Chapter 54), and evaluating nerve roots.

Nuclear Scintigraphy

Nuclear scintigraphic evaluation of the pelvic region is useful for identifying fractures, stress reactions in bone, increased bone modeling associated with osteoarthritis and other bony lesions, and evidence of rhabdomyolysis; for evaluating blood flow in the aorta, iliac, and femoral arteries; and for assessing the sacroiliac joints. Sensitivity of the technique in part depends on the angle of the gamma camera to the area of interest and the degree of overlying muscle mass. It is important to recognize that some lesions may be bilateral; therefore recognition of the normal scintigraphic appearance of the region in horses of different ages and different disciplines is important. The clinician should bear in mind that superficial bony structures such as the tubera coxae and tubera sacrale always appear "hotter" than deeper structures. Unilateral muscle atrophy may also confound interpretation.

Radioactive urine in the bladder may complicate interpretation; therefore the judicious use of furosemide to induce urination before examination is essential.

Complete evaluation of the pelvic region requires dorsal views of the sacroiliac joints, oblique views of the ilial wings, caudodorsal and caudal views of the tubera ischii, and lateral views of the coxofemoral joints. Care must be taken in interpreting the appearance of the sacroiliac joints, because age-related changes occur in normal horses. Swaying movement of the horse during image acquisition can result in images that mimic abnormalities and using motion correction software is invaluable.

DIFFERENTIAL DIAGNOSIS

Fractures

Clinical features, diagnosis, and treatment of fractures of the pelvis in the young Thoroughbred (TB) racehorse have been dealt with in depth (see Chapter 51), and this section focuses on differences in mature athletic horses. The incidence of stress or fatigue fractures of the pelvic region in the mature horse is low, except in horses that race over fences, which have a substantial incidence of ilial stress fractures. The majority of fractures result from external trauma. The clinical features are similar to those in the young racehorse (see Chapter 51).

Tuber Ischium

Fractures of the tuber ischium sometimes occur in event horses that fall when jumping up onto a bank, may also occur in any horses as a result of a fall on the flat, and also have been recognized in horses from other disciplines with no known history of trauma. Lameness is usually acute in onset and severe. Mild localized swelling is easily overlooked unless the tuber ischium is suspected as a site of injury. The ipsilateral semimembranosus and semitendinosus muscles are usually sore to palpation. Atrophy of the muscles around the tail head often develops within 7 to 10 days. Usually crepitus is not palpable. In horses with chronic lameness, pain on palpation may not be evident, although the tubera ischii may appear asymmetrical, and the lameness may be only mild or moderate.

Diagnosis of a fracture of the tuber ischium can be confirmed using nuclear scintigraphy. Dorsal oblique and caudal views are useful. Usually increased radiopharmaceutical uptake and an abnormal pattern of uptake are apparent.[3,4] In some horses determining whether the fracture is complete and whether it has become significantly displaced may be possible. Discontinuity of the bone outline may also be confirmed using diagnostic ultrasonography. Radiographic examination can be performed, but it is most easily and safely done with the horse under general anesthesia.

Treatment by restriction to box rest usually results in a satisfactory outcome, although occasionally sequestration of the fracture fragment occurs, necessitating surgical removal.

Occasionally a horse shows no obvious lameness, but it has reduced performance and a tendency to jump drifting consistently to one side because of pushing off unevenly with each hindlimb. This symptom is associated with reduced muscle development over one of the tubera and increased radiopharmaceutical uptake in the tuber ischium (see Fig. 12-4). The outline of the tuber ischium appears irregular in an ultrasonographic image.

Greater Trochanter of the Femur

Fracture of the greater trochanter of the femur is an unusual injury causing severe lameness. A tendency exists for the fracture fragment to be displaced cranially because of the pull of the attachments of the deep and middle gluteal muscles.

Usually no localizing clinical signs are apparent, unless the horse is poorly muscled and the greater trochanter is readily palpable. The diagnosis is based on nuclear scintigraphic examination with or without diagnostic ultrasonography. The prognosis for return to athletic function with conservative treatment is guarded.

Sacrum

Fractures of the sacrum may be complete or incomplete and result in bilateral hindlimb lameness. If the fracture is complete, the contour of the hindquarters when viewed from the side changes, so that the rump has abnormal angulation (Fig. 51-2). Associated neurological signs include flaccid paralysis of the tail, reduced sensation around the tail head, urine dribbling in a mare, and loss of anal tone. The onset of neurological signs may be delayed for several weeks after the primary fracture. The fracture may be palpable per rectum. The fracture may be confirmed radiographically and using diagnostic ultrasonography per rectum. The prognosis for return to athletic function is guarded.

Equine Rhabdomyolysis (Tying Up)

Equine rhabdomyolysis is considered in depth elsewhere (see Chapter 84). This section focuses on aspects of diagnosis and differential diagnosis of lameness associated with the hindquarters and pelvic injuries in sports horses used for different disciplines and is restricted to recurrent exertional rhabdomyolysis (RER).

The spectrum of clinical signs associated with RER is enormous. A horse may have mild bilateral hindlimb stiffness or loss of freedom of action that may deteriorate slightly with work, without the horse becoming unduly distressed, but sometimes requires a prolonged recovery period after work. Such horses may have no palpable firmness of the hindquarter musculature or pain induced by firm palpation and a normal pattern of sweating. The horse may be able to compete but performs below expectations. These clinical signs are not unique to exertional rhabdomyolysis and may be seen in horses with severe thoracolumbar discomfort associated with impinging dorsal spinous processes, pain associated with the sacroiliac joints, or bilateral hindlimb lameness. Some horses show progressive agitation during ridden exercise and awkwardness to ride, without recognition of a gait abnormality. Careful clinical evaluation usually reveals a progressive shortening of stride.

Alternatively a horse may start to jump poorly during, for example, the cross country phase of a Three Day Event and pull up with a unilateral hindlimb lameness, with no

localizing clinical signs, that resolves within 24 hours. In contrast a different horse may have recurrent acute onset, severe episodes—often provoked by competition, for example, during the speed and endurance phase of a Three Day Event—that may be so bad as to result in recumbency.

The incidence of RER depends to some extent on the discipline in which the horse is involved, occurring most commonly in racehorses (see Chapters 84, 107, and 108), endurance horses (see Chapter 119), and event horses (see Chapter 118). RER is unusual in show jumpers and dressage horses, but occasionally occurs in competitive TB-type ponies. In all these horses the results of muscle biopsies usually indicate no evidence of abnormal glycogen metabolism as in polysaccharide storage myopathy,[3] which occurs more commonly in Draft and Draft crossbreeds and Quarter Horses. In the TB evidence indicates that RER may be a heritable condition, as an autosomal recessive trait with variable expression.[5] A familial trait has also been observed in some part-TB event horses.[3] However, RER in many event and endurance horses does not become apparent until the horse is middle aged, or even older. The condition is manifest more frequently in mares than in stallions or geldings.

Diagnosis is based on measuring raised serum muscle enzymes (CK and AST) after exercise (see page 723). The degree of muscle enzyme elevation frequently does not correlate with the severity of clinical signs. Interpretation is not always straightforward because asymptomatic endurance horses frequently have extremely high levels of CK and AST during and after a ride. Horses with low-grade RER, which occurs daily, often have constantly raised levels of CK and AST, even if rested.

Nuclear scintigraphy can be useful in horses with low-grade hindlimb stiffness and poor performance to validate a diagnosis of suspected RER,[6] to evaluate blood flow to the hindlimb musculature,[7] and to exclude any other concurrent musculoskeletal lesions. In association with RER in some, but not all horses, abnormal uptake of ^{99m}Tc–methylene diphosphonate occurs in the affected muscles in the bone phase of the scan, appearing usually as diagonal streaking (Fig. 52-1), but in horses with more severe, long-standing RER, affected muscles may show large areas of intense radiopharmaceutical uptake. Lesions are not restricted to the gluteal muscle mass, but they may also affect quadriceps, biceps femoris, semitendinosus, semimembranosus, and longissimus dorsi muscles. Lesions may be symmetrical or asymmetrical. However, normal radiopharmaceutical uptake does not exclude RER.

Muscle biopsy is used to determine whether any evidence exists of polysaccharide storage myopathy. Feeding horses a high-fat and low-carbohydrate diet may reduce the frequency and severity of attacks after a period of 3 to 6 months.[8]

Measuring fractional excretion of electrolytes (sodium, potassium, calcium phosphorus, and chloride) can be useful to identify those horses that seem unable to absorb or to utilize normally specific dietary electrolytes and that might benefit from dietary supplementation.[9,10] For accurate interpretation of results it is important that the horse is consuming its normal diet and has recovered from any recent acute attack of exertional rhabdomyolysis when blood and urine samples are collected. A mid-stream urine sample should be collected, preferably freely voided rather than by catheterization. Results are only valid if serum creatinine is within the normal range and the fractional excretion of creatinine is normal. Results should be compared with the normal ranges for a horse on a similar diet, because results for horses eating an oat- and hay-based diet are different for those on a cube-based diet or a diet high in alfalfa. Fractional excretion ratios for potassium tend to be high if the horse is allowed access to pasture. Low values for fractional excretion ratios for sodium or calcium indicate that the diet should be supplemented with sodium chloride or either calcium carbonate or calcium gluconate, respectively. Appropriate dietary supplementation may help to prevent further attacks.

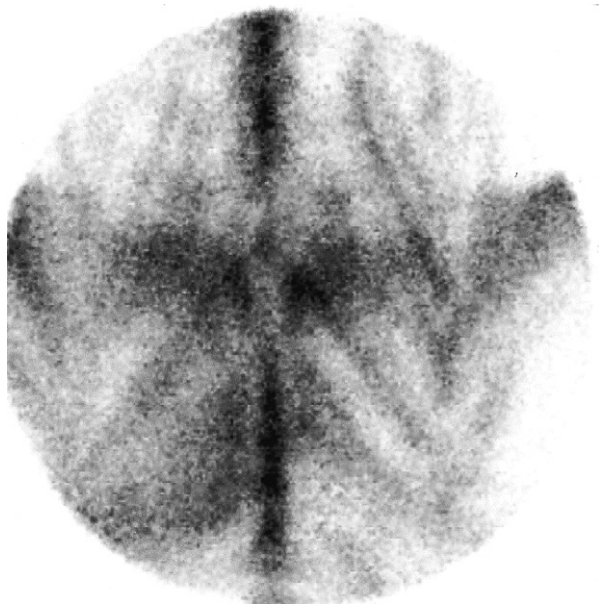

Fig. 52-1 Dorsal bone-phase scintigraphic view of the pelvic region of 12-year-old Thoroughbred mare, a former winner of the European Three Day Event Championships. The mare had shown slight but significant loss of performance but no overt lameness. She had never shown any signs typical of classical tying up. Abnormal radiopharmaceutical uptake appears in the gluteal muscles. This is compatible with recurrent exertional rhabdomyolysis and was asociated with persistently elevated levels of creatine kinase and aspartate aminotransferase.

Management practices may also help to prevent attacks in some horses. These include daily work, with a long, slow warm-up period, turnout as much as possible, and avoiding undue stress, especially in highly strung, nervous individuals. However, some horses, especially those with daily low-grade clinical signs that are not stress provoked, prove intractable to successful management.

Muscle Injury

Muscle soreness is frequently unassociated with any recognizable histopathological changes within the muscle and is often secondary to some other cause of lameness because of the altered way in which the horse is moving. Muscle soreness can often be induced by overuse of an undertrained muscle and can result in localized soreness and stiffness for several days. Focal intense muscle spasm and pain can cause sudden onset reduction in performance and, if primary, are usually alleviated by manipulation to relieve the muscle spasm, producing rapid amelioration of clinical signs.

Focal muscle soreness associated with localized swelling may be due to intramuscular hemorrhage, muscle fiber tearing, or exertional rhabdomyolysis. Diagnosis of the cause may be determined by measuring serum muscle enzyme concentrations and by ultrasonographic evaluation (Fig. 52-2). Hemorrhage results in an area of diffuse increase in echogenicity within the muscle. This should be differentiated from hyperechoic regions that result from chronic muscle fibrosis. Serum muscle enzyme concentrations are usually not elevated in those horses with hemorrhage, muscle fiber tearing, or fibrosis.

Damage to deep muscles of the hindquarters is difficult to identify because localizing clinical signs are frequently not

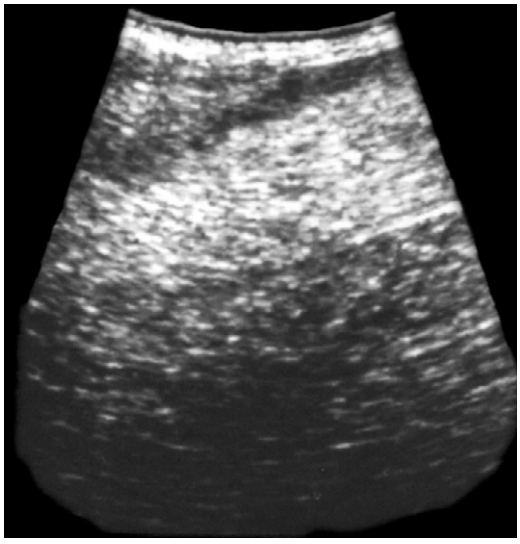

Fig. 52-2 Ultrasonographic image of the semimembranosus muscle of 6-year-old Thoroughbred with acute-onset, severe left hindlimb lameness. The horse had palpable enlargement of the muscle and localized soreness. The increased echogenicity reflects hemorrhage.

apparent to alert the clinician to the possible site of damage. Thermographic evaluation can be useful to help identify superficial muscle injury.

Some horses with reduced performance have pain on palpation of the psoas muscles per rectum. Pain may be primary or secondary to pathological conditions of the lumbosacral or sacroiliac regions and is an indication for nuclear scintigraphic evaluation of the pelvic region and ultrasonographic examination of the lumbosacral vertebrae.

Sacroiliac Joint Injury

See Chapter 53 for further discussion of sacroiliac joint injury. Detailed anatomy of the sacroiliac joints is discussed elsewhere (see page 501).

The diagnosis of sacroiliac joint disease has tended historically to be a dustbin diagnosis, frequently made by exclusion when the clinical signs could not be explained by any other condition. The high incidence of pathological degenerative lesions found in the sacroiliac joints of TB racehorses[11] and in mixed-breed horses[12] indicates that degenerative disease of the sacroiliac joint is likely to be a significant clinical problem, but definitive diagnosis remains difficult. In a recent study of 74 horses with sacroiliac joint pain, affected horses were older than the normal clinic population, and there was a high proportion of Warmblood horses.[1] Horses used for dressage or show jumping predominated. Affected horses were also of great body weight and height.

Pathological changes of the sacroiliac joint include lipping, cortical buttressing, and osteophyte formation, together with enlargement of the joint surfaces. These signs are thought to be a response to chronic instability of the joints, although no evidence of ligamentous laxity has been identified.[11,13] Erosion of the articular cartilage may also occur, but joint ankylosis has not been documented. A positive association has been recognized between the severity of the impingement of thoracolumbar dorsal spinous processes and lumbar transverse processes and the severity of sacroiliac lesions and also between the severity of articular process degeneration and the degree of pathological conditions of the sacroiliac region.

A separate entity of enthesophyte formation at the site of attachment of the sacroiliac ligaments has been described unassociated with pathological conditions of the sacroiliac joints.[14] The clinical significance of this finding has not been well defined.

Subluxation of the sacroiliac joint is comparatively rare[14,15] and results from acute, traumatic disruption of the dorsal sacroiliac ligament and the sacroiliac joint capsule. Subluxation should be differentiated from an acute ilial wing fracture resulting in depression of the ipsilateral tuber sacrale (see page 486).

The prominence of the tubera sacrale varies between horses and in part reflects the conformation of the back and hindlimbs. However, poor development of the epaxial muscles in the lumbar region caused by the horse not using its back and hindlimbs properly may make the tubera sacrale appear more prominent. Poor muscle development may be a reflection of pain or of the horse's previous training: if the horse has never been asked to engage the hindlimbs properly and work through its back, these muscles will not be well developed.

Many apparently clinically normal horses have some degree of asymmetry of the height and or shape of each tuber sacrale and the overlying soft tissues. Careful clinical appraisal of a small proportion of these horses may reveal subtle hindlimb gait abnormalities and mild discomfort induced by pressure applied over the tubera sacrale or by picking up one hindlimb and swaying the horse on the other. These findings are more likely to be detected in horses that are not fully fit and are often ameliorated when the horse is fitter and has greater muscle support. They may reflect mild instability of the sacroiliac joints but are not necessarily synonymous with degenerative change.

Osteoarthritis of the sacroiliac joints may be present despite symmetry of the tubera sacrale, is usually a bilateral condition, and is rarely associated with unilateral hindlimb lameness.[1] Osteoarthritis often manifests as reduced performance, failure properly to engage the hindlimbs, and back stiffness. Signs are often greatly accentuated when the horse is ridden. In horses with mild clinical signs the loss of hindlimb power and lack of suppleness through the horse's back may be much easier for the rider to feel than for an observer to appreciate. Gait irregularities may be most apparent as the horse changes direction through a tight circle. Specific movements such as half pass or sequence flying changes may be difficult. The horse may become progressively more unwilling to work under saddle.

A comprehensive clinical evaluation is essential to preclude other conditions that may present similarly, such as bilateral distal hock joint pain. Precluding the hindlimbs as a potential source of pain by performing perineural analgesia of the tibial and fibular nerves and intra-articular anesthesia of the femorotibial and femoropatellar joints of one hindlimb may be necessary to see if lameness becomes apparent in the contralateral limb.

Using a 9- to 15-cm needle inserted on the midline at the lumbosacral space and directed approximately 20° caudally, local anesthetic solution (20 ml per side) can be infiltrated in the direction of the sacroiliac joints (see page 506). This may improve clinical signs in some horses and resulted in significant change in all 34 horses with suspected sacroiliac pain in which local analgesia was performed.[1] However, in my experience a negative response does not preclude significant sacroiliac joint disease.

Nuclear scintigraphic examination may facilitate diagnosis by helping to preclude the presence of other significant causes of poor hindlimb action and by giving a positive indication of abnormalities of the sacroiliac joints.[16-18] Profile analysis and quantitative evaluation using regions of interest are required for accurate diagnosis. The results ideally should be compared with horses of similar age and work history because of apparent significant age-related variability between clinically normal

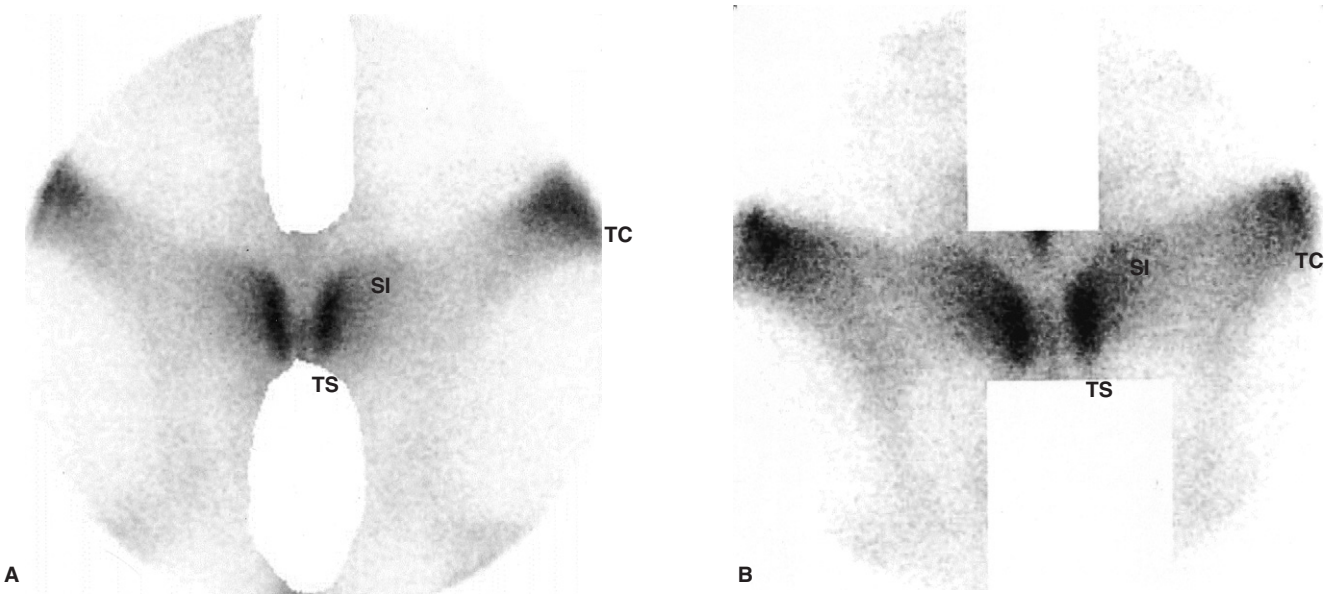

Fig. 52-3 Dorsal delayed (bone) phase scintigraphic images of the sacroiliac regions of (**A**) a normal 2-year-old Thoroughbred and (**B**) a normal 8-year-old Warmblood. The images were acquired as 35, 2-second frames, motion corrected and summed. *SI*, Sacroiliac joint region; *TS*, tuber sacrale; *TC*, tuber coxae.

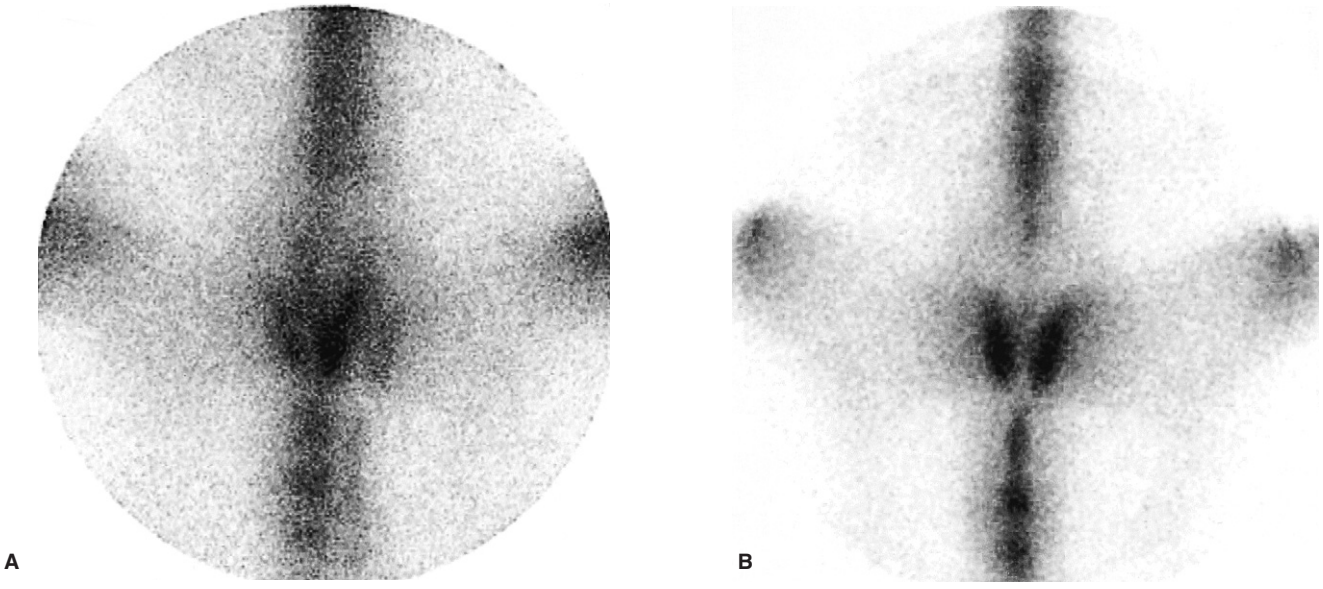

Fig. 52-4 Dorsal delayed (bone) phase scintigraphic image of the sacroiliac joint region of a normal 6-year-old Thoroughbred acquired dynamically as 35, 2-second frames. **A,** The images have been added, but without motion correction. The image is not of diagnostic quality. **B,** The image after motion correction. The oval-shaped tuber sacrale have the most intense radiopharmaceutical uptake, being closest to the gamma camera. The surrounding regions of the sacroiliac joint have less intense activity.

horses[17] (Fig. 52-3). Considerable overlap in ratios of uptake between each sacroiliac joint region and a standard reference site also occurs in clinically normal horses, horses with lameness unrelated to the sacroiliac joint, and horses with clinical signs compatible with sacroiliac joint disease.[18] However, in a normal horse radiopharmaceutical uptake is bilaterally symmetrical. Excessive motion during image acquisition can result in images that are not of diagnostic quality and may mimic abnormalities (Fig. 52-4); therefore, ideally, images should be acquired dynamically, and motion-correction software should be used.[17] Residual radiopharmaceutical in the bladder may also confound interpretation. Abnormalities are recognized as abnormal patterns of radiopharmaceutical uptake (Fig. 52-5) and asymmetrical ratios of uptake between the left and right

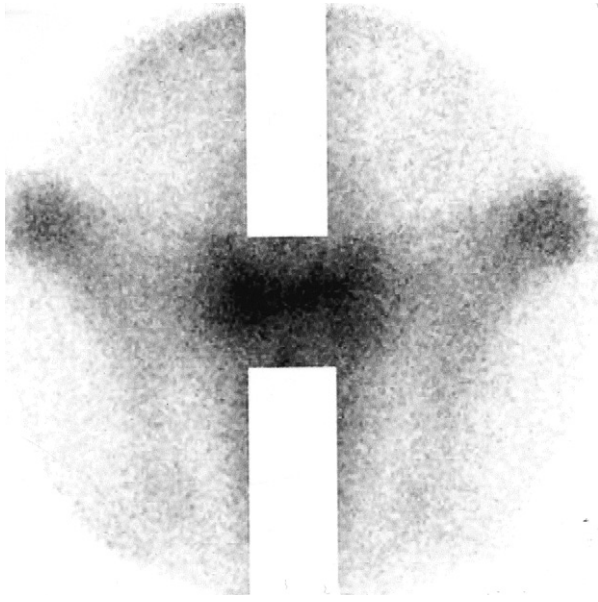

Fig. 52-5 Dorsal delayed (bone) phase scintigraphic image of a 9-year-old Warmblood with clinical signs compatible with sacroiliac joint disease. Compare with Fig. 52-3, *B*; the image is no longer symmetrical in appearance and there is no clear definition between the region of the tuber sacrale and sacroiliac joint regions. This is a motion corrected image. The diagnosis was confirmed post mortem.

sacroiliac joint regions.[18] Care must be taken to differentiate between uptake in the tubera sacrale and uptake associated with the region of the sacroiliac joints.

Radiographic examination requires general anesthesia and can be frustrating, because superimposition of abdominal viscera can preclude evaluation of the sacroiliac joints. However, detection of joint space irregularities or spur formation on the caudal aspect of the joints are poor prognostic indicators.

Ultrasonographic examination should be performed transcutaneously to evaluate the dorsal sacroiliac ligaments[19,20] and per rectum[20] to eliminate pathological conditions of the lumbosacral vertebrae.

Management is essentially palliative, and prognosis is generally inversely correlated with the severity of clinical signs. Local infiltration of a phenol-based sclerosing agent, P2G or a combination of corticosteroids (methylprednisolone acetate, 200 mg) and Sarapin appears to provide relief in some horses. Some horses benefit from treatment with non-steroidal anti-inflammatory drugs, which provide partial pain relief, enabling the horse to work better and develop increased muscle strength. Daily work on the lunge using side reins or a chambon, together with exercise in a cage horse walker in which the horse is free and not tied, and no ridden exercise for several weeks may be of significant benefit. Acupuncture therapy helps some horses. Affected horses should be maintained in work at all times to maintain muscular fitness.

Sacroiliac joint disease may occur with other conditions; therefore, careful appraisal of the whole horse is essential if a successful management strategy is to be achieved.[1] Nuclear scintigraphic evaluation should include the thoracolumbar region. Concurrent impingement of dorsal spinous processes in the mid- or caudal thoracic or cranial lumbar regions may occur with or without associated pain (see page 514). Infiltration of local anesthetic solution between or around the impinging dorsal spinous processes may be necessary to determine their contribution to the clinical problem. Careful evaluation of the synovial articulations, especially close to the thoracolumbar junction, is also important. Occasionally sacroiliac disease has been seen together with osteoarthritis of the coxofemoral joints. This warrants a guarded prognosis.

Desmitis of the Dorsal Sacroiliac Ligament

Desmitis of the dorsal sacroiliac ligament has been recognized in horses that have back pain, with or without focal pain on palpation.[19,20] Usually lesions have been restricted to one side and have been characterized by ultrasonography as enlargements of the ligament and disruption of normal architecture, with hypoechoic regions in transverse images and loss of parallel alignment of echoes in longitudinal images. Enthesophyte formation may occur on the tuber sacrale. Such lesions have been seen alone or with other causes of back pain.

New Bone on the Caudal Aspect of the Wing of the Sacrum

A small number of mature competition horses used for dressage or show jumping have insidious onset loss of hindlimb action, progressing to unwillingness to maintain a proper trot. These horses have appeared considerably worse when ridden compared with evaluation in hand or on the lunge. The horses have shown abnormal sensitivity to palpation in the general areas of the sacroiliac joints. However, careful analysis of nuclear scintigraphic images has shown relatively normal radiopharmaceutical uptake in the region of the joints themselves but increased uptake abaxial to the joints. The horses have responded poorly to treatment with non-steroidal anti-inflammatory or other analgesic drugs. Post-mortem examination has revealed spurs of new bone on the wings of the sacrum just caudal to the auricular surface but not involving the sacroiliac joint itself. This has been seen in association with fusion of the transverse processes of caudal lumbar vertebrae and osseous proliferation involving intervertebral foramina or synovial articulations.[3,14]

Aorto-Iliaco-Femoral Thrombosis

Aorto-iliaco-femoral thrombosis is a relatively uncommon cause of exercise-induced hindlimb lameness of variable severity.[21] Clinical signs may be sudden and severe in onset or subtle initially and slowly progressive. Horses of all ages may be affected. The incidence is higher in male horses than mares. The pathogenesis is unknown.

Clinical signs vary depending on the site(s) of thrombus formation, its size, and the degree of vessel occlusion. Lesions occur most commonly at the terminal aorta, but they may also involve the internal and external iliac arteries and the femoral arteries, unilaterally or bilaterally. Lesions restricted to the femoral artery have not been documented. With mild lesions the horse may show poor performance, early fatigue, or slight loss of hindlimb action during a work period. If the lesion(s) is predominantly unilateral, the horse may show episodic hindlimb lameness induced by work. With more advanced lesions progressive shortening of hindlimb stride may occur with exercise, followed by development of distress and sweating, except over the hindlimbs (Fig. 52-6, *A*). If the horse is allowed to stop, it may repeatedly flex its hindlimbs and stamp the feet to the ground. The affected limbs feel cool, and delayed filling of the saphenous veins may be seen (Fig. 52-6, *B*), with reduced pulse amplitudes in the dorsal metatarsal artery. Clinical signs usually resolve if the horse is allowed to stand still for a few minutes.

In horses with advanced thromboembolism, palpating a thrombus per rectum in the terminal aorta, which feels abnormally firm, is usually possible. Pulses in the iliac arteries may be reduced or absent. With less advanced lesions diagnostic ultrasonography is required for identification of the lesion (Fig. 52-7). Ultrasonography is also useful to determine the

Fig. 52-6 A 9-year-old gelding with aortoiliac thrombosis. Clinical signs were provoked by just 5 minutes of lunging exercise. **A,** The horse repeatedly flexed each hindlimb, stamping it to the ground. No evidence of sweating over the hindquarters was apparent, but the horse was sweating profusely over the neck and flanks. **B,** The saphenous vein cannot be seen because of delayed filling.

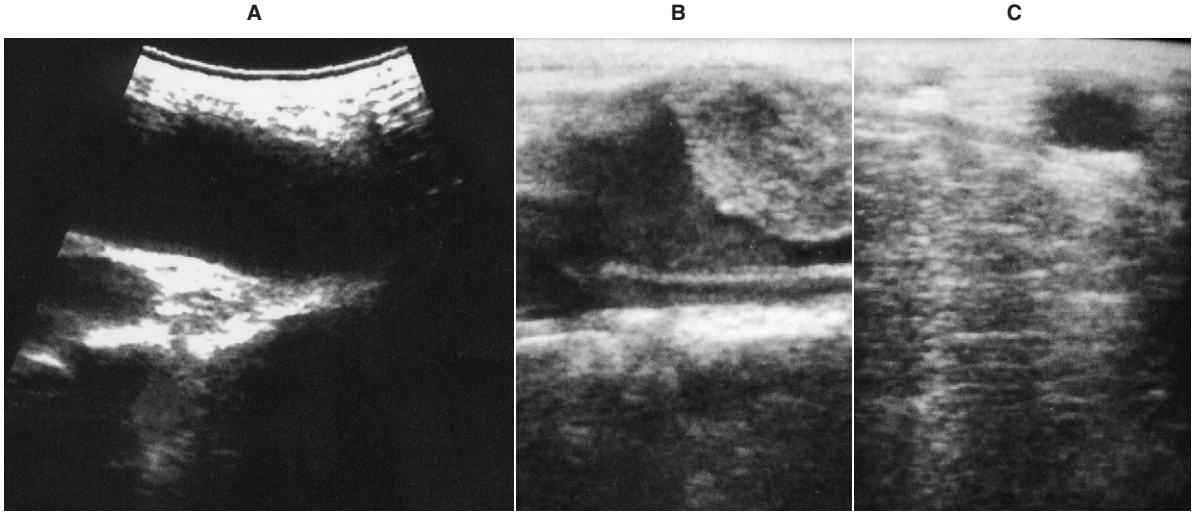

Fig. 52-7 Longitudinal ultrasonographic images of the terminal aorta of (**A**) a normal horse and (**B**) a horse with aortoiliac thrombosis. Cranial is to the left. A large echogenic mass appears in the aorta of the clinically affected horse. **C,** Transverse ultrasonographic image of the right external iliac artery. This appears normal but at post-mortem examination, an extensive thrombus was identified farther distally.

extent of the lesions.[22] Examination of part of the femoral artery can be performed transcutaneously on the medial aspect of the crus,[23] and the use of Doppler ultrasonography to measure blood flow characteristics should help to determine if a more proximal site of obstruction exists.[24]

First-pass radionuclide angiography can be used to determine blood flow in the aorta and iliac arteries[7,25] and also the femoral arteries.[3] However, the sensitivity of the technique for detecting subtle lesions has yet to be determined.

The aims of treatment are to try to prevent further thrombus formation and to promote the development of a collateral blood supply for adequate perfusion. No drugs are available that alter a pre-formed thrombus. Treatment rationale has been based on pain relief and the use of anti-inflammatory drugs, platelet inhibitors, anthelmintics, fibrinolytic agents, and anticoagulant drugs. Those most commonly used include phenylbutazone (2.2. mg/kg BID for 2 months), aspirin (5 mg/kg SID for several months), and isoxsuprine (1 mg/kg BID for 3 months). Successful treatment presumably is based on development of an effective collateral blood supply.

I have successfully managed some mildly affected horses with long-term aspirin therapy, but horses with more severe lesions are usually refractory to treatment. Only 2 of 29 horses returned to former athletic function, with resolution of clinical signs, following medical treatment.[21] Surgical removal is feasible,[26] although the rate of recurrence is high.

Coxofemoral Joint

The coxofemoral joint is rarely a source of pain causing lameness in the horse.

Dysplasia

Dysplasia of the coxofemoral joint is rare, usually occurs bilaterally, and predisposes relatively young horses to develop osteoarthritis. The prognosis for athletic function is poor. Dysplasia may be a heritable condition in the Norwegian Dole.

Osseous Cyst-Like Lesions

An osseous cyst-like lesion occasionally has been identified in young horses and associated with lameness.[3,27] The lesions have resulted in chronic lameness.

Osteoarthritis

Osteoarthritis of the coxofemoral joint is an unusual cause of hindlimb lameness in the horse, usually occurring unilaterally, but occasionally bilaterally. Osteoarthritis may occur secondary to dysplasia, rupture of the teres ligament (see page 500), or trauma.

Lameness varies from moderate to severe. The horse resents flexion of the limb and is unwilling to stand on the limb for long periods with the contralateral limb picked up. The degree of gluteal muscle disuse atrophy may be more than that from pain in the more distal part of the limb. Lameness may be characterized by a tendency for the horse to move on three tracks.

Intra-articular analgesia usually improves lameness, but it is rarely alleviated fully.

Nuclear scintigraphic evaluation may help in highlighting the coxofemoral joint as abnormal, especially if the results of intra-articular analgesia are equivocal. However, it is important to be aware that loss of muscle over the hindquarter of the lame limb may confound image interpretation. I have found it useful to evaluate ratios of radiopharmaceutical uptake in the region of the coxofemoral joint and another standardized location and compare this with values for normal horses. The clinician should be aware that radiopharmaceutical uptake associated with the coxofemoral joint is much less than that of the cranial and caudal parts of the greater trochanter of the femur.

Definitive diagnosis of osteoarthritis requires radiographic examination, and high-quality radiographs can only be achieved with the horse in dorsal recumbency under general anesthesia. Abnormalities include periarticular osteophyte formation, new bone formation along the femoral neck, lucent zones in the subchondral bone of the acetabulum or femoral head, and loss of congruity between the acetabulum and femoral head (Fig. 52-8). Care should be taken not to confuse the depression in the femoral head and underlying radiolucent zone at the site of insertion of the teres ligament as a lesion.

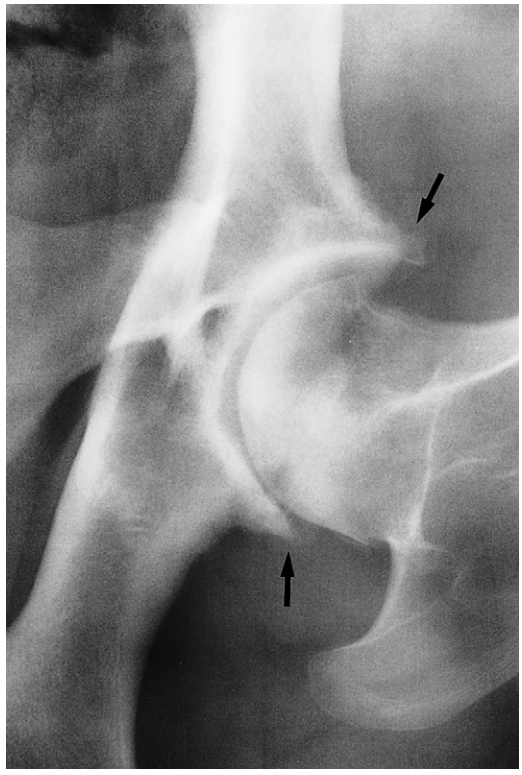

Fig. 52-8 Ventrodorsal radiographic view of the left coxofemoral joint of 9-year-old steeplechaser with osteoarthritis. The horse had raced successfully the previous season, but it now showed moderate left hindlimb lameness at trot and carried the left hindlimb at canter. Note the marked periarticular osteophyte formation on the pelvic acetabulum (*arrows*) and the irregular subchondral bone opacity.

Intra-articular medication of a coxofemoral joint with radiographic abnormalities has yielded disappointing results. The prognosis for return to athletic function is guarded.

Trochanteric Bursitis

Trochanteric bursitis has been described in the older literature, but the Editors have not recognized this condition. The condition is discussed elsewhere (page 472).

Luxation with or without Secondary Upward Fixation of the Patella

Luxation or subluxation of the coxofemoral joint is an unusual injury and can occur as a primary injury or secondary to an unstable fracture of the ilial shaft. The trauma causing luxation also can result in articular fractures of the acetabulum. Permanent upward fixation of the patella may develop as a sequel because of displacement of the femur. The femur is displaced proximally; therefore the greater trochanter of the femur appears higher on the lame limb. However, this can be difficult to assess, because the horse is usually reluctant to bear weight on the limb. Upward fixation of the patella results in an abnormally straight hindlimb stance and an inability to flex the limb. The diagnosis can be confirmed by radiography, and with high-output x-ray machines, diagnostic radiographs

can be obtained with the horse standing; however, determining if concurrent fractures exist may be difficult. The prognosis for athletic function is hopeless.

Rupture of the Teres Ligament

Rupture of the teres ligament results from trauma. It has been seen in a horse that tried to get up prematurely from general anesthesia while the limbs were still restrained in hobbles.[3] Lameness is severe, with the horse being unwilling to bear weight on the limb. Secondary osteoarthritis rapidly ensues. Definitive diagnosis is only possible post mortem. The prognosis for athletic function is hopeless.

Displacement of the Femoral Head

Displacement of the femoral head has been seen occasionally in young horses with severe lameness and reluctance to bear weight on the limb. Diagnosis is confirmed radiographically. The prognosis is hopeless.

Fracture (or Enthesopathy) of the Third Trochanter of the Femur

Fracture of the third trochanter of the femur is a relatively unusual injury, resulting in acute onset, severe lameness that often improves rapidly with box rest. In a lean, poorly muscled horse, eliciting pain by palpation may be possible, but in a well-muscled Warmblood type, eliciting pain is usually not possible, even in acute injuries. No particular gait characteristics are apparent. Nuclear scintigraphy is particularly valuable for tentative diagnosis of a fracture.[3,4] Increased radiopharmaceutical uptake and sometimes a change in the pattern of uptake occur. Diagnosis may be confirmed radiographically, but good-quality radiographs can only be achieved under general anesthesia. Fractures are often longitudinal, occurring at the base of the trochanter.[2-4] Displacement is usually minimal. Diagnostic ultrasonography has not been useful in my experience in helping to confirm a fracture. However, ultrasonography is useful to exclude abnormalities of the superficial gluteal muscle, which inserts on the third trochanter. Insertional tears of this muscle may be associated with a similar scintigraphic appearance. Treatment is box rest for 2 months, followed by walking exercise for another month. Healing may occur by osseous or fibrous union. Prognosis is good.[3]

CHAPTER • 53

Diagnosis and Management of Sacroiliac Joint Injuries

Kevin K. Haussler

ANATOMICAL AND FUNCTIONAL FEATURES

The sacroiliac joint is a synovial articulation located at the junction between the ventral wing of the ilium and the dorsal wing of the sacrum (Fig. 53-1). The sacroiliac joint functions in pelvic attachment to the axial skeleton, providing support during weight bearing and helping to transfer propulsive forces of the hindlimb to the vertebral column. The sacroiliac joint is an atypical synovial articulation because of hyaline cartilage on the sacral articular surface and a thin layer of fibrocartilage on the ilial articular surface.[1] The articular surfaces of the sacroiliac joint are nearly flat and closely apposed to support gliding movements. The sacroiliac articular surfaces diverge cranially at about 40° from a transverse plane and are angled craniodorsally to caudoventrally at about 60° from the horizontal plane. The joint capsule is thin and closely follows the margins of the sacroiliac articular cartilage. The sacroiliac joint capsule is reinforced ventrally by the ventral sacroiliac ligament.[2] A small amount (<1 ml) of synovial fluid is normally present in the joint.[1] Because of articular surface remodeling, the size and shape of the sacroiliac joint margins vary considerably according to age and body weight.[3] Typically the sacroiliac joint outline is L-shaped, with the convex border directed caudoventrally.

The pelvis is firmly attached to the axial skeleton by sacroiliac and sacrosciatic ligaments, which form a strong ligamentous sling (see Fig. 53-1). The weight of the caudal vertebral column is suspended from the sacroiliac ligaments, which function similarly to the fibromuscular sling found between the proximal forelimb and the lateral thoracic body wall. Subsequently the sacroiliac articular cartilage may never be fully weight bearing, unlike most articular cartilage. The sacroiliac joint is supported by three pairs of strong ligaments: the dorsal, interosseous, and ventral sacroiliac ligaments. The dorsal sacroiliac ligament consists of dorsal and lateral portions (Fig. 53-2). The dorsal portions form two round cords that span from the dorsal aspects of the tubera sacrale to the dorsal apices of the sacral spinous processes. The lateral portion forms a sheet of connective tissue that spans from the caudal margin of each tuber sacrale and iliac wing to the lateral border of the sacrum. The lateral portion of the sacroiliac ligament is continuous ventrally with the sacrosciatic ligament. The interosseous ligament of the sacroiliac joint is robust and consists of a series of vertical fibers that connect the ventral wing of ilium to the dorsal wing of the sacrum (see Fig. 53-1). The interosseous sacroiliac ligament provides the major resistance to vertically oriented weight-bearing forces acting on the sacrum. The ventral sacroiliac ligament interconnects the ventral wings of the ilium and sacrum. The ventral sacroiliac ligament is thin and closely applied to the ventral margins of the sacroiliac joint capsule.

Neurovascular structures adjacent to the sacroiliac joint include the sciatic nerve, cranial gluteal nerve, and cranial gluteal artery and vein. These structures collectively travel

through the greater sciatic foramen, ventromedial to the sacroiliac articulation (see Fig. 53-2). The cranial gluteal artery and vein arise from the internal iliac vessels and travel over the ventral sacroiliac ligament and the caudomedial aspect of the sacroiliac joint before emerging at the greater sciatic foramen. The cranial gluteal artery and vein continue dorsally into the gluteal musculature. The middle and accessory gluteal muscles originate from the dorsal iliac wing and have attachments near the caudomedial aspect of the sacroiliac joint. Within the pelvic canal a portion of the internal obturator and iliacus muscles cover the ventral sacroiliac joint margins.

The robust sacroiliac and sacrosciatic ligaments limit motion at the sacroiliac articulations.[4] Shear forces would be expected at the sacroiliac articular surfaces more than compressive forces, which are common in most limb articulations.[5] Sacroiliac joint movements are restricted to small amounts of flexion (nutation) and extension (counternutation), with an apparent axis of rotation oriented transversely near the caudomedial aspect of the joint. Lateral movements at the sacroiliac articulations are severely restricted, primarily because of lateral attachments of the ventral sacroiliac ligaments, and to a lesser degree the lateral portion of the dorsal sacroiliac ligaments and the sacrosciatic ligaments. The wings of the ilium overlay the sacral articular surfaces dorsally and laterally, which precludes any axial rotation from occurring at the sacroiliac joint. Dorsal displacement of the ilial wings is limited by the robust interosseous ligament, the ventral sacroiliac ligament, and lateral portion of the dorsal sacroiliac ligaments.[6] Propulsive forces of the hindlimb are transmitted dorsally and cranially to the vertebral column by the articular configuration of the overlapping and divergent ilial wings over the sacrum and by reinforcement from the dorsal and interosseous sacroiliac ligaments. The dorsal sacroiliac ligament also provides resistance against contraction of the powerful longissimus muscle and robust thoracolumbar fascia, which attach along the cranial border of the ilial wing.

PATHOLOGICAL CONDITIONS

The antemortem diagnosis of sacroiliac joint injury in horses is difficult and often based on a diagnosis of exclusion.[7] Diagnosis is complicated by anatomical inaccessibility, mild chronic clinical signs so that opportunities for correlation with necropsy findings are uncommon, and ongoing controversies over the clinical significance and prevalence of pathological conditions of the articular surface and ligaments.[4] Terms used to describe pathological conditions of the sacroiliac joint include sacroiliac sprain or instability,[8,9] sacroiliac joint subluxation,[10] and sacroiliac arthrosis.[11,12] The prevalence of pathological conditions of the sacroiliac joint in performance horses is probably high and many may go undiagnosed.[4,11,13] In a necropsy survey of 36 Thoroughbred (TB) racehorses with no known back or sacroiliac joint problems, we observed various degrees of degenerative sacroiliac joint changes in all specimens.[14] The clinical significance of osseous sacroiliac joint pathological conditions is difficult to determine, because many presumed normal horses have degenerative joint changes similar to horses with known back or sacroiliac problems.[1,4] Possibly the majority of sacroiliac joint pathological conditions are subclinical; however, if similar findings were noted in any other musculoskeletal location, the articular changes would be considered clinically significant and a likely contributing cause of lameness. A more likely scenario is that deep sclerotogenous pain (e.g., vertebral or sacroiliac joint osteoarthritis) is often poorly localized and perceived as deep aching pain, based on reports of similar pathological conditions of the sacroiliac joint in affected people. Clinically the most common reported signs of sacroiliac joint disorders in horses are poor performance, lack of impulsion, and a mild, chronic hindlimb lameness, which can easily be overlooked or dismissed as not clinically significant.[4,7] Obvious signs of lameness and localized pain or inflammation are not typical clinical characteristics of sacroiliac joint or pelvic injuries, unless pelvic fractures or substantial joint disruption are present.

Osseous changes of the sacroiliac joint include (in apparent order of increasing severity) articular surface lipping, cortical buttressing, articular recession, osteophytes, and intra-articular erosions (Fig. 53-3). In our survey of 36 TB racehorses, sacroiliac degenerative changes were classified as mild in 8% of specimens, moderate in 61%, and severe in 31%. Age has not been associated with the overall prevalence or severity of sacroiliac joint degenerative changes.[14] Osseous changes are usually bilaterally symmetrical and most commonly located at the caudomedial aspect of the articulation.[1,14] The pathogenesis of proliferative sacroiliac joint changes is uncertain, but it is thought to be related to chronic instability resulting in gradual remodeling and subsequent enlargement of the caudomedial joint surfaces. Histologically the caudomedial extensions consist of apparently normal cancellous bone.[4] Articular cartilage erosion is a lytic process of articular surfaces that presumably leads to eventual sacroiliac joint ankylosis.[14] However, ankylosis of the sacroiliac joint has not been reported, which is surprising based on the limited joint motion and the potential severity of osseous pathological conditions present.[1,14,15] Fibrous interconnections between the articular surfaces have also been reported in presumed normal sacroiliac joints.[1] Articular cartilage discoloration, a presumed indicator of sacroiliac joint degeneration, is common in racehorses, but it has a reported higher prevalence in Standardbreds (STBs) compared with TBs.[11] One theory is that these changes are caused by differences in pelvic and sacroiliac joint biomechanics associated with pacing and trotting (i.e., lateral bending or shear forces) in STBs compared with galloping (i.e., flexion and extension movements) in TBs.[16] Biomechanical studies are warranted to support or refute these claims.

Sacroiliac desmitis, the most common soft tissue injury, has been documented by ultrasonography in the dorsal portion of the dorsal sacroiliac ligament.[17] A diagnosis of sacroiliac desmitis is based on loss of normal echogenicity on a transverse view and a decrease in parallel fiber pattern on a

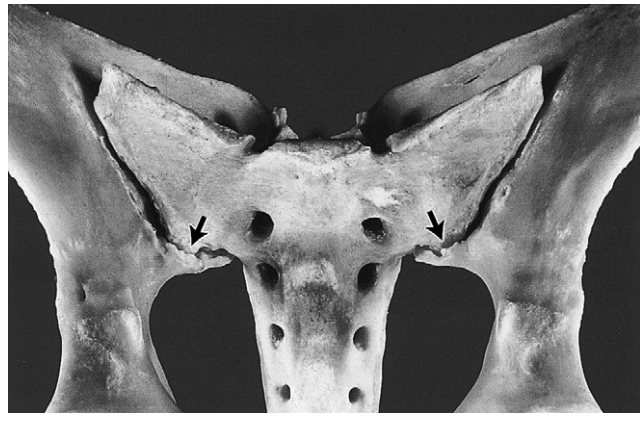

Fig. 53-3 Bilateral osteoarthritis of the sacroiliac articulations (ventral view). Severe proliferative changes of the caudomedial one third of the sacroiliac joints (*arrows*) in 8-year-old racing Thoroughbred gelding that was euthanized because of an acute colic episode. longitudinal view. Sacroiliac ligament injuries usually occur because of acute trauma, but few horses with documented injury have been reported.[14,18]

Complete sacroiliac ligament disruption is most likely caused by substantial trauma, such as flipping over backward, or catastrophic musculoskeletal injuries associated with race training.[14] Post-mortem findings associated with traumatic sacroiliac ligament injuries include either unilateral or bilateral joint capsule disruption, avulsion fractures of the sacroiliac ligament attachment sites, and noticeable sacroiliac joint laxity. Dorsal or ventral sacroiliac ligaments can be affected, depending on the inciting mechanism of injury.[6,14,18] Complete sacroiliac ligament disruption may produce unilateral or bilateral dorsal displacement of the tubera sacrale, depending on the extent of injury (Fig. 53-4).

Acute sacroiliac ligament injuries have been reported to contribute to development of chronic sacroiliac joint instability.[8,18] However, the presence and significance of chronic sacroiliac ligament injury and sacroiliac joint laxity are controversial. Rooney et al. reported on chronic sacroiliac joint injuries of the cranial portion of the ventral sacroiliac ligaments, which were found to be elongated or torn on the affected side.[18,19] Desmitis of the insertion site of the dorsal portion of the dorsal sacroiliac ligament at the insertion on the tuber sacrale has been reported.[6] In other studies osseous changes were found at the caudomedial sacroiliac joint margins in horses suspected of having chronic sacroiliac injury; however, no obvious sacroiliac ligament laxity was observed.[4,8,9] Radiographically some of these horses had an apparent increase in the sacroiliac joint space; however, no visible sacroiliac ligament injury, joint laxity, or subluxation was observed at necropsy.[4,9] In our necropsy survey of 36 TB racehorses no evidence of chronic ligament injury or sacroiliac joint subluxation was observed.[14] However, this could be related to the prior removal of horses from race training with poor performance or hindlimb lameness associated with chronic sacroiliac joint injury.

The pathogenesis of apparent spontaneous or insidious differences in tuber sacrale height needs to be further researched.[4] Unilateral or bilateral dorsal displacement of the tubera sacrale is often a presumed indication of sacroiliac subluxation.[20] In my opinion, variable degrees of tubera sacrale height asymmetry occur frequently and may be caused by chronic asymmetric muscular or ligamentous forces acting on the malleable osseous pelvis and not by direct sacroiliac ligament injury.[21] Tubera sacrale height asymmetries are common in horses without documented sacroiliac joint injuries (see Fig. 53-4). In only a few horses have tubera sacrale height asymmetries been associated with chronic sacroiliac ligament injuries or joint laxity.[19] In a study of 4-year-old STB trotters with tubera sacrale height asymmetries of more than 1 cm, associations were found with poor performance, but otherwise the asymmetry was of questionable clinical significance.[13] If substantial tubera sacrale height differences are identified, which side is affected is unclear and difficult to determine: the seemingly dorsally displaced tuber sacrale or the less prominent tuber sacrale on the opposite side.[4,13] Presumed sacroiliac joint subluxation produces an elevated tuber sacrale on the affected side, whereas complete ilial wing fractures (the most common type of pelvic fracture) typically produce a palpably depressed tuber sacrale on the affected side.[22]

CLINICAL PRESENTATION

Horses with sacroiliac joint injuries vary in clinical presentation, usually based on the duration and extent of injury present. The history of acute sacroiliac joint injury usually includes slipping, falling, or trauma that causes pelvic rotation or induces high stresses.[20] Horses with acute sacroiliac joint injuries often have noticeable lameness and localized sensitivity to palpation of the surrounding soft tissues or tubera sacrale (Fig. 53-5), which must be differentiated from other sources of back, pelvic, or hindlimb pain. Diagnosis of acute sacroiliac ligament rupture and subsequent sacroiliac joint subluxation or luxation is based on history, physical examination, and diagnostic imaging. Because the majority of horses have some degree of tuber sacrale height asymmetry, a diagnosis of acute sacroiliac joint subluxation can only be confirmed if symmetry of the tuber sacrale was documented immediately before the injury, and subsequently gross asymmetry of the tubera sacrale is noted with localized signs of pain or inflammation.

Significant historical findings in horses with chronic sacroiliac joint injuries usually involve repetitive overuse

versus a single traumatic event.[11] The most consistent clinical feature of chronic sacroiliac joint injury is a prolonged, nonprogressive history of poor performance.[4] Changes in performance include back stiffness, resisting jumps, and lack of impulsion from one or both hindlimbs. Subtle gait asymmetries may be noticed at slow speeds during ground work or dressage movements and in harness horses at racing speeds.[7] Chronic sacroiliac joint injuries usually produce a low-grade or intermittent hindlimb lameness or stiffness that cannot be localized by routine lameness examination techniques and is improved only temporarily with anti-inflammatory medications.[4] The affected sacroiliac joint usually corresponds to the side of lameness or reduced cranial swing phase of the affected hindlimb, but bilateral gait abnormalities can occur. Gait asymmetries involve subtle differences in pelvic movement or reduced hindlimb flexion or stride lengths. Affected horses commonly resent standing on the affected hindlimb while the contralateral hindlimb is lifted off the ground during hock flexion or shoeing.[7] Affected horses may also drag a hind foot and have mild hindlimb abduction before hoof contact (i.e., plaiting or rope walking).[4] Disuse atrophy of the gluteal musculature is an inconsistent finding; however, some horses have pelvic asymmetry with a lower tuber coxae and noticeable gluteal muscle atrophy on the affected side.[4,23] Observation of the tubera sacrale may reveal unilateral or bilateral (i.e., hunters' or jumpers' bumps) differences in height or dorsal prominence (see Fig. 53-4).

PHYSICAL EXAMINATION

Clinical signs of sacroiliac joint injury vary. The sacroiliac joint is relatively inaccessible to direct evaluation or palpation, and the normally small amount of sacroiliac joint motion is difficult to detect clinically.[24] Horses with acute sacroiliac joint injuries may have localized sensitivity to palpation of the surrounding soft tissues in the dorsal croup region.[4] A localized region of edema may occasionally be palpated over the lumbosacral junction[25]; however, this is not a specific finding related to sacroiliac joint injury. Protective muscle spasms may be palpated in the adjacent middle gluteal musculature and the vertebral portions of the biceps femoris, semitendinosus, and semimembranosus muscles. In acute sacroiliac injuries asymmetry in gluteal muscle development is uncommon, unless pronounced osseous pelvic asymmetry is also present. Pain may be elicited by applying firm digital pressure over the dorsal aspects of the tubera sacrale or caudal lumbar and sacral dorsal spinous processes. Unilateral or bilateral prominence of the tubera sacrale may be noted, but it is not usually clinically significant unless associated with clinical signs of localized pain or inflammation, or positive findings on diagnostic imaging (e.g., scintigraphy). Normally the tubera sacrale move in unison during pelvic movement in locomotion. A palpable or visible independent movement of the tubera sacrale at a walk or during treadmill locomotion indicates sacroiliac joint luxation or a complete pelvic fracture. Crepitus associated with sacroiliac joint instability, or complete pelvic fracture, may be palpable or auscultated with a stethoscope placed over the gluteal musculature as the pelvis is repeatedly rocked laterally. Horses with acute sacroiliac joint injuries may also resent flexion of the hindlimb on the affected side or rectal palpation in the region of the sacroiliac joint.

Horses with chronic sacroiliac joint injuries often have compensatory stiffness and pain in the proximal hindlimb.[20] Induced upper limb flexion (i.e., spavin test) is often negative.[4] Rectal examination for chronic sacroiliac joint subluxation is usually unrewarding and will not be diagnostic unless bone proliferation, excess joint motion, or joint crepitus during externally applied movements are identified.[20] A pain response or palpable muscle hypertonicity in the iliopsoas muscles may be noted during rectal examination. Serum chemistry indicators of skeletal muscle injury or inflammation (i.e., creatine kinase and aspartate aminotransferase) are often negative.

The apex of the second sacral spinous process is a reliable landmark used to evaluate relative unilateral or bilateral tubera sacrale displacement. The robust dorsal portion of the dorsal sacroiliac ligament spans between the tubera sacrale and the sacral spinous processes. Normally the dorsal apices of the tubera sacrale and the second sacral spinous process lie in close apposition and follow the contour of the croup. Using palpation, ultrasound, or radiographs, a physical discrepancy in height often can be identified between the dorsal profile of the sacral spinous processes (which should remain constant, unless fractured) and the potentially dorsally or ventrally displaced tuber sacrale. In this manner, unilateral (i.e., tubera sacrale height asymmetry) or bilateral tubera sacrale displacement (i.e., hunters' or jumpers' bumps) can be diagnosed, depending on if one or both tubera sacrale are elevated relative to the apices of the sacral spinous processes. Bilateral tubera sacrale displacement has an unknown clinical significance and may be occur in many high-level competition horses.[25] Theoretically the hunters' or jumpers' bumps may provide a longer lever arm for the strong longissimus and thoracolumbar fascia to produce extension at the lumbosacral joint, resulting in increased impulsion and range of hindlimb motion, with subsequent improved performance.

Firm digital pressure applied to the dorsal aspects of each tuber sacrale has been reported to produce a variable and inconsistent pain response.[7] In my experience, dramatic pain responses have been produced in affected horses with specific provocation tests, which are useful to establish a presumptive diagnosis of pelvic stress fracture or sacroiliac joint injury. The first procedure involves simultaneous manual compression of the dorsal aspects of both tubera sacrale, which induces a bending moment on the iliac wing and presumably compresses the sacroiliac articulations (see Fig. 53-5). Acutely affected horses may have a dramatic reaction to this manipulation and demonstrate sudden hindlimb flexion and an apparent inability to bear weight in the hindlimbs when pressure is applied. Clinicians should gradually apply increasing pressure, because affected horses may actually collapse in the hindlimbs and fall to the ground if excess force is applied to the painful tubera sacrale. A negative response is characterized by minimal pain response and slight extension of the lumbosacral joint during manual compression of the tubera sacrale. This test is not specific for pathological conditions of the sacroiliac joint, because horses with incomplete or stress fractures of the ilial wing may respond even more dramatically to the applied pressure.

A second procedure used to identify sacroiliac ligament injury involves rhythmically applying a ventrally directed force over the lumbosacral dorsal spinous processes in an effort to stress the supporting sacroiliac ligaments. This procedure requires the clinician to get up on an elevated surface (e.g., mounting block) so that the applied forces can be directed vertically over the sixth lumbar and second sacral dorsal spinous processes. Horses with sacroiliac ligament injuries would be expected to resent the induced movement because it specifically stresses the interosseous sacroiliac ligament (i.e., ligamentous sling of the sacropelvic junction). Horses with lumbosacral vertebral joint dysfunction (i.e., localized pain, reduced joint motion, and muscle hypertonicity without structural pathological conditions) may also resent this procedure. Rhythmically applied ventrally directed forces over the dorsal spinous processes at the sacrocaudal junction would be expected specifically to stress the dorsal portion of

the dorsal sacroiliac ligament. A positive response to this test combined with positive ultrasound findings of desmitis of the dorsal sacroiliac ligament would be highly suggestive of clinically significant sacroiliac ligament injury.

A similar procedure involves rhythmically applying a ventrally directed force over the tuber coxae to induce general sacroiliac and lumbosacral joint motion. A normal response to the induced movement is fluid vertical motion of the lumbosacral region, with an amplitude of 1 to 2 cm of dorsoventral movement measured over the lumbar dorsal spinous processes. Affected horses have a noticeable pain response, resent the induced movement, or have protective gluteal or sublumbar muscle spasms. The vertically directed force also induces movement at the lumbosacral junction, which must be differentiated from sacroiliac joint injury.

Additional procedures used to localize sacroiliac joint or ligament injuries involve indirectly evaluating pain and ligamentous laxity in the sacroiliac joint using laterally applied forces (Figs. 53-6 and 53-7). These procedures are similar to valgus-varus stress tests used to evaluate collateral ligaments of the distal limb articulations. Caution should be taken not to apply excessive force because of the long lever arm action of

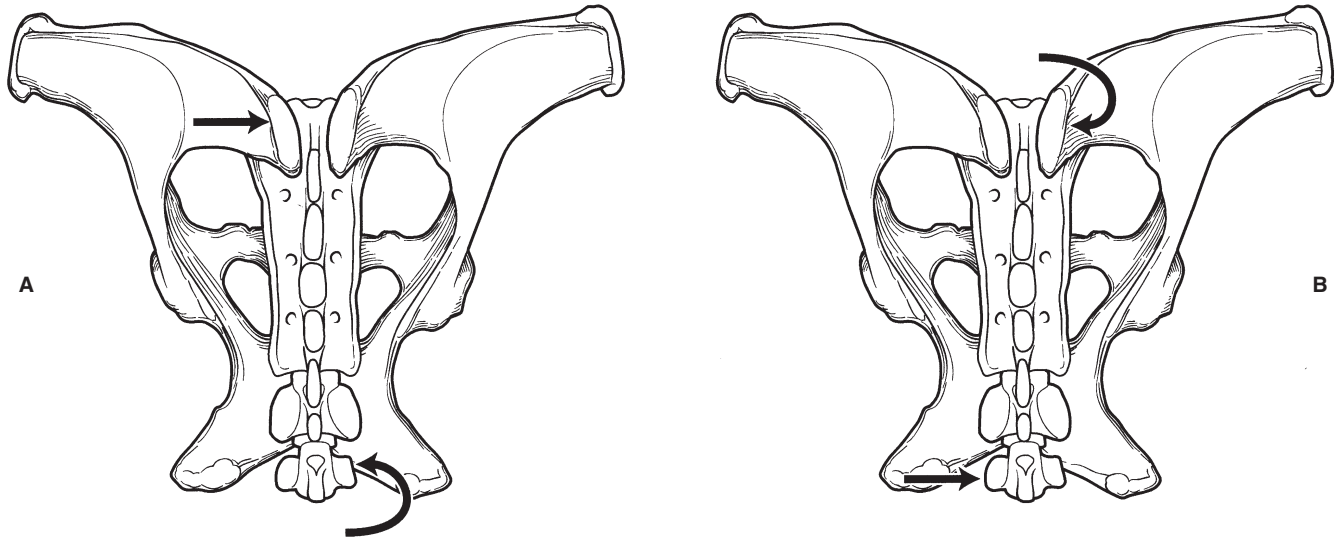

Fig. 53-6 Diagram of second sacroiliac joint provocation test (dorsal view). **A,** Firm pressure is applied by both hands, pushing with the hand at the ipsilateral tuber sacrale away from the clinician, while simultaneously pulling with the hand at the tail head toward him or her. **B,** Firm pressure is applied by both hands, pulling with the hand at the contralateral tuber sacrale toward the clinician, while simultaneously pushing with the hand at the tail head away from him or her.

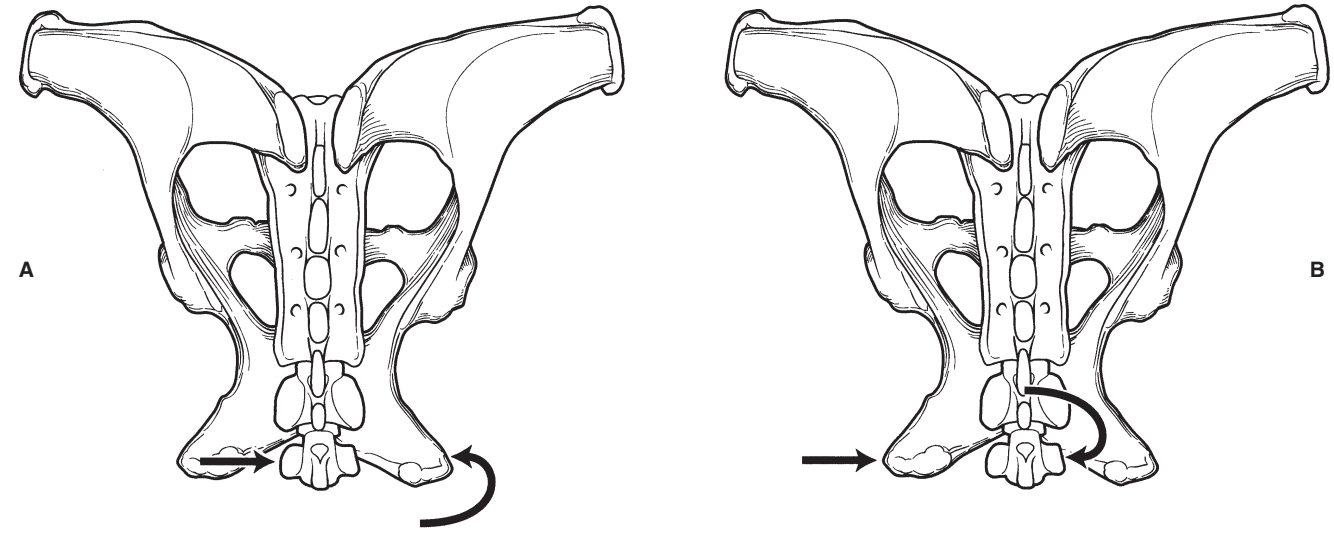

Fig. 53-7 Diagram of third sacroiliac joint provocation test (dorsal view). **A,** Firm pressure is applied by both hands, pushing with the hand at the tail head away from the clinician, while simultaneously pulling with the hand at the contralateral ischial tuberosity toward him or her. **B,** Firm pressure is applied by both hands, pulling with the hand at the tail head toward the clinician, while simultaneously pushing with the hand at the ipsilateral ischial tuberosity away from him or her.

the sacral apex on the sacroiliac ligaments, which can unduly stress unstable or partially torn ligaments or aggravate an acutely inflamed sacroiliac joint. The proposed mechanism of action of these tests is to use the base of the tail and sacrum as a handle to apply a lateral (horizontal plane) stress to the sacroiliac joint as the wing of the ilium is stabilized. The technique involves two parts. First, the base of the hand closest to the horse's head is placed over the lateral aspect of the tuber sacrale. The hand closest to the tail grasps the base of the tail head (the second and third coccygeal bones). The sacroiliac joints are then evaluated as firm pressure is simultaneously applied by both hands, pushing with the hand at the tuber sacrale away from the clinician and pulling with the hand at the tail head toward him or her (see Fig. 53-6, *A*). Theoretically, this maneuver produces compression of contralateral sacroiliac articular surfaces and distraction of the ipsilateral sacroiliac articular surfaces.

The second portion of the technique involves repeating the procedure and reversing the direction of the applied forces (see Fig. 53-6, *B*). The fingers of the hand closest to the horse's head are placed over the contralateral tuber sacrale, and the base of the hand closest to the tail is placed against the ipsilateral base of the tail head (second and third coccygeal bones). The sacroiliac joints are again evaluated as firm pressure is applied by both hands, pulling with the hand at the tuber sacrale toward the clinician and pushing with the hand at the tail head away from him or her. Theoretically the contralateral sacroiliac articular surfaces are distracted and the ipsilateral sacroiliac articular surfaces are compressed. A pain response to the induced movements may be identified unilaterally or bilaterally, depending on the extent of inflammation or injury present. In general, sacroiliac joint compression would be expected to aggravate osteoarthritic changes, whereas joint distraction would be expected to stress any injured or inflamed sacroiliac ligaments.

A variation of this basic technique uses repeatedly applied laterally directed forces over the ischial tuberosity instead of the tuber sacrale (see Fig. 53-7). This procedure incorporates two long lever arms to stress the supporting sacroiliac ligaments. Again caution should be taken not to apply excessive force because of the long lever arm action of the sacral apex and ischial tuberosities on the sacroiliac ligaments. Lastly, proximal hindlimb manipulation is done to assess coxofemoral and stifle joint range of motion and the willingness to actively extend the hindlimb. Concurrent joint stiffness or muscle hypertonicity can be identified and localized as the proximal hindlimb is passively protracted, abducted, flexed, and retracted.

REGIONAL ANALGESIA

Intra-articular analgesia of the sacroiliac joint is nearly impossible because of its deep anatomical location and inaccessible joint capsule. Experimentally, intra-articular sacroiliac injections have been accomplished by drilling a hole through the wing of the ilium, dorsal to the sacroiliac joint.[7] Regional perfusion with local anesthetic solutions or anti-inflammatory drugs for diagnostic or therapeutic purposes has been described. Approaches from the cranial wing of the ilium and the lumbosacral junction are typically used[25]; however, because of the wide overlying wing of the ilium, the proximity and diffusion of the medication near the sacroiliac joint is questionable.

I recommend a caudomedial approach to the sacroiliac joint region because of anatomical and pathological considerations. The caudomedial portion of the sacroiliac joint is the most frequent site of pathological conditions of the sacroiliac joint.[1,4,14] Therefore diagnostic analgesia or therapeutic analgesia or anti-inflammatory drugs should be directed toward the caudal

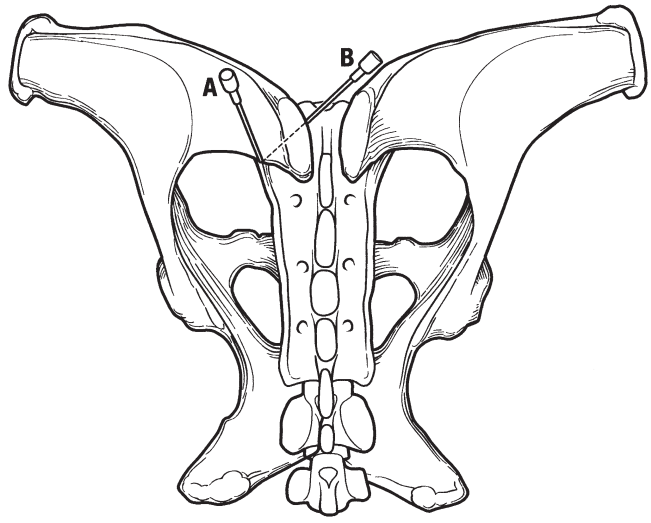

Fig. 53-8 Diagram of two approaches to the sacroiliac joint for diagnostic analgesia and therapeutic analgesia or administration of anti-inflammatory drugs (dorsal view). **A,** Dorsal approach over the ipsilateral iliac wing near the caudomedial aspect of the affected sacroiliac joint. **B,** Medial approach from the cranial aspect of the contralateral tuber sacrale with the needle directed toward the caudomedial aspect of the affected sacroiliac joint.

aspect of the sacroiliac joint in the region of documented pathological condition. Two approaches are described, using 20 to 25 cm long needles, depending on the depth and conformation of the gluteal musculature (Fig. 53-8). Surgical preparation of the injection site is recommended, similar to other joint injection techniques. Ultrasound guidance is also recommended to allow the caudomedial aspect of the sacroiliac joint to be seen and identification of neurovascular structures that must be avoided at the greater sciatic foramen (see Fig. 53-2). The cranial gluteal artery and nerve emerge laterally around the caudal margin of the ilial wing and travel dorsocaudally, adjacent to the sacroiliac joint. Other vital structures, including the sciatic nerve, lie ventral to the sacroiliac joint and travel on or within the substance of the sacrosciatic ligament.

The first approach involves needle placement dorsally over the iliac wing, ipsilateral to the affected sacroiliac joint (Fig. 53-8, *A*). This approach is technically easier, but it potentially has a higher risk of injury to the adjacent neurovascular structures. The needle is directed ventrally, toward the region of the sacroiliac joint, and walked off the caudal border of the iliac wing in the region of the sacroiliac joint. To avoid the deeper neurovascular structures, the needle is not advanced once it is walked off the caudal aspect of the iliac wing. Diffusion of the injected material occurs within the middle or accessory gluteal muscles, near the caudomedial attachments of the ventral sacroiliac ligament. Care must be taken to avoid the adjacent and deeper neurovascular structures mentioned previously.

A second preferred approach involves needle placement at the cranial margin of the contralateral tuber sacrale (Fig. 53-8, *B*). This approach is slightly more technically challenging but has a lower risk of injury to the adjacent neurovascular structures. The needle is inserted along the cranial aspect of the contralateral tuber sacrale and directed toward the cranial edge of the ipsilateral greater trochanter. The needle is placed contralateral to the affected sacroiliac joint, because the needle has to be guided between the divergent sixth lumbar and first sacral dorsal spinous processes and directed into the space formed by the ventral aspect of the ilial wing and the dorsal portion of the sacrum. The needle is advanced

caudolaterally along the medial aspect of the affected ilial wing toward the caudomedial portion of the affected sacroiliac joint until contact is made with bone, near the sacroiliac joint margin. Diffusion of the injected material is expected to occur within the longissimus muscle or interosseous sacroiliac ligament. The dorsal nerve branches of the sacral nerves possibly may also be affected with this approach, as the nerves exit the first and second dorsal sacral foramina.

DIAGNOSTIC IMAGING

Ultrasonography has been used to evaluate the dorsal surface of the iliac wing and caudal margin of the sacroiliac articulation to identify dorsal cortex irregularities associated with incomplete and complete ilial wing fractures.[26,27] The dorsal sacroiliac ligament can be readily imaged on either side of the sacral dorsal spinous processes caudal to the tubera sacrale.[6] Abnormal ultrasound images of the dorsal sacroiliac ligament include enthesopathies at the tubera sacrale attachment sites, hypoechoic changes within the ligament, and modification of fiber orientation.[6,17] The interosseous sacroiliac ligament has not been imaged because of its inaccessible location underneath the ventral aspect of the ilial wing. In contrast, the ventral sacroiliac ligament and the ventral joint margins of the sacroiliac joint can be seen on transrectal ultrasonography.[6] Ventral periarticular remodeling of the sacroiliac joint has been observed with transrectal ultrasound approaches.

Primary indications for radiography of the pelvis include acute or severe pelvic asymmetries, upper hindlimb lameness, and pelvic crepitus or fractures.[28] Ilial wing overlap and the deep anatomical location of the sacroiliac joint make radiographic imaging difficult at best. The radiographic features of chronic sacroiliac joint disease are minimal and include nonspecific increases in the joint space and apparent enlargement of the caudomedial aspect of the sacroiliac joint.[4] Linear tomography has also been used to examine the lumbosacral and sacroiliac regions of horses, but limited access to equipment has restricted its clinical usefulness.[12] Positive findings include widening of the sacroiliac joint and irregular joint outlines, with osteophyte formation at the caudal aspect of the joint. Osseous changes are common bilaterally, but they may be more pronounced on the clinically affected side.[12]

Nuclear scintigraphy is considered by some authors to be an accurate and diagnostically useful technique for identifying acute and chronic sacroiliac joint injuries. Subjective evaluation or quantitative analysis of bone scans typically is able to identify asymmetric radiopharmaceutical uptake over the affected tuber sacrale. However, presumed normal horses, without a history of hindlimb or sacroiliac joint injuries, may also have asymmetrical uptake over the tubera sacrale. A dorsal view of the sacrum is considered the most diagnostic image for evaluating and comparing the sacroiliac joints.[7] However, overlap of uptake in the tubera sacrale and the sacroiliac joints on the dorsal view is usually extensive. Oblique views of the ilial wings are recommended to confirm left to right asymmetries in radiopharmaceutical uptake and to separate the tuber sacrale dorsally from the sacroiliac joint region ventrally.[29] However, oblique views may be difficult to interpret because of inconsistent camera positioning on the left and right sides. The thick overlying gluteal musculature may also attenuate radiopharmaceutical uptake from an affected sacroiliac joint. Stress fractures of the ilial wing may be difficult to differentiate from sacroiliac joint injuries because of the common location and extension of the incomplete fracture line into the sacroiliac joint.[7,22,30]

Thermography has been used to diagnose muscle strain, or inflammation in the region of the sacroiliac and croup regions. Horses with sacroiliac joint injuries are expected to have protective muscle spasms in the adjacent musculature. Palpation of muscle sensitivity has been correlated with abnormal thermographic images in most horses.[31]

DIFFERENTIAL DIAGNOSIS

Causes of sacroiliac joint pain or injury have been postulated to result from sacroiliac or lumbosacral arthrosis, sacroiliac desmitis or sprain, sacroiliac subluxation or luxation, pelvic stress fractures, complete ilial wing fractures, or sacral fractures.[25] Additional differential diagnoses include thrombosis of the caudal aorta or iliac arteries, exertional rhabdomyolysis, trochanteric bursitis, and impinged dorsal spinous processes in the lumbar vertebral region.[20] Horses with presumed thoracolumbar vertebral problems may also have concurrent chronic sacroiliac joint injuries. In a report on 443 horses with back problems, chronic sacroiliac joint problems were identified in 15%.[8] Clinical signs of lower hindlimb lameness may overlap and mimic signs of presumed pathological conditions of the sacroiliac joint. It is important that a thorough and complete lower limb lameness evaluation is completed before, or along with, an upper hindlimb or sacroiliac joint workup.

Based on a review of the literature, osteoarthritis of the sacroiliac joint is the most prevalent disease process affecting horses with sacroiliac joint pain or dysfunction.[1,4,8,14] Sacroiliac desmitis has been documented in horses and may be a significant cause of pathological conditions in horses with acute sacroiliac joint injuries.[6] Documented complete rupture of the sacroiliac ligaments has only been reported in the veterinary literature in a few horses with acute and chronic disease.[14,19] The presumed diagnosis of sacroiliac joint subluxation based solely on tubera sacrale height asymmetry is inappropriate.[24] Horses with chronic sacroiliac problems and presumed sacroiliac joint subluxation have not had identifiable changes in the sacroiliac ligaments at necropsy.[4] In addition, STB trotters with substantial tubera sacrale height asymmetries did not have significant increases in sacroiliac pain compared with horses with lesser degrees of asymmetry.[13] In my opinion, an antemortem diagnosis of sacroiliac joint luxation can only be supported if an acute change in tubera sacrale height caused by substantial trauma has been documented or if sacroiliac joint instability (i.e., crepitus or independent tubera sacrale movement) is evident during physical examination. Pelvic stress fractures also need to be ruled out in horses with sacroiliac pain or dysfunction.[32] A high prevalence of occult pelvic stress fractures has been reported in TB racehorses.[30] The incomplete fracture lines extend into the caudomedial aspect of sacroiliac joint, which could possibly produce concurrent sacroiliac joint inflammation and osteoarthritis. A diagnosis of sacroiliac joint injury is often based on a diagnosis of exclusion because of difficulties in clinical evaluation and diagnostic imaging. We are hopeful future investigations into sacroiliac joint problems in horses will produce a better and more comprehensive understanding of this often misdiagnosed clinical entity.

TREATMENT

Because definitive diagnosis of pathological conditions of the sacroiliac joint is difficult, treatment recommendations are usually symptomatic. Few studies on treatment efficacy have been reported in the equine literature. In general, rest and various forms of physical therapy are indicated for ligamentous injuries. Prolonged rest (6 to 12 months) and systemic anti-inflammatory medications have been prescribed for horses with acute and chronic sacroiliac joint injuries. Complete box stall rest for 30 to 45 days has been recommended to support ligamentous healing in horses with acute injuries.[20] The local injec-

tion of irritants or sclerosing agents have also been suggested to stimulate fibrosis and subsequent sacroiliac joint stability.[20] In my opinion, no scientific support or clinical indication exists for such proposed treatments of back or sacroiliac joint problems. With such haphazard and potentially injurious treatment modalities there appears to be a better chance of inducing further injury, rather than of stimulating any healing response. Treatment of chronic sacroiliac joint injury typically focuses on a gradual return to a low level of exercise to maintain muscle development of the back and gluteal regions to counteract the clinical signs of poor performance and reduced hindlimb impulsion.[23] Extended rest is contraindicated because reduced muscle tone may exacerbate the injury.

Because of the deep and inaccessible location of the sacroiliac joint, intra-articular injections of analgesic or anti-inflammatory medications for diagnostic or therapeutic purposes are impractical.[7] However, regional perfusion of the sacroiliac joint with local anesthetic solutions or anti-inflammatory drugs for diagnostic and therapeutic purposes is a viable alternative.[25] Concurrent lameness of the ipsilateral lower hindlimb has been reported in horses with signs of chronic sacroiliac joint injuries.[7] Therefore a detailed lameness examination coupled with appropriate treatment of the pathological conditions of the lower hindlimb is often indicated. Additional factors such as corrective shoeing and modifications in exercise or training programs also need to be addressed. Acupuncture and chiropractic are non-traditional approaches that have been used by some clinicians to assist in the diagnosis and symptomatic treatment of horses with presumed sacroiliac joint problems. Additional research into these modalities needs to be conducted before further recommendations can be made about their efficacy for horses with documented sacroiliac joint pathology.

PROGNOSIS

Long-term follow-up suggests that prognosis for horses with sacroiliac joint injury is poor for return to the previous level of activity.[7] Some horses may have an improvement in performance or lameness but will not be able to return to normal athletic activities because of recurring, low-grade lameness. Most horses will be pasture sound or able to function only at low levels of exercise. We are hopeful that improvements in providing a specific diagnosis of the type of sacroiliac joint injury present will provide affected horses with better and more specific treatment options in the future.

ACKNOWLEDGMENT

I thank Michael Simmons for assistance with the illustrations.

CHAPTER • 54

Thoracolumbar Spine

Jean-Marie Denoix and Sue J. Dyson

Back problems are a major cause of altered gait or performance (see Chapters 52, 53, and 100). Identification and documentation of vertebral lesions is difficult in horses; therefore treating back pain is a real challenge for the equine clinician. The equine back is a large area covered by thick muscles. Assessment of the bony elements is therefore limited. Every joint in the thoracolumbar region has restricted mobility, and therefore detecting changes in restricted movement when the horse is working is difficult. Diagnostic imaging of the thoracolumbar region is also limited, and radiographic assessment requires special equipment. Specific treatment of back pain can only be performed after complete identification of the site and nature of the lesions.

ANATOMY AND FUNCTION

Bones

The thoracolumbar spine is basically composed of 18 thoracic vertebrae (T1 to T18), 6 lumbar vertebrae (L1 to L6), and 5 fused sacral vertebrae (S1 to S5). Some horses have individual (congenital) variations at the cervicothoracic, thoracolumbar, and lumbosacral junctions. The most common is the sacralization of the last lumbar vertebra (sacralization of L6), which can be seen by ultrasonography. Transitional vertebrae, with a rib on one side and a transverse process on the other side, can be found at the thoracolumbar junction. Intervertebral ankylosis alters the biomechanical behavior of the involved part of the spine, especially at the lumbosacral junction, which in normal horses is the most mobile joint between T2 and S1. Ankylosis of this joint puts more stresses on the caudal lumbar intervertebral joints and may predispose to osteoarthritis of the facet joints and intervertebral disk lesions. Fusion of the lumbar transverse processes (see the following discussion) is also sometimes seen, and this has similar consequences on adjacent intervertebral joints, but the consequences are fewer because little movement usually occurs in these joints. Transitional transverse processes, or ribs that do not involve the vertebral body, have less biomechanical significance.

The first 10 thoracic vertebrae have long spinous processes. These have a dorsocaudal orientation and provide insertion for the strong but elastic supraspinous ligament. The anticlinal vertebra, the vertebra with a spinous process perpendicular to the vertebral axis, is usually T15. Caudal to the anticlinal vertebra the spinous processes are orientated obliquely dorsocranially. The spinous processes are higher between L2 and L5. Therefore lumbar muscular atrophy results in a kyphotic appearance of the lumbar area.

In most horses the spinous processes of L6 and S1 are divergent, allowing a range of flexion and extension movements at the lumbosacral joint. The transverse processes from L5 (sometimes L4) to S1 articulate through inter-transverse synovial joints, which limit lateral flexion in this area. The lumbar vertebral bodies are bigger than the thoracic ones and have a ventral crest for the insertion of the diaphragm.

Joints

Stability of the thoracolumbar vertebrae is provided by the supraspinous and interspinous ligaments, the joints between the cranial and caudal articular processes (the facet joints), the joints between the vertebral bodies, and the dorsal and ventral longitudinal ligaments. Stability of the spinous processes is provided by the supraspinous and interspinous ligaments (Fig. 54-1). These ligaments are wider and more elastic in the cranial and middle thoracic areas, permitting more movement than in the caudal thoracic and lumbar regions.

The caudal and cranial articular processes articulate via synovial intervertebral articulations (the facet joints). At the base of the spinous processes these joints are symmetrically placed on each side of the median plane (Fig. 54-2). These are

typical synovial (diarthrodial) joints with articular cartilage, a closed synovial cavity containing synovial fluid, a synovial membrane, and a fibrous capsule. They have a single flat articular facet in the cranial thoracic area (up to T12) and two angulated articular facets between T12 and T16. From T17 to S1 the articular facets are congruent, with a cylindrical shape aligned on a paramedian axis. These regional variations are correlated with the limited mobility of the lumbar spine and the wider range of movement in the thoracic region, including flexion and extension in the median plane, lateral flexion in the horizontal plane and rotation. The vertebral bodies are stabilized by joints composed of a fibrous intervertebral disk and two longitudinal ligaments. The ventral longitudinal ligament is replaced by the longissimus cervicis muscle in the cranial thoracic area. The dorsal longitudinal ligament is located in the vertebral canal and adherent to the dorsal border of each intervertebral disk.

Muscles

The vertebral column is moved by wide muscles (Fig. 54-3). The strong epaxial muscles, located dorsal to the vertebral axis, have an extensor effect when contracted bilaterally. Unilateral contraction induces lateral flexion and contributes to rotation of the vertebral column. Electromyographic studies show that the epaxial muscles limit flexion and stabilize the vertebral column during the suspension phase at the trot.[1,2]

The epaxial muscles include the following:

1. Spinosus muscle, inserting on the spinous processes
2. Longissimus dorsi muscle, which extends to the caudal cervical spine
3. Iliocostalis muscle

The longissimus dorsi is the strongest muscle. The iliocostalis muscles are small but have a greater role in lateral flexion because of their eccentric location. Caudally, these muscles

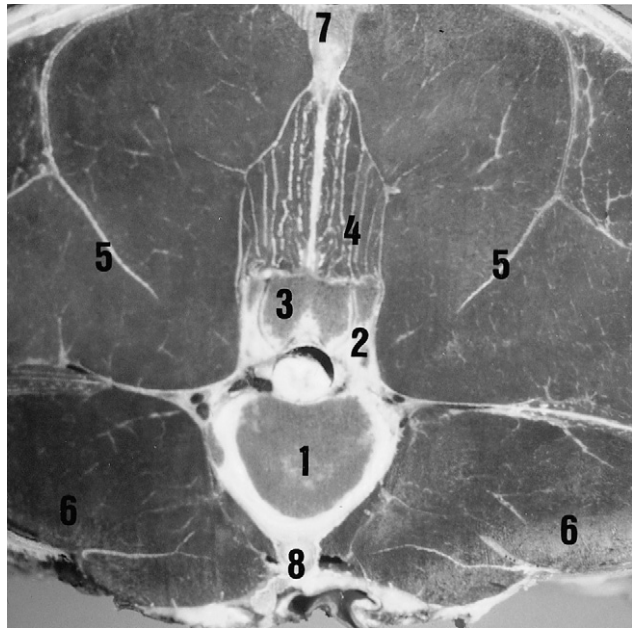

Fig. 54-3 Transverse anatomical section of the normal lumbar region of 6-year-old Selle Français mare. *1*, Vertebral head of third lumbar vertebra; *2*, cranial articular process of third lumbar vertebra; *3*, caudal articular process of second lumbar vertebra; *4*, multifidus muscle; *5*, erector spinae muscle; *6*, psaos muscles; *7*, supraspinous ligament; *8*, ventral longitudinal ligament.

fuse to form the erector spinae muscle. The multifidus muscle lies under the spinosus muscle and is in close contact with the vertebrae (juxtavertebral muscle). This muscle plays a major role in the stability of the vertebrae and in the proprioceptive adjustment of the spine.

The hypaxial muscles, located ventral to the vertebral axis, have a flexor effect on the spine when contracted bilaterally. Unilateral contraction induces lateral flexion and contributes to rotation of the vertebral column. The hypaxial muscles include psoas minor and major, rectus abdominis, and rectus oblique.

The psoas minor and major muscles insert on the ventral aspect of the lumbar and caudal three thoracic vertebrae (juxtavertebral muscles). They act mainly at the lumbosacral junction but are also able to flex the thoracolumbar junction and the lumbar spine. The rectus abdominis muscle is an effective flexor of the complete thoracolumbar spine because of its eccentric insertions on the pubis, sternum, and ventral part of the ribs. The oblique muscles can create lateral flexion and rotation of the thoracolumbar spine because of eccentric insertions on the tubera coxae and ribs. Electromyographic studies show that the rectus abdominis muscles act to limit extension and stabilize the vertebral column during each diagonal stance phase at the trot.[1,2]

Blood Vessels and Nerves

The vertebrae, intervertebral joints, and axial muscles are supplied by segmental thoracic and lumbar arteries and veins. Innervation is provided by thoracic and lumbar spinal nerves that pass through the intervertebral foramina.

DIAGNOSIS OF BACK PAIN

The objectives of clinical examination of the horse's back[3-5] are to determine if back pain is present, the site or sites of pain, and the potential lesions responsible for the pain. Acute back

pain can arise after traumatic injuries, such as a fall, or after an awkward jump. Acute pain and muscle spasm may be identified and may be the primary lesion, but a complete radiographic examination of the thoracolumbar spine may be indicated to assess for vertebral fractures or long-standing bony lesions that may be responsible for the accident. These lesions may become clinically significant because of over-stress on the intervertebral structures. For example, long-standing spondylosis lesion may cause acute pain on landing after a jump.

A poor rider or an ill-fitting saddle may cause back pain, but correction of these problems may not be easy. It is important to manage these causes of back pain before proceeding with more advanced imaging techniques.

Back pain may also be manifest by abnormal behavior, for example, bucking (see page 829).

Physical Examination

Physical examination is essential in diagnosing back pain. Only the main criteria for each step or procedure are discussed. It is obviously important to perform a comprehensive evaluation of the whole horse to identify any other potential problems that may be contributing to gait abnormalities or poor performance.

Inspection

The most commonly described abnormal curvatures of the back are lumbar kyphosis and thoracic lordosis. These can be seen in the same horse. Atrophy of the epaxial muscles in the lumbosacral regions results in prominence of the normal summits of the spinous processes and apparent kyphosis of the lumbar spine. Detection of atrophy of the epaxial muscles is a key finding in a horse with potential back pain, because atrophy reflects the reduction of movement in the painful areas. The finding can help provide information on the possible location of the lesions. However, one should bear in mind that muscular development also reflects the horse's previous work history, and if the horse has never worked properly through its back, the epaxial muscles will be poorly developed.

Thoracic lordosis may be seen in clinically normal horses and does not necessarily imply the presence of back pain. However, a short coupled horse with lordosis is more likely to have impinging spinous processes, a reflection of the horse's normal conformation.

Abnormal swellings in the saddle area or abnormal hair loss may reflect a poorly fitting saddle or the position and balance of the rider. A rider that sits crookedly predisposes to excessive movement of the saddle.

Palpation

Palpation of the thoracolumbar region should be performed with the horse standing quietly, bearing weight evenly on all limbs. Time should be spent getting the horse accustomed to the clinician's presence, especially with an apprehensive horse, so that the horse's true reactions to pain and pressure can be assessed. A thin-skinned Thoroughbred (TB)-type may give a false impression of guarding the back and having protective spasm of the epaxial muscles, unless approached quietly.

Palpation of the superficial structures of the thoracolumbar region helps to identify supraspinous desmopathy and deformation or malalignment of the spinous processes. Identification of localized muscle tension can be a key feature in establishing the presence of a significant lesion. The thickness of the epaxial muscles prohibits accurate assessment of deeper structures.

Pressure

Pressure on the superficial structures such as the supraspinous ligament and the epaxial muscles is useful to assess pain. Reliably assessing the response to pressure applied to deeper structures, such as the epaxial synovial intervertebral articulation complexes, is not possible.

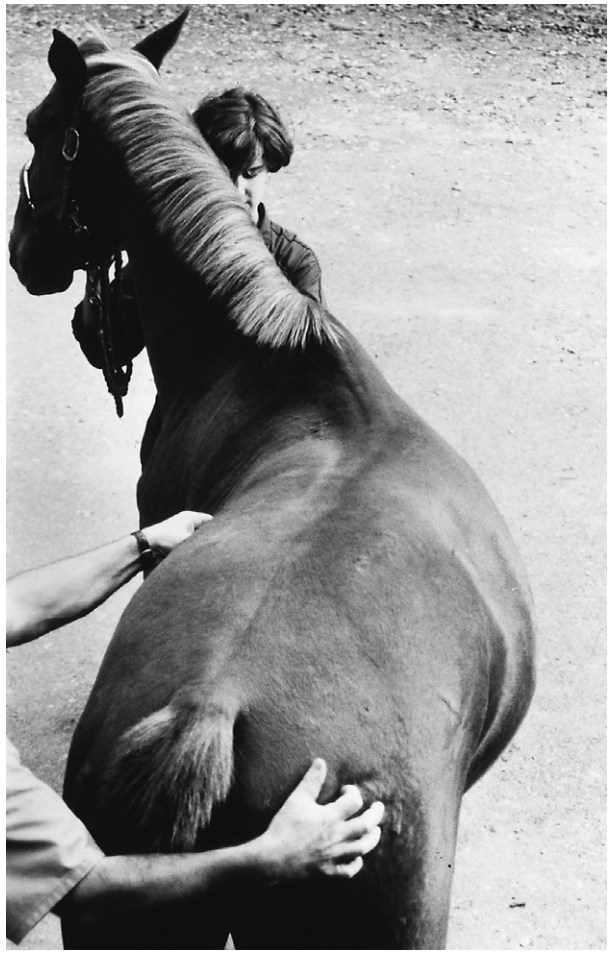

Fig. 54-4 Physical examination by left lateral flexion of the thoracolumbar spine. The two main criteria evaluated are the amount of movement and manifestations of pain.

Mobilization

Stimulation of movement of the thoracolumbar spine (Fig. 54-4) is important to assess the amount of movement tolerated by the patient and any signs of pain, such as flexion of the limbs, alteration of facial expression, tension of the back muscles, movement of the tail, and alteration of behavior (kicking, rearing, bucking, and grunting).

The following protocol is recommended:

1. Assessment of thoracic flexion, thoracic extension, thoracolumbar extension, lumbosacral extension, and complete thoracolumbar and lumbosacral flexion in the median (sagittal) plane
2. Assessment of right and left thoracolumbar lateral flexion (and rotation) (see Fig. 54-4)
3. Assessment of left and right cervical (and thoracic) lateral flexion (and rotation)

The clinician should try to determine which movements are restricted or not tolerated so as to determine potential sources of pain. These movements can be induced by skin stimulation of the dorsal and lateral aspects of the trunk and hindquarters. Although some horses respond to soft digital stimulation, in others a stronger stimulus is required, for example, using the tips of a pair of artery forceps. Firm stroking with a hard instrument displaced craniocaudally and inducing spectacular wide extension and flexion movements may lack sensitivity and specificity in determining the site of back pain, but firm stroking may be necessary in extremely stoical cob-type horses to induce any movement. A normal, relaxed horse is

able to flex and extend the thoracolumbar spine smoothly and repeatedly. The degree of movement reflects in part the type of horse. Cob-type animals naturally tend to have much more restricted movement than TBs or Warmbloods. The clinician will find it useful to keep one hand resting on the mid-back region during these maneuvers to detect induced muscle spasm or abnormal cracking of the muscles or ligaments (a crepitus-like feeling as the epaxial muscles or ligaments contract and relax).

Examination During Movement

Evaluation of the horse moving at walk, trot, and canter is essential to assess if pain is present and to identify functional disorders, such as limitation of regional intervertebral mobility (Fig. 54-5). The clinician should always bear in mind that impinging spinous processes can be present asymptomatically. Therefore the significance of impinging spinous processes should not be over-interpreted, unless clinical signs of back pain are evident. The horse should be assessed moving in straight lines and in small circles at a walk and trot on a hard surface and moving at a trot and canter on the lunge to determine if any reduction of back mobility is apparent (Table 54-1).

In vivo kinematic studies have quantified dorsoventral flexibility of the back in sound horses trotting[6,7] and at various gaits on the treadmill.[8] Horses with vertebral lesions showed a reduction of passive flexibility of the back at trot,[9] with reduced flexion and extension, lateral flexion, and rotation. Thus the horse may appear to hold its back rather stiffly. This can be caused by mechanical problems (partial or complete ankylosis) or pain. Back pain may also influence stride length and limb flight, resulting in a more restricted and less animated gait. On the lunge the horse may show loss of balance and a tendency to lean the body rather than bend the trunk toward the direction of circle.

Examination of the Horse Being Ridden or in Harness

The presence and the degree of back pain may be underestimated unless the horse is evaluated under its normal working conditions, that is, ridden or in harness. The clinician should watch carefully as the tack or harness is applied, particularly as the girth is tightened. However, the clinician should bear in mind that cold-back behavior (see page 829) is not necessarily a reflection of back pain, although it may be. The fit of the saddle for the horse and the rider should be evaluated. Back mobility,[3] the movements that the horse finds difficult, and the horse's attitude toward work should all be assessed (see page 830).The clinician should pay attention also to the observations of the rider, because the horse may feel considerably worse than it appears. The rider may describe lack of hindlimb power, lateral stiffness of the back to the left or right, unwillingness of the horse properly to take the bit, or loss of fluidity in the paces. The rider may complain of back pain induced by riding the horse.

Fig. 54-5 Dynamic examination by evaluating the active back movement at the canter on the lunge.

Table • **54-1**

Criteria Used for Evaluating Back Disorders*

GROUND	GAIT	DIRECTION OF MOVEMENT	CRITERIA
Hard	Walk	Straight line	Rotation (tuber coxae mobility) (lateral flexion)
		Figure eight (3 m diameter)	Lateral flexion
	Trot	Left circle (7 m diameter)	Lateral flexion
		Right circle (7 m diameter)	(Passive TL flexibility)
Soft	Trot	Right circle (10 m diameter)	Passive DV flexibility (TL>LS)
			Lateral flexion
			Hindlimb propulsion
	Canter	Right circle (10 m diameter)	Active flexion and extension movements (LS>TL)
			Hindlimb protraction/propulsion
			Hindlimb placement (rotary canter)
			Coordination and balance
	Trot Canter	Left circle (10 m diameter)	Same as above
Hard	Trot	Left circle (7 m diameter)	Lateral flexion
		Right circle (7 m diameter)	(Passive TL flexibility)
		Straight line	Passive DV flexibility (TL>LS): side aspect
			Rotation (tuber coxae mobility); lateral flexion: caudal aspect

TL, Thoracolumbar; *LS*, lumbosacral; *DV*, dorsoventral.
*Assessment involves a horse moving first on a hard surface, then on a soft surface, and then on a hard surface, in straight lines and circles, at walk, trot, and canter.

Examination of the horse while it is ridden also gives the clinician the opportunity to assess the rider, because back pain is readily induced by poor riding, a situation which may not be easy to handle diplomatically.

Local Analgesia

Diagnostic infiltration of local anesthetic solution may be useful to assess the clinical significance of impingement of spinous processes, where only the bones, ligaments, and adjacent muscles are affected by the analgesia. If impingement is severe, local anesthetic solution can only be deposited around the spinous processes and not between them. The volume of local anesthetic solution required depends on the number of spinous processes involved. Sixty to 80 ml of mepivacaine is injected at several sites using 4-cm needles if 4 to 5 impinging spinous processes exist. The response is assessed in 15 to 20 minutes and is most accurately evaluated by observing the horse while it is ridden and by the rider's feel. If kissing spines is the only significant lesion, then significant improvement should be anticipated, but if other lesions are contributing to pain, the response is limited.

If deeper injections are performed in the region of the epaxial synovial intervertebral articulations, interpretation is confounded, because the injections are effectively intramuscular injections, and the local anesthetic solution may readily diffuse to affect sites on the dorsal and ventral rami of the spinal nerves. Thus local analgesia has little value for the assessment of osteoarthritis of the synovial intervertebral articulation, intervertebral disk disease, and spondylosis.

IMAGING

Radiography and ultrasonography are essential to determine potential causes of pain or mechanical restriction. Nuclear scintigraphy is also a useful tool to detect abnormal bone activity and to help establish the clinical significance of radiographic findings.

Radiography

Indications for the radiographic examination of the thoracolumbar spine include owner complaints of a back problem in their horse, abnormal clinical findings, poor performance, or as part of the assessment of an obscure lameness.

The horse should stand squarely on all limbs.[10] Sedation may be necessary using detomidine (3 to 7 mg) or romifidine (12 to 25 mg). A high-output x-ray machine is necessary, with a rotating anode and an 80-kW power generator, for example.

Cassettes (20 × 40-cm format) with fast screens and sensitive or high-sensitive films are used to provide highly sensitive film-screen combinations. The cassettes should be placed in a vertically orientated ceiling or wall-mounted cassette-holder, which can be aligned with the x-ray machine. The cassette should be placed as close to the trunk of the horse as possible. A 10:1 ratio focused grid is used to reduce radiation scatter. The focus-film distance varies between 1.15 and 1.30 m. The x-ray beam is directed perpendicular to the vertebral column axis. Five exposures are required (Fig. 54-6) to obtain a complete evaluation of the thoracolumbar spine between T10 and L4. In some horses L5 may also be imaged. The exposure parameters are summarized in Table 54-2. To reduce motion, the exposure is performed during the last part of the expiration.

Ultrasonography

Ultrasonographic examination of all the epaxial structures is possible.[11,12] Imaging of the spinous processes and associated ligaments is performed with 7.5-MHz or 10-MHz probes. A standoff pad is used to improve detection of the superficial structures. Imaging of the articular and transverse processes

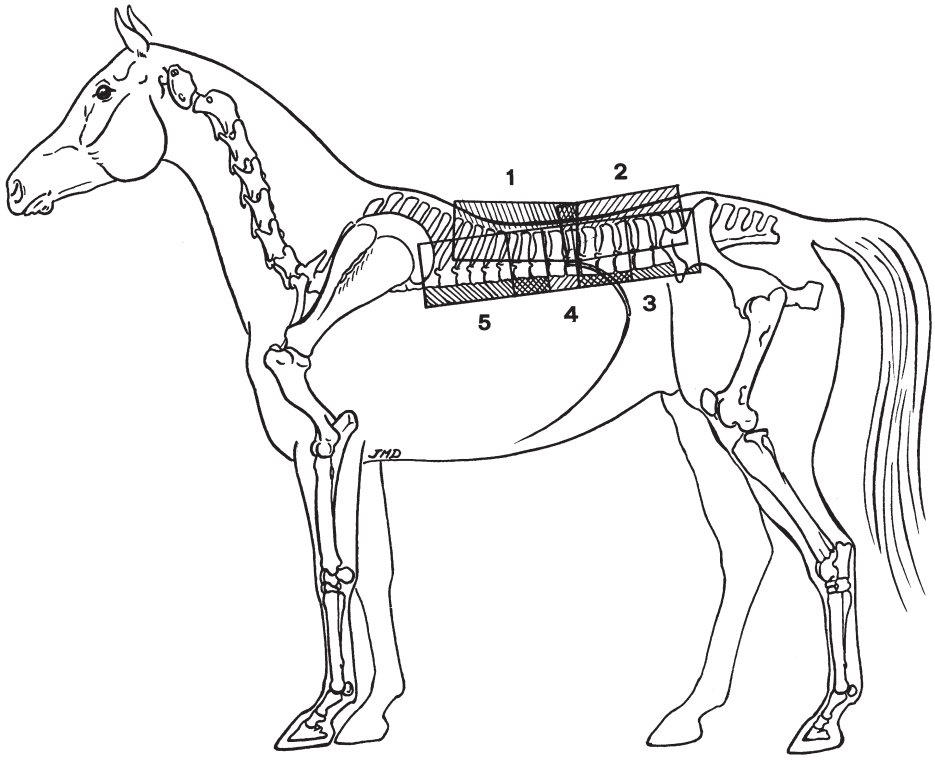

Fig. 54-6 Position of the cassettes for radiographic examination of the thoracolumbar spine: *1*, Thoracic spinous processes; *2*, lumbar spinous processes; *3*, lumbar vertebral bodies and synovial intervertebral articulation; *4*, thoracolumbar vertebral bodies and synovial intervertebral articulation; *5*, thoracic vertebral bodies and synovial intervertebral articulation.

Table • **54-2**

Technical Parameters Used for the Exposure of Different Regions of the Thoracolumbar Spine*

REGIONS	FILM	kV	MA	EXPOSURE DURATION (msec)
Thoracic dorsal spinous processes	Sensitive	73-77	80-110	71-107
Lumbar dorsal spinous processes	Sensitive	77-83	110-160	110-182
Mid-thoracic region, vertebral bodies, and facet joints (T10-T16)	High sensitive	70-77	100-140	86.5-141
Thoracolumbar junction, vertebral bodies, and facet joints (T15-L2)	High sensitive	81-85	160-250	177-344
Lumbar region, vertebral bodies, and facet joints (T18-L4)	High sensitive	85-93	280-320	406-580

*All examinations performed using a 10:1 grid and rare earth fast screen. Horses of 450 to 650 kg body weight.

can be performed with 5- to 2.5-MHz probes. Longitudinal median and paramedian scans and transverse scans are combined to image all dorsal vertebral structures. For ultrasonographic examination the hair on the median plane over the spinous processes is removed with a No. 40 clipper blade and the skin is cleaned. The skin is never shaved. When the hair is short (during the summer time) wetting the hair and skin with hot water for several minutes allows examination without clipping. Aqueous contact transmission gel is applied to the wet skin to couple the transducer to the skin to avoid air interference and artifacts.

Scintigraphy

Nuclear scintigraphy is used to detect lesions in the thoracolumbar spine. In a retrospective study of 50 horses the most common abnormal finding was abnormal radiopharmaceutical uptake in the spinous processes between T12 and L2, identified in 48 horses.[13] Three horses had abnormal radiopharmaceutical uptake in the vertebral bodies of L3 to L6 and T11 to T14.

Lateral or slightly oblique lateral images give the most information. Scattered radiation is a problem because of the large muscle mass overlying the vertebrae, so use of a high-resolution collimator is preferred. This requires longer acquisition times to obtain an adequate number of counts to give adequate image quality. Slight swaying movement of the horse during image acquisition and the movement of breathing detract from image quality unless motion-correction software is used. The gamma camera may need to be angled slightly to avoid the kidneys being superimposed over the caudal thoracic vertebrae. At least three images are required to evaluate the entire length of the thoracolumbar spine, and comparable images from the left and right sides can be useful. The summits of the spinous processes in the withers region, the caudoproximal aspect of the scapula, and the kidneys may all have greater radiopharmaceutical uptake than the rest of the thoracolumbar spine and may effectively conceal lesions (Fig. 54-7). Masking these areas out after image acquisition potentially results in more information. Using a high-frequency filter can also yield additional information. Image resolution in fat horses may be compromised by scattered radiation in the soft tissues.

Thermography

Thermography may be useful in identifying acute superficial muscle injuries or demonstrating to an owner the impact of a poorly fitting saddle or a rider sitting crookedly. However, in horses with chronic back pain, thermography does not usually add useful information and lacks sensitivity and specificity.

LESIONS

Spinal Processes and Associated Ligaments

Impingement of the Dorsal Spinous Processes: Kissing Spines

Impingement of the summits of the spinous processes, or kissing spines, is a well-known pathological entity of the horse's back,[14] but it is important to recognize that lesions may not be restricted to the summits. The most common location of these lesions is the vertebral segment between T10 and T18 (Fig. 54-8), although lesions do also occur between L1 and L6.[10] Remodeling of the dorsal aspect of a spinous process or an avulsion fracture reflects an insertional lesion of the supraspinous ligament. We grade impingement of the dorsal part of the spinous processes as follows:

- Grade 1: Narrowing of the interspinous space with mild sclerosis of the cortical margins of the spinous processes
- Grade 2: Loss of the interspinous space with moderate sclerosis of the cortical margins of the spinous processes
- Grade 3: Severe sclerosis of the cortical margins of the spinous processes, caused in part by transverse thickening, or radiolucent areas
- Grade 4: Severe sclerosis of the cortical margins, osteolysis, and change in shape of the spinous processes

Over-riding of spinous processes is a congenital condition with abnormal orientation of the spinous processes and similar changes in the margins of adjacent spinous processes. The contour of the middle part of a spinous process may be altered because of enthesophyte formation at the insertion of the interspinous ligaments. Kissing lesions may also be seen at the ventral part of a spinous process with type 4 lesions of the epaxial synovial intervertebral articulation (see page 518).

Ultrasonographic examination can easily demonstrate contact or remodeling between two adjacent spinous processes, transverse thickening of the processes, and abnormal alignment. However, ultrasonography is more useful to assess concomitant supraspinous ligament lesions, including insertion desmopathies (enthesopathies) on the summits of the spinous processes.

Nuclear scintigraphy can help identify evidence of active bone modeling of the spinous processes and other potential lesions. However, one must bear in mind that active bone modeling is not synonymous with pain. Increased modeling of the dorsal aspects of the spinous processes may reflect impingement or insertional desmopathy of the supraspinous ligament (Fig. 54-9). The degree of increased radiopharmaceutical uptake does not always appear to be well correlated

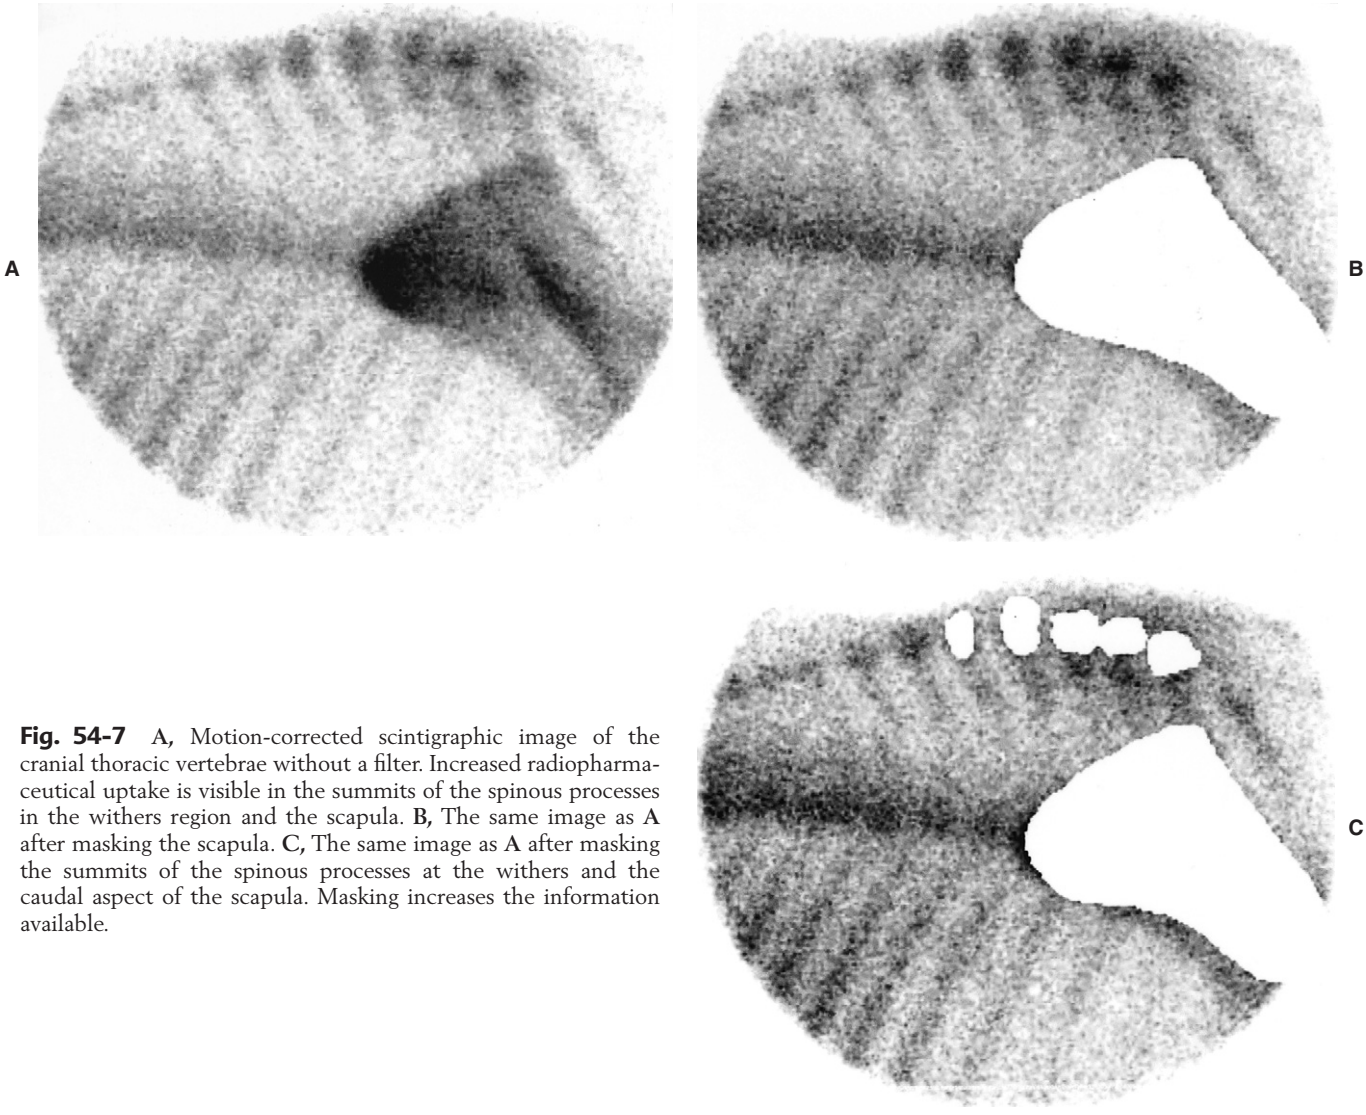

Fig. 54-7 **A,** Motion-corrected scintigraphic image of the cranial thoracic vertebrae without a filter. Increased radiopharmaceutical uptake is visible in the summits of the spinous processes in the withers region and the scapula. **B,** The same image as **A** after masking the scapula. **C,** The same image as **A** after masking the summits of the spinous processes at the withers and the caudal aspect of the scapula. Masking increases the information available.

with the severity of the clinical signs or the radiological abnormalities (see Fig. 54-9, *A*). Obvious focal increased radiopharmaceutical uptake (IRU) can be seen in horses with neither back pain nor radiological abnormality, whereas some horses with back pain associated with impinging spinous processes have only mild IRU. Mechanical limitations may contribute to back stiffness.

Kissing spines can be found in performance horses with no clinical manifestations of back pain. Therefore the clinical significance of kissing spines must be carefully assessed. Kissing spines may also be present with another vertebral lesion, which may have a greater influence on prognosis; therefore a comprehensive evaluation of all structures should be performed, even if kissing spines have been identified. Radiographic findings should be carefully correlated with the results of the physical examination and preferably with nuclear scintigraphic examination and the response to local analgesia.

Desmopathies: Supraspinous Ligament Injuries

Injuries of the supraspinous ligament occur most commonly between T15 and L3 and may be associated with palpable

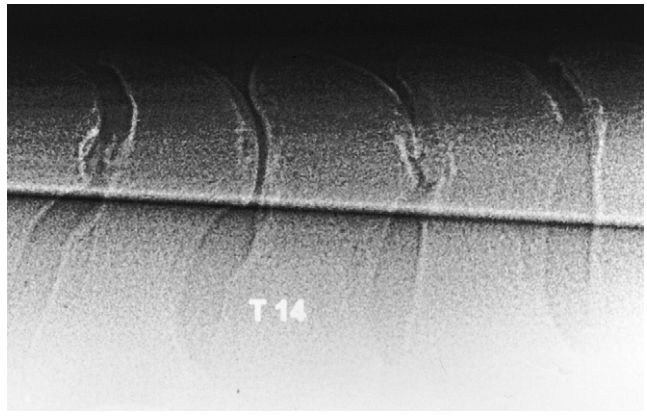

Fig. 54-8 Lateral radiographic view of the spinous processes of the twelfth to sixteenth thoracic vertebrae. Cranial is to the left. There are radiographic signs of impingement of the spinous processes between the eleventh and sixteenth thoracic vertebrae, with significant marginal bone remodeling. *T14,* Fourteenth thoracic vertebra.

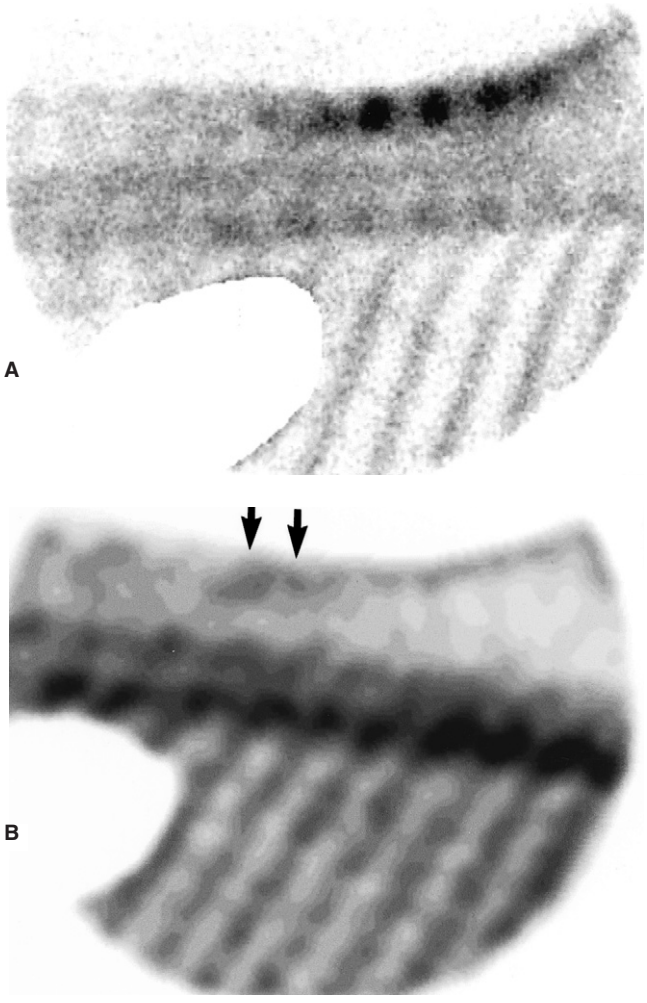

Fig. 54-9 **A,** Lateral nuclear scintigraphic image of the thoracolumbar region of 10-year-old Grand Prix dressage horse with loss of action. Increased radiopharmaceutical uptake is visible in the dorsal aspects of six adjacent spinous processes. The horse showed clinical signs of restricted mobility of the back. Radiographic evidence showed impinging spinous processes. The horse's gait was dramatically improved by infiltration of local anesthetic solution around the affected spinous processes. **B,** Lateral nuclear scintigraphic image of the thoracic region of 8-year-old show jumper gelding with stiffness of the thoracolumbar region and poor hindlimb impulsion. A high-resolution filter has been applied to the image. Only slight radiopharmaceutical uptake is visible in the summits of two spinous processes in the caudal thoracic region (*arrows*). However, five adjacent spinous processes were impinging, and infiltration of local anesthetic solution produced a profound clinical improvement. No soft tissue lesions were identified by ultrasonography.

localized thickening and pain. Lesions are identified best by ultrasonography.[11,12]

Thickening of the supraspinous ligament induces a local deformation (bump) of the dorsal profile of the thoracolumbar area, which can be measured by ultrasonography and compared with two adjacent equivalent locations. Lesions usually occur at a spinous process, sometimes extending between two adjacent spinous processes. The normal supraspinous ligament is uniformly echogenic (Fig. 54-10). Hypoechogenic lesions in the deep and intermediate part of the supraspinous ligament (Fig. 54-11) are compatible with recent or chronic desmopathies of the supraspinous ligament. Hyperechogenic foci,

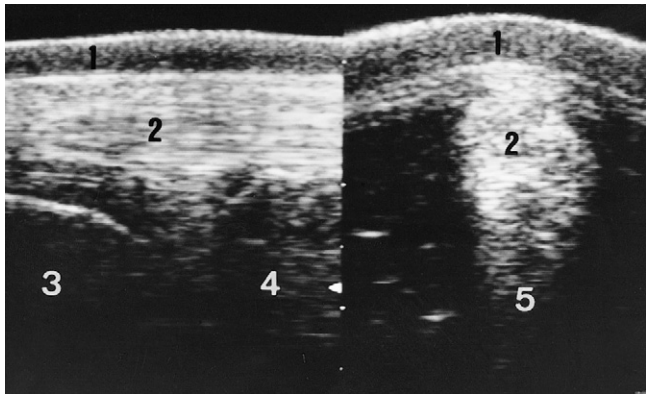

Fig. 54-10 Median (*left*) and transverse (*right*) ultrasound scans of the normal supraspinous ligament in the lumbar area. *1*, Skin; *2*, supraspinous ligament; *3*, second lumbar vertebra; *4*, third lumbar vertebra; *5*, interspinous ligament.

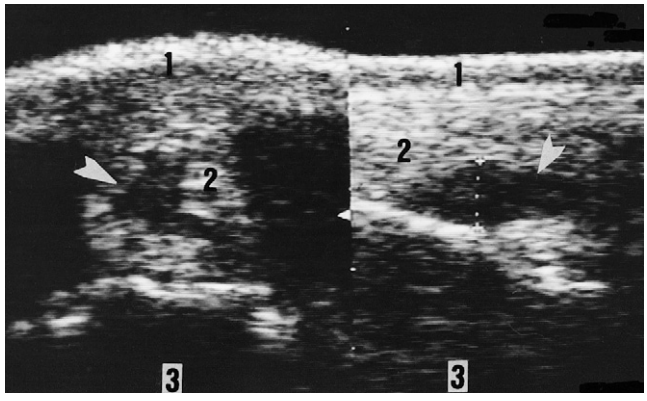

Fig. 54-11 Transverse (*left*) and median (*right*) ultrasound scans indicate supraspinous desmopathy. The ligament is thickened and presents a central hypoechoic zone (*arrowheads*). *1*, Skin; *2*, supraspinous ligament; *3*, seventeenth thoracic spinous process.

with or without acoustic shadows, may be seen in the supraspinous ligament. They reflect chronic or old desmopathy. Insertion desmopathy (enthesopathy) of the supraspinous ligament can be identified by irregularity of the surface of the spinous process, with a thicker appearance. Alteration of echogenicity and fiber orientation occurs in the supraspinous ligament.

With low-exposure radiographs, the soft tissue thickening and some focal radiopacities may be seen in long-standing injuries. Avulsion fractures or bone remodeling and sclerosis of the dorsal surface of the spinous processes may also be noted.[15]

Nuclear scintigraphic examination reveals increased radiopharmaceutical uptake in the summit of one or more spinous processes in association with insertional lesions of the supraspinous ligament.

Articular Processes: Synovial Intervertebral Articulations

Normal References

The articular processes synovial intervertebral articulation complex is located dorsal to the vertebral canal and is composed of the caudal articular process of one vertebra, the joint space, and the cranial articular process of the following vertebra (Figs. 54-12 to 54-14).[10]

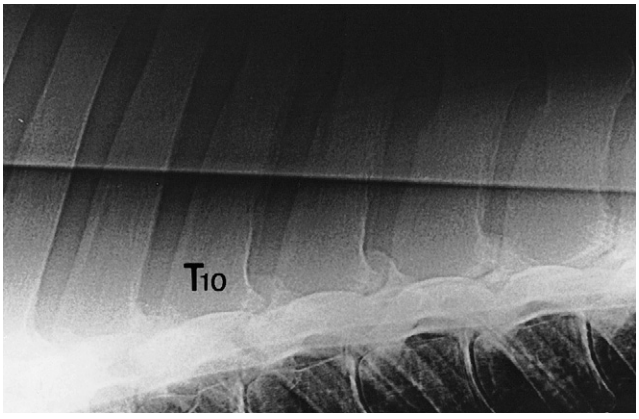

Fig. 54-12 Normal radiographic appearance of the synovial intervertebral articulations in the mid-thoracic area. Cranial is to the left. T_{10}, Tenth thoracic verterbra.

On lateral radiographic views, in the middle of the film, the left and right synovial intervertebral articulations are superimposed. On the extremities of the film the images of the left and right synovial intervertebral articulations are progressively dissociated because of the divergent x-ray beam. In some horses the ribs are extremely convex dorsally and are superimposed over the thoracic and the first lumbar synovial intervertebral articulations, prohibiting assessment. The radiolucent cartilaginous joint space is thin and more clearly defined in the thoracic areas, where the articular facets are flat (Fig. 54-12), than in the lumbar area because of the condylar shape. Between T12 and T16 the joint space is a wide V shape, with a cranial oblique branch and a shorter vertical caudal branch (Fig. 54-13). At the thoracolumbar junction and in the lumbar region the joint space is less well defined. Usually, the joint space is linear and makes a 40° angle with the horizontal (Fig. 54-14). The caudal articular process is dorsal to the corresponding intervertebral foramen and is triangular with a caudal apex in the lumbar region. The thickness of the dense subchondral bone of the cranial articular process increases caudally. The cranial articular process is extended dorsocranially by a mamillary process, which is larger in the thoracic area than in the lumbar area.

On transverse ultrasonographic images obtained using 2.5- to 5-MHz probes, the synovial intervertebral articulations can be imaged (Fig. 54-15). On each side the joint space separating the cranial (lateral) and caudal (medial) articular process can be identified.[12] This joint space is limited dorsally by a thin articular capsule. Comparison of the left and right synovial intervertebral articulations of the same intervertebral joint is helpful to assess size and shape.

Abnormal Findings

Eight types of abnormal findings associated with osteoarthritis have been identified radiographically in the synovial intervertebral articulations of the equine thoracolumbar spine[10] (Table 54-3). These findings were mainly present at the thoracolumbar junction and in the lumbar area. Types 2, 4, and 6 (Figs. 54-16 to 54-19) were mainly found between T16 and L3. Types 5 and 7 have mainly been found in the lumbar area. Abnormalities have been found in mature riding horses and immature racehorses.

Dorsal peri-articular proliferation (types 4 and 6) can be imaged with ultrasonography, and with this procedure determining if the proliferation is symmetrical or, if not, which side is the most affected is possible (Fig. 54-20).

Nuclear scintigraphy can be helpful in identifying evidence of abnormal bone modeling in the region of synovial intervertebral articulations, especially in horses where radiographic appraisal is limited by the ribs. In our experience, synovial

Table • **54-3**

Types of Radiographic Lesions of the Thoracolumbar Synovial Intervertebral Articulations

TYPES	GENERAL CRITERIA	RADIOGRAPHIC SIGNS
1	Asymmetry	No clear joint space; double joint space
2	Modification of opacity of the articular process	Sclerosis of the subchondral bone Increased opacity of the synovial intervertebral articulations
3		Radiolucent areas in the subchondral bone Increased opacity of the articular process
4	Peri-articular proliferation	Dorsal peri-articular proliferation Increased size of the synovial intervertebral articulations Often associated with alteration in opacity of subchondral bone
5		Ventral peri-articular proliferation
6	Ankylosis	Dorsal bridge between two adjacent vertebrae
7		Osteolysis of the synovial intervertebral articulations No joint space
8	Fracture	Radiolucent line on the caudal (or cranial) articular process

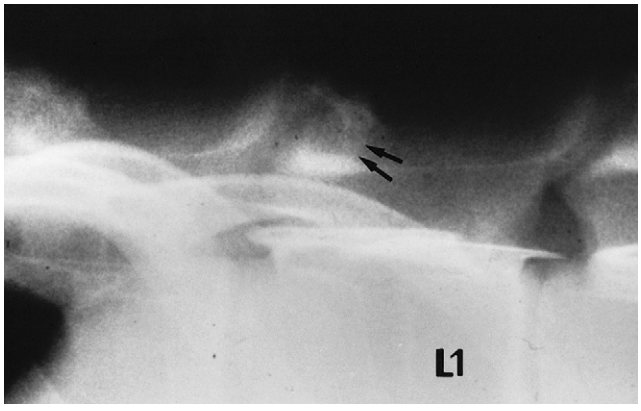

Fig. 54-16 Lateral radiographic view of the thoracolumbar junction. Cranial is to the left. There are type 2 lesions *(arrows)* of the synovial intervertebral articulations between the eighteenth thoracic and second lumbar vertebrae in this 5-year-old French trotter male. Compare with the opacity of the cranial articular processes in Fig. 54-14.

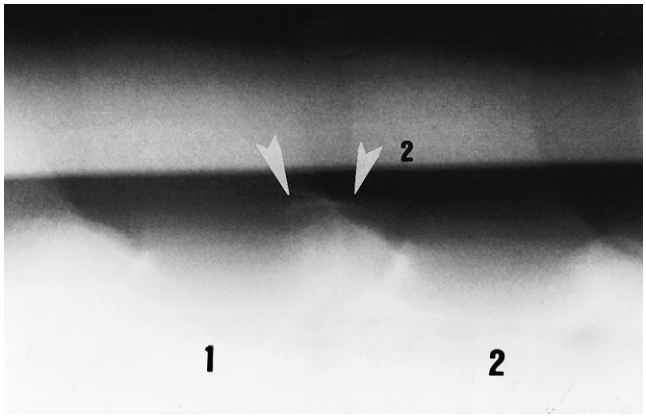

Fig. 54-17 Lateral radiographic view of the cranial lumbar vertebrae. Cranial is to the left. There is a mild (grade 1) type 4 lesion of the synovial intervertebral articulation complex between the first (*1*) and second (*2*) lumbar vertebrae in this 8-year-old mare.

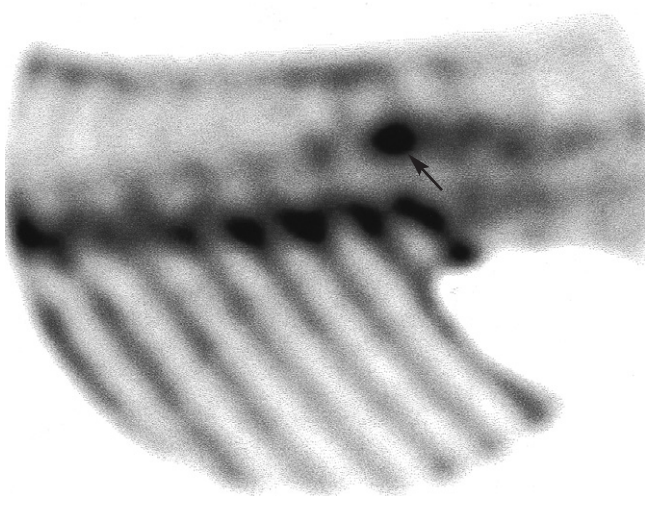

Fig. 54-22 Lateral scintigraphic image of the thoracolumbar region of 2-year-old Thoroughbred filly with back pain and loss of performance. A focal region of increased radiopharmaceutical uptake is visible at the thoracolumbar junction *(arrow)*, compatible with a laminar stress fracture.

intervertebral articulation lesions are much more consistently associated with back pain than are kissing spines.

Vertebral Bodies and Disks

Lesions of the vertebral bodies are less commonly found in horses[14] and cannot be imaged by ultrasonography in the thoracolumbar area (except caudal to L4 with a transrectal approach). These lesions include the following[10]:

1. Ventral, ventrolateral, or lateral bony proliferation (often called vertebral spondylosis). These lesions are mainly found in the mid-thoracic area (Fig. 54-21), but they can be seen in the lumbar area.
2. Vertebral body deformation (trapezoid shape) of the caudal thoracic vertebrae
3. Deformation of the adjacent vertebral head and fossa (disk enthesopathy) found in the caudal thoracic area
4. Ski jump deformation (dorsal bony extension of the vertebral fossa) found in the caudal thoracic area

These lesions have been found in horses with a history or clinical manifestations of back pain—acute, intermittent, and chronic—and are considered to be of likely clinical significance. However, spondylosis also is an incidental finding in low-level performance horses with no history or clinical manifestations of back pain. Nuclear scintigraphy may help to elucidate the significance of these findings in horses with back pain.

Fracture and subluxation of a lumbar vertebra normally results in neurological abnormalities, but occasionally horses have acute severe back pain, with rapid atrophy of the epaxial musculature, but no evidence of ataxia.

Vertebral laminar stress fractures have been identified using nuclear scintigraphy in young TB flat race horses with loss of performance and clinical evidence of back pain (Fig. 54-22). They have been seen most commonly at the thoracolumbar junction and in the lumbar vertebrae. In a post-mortem sample of TB race horses, 18 (50%) of specimens had evidence of vertebral stress factures.[16]

PROGNOSIS

The prognosis for horses with any back lesion depends on a number of factors, including the individual pain tolerance of the horse, the skill of the rider and trainer, the discipline in which the horse is involved, and the type, number, and severity of lesions. Vertebral lesions are tolerated better by flat race horses than by Three Day Event horses, show jumpers, and dressage horses. Racing trotters tolerate vertebral lesions poorly. The prognosis for each lesion is not influenced by the level of work but more by the rider's or trainer's ability to exploit the horse despite its problems. A horse with an acute isolated supraspinous ligament injury has a good long-term prognosis, whereas horses with restricted mobility of the back caused by extensive kissing spines or type 6 or 7 synovial intervertebral articulation lesions have a poor prognosis. Horses with grades 3 and 4 dorsal kissing spines have a guarded prognosis, as do those with ventral kissing spine lesions. The prognosis for horses with synovial intervertebral articulation lesions depends on severity and the number of joints affected. Patient tolerance of ventral thoracic spondylosis seems to vary more, but generally the larger the number of vertebrae affected, the poorer the prognosis.

SPECIFIC MANAGEMENT

The general aims of management of back problems are to remove pain and to make the horse as comfortable as possible, as soon as possible, to allow it to be exercised to avoid further muscle loss and to promote muscle function and strength. Medical treatment aims to remove pain and muscle spasm.

Systemic Treatment

Treatment of back pain with non-steroidal anti-inflammatory drugs (NSAIDs) is usually disappointing. Many horses are brought in for in-depth investigation of the cause of back pain because of lack of response to treatment with phenylbutazone or other NSAIDs. Treatment of muscle spasm with myorelaxants is indicated and sometimes useful; for example, thiocolchicoside (2 to 4 mg/100 kg twice weekly for 4 weeks) and methocarbamol (10 mg/kg IV). Repeated treatments may be necessary.

Local Injections

Local perispinal or interspinal injections of corticosteroids, sometimes in association with myorelaxants or Sarapin, are used to treat horses with kissing spines: flumethasone (0.5 to 1 mg per injection site with a maximum total dose of 4 mg); dexamethasone (isonicotinate, 1.5 to 2.5 mg per injection site, with a maximum total dose of 10 mg); methylprednisolone acetate (40 to 60 mg per injection site, with a maximum total dose of 200 mg).

Osteoarthritis of the synovial intervertebral articulations is treated by deep paramedian injections of corticosteroids (see the previous discussion) into the multifidus muscle on each side at the level of the lesion, 2 cm apart from the median plane, using 9- to 11-cm needles. These local injections are best performed using ultrasonographic guidance (Fig. 54-23). Injections are made into the multifidus muscles that provide proprioceptive information on intervertebral movements. We therefore suggest that the use of Sarapin is contraindicated in this situation. Local infiltrations can be performed alone or with mesotherapy.

Mesotherapy

Mesotherapy is a technique that has been used for more than 30 years in France and consists of intradermal injections with short and thin needles (5 mm long) in the dermatomes corresponding to the site(s) of the lesion(s).

The principle is based on the theory of the gait control of pain, which takes place in the dorsal horn of the spinal cord. According to this theory, which is currently controversial, types I and II nerve fibers coming from the skin have collateral fibers that can inhibit the conduction of information in the spinothalamic fasciculus, transmitting painful information from deep structures of the same spinal segment to the thalamus and cerebrum.

After aseptic preparation of the skin, mesotherapeutic injections are usually made using a local anesthetic solution (lidocaine, 140 mg), a short-acting corticosteroid (dexamethasone, 15 mg), and a myorelaxant (thiocolchicoside, 20 mg). Injection with only saline solution may also have beneficial effects. Because most horses are sensitive to the procedure, the patient is placed in stocks, and the use of a twitch and sedation is recommended. A multi-injector (Coveto, Montaigu, France) is used. These intradermal injections are performed at the level of the lesion and caudal to it, taking into account the caudal orientation of the segmental nerves. For example, if one is treating kissing spines between T10 and T15, the treated region extends from T10 to L1. If the lesions involve the synovial intervertebral articulation between T17 and L2, the treated area should extend between T17 and the lumbosacral junction. If lesions are at the lumbosacral junction, the treated area should extend caudally to the croup. Two to three rows of injections are made on each side of the median plane.

After local injections or mesotherapy, the horse is restricted to light work on the lunge, without a surcingle, for 3 days. Normal training is progressively resumed over 5 days. A substantial improvement is anticipated within 7 to 14 days. If improvement is limited, mesotherapy should be repeated 2 to 3 weeks after the first treatment. The expected duration of action varies between 3 and more than 12 months. In horses with chronic pain, ideally a maximum of two local infiltrations should be performed each year with, or alternately with, mesotherapy.

Acupuncture

Acupuncture can be useful for treating chronic pain in some horses (see Chapter 93).

TRAINING MANAGEMENT

With the medical treatment to reduce pain, modification of the training program is an essential part of the management of back problems.[17] The aims of the exercise management are to avoid further muscle atrophy and to develop the back proprioceptive control and intervertebral stability. Rest is contraindicated, except in untreatable horses that are not improved by any kind of treatment and management. The general recommendations include the following:

- Check the saddle fitting.
- In young horses, recognize that training must be progressive.
- Use a progressive warm-up program, first on the lunge without a saddle, then on the lunge with a saddle, then with the rider at walk, and so on.
- After the warm-up period at the walk, in sport horses, first work at the canter rather than at the trot. During cantering the vertebral column undergoes only one slow and active flexion/extension cycle per stride, whereas the vertebral column undergoes two passive flexion/extension movements per stride at the trot.
- Identify and then remove every exercise that induces discomfort. For example, do no short turns to the right for 2 weeks, then re-assess if the horse is more comfortable turning to the right.

Some physical exercises, such as lowering of the neck (flexion of the cervicothoracic junction), may have a therapeutic value because they induce an associated thoracic flexion, which provides more support to the weight of the rider. A separation of the spinous processes reduces the contact between them.[18,19] An elongation of the strong epaxial muscles reduces muscle contraction.[17]

ALTERNATIVE MEDICINES

Much interest exists in using alternative therapeutic techniques to manage back pain in horses. Once a clear diagnosis is established, alternative techniques, if appropriately applied and objectively assessed for each pathological entity, may be useful in managing back problems (see Chapters 94 through 99).

SURGERY

Surgical treatment of kissing spines by resection of the summit of one or more spinous processes has been successful in some horses that had not responded to conservative management. Case selection is important and should be restricted to horses with lesions only involving the dorsal aspect of the spinous processes. A post-operative convalescent period of 6 months is generally required. Twenty-seven of 50 Warmblood horses (54%) used for dressage or show jumping returned to full athletic function at the previous level of performance.[20] One hundred fifty of 209 horses (72%) used for various disciplines returned to full work after removal of the summits of 1 to 6 dorsal spinous processes, although the level of work was not specified.[21] There was no significant difference between the number of spines removed and the outcome.

CHAPTER • 55

The Cervical Spine and Soft Tissues of the Neck

Sue J. Dyson

This chapter discusses disorders of the neck that may give rise to lameness or poor performance or result in an abnormal neck shape, abnormal neck posture at rest or while moving, or neck stiffness. Transient neurological conditions, or those caused by trauma resulting in other injuries, or gait abnormalities that may be confused with lameness are considered, but those associated with compression of the cervical spinal cord are discussed in Chapter 62.

ANATOMY

The neck comprises seven cervical vertebrae, which articulate both by intercentral articulations and synovial articulations, which have large joint capsules to accommodate the degree of movement between adjacent vertebrae. Interposed between the vertebral bodies are intervertebral fibrocartilages to which is attached the dorsal longitudinal ligament, which lies on the floor of the vertebral canal. The ligamentum flava connects the arches of adjacent vertebrae. The atlas (the first cervical vertebra) and the axis (the second cervical vertebra) have a unique shape and specialized joints. The atlanto-occipital joint is a ginglymus joint, which permits flexion and extension and also a small amount of lateral oblique movement. The atlantoaxial joint is a trochoid or pivot joint; the axis and head rotate on the axis. The ligament of the dens is strong and fan-shaped and extends from the dorsal surface of the odontoid peg (dens) to the ventral arch of the axis. The ligamentum nuchae extends from the occiput to the withers and comprises funicular and lamellar parts. The lamellar part separates the two lateral muscle groups. The atlantal bursa is interposed between the funicular part of the ligamentum nuchae and the dorsal arch of the atlas; a second bursa may exist between the ligament and the spine of the axis. The muscles of the neck can be divided into lateral and ventral groups. The neck has eight cervical nerves, the first of which emerges through the intervertebral foramen of the atlas, the second through that of the axis, and the eighth between the seventh cervical vertebra and the first thoracic vertebra. The sixth to eighth cervical nerves contribute to the brachial plexus.

REASONS FOR CLINICAL PRESENTATION

A horse may be presented for evaluation of the neck for a variety of reasons. The horse may have a history of a fall on the neck while jumping, having reared up and fallen over backward, or having collided with another horse or solid object, thus sustaining neck trauma. The horse may have neck pain from having pulled backward while being tied up. The horse may have no history of trauma but have abnormal neck posture, swelling, a stiff neck, neck pain, or difficulties in lowering and raising the head. The horse may have a performance-related problem such as unwillingness to work on the bit, an unsteady head carriage, or abnormal head posture. A neck lesion should also be considered in a horse with forelimb lameness, when pain cannot be localized to the limb. Subtle hindlimb gait abnormalities, such as a tendency to stumble, may be caused by a neurological deficit without overt ataxia, reflecting a compressive lesion of the cervical spinal cord.

CLINICAL EXAMINATION

It is important to recognize that head and neck carriage depends in part on conformation: the way in which the neck comes out of the shoulder and the shape of the neck. The shape of the neck is also influenced by the way in which the horse works. If a horse carries the head and neck high, with the head somewhat extended, the ventral strap muscles tend to be abnormally well developed, resulting in a ewe-neck conformation. Many horses naturally bend more easily to the right than to the left or vice versa, and the muscles on the side of the neck, especially dorsocranially, are developed asymmetrically. Such asymmetry is particularly obvious if the neck is viewed from above by the rider. If a horse is excessively thin, then the cervical vertebrae become prominent and the caudodorsal neck region becomes dorsally concave, whereas in a fit, well-muscled horse that works regularly on the bit, this region is dorsally convex. Most stallions and many native pony breeds have a prominent dorsal convexity to the neck region, resulting in a cresty appearance. A horse that is excessively fat tends to lay down plaques of fat throughout the body, including the neck region and this can be misinterpreted as abnormal neck swelling.

If a horse is particularly thick through the jaw, that is, has a large mandible, it is physically difficult to work on the bit (i.e., flexing at the poll so that the front of the head is in approximately the vertical position). Although neck pain can cause a reluctance to work on the bit, more common causes include rider-associated or training problems, mouth pain, forelimb or hindlimb lameness, or back pain. Some horses strongly resist the rider's aids to work on the bit, despite the absence of pain. The use of artificial aids such as draw or running reins, which give the rider a mechanical advantage, may help to break a vicious cycle and encourage the horse to become more submissive and compliant. Similarly, work on the lunge line using a chambon (a device that runs from the girth via a headpiece to the bit rings) can encourage the horse to work in a correct outline and develop fitness and strength of the appropriate musculature. Working the horse in trot over appropriately spaced trotting poles can also help to encourage a horse to work in a correct outline, with a round and supple back.

A rider may complain of neck stiffness or difficulties in getting a horse to bend correctly in a circle. Although this may be caused by neck pain, neck stiffness may be a protective mechanism by the horse to avoid pain associated with lameness, especially forelimb lameness. A horse with left forelimb lameness, for example, may be reluctant to bend properly to the left, and when unrestrained by a rider on the lunge, on the left rein may hold the neck and head slightly to the right,

giving the appearance of looking out of the circle. Thus load distribution is altered and lameness minimized. Such lameness actually may not be evident during riding, although this may be the only circumstance under which the rider recognizes the problem. The lameness may be more obvious on the lunge or even in hand in straight lines. When a horse has an abnormal neck and/or head posture, a comprehensive clinical evaluation of the entire horse should be performed. Neck pain or abnormal posture may reflect a primary lesion elsewhere (e.g., central or peripheral vestibular disease, fracture of the spinous processes of the cranial thoracic vertebrae, a mediastinal or thoracic abscess, or a systemic disease such as tetanus).

Detailed examination of the neck should include assessment of the neck conformation, shape and posture at rest, and the position of the head relative to the neck and trunk. The veterinarian should note any patchy sweating or change in hair color reflecting intermittent sweating that may suggest local nerve damage. Look carefully at the musculature to identify any localized atrophy. Palpate the right and left sides of the neck to assess symmetry and the presence of abnormal swellings or depressions and to identify any neck muscle pain, tension, or fasciculation. Deep palpation should be performed on the left and right sides of the neck to identify pain.

A series of nine equidistant acupoints (acupuncture points) exist along an arc on the crest of the neck.[1] The most cranial is in the depression just cranial to the wing of the atlas and just caudal to the ear. The most caudal point is a few centimeters dorsocranial to the dorsocranial aspect of the scapula. Six intervertebral acupoints also exist between the vertebrae. An abnormal response to firm palpation of these points may reflect neck pain.

Neck flexibility should be assessed from side to side and up and down. This can be done by manually manipulating the neck, but many normal horses resist this. Holding a bowl of food by the horse's shoulder to assess lateral flexibility is helpful. The clinician should try to differentiate between the horse properly flexing the neck or twisting the head on the neck. Compare flexibility to the left and to the right. To assess extension of the neck, the veterinarian should evaluate the ease with which the horse can stretch to eat from above head height. Observing the horse grazing is helpful to assess ventral mobility of the neck. Especially with lesions in the caudal neck region a horse may have to straddle the forelimbs excessively to lower the head to the ground to graze (Fig. 55-1, *A*).

Assessing skin sensation and local reflexes, such as the cervicofacial and the thoracolaryngeal reflexes, and comparing carefully the right and left sides may be useful. The consistency and patency of the jugular veins should be evaluated.

The horse should be observed moving in hand and on the lunge, and if necessary should be ridden, to assess neck posture and the presence of neurological gait abnormalities, restriction in forelimb gait or lameness. The clinician should note how any gait abnormality is influenced by the positions of the head and neck. Forelimb lameness occasionally is associated with a primary cervical lesion, usually, but not invariably, together with other clinical signs referable to the neck.[2]

IMAGING CONSIDERATIONS

Radiography

Comprehensive radiographic examination of the neck requires at least five exposures, assuming that large cassettes are used, including the poll, cranial, mid- and caudal neck regions, and the base of the neck to evaluate the first thoracic vertebra.[3] Lateral views are obtained easily in the standing position, but ventrodorsal views are best obtained with the horse in dorsal recumbency under general anesthesia, except in small ponies

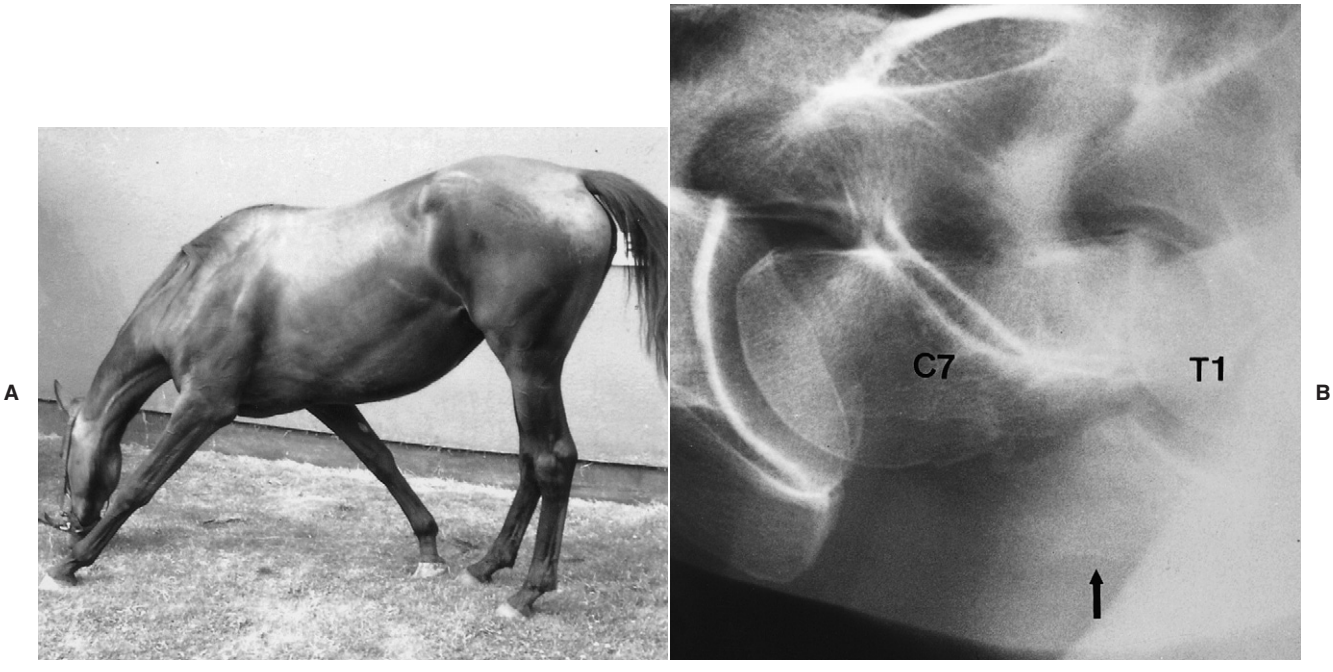

Fig. 55-1 **A,** A 3-year-old Thoroughbred filly with severe neck pain and restricted forelimb gait associated with a displaced articular fracture of the ventral processes of the seventh cervical vertebra. The horse must adopt the straddled forelimb stance to lower the head to graze. **B,** Lateral radiographic view of the caudal cervical vertebrae (sixth cervical to first thoracic vertebrae) of the same horse. Cranial is to the left. The ventral processes of the seventh cervical vertebra are displaced *(arrow)*. The intercentral joint space between the seventh cervical *(C7)* and first thoracic *(T1)* vertebrae is narrowed greatly, with abnormal orientation of the vertebral bodies.

and foals. Positioning of the neck is important, because any rotation of the head and neck makes evaluating the synovial articulations in particular difficult. Relatively large exposures are required for the more caudal neck regions, so radiation safety is important, and the cassette should be supported in a holder, not held by hand. A grid is useful, especially in the caudal neck region, to reduce scattered radiation. Obtaining exposures from left to right and right to left may be useful.

A number of variations of the normal radiographic appearance of the cervical vertebrae should not be confused as lesions. A spur on the dorsocaudal aspect of the second cervical vertebra may project into the vertebral canal. The ventral processes of the sixth cervical vertebra and occasionally other vertebrae have small separate centers of ossification. The ventral lamina on the sixth cervical vertebra may be transposed onto the ventral aspect of the seventh cervical vertebra, unilaterally or bilaterally. The seventh cervical vertebra has a small spinous process, which may be superimposed over the synovial articulation between the sixth and seventh cervical vertebrae and should not be confused with peri-articular new bone. In older horses small spondylitic spurs may be seen on the ventral aspect of the vertebral bodies. Modeling of the dorsal synovial articulations between the fifth and sixth and between the sixth and seventh cervical vertebrae is common in middle-aged and older horses[3,4] (Fig. 55-2).

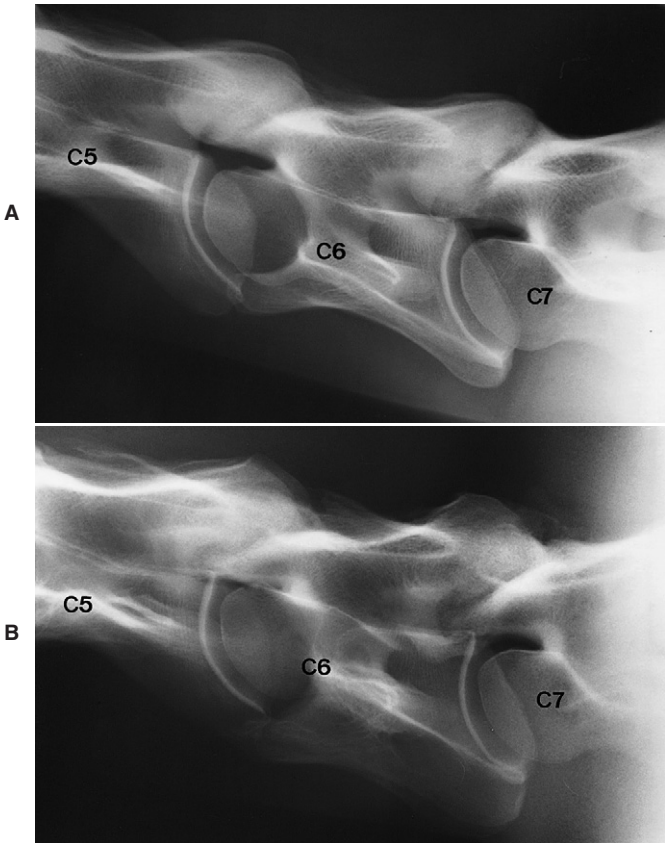

Fig. 55-2 **A,** Lateral radiographic view of the caudal cervical vertebrae of normal 4-year-old Thoroughbred. The synovial articulations between the fifth (C5) and sixth (C6) cervical and sixth and seventh (C7) cervical vertebrae are outlined smoothly. The intervertebral foramina are distinct. Compare with part **B** and Figure 55-8. **B,** Lateral radiographic view of the caudal cervical vertebrae of 9-year-old clinically normal horse. The synovial articulations are enlarged between the fifth (C5) and sixth (C6) cervical vertebrae and particularly between the sixth and seventh (C7) cervical vertebrae.

Major radiographic abnormalities such as fusion of two adjacent vertebrae can be present subclinically, in part because of the great mobility between adjacent vertebrae (Fig. 55-3, *A*). The significance of such lesions may also be determined by the athletic demands placed on the horse.

Nuclear Scintigraphy

Lateral and ventral scintigraphic images of the neck can be obtained. Ideally, images should be obtained from the left and right sides. In normal horses there is usually increased radiopharmaceutical uptake (IRU) in the synovial articulation between the sixth and seventh cervical vertebrae, compared with the more cranial articulations. There is often greater radiopharmaceutical uptake in the odontoid peg (dens) of the axis, compared with the surrounding vertebrae.

Abnormal IRU is not necessarily synonymous with a lesion that is clinically significant; therefore images must be interpreted with care (Fig. 55-3, *B*). The clinician should compare images obtained from the left and right sides carefully, because disparity in radiopharmaceutical uptake may be significant. The veterinarian should evaluate the actual conformation of the synovial articulations, because a change in shape, even

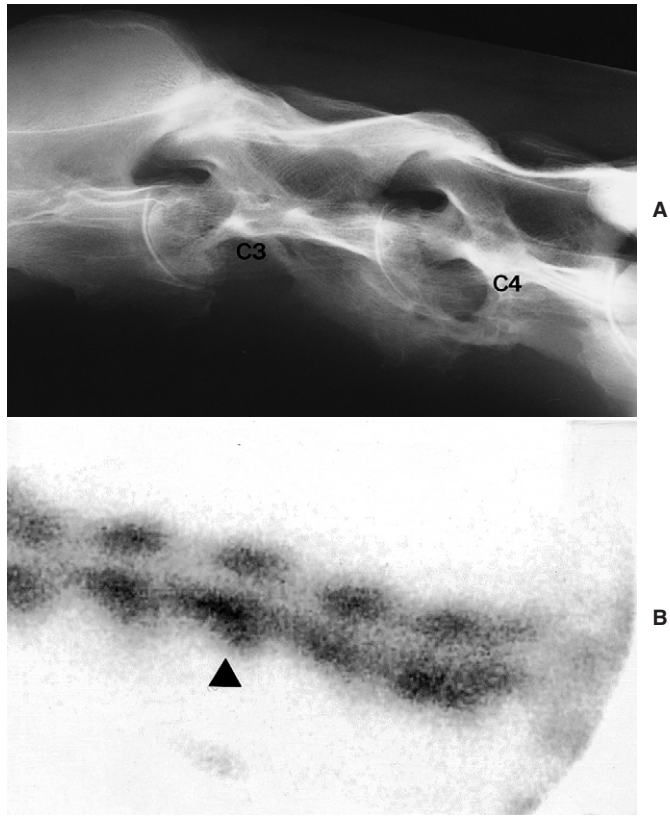

Fig. 55-3 **A,** Lateral radiographic view of a 15-year-old Arabian international-level endurance horse that had been competing successfully with no clinical signs referable to the neck. There is abnormal angulation between the third (C3) and fourth (C4) cervical vertebrae. The vertebral bodies of the third and fourth cervical vertebrae are osteoporotic. Extensive new bone has formed over the ventral aspect of the intercentral articulation between the third and fourth cervical vertebrae, with narrowing of the intercentral joint space and thinning of the caudal end plate of the third cervical vertebra. The ventral profile of the more cranial aspect of the third cervical vertebra is abnormal. **B,** Lateral scintigraphic image of the mid-neck region of the same horse. Note the increased radiopharmaceutical uptake in the vertebral body of the fourth cervical vertebra *(arrow)*.

without IRU may be important. Fractures are not always associated with a significant IRU, and lesions may be missed in the caudal neck region because of the overlying muscle mass and the scapulae.

Ultrasonography

The indications for ultrasonographic examination include evaluating swellings, assessing painful muscles and lesions of the ligamentum nuchae, and documenting jugular vein thrombophlebitis.[5]

Computed Tomography

Computed tomography (CT) has the potential to give three-dimensional information about the cervical vertebrae and with contrast-enhanced studies can give information about spinal cord and nerve compression. However, general anesthesia is required, and it is only practical to image the cranial cervical vertebrae.[6-8]

Thermography

Thermographic examination of the neck is discussed in detail elsewhere (see Chapters 25 and 98). However, I have found thermography of limited usefulness, except for identifying acute superficial muscle injuries.

OTHER DIAGNOSTIC TESTS

In selected horses with neck pain, valuable information may be obtained from hematological and serum biochemical tests. Measuring *Brucella* titers and tuberculosis testing are occasionally useful. Bone biopsy may be valuable for determining the cause of some bony lesions.

CLINICAL CONDITIONS

Occipito-Atlantoaxial Malformation

Occipito-atlantoaxial malformation (OAAM) is a congenital abnormality,[9] and although it can occur in any breed,[10] OAAM appears to be a heritable condition in Arabian horses[11] (see Chapter 124). Clinical signs are usually recognizable within the first few weeks of life and include an abnormal neck shape in the poll region, with prominence on the left or right sides or both, and/or scoliosis (Fig. 55-4, *A*). These signs are best appreciated when viewed from above. Usually no associated soft tissue swelling or pain exists, although an abnormal clicking sound may be audible because of subluxation of the atlantoaxial joint. The horse may have an abnormal limitation of movement in the poll region. The gait should be assessed carefully for neurological abnormalities; however, in many horses no neurological gait deficits are apparent.

Diagnosis is confirmed radiographically using lateral and ventrodorsal views. Bony abnormalities include fusion of the atlas to the occiput, atlantoaxial luxation, and abnormal shapes of the atlas and axis, often asymmetrical (Fig. 55-4, *B*).

No treatment is available for OAAM. Prognosis for athletic function is determined by the degree of neck stiffness. Because of the heritable nature of this condition in Arabian horses, breeding of affected horses, or the sire or the dam, is inadvisable.

Other Congenital Abnormalities

OAAM is the most common congenital abnormality of the cervical vertebrae, but congenital torticollis is seen occasionally, caused by malformation of more caudal cervical vertebrae. Vertebral body fusion usually is seen with a meningomyelocele, resulting in neurological abnormalities, and therefore is not considered further.

Subluxation of the First and Second Cervical Vertebrae

Subluxation of the first and second cervical vertebrae is an unusual condition, probably related to trauma, although the horse may have no recent history of such.[12,13] The condition is associated with damage of the ligament of the dens or the

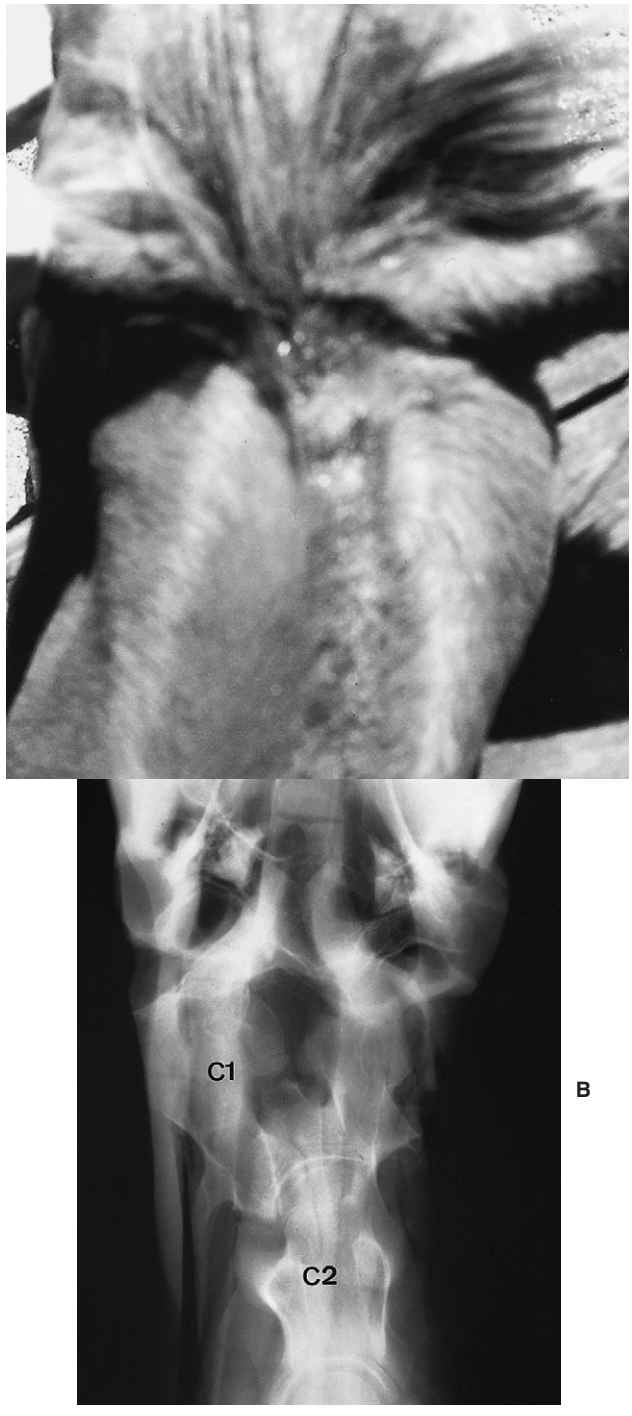

Fig. 55-4 **A,** Dorsal view of the poll region of a 6-month-old Thoroughbred filly with an abnormal asymmetrical shape and scoliosis of the cranial neck region and neck stiffness associated with occipito-atlantoaxial malformation. **B,** Ventrodorsal radiographic view of the same horse. Note the distorted shape of the atlas, its fusion with the occiput, and the abnormal orientation of the intercentral articulation between the first (*C1*) and second (*C2*) cervical vertebrae.

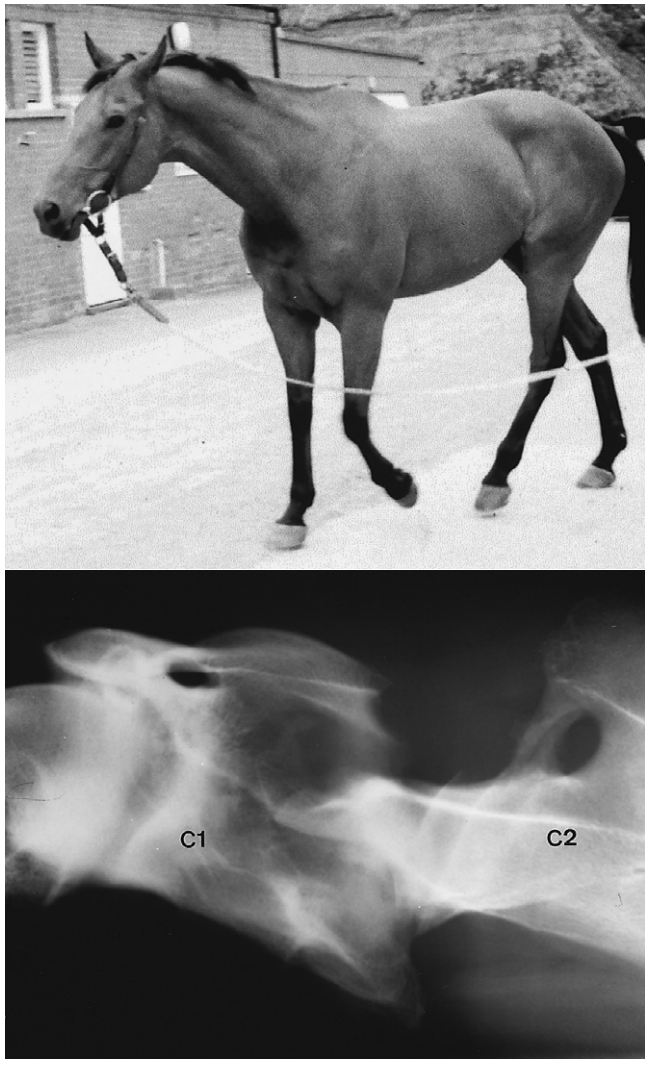

Fig. 55-5 **A,** A 9-year-old advanced event horse that had shown neck stiffness since traveling from America to Great Britain. The head is extended somewhat, and there was significant neck stiffness or guarding. A clicking sound emanated from the cranial neck region. **B,** Lateral radiographic view of the cranial neck region of the same horse. There is an abnormal orientation between the first *(C1)* and second *(C2)* cervical vertebrae. Space between the dorsal aspect of the dens and the ventral aspect of the dorsal lamina of the vertebral arch of the first cervical vertebra is reduced. The dorsal aspect of the dens is irregular because of new bone formation. Post-mortem examination confirmed partial disruption of the ligament of the dens.

ventral longitudinal ligament between the first and second cervical vertebrae or occurs secondary to a fracture of the dens.[14,15] An affected horse usually has a stiff neck and a tendency for the head and neck to be somewhat extended (Fig. 55-5, *A*). Differentiating between neck pain and stiffness may be difficult. An audible clicking noise may emanate from the region, and occasionally abnormal movement between the vertebrae can be appreciated. Because of the relatively wide sagittal diameter of the vertebral canal at this site, generally no associated compression of the cervical spinal cord occurs. Occasionally, neurological abnormalities are seen in horses with a displaced fracture of the dens.

Diagnosis is based on radiographic examination, using lateral views with the neck in natural (neutral) and extended positions. Radiological abnormalities may include abnormal orientation between the first and second cervical vertebrae (Fig. 55-5, *B*). The position of the dens may be abnormal, resulting in narrowing of the space between it and the dorsal lamina of the vertebral arch of the first cervical vertebra. In a study of yearling Thoroughbreds the mean minimum sagittal diameter was 34 mm and the minimum was 26 mm.[16] Narrowing of the distance between the vertebral arch of the first and second cervical vertebrae may occur in the extended versus neutral positions of the neck. The shape of the dens may be altered because of secondary new bone formation; occasionally the dens is fractured. The synovial facet joints between the first and second cervical vertebrae may be altered in shape.

Foals with fractures of the odontoid peg have been successfully treated by surgical stabilization, but limited information exists about long-term prognosis.[14,15,17] Foals with subluxation without neurological abnormalities have a good prognosis for life; prognosis for athletic function is fair, depending on the intended level of competition. No reports of successful management of subluxation in adult horses exist, and the prognosis for return to athletic function with conservative management is poor.

Insertional Desmopathy of the Nuchal Ligament and Injury to Semispinalis

The nuchal ligament is a bilobed structure, fans at its insertion on the occiput, and is surrounded by muscle, the semispinalis to the left and right and rectus capitis ventrally. New bone formation at the insertion on the occiput may be an incidental finding. Examination of 302 Warmbloods from 1 to 22 years of age revealed new bone in 85%. A post-mortem study of Warmbloods revealed a similar high proportion of horses with chondroid metaplasia at the insertion of the ligament and dystrophic mineralization.[18] A smaller radiographic study of Thoroughbreds revealed new bone on the caudal aspect of the occiput in only 5%.[19]

Horses with insertional desmopathy of the nuchal ligament or injury to the tendon of insertion of semispinalis often have a history of trauma to the region (e.g., pulling back when tied up) or an excessive amount of lunging exercise while restricted with side or draw reins.[18,20,21] Horses should be examined while being lunged, with and without side reins, and ridden. Clinical signs include permanent resistance against the reins, with difficulty or unwillingness to lower and flex the head and neck when ridden and poor flexion at the poll. In contrast to horses with back pain, hindlimb impulsion is usually good. The horse may have a tendency to rear or shake its head.

Pain cannot usually be elicited by palpation. Radiographic examination may reveal new bone on the caudal aspect of the occiput that may extend farther ventrally and dorsally than the actual insertion of the ligamentum nuchae (Fig. 55-6). Mineralization sometimes is seen dorsal to the first cervical vertebra as an incidental radiological finding, unassociated with clinical signs. Scintigraphic examination may be negative. Ultrasonographic examination is not easy and interpretation is difficult. Mineralization within the ligament may cause shadowing artifacts. CT offers the most sensitive means of detecting lesions in either the nuchal ligaments of the border of insertion of semispinalis.[21] Diagnosis depends on a positive response to infiltration of local anesthetic solution. Fifteen milliliters of mepivacaine is infiltrated on the left and right sides, and the response is assessed after 15 to 30 minutes.

Treatment comprises repeated infiltration of corticosteroids, Traumil (a homeopathic remedy), and local anesthetic solution and modification of the training program, with no work on the bit for 8 weeks.[21] The horse should be worked principally in straight lines. In the stable the horse should be encouraged to flex gently the poll region from side to side and up and down. The use of acupuncture or magnetic field therapy, laser, ultra-

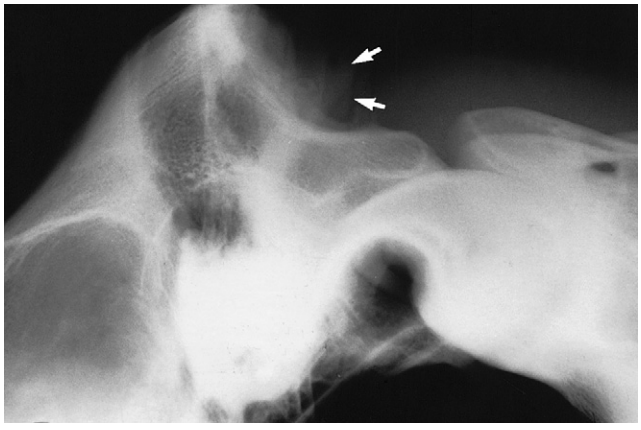

Fig. 55-6 Lateral view of the head of 8-year-old Warmblood show jumper with a history of reluctance to accept and go forward to the bit and stiffness. There is enthesophyte formation on the caudal aspect of the occiput at the insertion of the nuchal ligament (*arrows*). The horse responded well to local infiltration with corticosteroids and local anesthetic solution and modification of the training program.

sound, or shock wave therapy may help some horses. The results vary. Seventy percent of 26 horses return to full work, although not all were completely normal. Surgical treatment by transection of the nuchal ligament and the fascia of semispinalis has resulted in improvement in a small number of horses refractory to conservative management.[21]

Disorders of the Neck Musculature

The significance of localized muscle soreness and or tenseness is poorly understood and documented. I have had experience with a number of horses with subtle performance problems, including slight neck stiffness, reluctance to work properly on the bit and to accept an even contact, and intermittent, slight gait irregularities associated with significant soreness around and in front of the wings of the axis. Clinical improvement has been seen after relief of this pain by rapid and sudden rotation of the head about the axis.[22]

Many horses resent firm palpation of the braciocephalicus muscles at the base of the neck. This may be more obvious in horses with forelimb lameness, especially those with pain in the distal part of the limb. This muscle soreness is generally a secondary rather than a primary cause of lameness. Transient improvement in gait may be seen after local therapy using laser, H-wave, ultrasound, and/or massage.

Local muscle soreness also may be seen with a poorly fitting saddle or girth or with a rider who is unable to ride truly in balance with the horse. The primary problem must be addressed if treatment is to be successful. Some driving horses develop forelimb lameness that is seen only when the horse is pulling and may be associated with pressure from the harness. Adaptation of the harness may relieve the problem.

Some horses seem to need to learn how to use to maximum advantage the neck and forelimb musculature and have a restricted forelimb gait, without appearing overtly lame. The gait is not altered by distal limb nerve blocks. Some improvement may be achieved by daily massage of the muscles at the base of the neck and manual full protraction of the forelimbs. This is combined with exercise to encourage the horse to lengthen the forelimb stride and to round the back. Lunging in a chambon, trotting over appropriately placed trot poles, and repeated lengthening and shortening of the stride all may be beneficial. Trotting down the tramlines in a field of corn or rapeseed can also be of enormous help.

Occasionally as the result of a fall or pulling back when tied, acute severe neck muscle soreness develops. The horse is best treated initially with non-steroidal anti-inflammatory drugs (NSAIDs), rest, and local physiotherapy, followed by progressive remobilization, when the acute muscle soreness has subsided. The prognosis is good.

I have examined several horses that have had episodic transient attacks of profound neck pain and stiffness, holding the neck relatively low. In some horses a severe unilateral forelimb lameness occurs, often resulting in the limb being held in a semi-flexed position at rest. These attacks vary in duration (hours to days), and generally horses have been completely normal between episodes. To date, neither a definitive cause nor an effective treatment has been identified for this syndrome.

Dystrophic mineralization is seen sometimes as an incidental radiological finding in the neck musculature, secondary to previous intra-muscular injections.

Muscle Abscess

Horses sometimes develop localized muscle soreness and swelling at the site of intramuscular injection, especially equine influenza injections, which can result in neck stiffness and a restricted forelimb gait. Signs usually resolve within 24 to 48 hours. Treatment is generally unnecessary, although hot packing and analgesia may be beneficial. More irritant drugs, such as iron injections, may result in the development of a sterile abscess.

The development of a single or multi-loculated abscess cavity filled with malodorous material is usually a sequel to an intra-muscular injection of a variety of drugs administered within the past few weeks. Clinical signs include neck pain and stiffness, localized neck swelling with or without focal patchy sweating, and sometimes pyrexia. Diagnosis is based on the history and clinical signs and can be confirmed by ultrasonography. The abscess cavity is usually filled with anechogenic material, surrounded by a hyperechogenic abscess wall.

Treatment is by surgical drainage, which is easily performed in the standing horse. The abscess cavity should be thoroughly lavaged. Systemic anti-microbial drugs usually are not required, unless clostridial myositis is suspected based on the fulminant nature of the condition (see Chapter 84). The prognosis for most horses with muscle abscesses is good, provided that adequate drainage is established.

Osteoarthritis

Anatomical studies have shown that approximately 50% of normal mature horses have some unilateral or bilateral modeling of the synovial facet joints between the sixth and seventh cervical vertebrae.. The modeling often is accompanied by extension of fibrocartilage across the cranial border of the dorsal arch of the seventh cervical vertebra and irregular enlargement of the articular processes.[4] The spinous process of the seventh cervical vertebra may become flattened or fragmented by contact with the sixth cervical vertebra when the neck is extended. Radiographically these changes result in irregularity of the normally smooth outline of the synovial articulations. Similar modeling changes also occur in the synovial articulation between the sixth and seventh cervical vertebrae.[19] A bony knob may develop on the ventral aspect of one or both cranial articular processes at the articulations between the fifth and sixth cervical vertebrae and between the sixth and seventh cervical vertebrae. When well developed, this knob forms a buttress that impinges onto the body or the arch of the more cranial vertebra and forms a false joint. The buttress partially obliterates the intervertebral foramen, but it is often of no clinical significance.[3,4]

The potential exists for large amounts of new bone associated with osteoarthritis of the cervical synovial articulations

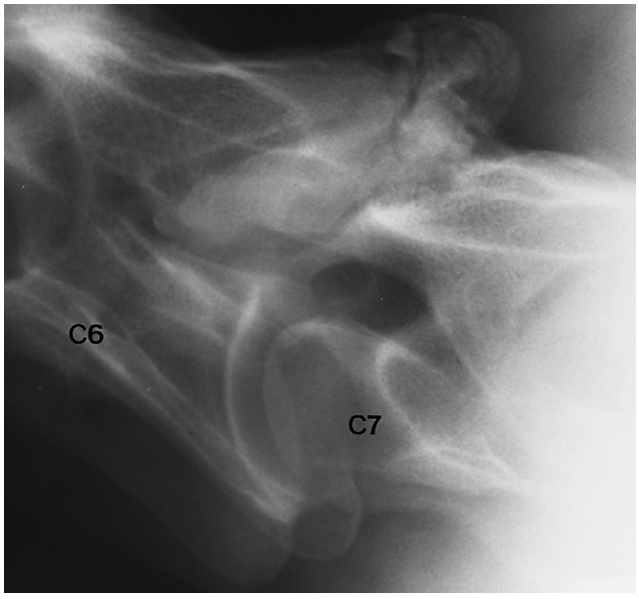

Fig. 55-7 Slightly oblique lateral view of the caudal cervical region of a 7-year-old riding horse with mild right forelimb lameness and an abnormally low head and neck carriage. Lameness was unaltered by comprehensive diagnostic analgesia of the right forelimb. There is extensive modeling of the articular facet joints between the sixth (C6) and seventh (C7) cervical vertebrae, with a large radiopaque mass with heterogeneous opacity extending dorsally. Obtaining a true lateromedial projection was not possible. The obliquity of the radiograph makes it difficult to assess the intervertebral foramen. Post-mortem examination revealed compression of the seventh cervical spinal nerve at the level of the foramen.

to encroach axially into the vertebral canal, resulting in compression of the spinal cord and hindlimb weakness and ataxia, or into the intervertebral foramen, resulting in nerve root compression, with local or referred pain and possibly lameness and patchy sweating. Severe osteoarthritic change may progress to partial or complete fusion and thus neck stiffness. With enlargement of a synovial articulation also generally comes enlargement of the joint capsule, and synovial outpouchings or cysts may develop, which may impinge on the spinal cord.

Radiographic abnormalities associated with osteoarthritis include enlargement of one or more of the articular facets and alteration in joint space width (Fig. 55-7). Widening of the joint space is usually associated with asymmetrical facet enlargement; narrowing is caused by articular cartilage degeneration. Pitted lucent zones may develop in the articular facets, with extension of the dorsal laminae between adjacent vertebrae and partial or complete obliteration of the adjacent intervertebral foramina. Sometimes fractures are seen dorsal to a joint. Abnormalities often develop on the left and right sides but are frequently asymmetrical. With substantial asymmetry of the synovial articulations the affected and immediately more cranial vertebrae may appear rotated on a lateral radiographic view, although the horse had appeared to be standing with its head and neck straight in the sagittal plane. Radiographic examination from left to right and from right to left can help to determine on which side a unilateral lesion is present. A lesion that is close to the cassette is clearer and magnification is less than if the lesion is on the opposite side of the neck.

The clinical significance of osteoarthritis of one or more synovial articulations can be difficult to determine by clinical and radiographic examinations alone, except by exclusion. The greater the degree of abnormality and the larger the number of articulations involved, the more likely the condition is clinically significant. In normal horses finding osteoarthritic change cranial to the articulation between the fifth and sixth cervical vertebrae is rare. Unilateral forelimb lameness has been seen with lesions between the fourth cervical and first thoracic vertebrae.[2] Nuclear scintigraphic examination may give further information in horses with neck stiffness or forelimb lameness apparently not referable to the limb itself.

Seven of eight horses with forelimb lameness associated with radiographic abnormalities of the cervical vertebrae also had subtle to obvious signs of neck pain.[2] Patterns of muscle atrophy in the neck and shoulder regions varied. The character of lameness varied. Radiographic abnormalities included significant modeling of the synovial articulations in the caudal neck region in three horses; a fourth had modeling and a fracture involving the synovial articulation between the fourth and fifth cervical vertebrae. One horse had abnormalities of the intercentral articulation between the seventh cervical and first thoracic vertebrae and a discrete mineralized fragment dorsal to it. Large lucent zones were identified in a vertebral body (the fourth and sixth cervical vertebrae) in two horses. A fracture of the vertebral body of the seventh cervical vertebra was seen in one horse.

Nerve root impingement in the caudal neck may cause radicular or referred pain and account for forelimb lameness. Neck pain itself can also cause forelimb lameness. Compression of the seventh cervical nerve was confirmed post mortem in a horse with osteoarthritis of the articulations between the sixth and seventh cervical vertebrae and between the seventh cervical and first thoracic vertebrae.[2] Nerve root compression with severe osteoarthritis has also been demonstrated using contrast-enhanced CT.[6]

In horses with neck stiffness or forelimb lameness associated with osteoarthritis of cervical synovial articulations, the response to rest and treatment with NSAIDs has been limited. Local peri-articular or intra-articular infiltration of corticosteroids, performed using ultrasonographic guidance, may bring temporary relief. Epidural injection of corticosteroids performed with the horse under general anesthesia resulted in relief of neck stiffness in a horse with osteoarthritis of the synovial articulation between the fourth and fifth cervical vertebrae and clinical evidence of nerve root compression.[23]

Osteoarthritis, especially in the caudal neck region, may result in associated enlargement of the joint capsule(s) and subsequent pressure on the spinal cord. In horses with mild osteoarthritis obvious ataxia may not be seen, but the history may include the tendency to stumble or to knuckle behind. Such signs often have been attributed to lameness but are invariably unaltered by diagnostic treatment with NSAIDs. Clinical signs may be subtle and intermittent. Such horses usually show abnormal weakness if pulled to one side by traction on the tail while the horse is walking, the sway test. A normal horse easily may be pulled off line once, but then strongly resists. A weak horse can be pulled off line repeatedly. Weakness may also be apparent as the horse decelerates from trot to walk, with exaggerated up and down movement of the hindquarters. This may result in irregular movement of each patella and may be confused with mild intermittent upward fixation or delayed release of the patella (see Chapter 47, page 459, and Chapter 49, page 475). At faster speeds the horse may look completely normal. In a young horse, advanced osteoarthritis of one or more caudal cervical synovial articulations is strong circumstantial evidence of cause and effect (Fig. 55-8). Definitive diagnosis in an older horse is much more difficult, because radiographic evidence of osteoarthritis may be present without associated clinical signs. Myelography may

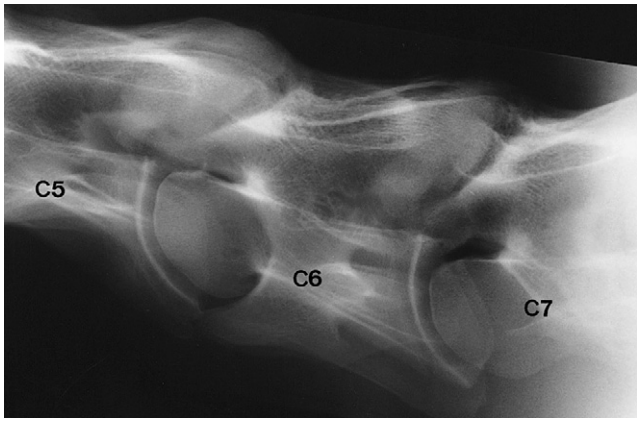

Fig. 55-8 Lateral radiographic view of the caudal cervical vertebrae of 4-year-old dressage horse with mild hindlimb weakness and a tendency to stumble behind, especially in downward transitions from trot to walk. The synovial articulations between the fifth (C5) and sixth (C6) cervical and sixth and seventh (C7) cervical vertebrae are enlarged greatly (compare with Fig. 55-2, *A*). The joint spaces are widened, reflecting asymmetrical modeling of the articular processes. There is a ventral buttress at the articulation of the sixth and seventh cervical vertebrae, with reduction in size of the intervertebral foramen.

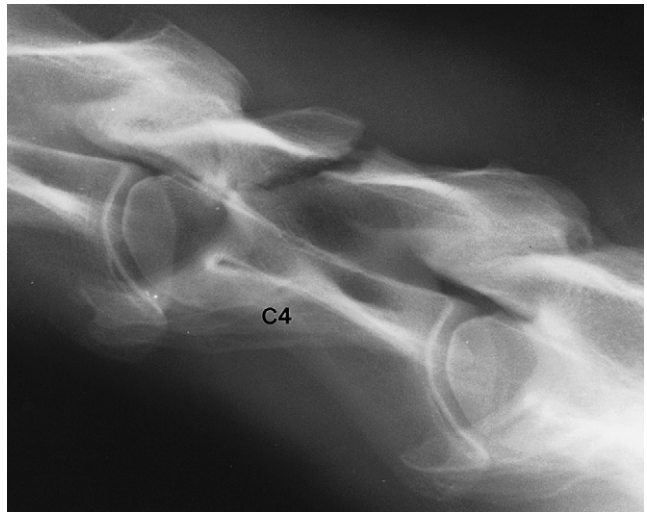

Fig. 55-9 Lateral radiographic view of the third to fifth cervical vertebrae of 9-year-old Dutch Warmblood dressage horse with severe neck pain, stiffness, and incoordination after a fall 12 days previously. The fourth cervical vertebra (C4) has a comminuted, slightly displaced fracture of the dorsal arch. Ataxia resolved within another 14 days, and the horse made a complete functional recovery.

help.[24] The prognosis is poor, and the horse may be potentially unsafe to ride.

Diskospondylitis

A survey of the cervical intervertebral disks of 103 horses from birth to 23 years of age confirmed that they consisted solely of fibrocartilage, with no nucleus pulposus.[25] Significant age-related degenerative changes were identified, but even with severe disintegration of the disks, no referable clinical signs had been apparent.

Diskospondylitis is a rare cause of neck pain, forelimb lameness, or ataxia. Although diskospondylitis is usually an infectious condition in dogs, no proven relationship occurs in the horse, and trauma may be an inciting cause. Lesions in the horse have been identified in the caudal neck region (the articulations between the sixth and seventh cervical vertebrae and the seventh cervical and first thoracic vertebrae) in association with severe neck pain and a bilaterally short, stiff forelimb lameness or episodic, unilateral forelimb lameness. High-quality radiographs of the caudal neck region are required for accurate diagnosis. Scintigraphic examination may help to localize the affected joint(s). The prognosis is guarded, although a broodmare that was presented with profound neck pain and periodic severe left forelimb lameness, associated with roughening of the end plates at the intercentral articulation between the sixth and seventh cervical vertebrae and narrowing of the intercentral space, after a collision with a fence, made a spontaneous recovery.[26]

Fracture

Fractures of the cervical vertebrae usually result from trauma: the horse rearing up and falling over backward or sideways, the horse pulling back when tied up, or falling while jumping, usually at speed. Clinical signs are sudden in onset and include holding the neck in an abnormally low position, stiffness, a focal or more diffuse area of pain, with or without localized or more diffuse soft tissue swelling, and muscle guarding. Audible or palpable crepitus is sometimes detected. The horse may be unable to lower its head to the ground or only able to do so by straddling of the forelimbs (see Fig. 55-1, *A*). Associated hindlimb and forelimb ataxia may be apparent, which can be transient and self-resolving, or persistent. Patchy sweating and localized muscle atrophy may develop. Occasionally an associated unilateral or bilateral forelimb lameness occurs.

Diagnosis is confirmed radiographically (Figs. 55-1, *A*, and 55-9). Most fractures are detectable on lateral views, although ventrodorsal views give additional information about the extent of the fractures, especially those involving the atlas or axis. Care should be taken not to confuse physes and separate centers of ossification with fractures.

The prognosis depends on the site and configuration of the fracture(s), the degree of displacement, and hence the likelihood of permanent compression of the spinal cord, either by a displaced fracture or by subsequent callus formation.

Fractures of the atlas and axis, especially through the physis of the separate center of ossification of the dens, are particularly common in foals. The prognosis for complete recovery is fair with conservative management, provided that no evidence of ataxia exists. Usually no treatment is required other than confinement to a box or small pen.

Fractures of the cervical vertebrae in adults more commonly involve the vertebral body or arch in the mid-neck region (the third to sixth cervical vertebrae) or the synovial articular facets of the more caudal vertebrae (the fifth to seventh cervical vertebrae). Local hemorrhage and edema may result in ataxia, which usually resolves within a few days. Persistence of ataxia warrants a guarded prognosis. Most fractures heal by callus formation, and this may subsequently impinge on the spinal cord, causing later ataxia. A fracture of a vertebral body also may result in damage to the adjacent intervertebral disk and associated ligaments, which subsequently may protrude into the vertebral canal and cause ataxia. Thus in the acute stage giving an accurate prognosis may be difficult. However, many fractures of the vertebral bodies and synovial articulations do heal, and horses may be able to return to athletic function although residual neck stiffness may be present.

In the acute stage the horse should be confined to box rest. Analgesics may be necessary to control severe pain, but they should be used judiciously to avoid encouraging excessive

movement of the neck. The position of the water bucket and manger should be adjusted so that the horse can drink and eat from normal head height. The hay should be fed at a height level with the head, preferably loose, or if in a hay net, a net with large holes, with the hay well shaken first. The horse should not be tied up during the convalescent period in case it pulls back. Re-appraising the horse clinically and radiographically every 6 to 8 weeks is helpful. Maximum clinical improvement may not be seen until 6 to 9 months after injury. Selected fractures may require surgical stabilization.[7]

Myeloma

Myeloma is a myeloproliferative disorder that can cause radiolucent lesions in any bone, including the cervical vertebrae, with associated bone pain.[19,27] Cervical vertebral myeloma was diagnosed in several horses of a wide range of breeds and ages.[19] Clinical signs included intermittent pyrexia, severe neck pain and stiffness, episodic forelimb lameness, weight loss, and a variety of other abnormalities. Diagnosis is based on hematological, radiographic, and bone biopsy examinations. Hematological abnormalities include anemia, leukocytosis, neutrophilia, and lymphocytosis. Total protein concentration is elevated greatly. Protein electrophoresis shows a significant monoclonal peak in the gamma region. Radiographic examination of affected bones reveals clearly demarcated lucent zones, usually without a sclerotic rim. Bone biopsy is useful to confirm the diagnosis, but currently no treatment is available and the prognosis is hopeless.

Other Cyst-like Lesions in Cervical Vertebrae

Occasionally, single or several well-demarcated radiolucent zones have been identified in one or more adjacent vertebrae, associated with profound neck pain, with or without forelimb lameness.[28] These lesions have not been proved to be caused by osteomyelitis or myeloma, although a definitive diagnosis has not always been possible by bone biopsy or post-mortem examination. One horse with extremely severe neck pain and forelimb lameness had radiolucent zones in the fifth and sixth cervical vertebrae, and bone biopsy revealed accumulation of abnormal plasma cells, but the horse made a most spectacular and complete recovery after exploratory surgery and returned to international show jumping. A show pony had a large cyst-like lesion in the fourth cervical vertebrae with profound neck pain and left forelimb lameness (Fig. 55-10). Post-mortem examination revealed a cavity filled with granulation tissue, surrounded by a large area of bone necrosis, but no suggestion of the underlying cause.

Vertebral Osteomyelitis

Cervical vertebral osteomyelitis usually occurs secondary to a systemic disease such as *Rhodococcus equi* infection in foals, *Streptococcus equi* infection (strangles), tuberculosis, or brucellosis; or as an extension of soft tissue infection[4]; or through hematogenous spread. Clinical signs may include pyrexia, neck stiffness or pain, and an abnormal neck posture, poor appetite, and weight loss. Usually leukocytosis, neutrophilia, and hyperfibrinogenemia are also present. Radiographic examination of the cervical vertebrae may reveal focal radiolucent zones, with or without surrounding sclerosis, in one or more vertebrae.[4] Useful diagnostic tests include bone biopsy, tuberculosis skin testing, and measurement of *Brucella* titers. Aggressive anti-microbial treatment may result in amelioration of clinical signs, but the prognosis is guarded.

Jugular Vein Thrombophlebitis

Thrombophlebitis of the jugular vein is a common condition associated with intravenous injection and chemical irritation, mechanical trauma to the vessel wall through catheterization, or a coagulation disorder. The vein feels abnormally hard, but unless the left and right sides are affected, the thrombus is infected, or thromboemboli settle elsewhere, usually no other clinical signs are apparent.

Occasionally a long length of the jugular vein is occluded by a thrombus in which bacteria are seeded, resulting in infectious thrombophlebitis. Clinical signs include neck stiffness and pain, localized heat and swelling, and pyrexia. If a long length of the vessel is involved, ipsilateral swelling of the head may occur. Diagnosis is based on clinical signs and ultrasonography.[5] A heterogeneous, cavitating echogenic thrombus can be seen in the jugular vein. Usually leucocytosis, neutrophilia, and hyperfibrinogenemia are present. A horse with a localized, small infected thrombus usually responds well to systemic anti-microbial therapy, but with more extensive lesions or associated toxemia or bacteremia, surgical ligation and removal of the vein may be required, combined with systemic anti-microbial treatment.

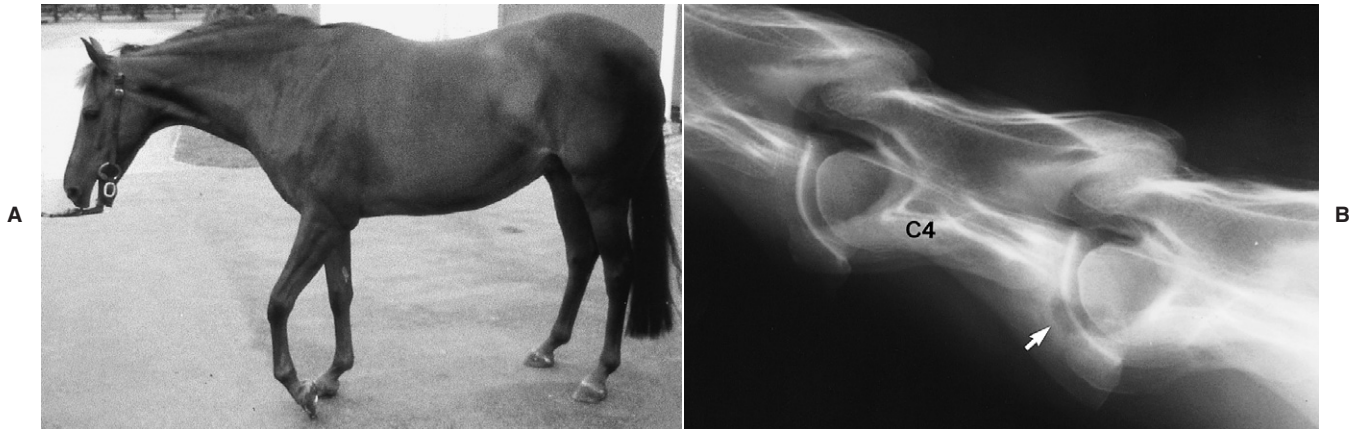

Fig. 55-10 **A,** A 13-year-old show pony with exquisite neck pain, worse on the left side, and episodic severe left forelimb lameness. The pony showed a shortened cranial phase of the stride at the walk, and periodically the pony stopped, holding the limb in a semi-flexed position, and was reluctant to move forward. There was significant hyperesthesia of the caudal half of the left side of the neck. **B,** Lateral radiographic view of the mid-neck region of the same pony. A large radiolucent zone (*arrow*) is visible in the caudal aspect of the vertebral body of the fourth cervical vertebra (*C4*). There is a loss of continuity of the caudal cortex.

Inadvertent perivascular injection of an irritant drug, such as phenylbutazone, may result in the rapid development of localized pain and swelling caused by chemical irritation. This may be followed by an aggressive inflammatory response, leading to sloughing of the skin. If perivascular injection is suspected, then the area should be treated by local infiltration with a balanced electrolyte solution (1 L) to dilute the drug, combined with local anesthetic solution (10 to 20 ml mepivacaine) to reduce pain. Periodic hot packing seems to ameliorate clinical signs. If initially untreated and local tissue necrosis supervenes, a skin slough is almost inevitable, and prophylactic antimicrobial therapy may be indicated.

Neck Stiffness and Cervical Vertebral Mobilization Under General Anesthesia

Assessment of neck flexibility has been described (see page 523). Restricted neck mobility associated with other clinical signs suggestive of neck pain, for example, reluctance to accept the bit, may be an indication for cervical vertebral mobilization under general anesthesia (see Chapter 98). The aim is to assist in restoring normal function to soft tissue components of joints. However, horses with pre-existing osteoarthritic changes are unlikely to respond. Repeated or maintained end-of-range passive joint movements may lower intra-articular pressure, inhibit reflex muscle contraction around a joint, and reduce muscle tension on the periarticular soft tissues and thus relieve pain. The manipulations are performed with the horse in left and right lateral recumbency under general anesthesia. A series of nine manipulations are performed in sequence to include extension of the head and neck, extension with rotation to the left and then to the right, rotation of the head to the left and to the right, flexion of the neck to the left and to the right, and flexion and rotation in each direction. For each maneuver the head and neck are moved to a position at the end of the resistance-free range. Constant pressure then is applied so that movement through the stiff and reduced range can be initiated. The pressure then is maintained until the joints and associated soft tissues move through the range of resistance. When movement ceases, a new end range is established and pressure is released. The maneuver may then be repeated. After treatment, horses are rested for 5 days and then start light work. Clinical improvement usually is appreciated within 2 weeks.[29] Repeated treatment may be necessary in selected horses. Occasionally, clinical signs deteriorate after treatment.

CHAPTER • 56

Pathogenesis of Osteochondrosis

Janet Douglas

Osteochondrosis traditionally has been defined as a failure of endochondral ossification. The disease is caused by a disturbance of the normal differentiation of cells in growing cartilage and results in retention of growth cartilage (Fig. 56-1). This early lesion may be followed by necrosis of affected tissues and development of fissures that extend from the deepest layers of the lesion to the articular surface. Cartilaginous or osteochondral fragments may then detach from the parent bone, forming intra-articular fragments.[1] Once lesions extend to the articular surface, thereby causing inflammation of the joint, the condition may be referred to as *osteochondritis.*[2,3] The term *osteochondritis dissecans* usually is reserved for horses in which a dissecting flap of tissue is present[1] (Fig. 56-2).

Endochondral ossification is the process by which growing cartilage systematically is replaced by bone to form the growing skeleton. This process occurs at three main sites: the physis, the epiphysis, and the cuboidal bones of the carpus and tarsus. Chondrocytes in the physis can be divided into a series of layers or zones (Fig. 56-3). The zone farthest from the metaphysis is known as the resting or reserve zone. Adjacent to this is the proliferative zone, in which chondrocytes divide. These cells progress to the hypertrophic zone, in which they enlarge and form ordered columns. During this stage the chondrocytes become surrounded by an increasing amount of extracellular matrix that gradually becomes mineralized in the zone of provisional calcification. The chondrocyte columns then are invaded by metaphyseal blood vessels and bone forms on the residual columns of calcified cartilage. This mixture of calcified cartilage and immature bone (primary spongiosa) then gradually is remodeled to produce the mature bone of the metaphysis.[4] Early descriptions characterized osteochondrosis by a lack of chondrocyte differentiation that prevented provisional calcification of the matrix and invasion of the cartilage by blood vessels.[1] As a result, endochondral ossification is prevented and cartilage is retained. Endochondral ossification, which continues throughout the period of growth, also occurs in the articular-epiphyseal cartilage complex at the ends of long bones (Fig. 56-4).[5] The chondrocytes of the articular-epiphyseal cartilage complex that are closest to the articular

surface produce articular cartilage. Chondrocytes closer to the epiphysis participate in endochondral ossification in the same manner as occurs in the physis. The growth cartilages of the physis and the articular-epiphyseal cartilage complex are both susceptible to osteochondrosis.[1,6-8]

Because osteochondrosis is primarily a defect of cartilage, the suggestion was made that the condition be referred to as *dyschondroplasia*.[1] Dyschondroplasia may be preferable,[5,9] but the term osteochondrosis remains in widespread use and in this chapter refers to the primary lesion. Dyschondroplasia is used only when referring to work by authors who prefer this term.

A number of inconsistencies have been highlighted between the traditional definition of equine osteochondrosis and findings in horses with the disease.[10] For example, osteochondrosis has been identified in sites where endochondral ossification has ceased,[11] and osteochondral fragments that are thought to result from osteochondritis dissecans do not always show evidence of thickened cartilage.[12] In addition, defective endochondral ossification is not the only cause of cartilage thickening and hypertrophy.[13] As a result of these and other observations, it was suggested that a number of other mechanisms should be considered when an osteochondritic lesion is identified.[10] These include loss of blood supply (e.g., resulting from biomechanically induced shearing of cartilage canals or blunt trauma to cartilage caused by rapid locomotion or incoordination), congenital deformities leading to excessive biomechanical force at one site, and conditions such as copper deficiency that lead to connective tissue fragility.

CHARACTERISTICS OF OSTEOCHONDROSIS LESIONS

The lesions of equine osteochondritis dissecans were described as early as 1947.[6] Since then the gross and histological characteristics of the manifestations of osteochondrosis have been described and defined by numerous authors. The end result is a wide-ranging, heterogenous, and somewhat confusing body of literature, in which osteochondrosis has been ascribed to genetic, dietary, endocrine, biomechanical, traumatic, vascular, and toxic causes.[10,14-19] The confusion

stems from a number of sources. First, defining osteochondrosis on anything other than clinical, gross pathological, and histological criteria is currently not possible. Moreover, histological definitions and descriptions vary and accurate identification of lesions can be difficult.[20] Even chondrocyte clusters (Fig. 56-5), considered by many to be one of the most consistent findings in osteochondrosis lesions,[18,20] are not pathognomonic for the disease.[20] In addition, cartilage and bone have a limited repertoire of responses to injury and abnormalities of development,[10] and many lesions are not identified until they have reached the chronic stage. Differentiation among osteochondral lesions with different pathogeneses can be difficult to impossible.[10,21]

Henson et al.[20] attempted to define osteochondrosis lesions histologically by studying articular-epiphyseal cartilage complex samples from the lateral trochlear ridge of the femur of horses ranging in age from 270 days of gestation to 4 years. Their definition of dyschondroplasia was the presence of cartilage cores (cartilage extending into subchondral bone). Any joint exhibiting secondary pathological changes was excluded. Among the 27 lesions examined, two types were identified. Lesions in group A showed disruption of the normal sequential transition of chondrocytes through the stages of proliferation and maturation. These lesions were characterized by accumulation of large numbers of small, rounded chondrocytes, apparently arrested at the pre-hypertrophic stage. Lesions in group B, not previously described, showed alteration in the staining pattern of mineralized cartilage and adjacent subchondral bone and the complete absence of invading capillaries into newly formed bone.[20,22] The two lesion types were also characterized by differences in the degree of type VI collagen immunoreactivity. Retained blood vessels, chondrocyte clusters, chondronecrosis, and fissure formation were present in both types. The suggestion therefore was made that equine dyschondroplasia may result from more than one causative mechanism, and that lesions resulting from different pathogeneses may be differentiated on the basis of histological and immunological studies.[20]

From a clinical standpoint, equine osteochondrosis characteristically presents as one or two lesions manifesting in known predilection sites. In this so-called typical pattern of the disease, lesions are often bilaterally symmetrical, although only one lesion may cause clinical signs.[10] The femoropatellar (lateral and medial femoral trochlear ridges, lateral facet of patella), tarsocrural (distal intermediate ridge and medial malleolus of tibia, lateral and medial trochlear ridges of talus), scapulohumeral (glenoid fossa and humeral head), and metacarpophalangeal/metatarsophalangeal joints (mid-sagittal ridge and condyles of the third metacarpal or metatarsal bone) are affected most commonly. Osteochondrosis of the elbow, hip, and cervical vertebral joints also has been described,[10,23] but lesions in these sites are less common and etiology is more controversial.[10] This typical pattern of osteochondrosis contrasts with that of the atypical pattern in which animals show multiple articular (and sometimes physeal) lesions.[10,21] Predilection and non-predilection sites may be affected in these horses, and bilaterally symmetrical lesions are absent or infrequent. A third pattern of lesion distribution, the mixed pattern, describes horses in which typical and atypical lesions are present.[21]

RELATIONSHIP BETWEEN PHYSEAL DYSPLASIA (PHYSITIS), SUBCHONDRAL BONE CYSTS, AND OSTEOCHONDROSIS

The relationship between physeal dysplasia (physitis or epiphysitis) and osteochondrosis remains poorly defined. Osteochondrosis lesions of the physis have been described,[3,7] and retained cartilage long has been regarded as a possible cause of physeal dysplasia.[24,25] In foals with experimentally induced osteochondrosis, physes and articular-epiphyseal cartilage complexes may be affected.[18,26] Because both these sites contain growth cartilage, this accords with the definition of osteochondrosis as a generalized disturbance of endochondral ossification. Some have questioned whether articular and physeal lesions have the same cause, however, and proposed that physitis be regarded as a manifestation of developmental orthopedic disease, not osteochondrosis.[10] The relationship between the two conditions remains unclear. Physitis is covered in more detail in Chapter 59 and is not discussed further here.

The relationship between osteochondrosis, subchondral bone cysts, and osseous cyst-like lesions is also controversial. Originally interpreted as a manifestation of retained cartilage of the articular-epiphyseal cartilage complex,[7,27-29] many cysts now are thought to be mechanical in origin.[30-32] Subchondral bone cysts of the medial femoral condyle (a predilection site) can be induced by creating a linear slit in the articular cartilage and then allowing normal weight bearing.[31] Osteochondrosis thus may be only one of several possible causative mechanisms,[10,33,34] and cysts may result from a number of non-specific articular injuries sustained at a load-bearing site.[10]

In the past decade, as knowledge of pathogenesis has grown and more sophisticated techniques have been applied to study osteochondrosis, osteochondral lesions have been classified more carefully. Until the pathogenesis is understood fully and osteochondral lesions can be classified according to cause, some degree of confusion is probably inevitable. The following discussion summarizes major findings relating to the pathogenesis of equine osteochondrosis.

PROPOSED CAUSATIVE FACTORS

Body Size and Growth Rate

Until recently, little objective evidence existed to support the widespread belief that osteochondrosis is more prevalent in large horses and those with a rapid growth rate. This theory gained support based on the results of a survey of 77 Standardbred (STB) foals born and raised over two seasons on one Swedish farm. Skeletal growth and weight gain were measured from the time of birth to 16 months of age, and the hock and fetlock joints were monitored radiographically for osteo-

chondral abnormalities. A positive relationship existed between osteochondrosis of the tarsocrural joint and body weight at birth, body weight during the growth period, average daily weight gain, and skeletal frame size. Seven of the eight foals that developed tarsocrural osteochondrosis were sired by the same stallion (a total of 14 stallions sired the progeny in this study), but the relationship between osteochondrosis, body measurements, and growth rate was still present when affected and unaffected foals by this sire were considered in isolation. No relationship existed between body size or growth rate and osteochondral lesions in the fetlock joint (palmar/plantar osteochondral fragments or ununited palmar/plantar eminences). The conclusion was that tarsocrural and fetlock osteochondral lesions have different pathogeneses.[35] This supports the general consensus that palmar/plantar osteochondral fragments and ununited palmar/plantar eminences are not a manifestation of osteochondrosis.[10,21,36]

A relationship between osteochondrosis, body size, and growth rate has also been documented in Warmbloods. Weight and height from the time of birth to 5 or 11 months of age were measured in 43 Warmblood foals with a presumed genetic predisposition to osteochondrosis of the femoropatellar or tarsocrural joints.[37] The stifle and hock joints of the foals were evaluated radiographically, macroscopically, and histologically. Development of femoropatellar osteochondrosis was associated with a higher overall rate of weight gain and greater final body weight and height. The period during which weight gain of the osteochondrosis-positive foals was significantly higher than that of the osteochondrosis-negative foals coincided with the period during which femoropatellar joint lesions become visible radiographically.[38] In contrast to the previously described findings in STBs,[35] no relationship existed between tarsocrural osteochondrosis and body size or growth rate in this population of Dutch Warmbloods.

Nutrition

The incidence of metabolic bone disease on 19 breeding farms in Ohio and Kentucky was recorded and correlated with the quality of the foals' ration. The authors scored the ration based on their own experience. Epiphysitis, distended joints, lameness, contracted tendons, and spinal ataxia (suspected or radiographically confirmed) were included in the diagnosis of metabolic bone disease. Radiographs did not form a routine part of the examination. This study thus gives no information about nutritional factors associated with osteochondrosis per se, but it does provide information on nutrition and skeletal development. A negative correlation existed between the incidence of metabolic bone disease and the quality of the ration.[39] Diets of farms with low incidence of skeletal problems tended to have higher calcium, phosphorus, and copper contents. Two points should be noted about the relationship between dietary copper content and the incidence of skeletal problems:

1. The correlation was mainly driven by two outliers comprising farms with relatively high dietary copper levels (approximately 30 to 40 ppm) and a low incidence of problems.
2. Three farms with a negligible level of available dietary copper did not have an excessively high incidence of problems.

The relationship between dietary zinc and skeletal problems was described as U-shaped, with an increased incidence of problems at low and high dietary zinc levels. No valid conclusion could be drawn concerning the relationship between dietary energy and the incidence of skeletal problems because energy levels were similar on all farms.

In a follow-up study the nutritional balance was improved on 17 of these farms and the incidence of metabolic bone disease was recorded in the following season.[40] Highly significant improvements in the incidence of orthopedic abnormalities occurred with the improvements in ration. These data suggest that sub-optimal nutrition adversely affects skeletal development but provide no information on the pathogenesis of osteochondrosis.

Digestible Energy and Protein

A high plane of nutrition has been implicated in the pathogenesis of osteochondrosis for many years.[7] The effects on growth plate morphology of over-feeding and under-feeding were described in 1984.[41] Twelve Thoroughbred (TB) weanlings aged 6 to 8 months were randomly assigned by age to three groups and were fed diets containing 70%, 100%, or 130% of the National Research Council recommendations (1978) for digestible energy and protein.[42] All diets contained 100% of the recommended level of calcium and phosphorus. After 8 months of these diets, biopsies of the distal radial growth plate showed that growth plate thickness was directly proportional to diet level. The growth plates of the over-fed horses showed many features similar to those described as osteochondrosis: the reserve and hypertrophic zones were enlarged, the hypertrophic cartilage had lost its normal columnar organization, and metaphyseal capillaries appeared unable to penetrate this abnormal hypertrophic cartilage. The morphological characteristics of the articular-epiphyseal cartilage complex were not assessed. The conclusion was that the lesions associated with over-feeding were similar to those caused by hypothyroidism and that the link between dietary excess and osteochondrosis is mediated by endocrine factors.[41]

More recent work has shown that the greater the amount of carbohydrate ingested by a young horse during a meal, the greater the magnitude and the shorter the duration of the ensuing increases in serum insulin, triiodothyronine (T_3), and thyroxine (T_4).[43] Transient post-prandial hypothyroxemia may thus be induced by diets high in energy. These findings suggested that the effects of insulin, T_3, and T_4 on growing skeletal tissues might be desynchronized by diet-induced alterations in the secretion and metabolism of these hormones, resulting in abnormal cartilage development.[14] The relationship between abnormal insulin levels and osteochondral lesions is supported by the finding that young horses with osteochondrosis have an exaggerated insulin response when fed a meal high in digestible energy.[44]

The effects on skeletal development of feeding 129% of National Research Council (NRC, 1989)[45] recommendations for digestible energy, or 126% of NRC recommendations for crude protein to foals approximately 5 months of age was investigated.[18] A control group received a diet containing 100% of NRC recommendations for energy and protein. The foals were allowed only limited exercise. After 12 to 16 weeks of the experimental diets, a comprehensive postmortem examination was performed on all foals. Growth plates and the growth cartilage of the articular-epiphyseal cartilage complex were examined, and a definitive diagnosis of dyschondroplasia was made only when a retained core of cartilage (i.e., disturbed endochondral ossification) was identified histologically. Gross lesions suggestive of dyschondroplasia were found in 1 (8%) of 12 control foals, 1 (17%) of 6 foals fed the high-protein diet, and 11 (92%) of the 12 foals fed the high-energy diet. Histological confirmation of dyschondroplasia occurred in 2 (17%) control foals, in 4 (67%) foals on the high-protein diet, and in all 12 foals on the high-energy diet. The lesions in the foals in the high-protein group were minor and were mainly single lesions of the growth plates, with the articular-epiphyseal cartilage complex left unaffected. No significant difference in incidence occurred between the control and high-protein groups. In contrast, many of the foals in the high-energy group had lesions of the articular-epiphyseal cartilage complex and the

growth plates, and the difference in incidence between the control and high-energy groups was significant.

Recent in vitro work suggests that insulin may promote the survival or depress the differentiation of chondrocytes in equine growth cartilage, thereby reducing the rate at which cells enter the terminal phases of hypertrophy. It was suggested that the resulting accumulation of pre-hypertrophic chondrocytes could reduce the rate of endochondral ossification, predisposing the animal to development of focal lesions.[46] This work provides evidence of a potential mechanism for the demonstrated links between dietary energy intake, hyperinsulinemia, and osteochondrosis.

Calcium and Phosphorus

The effects of over-feeding phosphorus (388% of NRC recommendations), calcium (342% of NRC recommendations), and calcium and digestible energy (342% and 129% of NRC recommendations, respectively) to foals aged 2½ to 6½ months were assessed.[26] The diets containing excessive phosphorus and calcium provided 100% of NRC recommendations for digestible energy. The foals were allowed only limited exercise. A comprehensive post-mortem examination was performed after 16 to 18 weeks of these diets. Histologically confirmed dyschondroplasia lesions were found in multiple joints and growth plates in 2 (17%) control foals, 5 (83%) foals fed excess phosphorus, 2 (33%) foals fed excess calcium, and 6 (100%) foals fed excess digestible energy and calcium. The lesions were more numerous and severe in the foals fed high-phosphorus, or high–digestible energy/calcium diets than in the control foals, or those fed high-calcium diets only. These findings show that dyschondroplasia is not induced by diets high in calcium and is not alleviated by excessive calcium in foals fed excessive energy. No mechanism for the apparent association between excessive dietary phosphorus and abnormal endochondral ossification was proposed.

Copper

Copper is a necessary co-factor of lysyl oxidase, the enzyme that catalyzes the oxidative deamination of lysine and hydroxylysine residues to the corresponding aldehydes. This is a necessary step in the formation of pyridinoline cross-links in collagen and elastin. Low-copper diets have been associated with an increase in the soluble fraction of articular collagen, reduced collagen cross-linking of cartilage and bone, and an increased incidence of osteochondral lesions in growing foals.[47,48]

An association between copper deficiency and equine osteochondral lesions was recognized for many years. Low serum copper levels were found in seven of eight foals with severe, generalized osteochondral abnormalities.[49] In some horses there was evidence that the copper deficiency was secondary to zinc toxicosis. Affected foals showed separation of articular and physeal cartilage from adjacent bone in the hypertrophic zone at many sites. In some joints the subchondral bone was almost denuded of cartilage. The lesions were thus much more widespread and severe than in a typical horse with naturally occurring osteochondrosis. Similar lesions were induced by experimental diets containing 1.7 ppm copper.[47] Early lesions were characterized by intrachondral splitting through the hypertrophic zone, and retention of cartilage was not a major feature of the pathological condition. As in an earlier report, lesions were widespread and severe.[49] Similar lesions develop in foals with zinc-induced copper deficiency.[50]

The effect on equine skeletal development of copper supplementation was studied during late gestation and the early growing period.[16] Twenty-one pregnant mares were assigned to a control group (diet containing 13 ppm copper) or a supplemented group (32 ppm) during the last 3 to 6 months of pregnancy. The foals were subsequently fed diets containing 15 ppm copper (control) or 55 ppm copper (supplemented) for up to 6 months. The dietary copper content of the control foals was close to NRC recommendations. Thickening of cartilage within the physis and lesions of the articular-epiphyseal cartilage complex demonstrating cartilage thickening (with or without separation of cartilage from subchondral bone and subchondral fibrosis) were defined as osteochondrosis. Compared with the foals given copper supplements, 6-month-old control foals had osteochondrosis nearly twice as frequently in the physes and more than five times as frequently in the articular-epiphyseal cartilage complex. Also, more than four times as many thickenings of the articular-epiphyseal cartilage complex occurred per foal in the control group compared with the group given supplements. Separation of cartilage from bone was observed in 13 lesions in the control foals and in none of the foals given supplements. The most notable lesions in the control group were cartilage thickening and separation of the distal intermediate ridge of the tibia.

The effects of 8 and 25 ppm dietary copper fed to 3-month-old foals for 6 months were compared. Cartilage and bone lesions were rare in the foals fed 25 ppm copper. In contrast, the majority of the foals fed 8 ppm copper were severely affected with many lesions. Cartilaginous flaps, and cartilage thinning, erosion, and eburnation composed the majority of the lesions identified at post-mortem examination. Lesions were most commonly found on the dorsal articular facets of the cervical spine. Many of the lesions were associated with microfractures within the physes and primary spongiosa of the long bones and cervical vertebrae. Biochemical analysis of tissues from four low-copper diet foals with osteochondritis dissecans–like lesions showed that they had significantly fewer pyridinoline cross-links in articular cartilage, physeal cartilage, and bone than a group of six foals with no osteochondritis dissecans lesions. The latter group comprised foals given copper supplements and two foals on low-copper diets. This demonstrated a link between low dietary copper, inferior collagen quality, and osteochondritis dissecans–like lesions.[48]

In these two cited studies, foals fed the lower amount of dietary copper typically had multiple lesions, many of which were present in the cervical vertebrae.[16,48] This lesion distribution would thus be described as atypical.[10,21] Biochemically the pathological condition induced was almost certainly secondary to copper deficiency.[48] Lesions were not caused by a primary failure of endochondral ossification but by insufficient dietary copper. However, these studies have shown that dietary copper levels of 8 to 15 ppm can induce lesions grossly and radiographically similar to those of osteochondrosis. Clinically, these lesions frequently may be diagnosed as osteochondrosis. How many horses with naturally occurring osteochondrosis are induced partly or completely by inadequate dietary copper is unknown, but these investigations show that close attention should be directed not only to the levels of copper in the diets of growing foals but also to the levels of known copper antagonists, such as zinc and molybdenum. Dietary copper is not a panacea, however. Relatively high levels of dietary copper (25 and 55 ppm) do not completely prevent osteochondral lesions,[16,48] and relatively low levels (11 ppm) do not always result in foals with multiple osteochondral abnormalities.[18] Copper is but one factor to which attention should be paid when faced with an increased incidence of osteochondral abnormalities in foals.

Heredity

There is no doubt that at least some manifestations of osteochondrosis have a genetic component. Heritability studies of equine osteochondrosis are still relatively scarce, however, and the true extent of the contribution made by genetic factors remains unknown, particularly in breeds other than the STB. Among Scandinavian STB populations, the heritability of tarsocrural osteochondrosis ranged from 0.24 to 0.52[17,51,52] (Table 56-1). These heritability coefficients describe the proportion of the total variation in incidence attributed to genetic

Table • **56-1**

Incidence and Heritability of Osteochondrosis Lesions

LESION	BREED	RANGE OF INCIDENCE AMONG PROGENY GROUPS (%)	HERITABILITY COEFFICIENT*	REFERENCE
Hock (lesions not defined)	Standardbred	0 to 8	—	Hoppe[53]
Hock (lesions not defined)	Warmblood	0 to 8	—	Hoppe[53]
DIR	Standardbred	3.4 to 30	0.26	Schougaard et al.[51]
Hock (lesions not defined)	Standardbred	0 to 24	0.24 to 0.27	Philipsson et et al.[17]
POF	Standardbred	11 to 44	0.17 to 0.19	Philipsson et al.[17]
DIR or LTR	Standardbred	0 to 69	0.52	Grøndahl and Dolvik[52]
POF	Standardbred	0 to 41	0.21	Grøndahl and Dolvik[52]

DIR, Distal intermediate ridge of tibia; *LTR*, lateral trochlear ridge of talus; *POF*, palmar/plantar osteochondral fragments in metacarpophalangeal and metatarsophalangeal joints.
*The heritability coefficient may over-estimate the true heritability if a high incidence of lesions exists in one progeny group (as in the study of Grøndahl and Dolvik[52]).

factors. Thus even the low end of this range indicates a substantial heritable component to the disease. Table 56-1 also shows the heritability of palmar/plantar osteochondral fragments of the fetlock joints. As discussed elsewhere in this chapter, whether these lesions are true manifestations of osteochondrosis is controversial. Nevertheless, data on the heritability of these lesions are presented here, in part for comparison with the heritability of hock osteochondrosis. Although a traumatic cause for palmar/plantar osteochondral fragments has been proposed, it is possible that trauma causes existing osteochondrosis lesions in this site to become clinically manifest.

The studies summarized in Table 56-1 provide an overview of the genetic contribution to tarsocrural osteochondrosis in STBs of three Scandinavian countries. Most of the progeny of nine stallions in Denmark were radiographed over the course of two breeding seasons.[51] Of the 325 yearlings evaluated, no more than two were provided by any one stud farm. The hock and fetlock joints of 793 randomly selected progeny of 24 Swedish STB trotting stallions were radiographed, including at least 29 offspring of each stallion.[17] An analysis of 644 Norwegian STBs used progeny groups of five or more from 39 stallions.[52] In all these studies the offspring of each stallion were reared in many different environments, strengthening the conclusion that differences among progeny groups were mainly genetically determined. In two of these studies, tarsocrural osteochondrosis had a stronger genetic component than palmar/plantar osteochondral fragments, with no significant relationship between the expression of lesions in these two sites.[17,52]

The data presented suggest that genetic selection against tarsocrural osteochondrosis and palmar/plantar osteochondral fragments is feasible in horses, but the relatively high incidence of lesions in the offspring of stallions free of osteochondrosis or palmar/plantar osteochondral fragments indicates that any selective breeding program would have to be based on progeny testing.[17,51] In addition, tarsocrural osteochondrosis and fetlock palmar/plantar osteochondral fragments appear to be inherited independently of each other.[17,52] These lesions therefore would have to be regarded as independent traits in any selection scheme.[17]

Gender

Early reports suggested that the incidence of equine osteochondrosis was substantially higher in males than females.[6,7] Non-significant relationships between male gender and osteochondrosis also have been reported in epidemiological studies, in which male/female incidence ratios of 1.6:1 and 1.4:1 were found.[53,54] However, in a controlled study of Warmbloods, no gender predisposition for osteochondrosis of the tarsocrural or femoropatellar joints was found.[37] In a recent study of feral horses (49% male, 51% female), osteochondrosis lesions were found only in fillies.[55] The evidence for an association between osteochondrosis and male gender is thus inconsistent.

Involvement of Cartilage Canals

Cartilage canals are channels containing arterioles, venules, and capillaries that assist in the nutrition of epiphyseal cartilage. Two recent studies have provided evidence that these structures may be involved in the pathogenesis of equine osteochondrosis.[19,56] The mechanisms of involvement proposed by the two sets of authors are different, however.

Gross, microradiographic, and histological examinations of three osteochondrosis predilection sites (medial femoral condyle, lateral femoral trochlear ridge, and distal tibia) were performed in 35 horses younger than 18 months of age. The distal end of the proximal phalanx, a non-predilection site, was also examined. The aims were to determine the age range over which cartilage canals are viable at these four sites and whether any association existed between these structures and the lesions of osteochondrosis. Cartilage canals containing patent blood vessels were present at all sites examined in foals younger than 3 weeks of age and were absent from all sites by 7 months of age. Overall, 34% of the animals had lesions of osteochondrosis and the prevalence rose to 56% in animals between 3 weeks and 5 months of age. All the lesions seen in this age group (3 weeks to 5 months) were associated with necrotic cartilage canal blood vessels. Lesions found in animals 7 months of age and older had extensive involvement of subchondral bone and bone marrow and were considered to be chronic. The conclusion was that osteochondrosis lesions develop before 7 months of age and that ischemic necrosis of cartilage is involved in the pathogenesis of the condition.[19]

The second study to determine an association between cartilage canals and equine osteochondrosis examined articular-epiphyseal cartilage complexes from various sites in 30 normal horses and 6 horses with dyschondroplasia. Normal horses ranged in age from 130 days gestation to 2 years.[56] Horses with lesions were younger than 15 months of age. Cartilage canals were present by 130 days of gestation and were never identified in normal articular-epiphyseal cartilage complex samples after 6 months of age. In five of the six osteochondrosis lesions, cartilage canals were associated with the retained cartilage. The cartilage canals in the region of these lesions contained patent vessels and were surrounded by chondrocytes that were unusually small for the position within the articular-epiphyseal cartilage complex.[22,56] In contrast to the previous study,[19] necrosis

was not a feature of these lesions. The conclusion was that under some circumstances chondrocytes adjacent to cartilage canals fail to hypertrophy, thereby leading to failure of endochondral ossification.[56] The authors proposed that patent blood vessels within cartilage canals may expose growth cartilage in the vicinity of the canal to any imbalance of systemic hormones, such as that induced by a high-energy diet. The authors suggested that chronicity of lesions accounted for the difference between these findings[56] and those of the previous study,[19] in which necrosis was found. These two studies suggest involvement of cartilage canals in the pathogenesis of equine osteochondrosis, but the mechanism remains to be determined.

Exercise

Conflicting evidence exists regarding the role of exercise in the pathogenesis of osteochondrosis. Increased incidence of osteochondrosis has been found in foals born later in the season,[17,35,54] and the suggestion was that the greater amount of exercise that these foals receive early in life may be partly responsible for the increased lesion frequency.[35] This hypothesis has not been supported by controlled studies, however.

The incidence of osteochondrosis in foals subjected to low-exercise and high-exercise regimens between the ages of 3 and 24 months was compared.[57] All foals were housed in groups or kept in boxes and were allowed to exercise for 2 to 4 hours per day in a paddock. In addition, the low-exercise group received 15 to 45 minutes of walking exercise per day. The high-exercise group received 15 to 45 minutes of walking and trotting, plus 8 to 20 gallop sprints of short duration (10 to 15 seconds). At the end of the study, hock and stifle joints were examined clinically and radiologically. Osteochondrosis was detected in only 3 (6%) of the 50 foals in the high-exercise group, but in 13 (20%) of the 66 foals in the low-exercise group, demonstrating a significant protective effect of high-intensity, short-duration exercise on the incidence of osteochondrosis.

These findings were not supported by the results of a recent extensive investigation into the effects of exercise on musculoskeletal development. Forty-three foals with a presumed genetic predisposition to osteochondrosis of the femoropatellar or tarsocrural joints were subjected to one of three exercise regimens: pasture exercise only, confinement to a box stall, or confinement to a box stall with an increasing number of gallop sprints. These exercise regimens were imposed from 1 week of age to 5 months, and the incidence of osteochondrosis including subchondral bone cysts at 5 and 11 months of age was determined. At 5 months of age, lesions were found in all foals.[58] Lesion frequency was highest in the tarsocrural joints (1.9 lesions per foal), with a lower incidence in the femoropatellar/femorotibial (1.0), cervical intervertebral (1.0), and metatarsophalangeal joints (0.6). Exercise did not influence the number of lesions, although the tendency was for lesions in the foals subject to box rest to be more severe. Exercise also appeared to influence lesion type and distribution within the stifle joint. The foals subjected to box rest developed lesions mainly in the femoral condyles (subchondral bone cysts), and the lesions in trained foals were mainly on the lateral trochlear ridge of the femur (osteochondrosis or osteochondritis dissecans). This difference may suggest an effect of mechanical loading on lesion development, because the lateral trochlear ridge is loaded by the patella during exercise,[10] and subchondral bone cysts tend to develop at the point of maximum load bearing during the support phase of the stride. It was concluded that exercise has no role in the pathogenesis of osteochondrosis, although exercise may alter the appearance and distribution of lesions.[33,34,58] By 11 months of age the prevalence of lesions had decreased significantly. The decrease was most dramatic in the femoropatellar/femorotibial joints. This study thus showed that many osteochondrosis lesions repair as foals develop, never becoming clinically apparent,[58] and also suggests that most osteochondrosis lesions develop before 5 months of age.

Trauma and Biomechanical Force

The roles of trauma and biomechanical force in the pathogenesis of osteochondral lesions are not well established. It is generally agreed that biomechanical forces are responsible for converting an osteochondrosis lesion into a dissecting osteochondritis dissecans lesion,[3,6,7] although little solid evidence exists to support this assertion. More pertinent, perhaps, is the establishment of the roles of trauma and biomechanical force as primary causative factors. The consistent location of typical osteochondrosis lesions within joints does suggest involvement of physical factors in the pathogenesis.[12] One proposal is that physeal dysplasia could result from excessive force on normal tissues or from the superimposition of normal force on structurally deficient tissues.[25] A similar hypothesis has been proposed for the development of osteochondrosis.[21,59] Many of the factors discussed previously could generate abnormal skeletal tissues, and abnormally high forces could result from excessive or inappropriate exercise, excessive body weight, or poor conformation.[25] A possible relationship between conformation and tarsocrural osteochondrosis was noted in a study of growing STB foals.[35] Of the 77 foals in the study, 39 (51%) had moderate or severe outward rotation of the hindlimb. This conformational feature was present in 7 (88%) of the 8 foals that developed tarsocrural osteochondrosis. These data suggest that a correlation may exist between osteochondrosis and conformation, but outward rotation of the limb is common in unaffected horses. Proof of a causative effect requires further research.

Some authors believe that many lesions currently classified as osteochondrosis arise purely as a result of mechanical factors, with no underlying developmental abnormality.[8,10,21] One author proposed that many osteochondrosis lesions with a typical distribution (solitary or symmetrically paired lesions in typical sites) be included in this category.[21] Causative factors were classified as sufficient (factors that can cause osteochondrosis by themselves), necessary (factors that must be present for expression of the disease, but do not cause osteochondrosis alone), and contributory (factors that modify the expression or severity of lesions). Of the mechanical factors considered, direct trauma and shearing of cartilage canals were deemed sufficient factors, biomechanical loading was classified as a necessary factor and conformational faults were considered contributory factors.[10] However, distinguishing between a developmental lesion and a traumatic lesion on gross and histological examination can be difficult, if not impossible,[2,21] especially if lesions are chronic and if the horses have undergone intense exercise before evaluation. Because a mechanical model of osteochondrosis induction is not available, determining the true role of biomechanics in the pathogenesis of osteochondrosis is difficult.

Transforming Growth Factor-β1

Transforming growth factor-β (TGF-β) plays an important role in controlling chondrocyte differentiation and hypertrophy.[60-62] Among the different isoforms of TGF-β, TGF-β1 is particularly important in controlling mammalian endochondral ossification.[63,64] The distribution of TGF-β1 messenger ribonucleic acid and protein in the articular-epiphyseal cartilage complex of the lateral trochlear ridge of the distal femur of horses with and without dyschondroplasia was compared. TGF-β1 expression was reduced at the site of dyschondroplastic lesions, and it was suggested that this may result in cessation of chondrocyte hypertrophy and an accumulation of pre-hypertrophic chondrocytes. The clinical significance of these findings has not yet been established, but this work does suggest that TGF-β1 may be involved in the pathogenesis of osteochondrosis.

Toxic Causes of Osteochondral Lesions

Foals exposed to excessive amounts of zinc and zinc and cadmium in combination have been shown to develop generalized, severe osteochondral lesions.[15,65-67] The gross lesions described in these reports were characterized by separation of articular cartilage from subchondral bone. Excessive dietary zinc can cause secondary copper deficiency.[68] The role of cadmium in the pathogenesis of these lesions is less clear.[15,65,67] These environmental contaminants are clearly toxic causes of osteochondral lesions and are not considered to be factors in the pathogenesis of osteochondrosis. However, they should be considered in the investigation of any unexplained outbreak of severe, generalized osteochondral lesions in foals, which in most instances do not resemble those seen in horses with naturally occurring osteochondrosis.

Osteochondral Lesions No Longer Considered as Osteochondrosis

Despite the controversies discussed previously, equine osteochondrosis is still most commonly regarded as a developmental condition.[22,32,55,58] There is general consensus that a number of lesions originally referred to as osteochondrosis have no developmental component, however, and should not be included under the osteochondrosis umbrella. These include juvenile spavin[10,21] and erosions of the palmar third metacarpal bone in racing TBs.[3,10,21] Debate continues concerning palmar/plantar osteochondral fragments and ununited palmar/plantar eminences of the fetlock joint, because although trauma may play a role in development, the high incidence in STBs suggests a possible developmental cause.[10,21,36]

SUMMARY

A range of conditions result in failure of endochondral ossification and retention of cartilage cores at the cartilage-bone interface, but the relative contribution to naturally occurring equine osteochondrosis is unknown. The strong heritable component[17,52,62] suggests that at least some manifestations of osteochondrosis may result from a complex interaction of environmental influences and genetic susceptibility. In support of this theory, osteochondrosis was more likely to develop in large, fast-growing offspring of a particular stallion than in the smaller, slower-growing siblings, suggesting that environmental influences can modify the expression of genetic factors.[35]

Recent studies have provided information on the age range at which lesions develop in different sites.[19,38,69] Early tarsocrural osteochondrosis lesions can be detected radiographically by 3 months of age. Lesions of the distal intermediate ridge of the tibia could be detected radiographically by 1 month of age in a population of foals genetically predisposed to osteochondrosis. Many of these lesions resolved, but osteochondrosis lesions of the hock (distal intermediate ridge and lateral trochlear ridge of the talus) that were still present at 5 months of age never regressed. Five months was designated as the age of no return for tarsocrural osteochondrosis lesions. In the same study, lesions of the lateral trochlear ridge of the femur became radiographically obvious from 3 to 4 months of age. As with tarsocrural lesions the majority of these lesions resolved, but any lesions remaining at 8 months of age appeared to be permanent. Eight months was designated as the age of no return for lateral trochlear ridge lesions.[38] A separate study found no evidence of new lesion development in the tarsocrural or fetlock joints after the age of 8 months,[69] and a third study concluded that osteochondrosis lesions of the medial femoral condyle, lateral femoral trochlear ridge, and distal tibia all develop before 7 months of age.[19] Researchers aiming to determine the pathogenesis of osteochondrosis can now focus their attention on the period during which lesions are known to develop.

It is generally agreed that equine osteochondrosis is a multifactorial condition.[3,5,22] This conclusion may be refined in the future, however, as the application of increasingly sophisticated investigational techniques leads to a more definitive definition of the condition and narrows the spectrum of conditions classified as osteochondrosis. Such a change is already occurring. Over the years, osteochondral lesions in numerous sites and with various pathogeneses have been described as osteochondrosis. It is now agreed that some of these lesions are not associated with a primary failure of endochondral ossification but are in fact traumatic or toxic in origin.[10,15,21,65] New techniques are allowing researchers to describe osteochondral lesions more fully and categorize lesions by cause. A recent example is the work in which osteochondral lesions associated with a low-copper diet were examined using histological, morphometric, and biochemical techniques.[48] These investigations strongly suggested that the lesions were caused by a copper deficiency rather than by a primary defect in the process of endochondral ossification. A second example is recent work in which histological and immunohistochemical techniques were applied to lesions with the gross appearance of osteochondrosis. The methods used allowed the lesions to be subdivided into two types, and it was proposed that these lesion types had different pathogeneses.[70]

It is obvious from this summary that opinions still differ widely on the major factors involved in the pathogenesis of equine osteochondrosis.[10,22] The last decade has brought a substantial amount of progress, however, and a firm foundation of knowledge involving many disciplines now exists on which future work can be built. However, until osteochondrosis is better defined and the pathogeneses of osteochondral lesions are more fully determined, the equine industry must work to reduce the inherent susceptibility of growing horses to osteochondrosis and control the environmental and husbandry influences that appear to predispose horses to osteochondral lesions.

The Role of Nutrition in Developmental Orthopedic Disease: Nutritional Management

Joe D. Pagan

Nutrition may play an important role in the pathogenesis of developmental orthopedic disease in horses. Deficiencies, excesses, and imbalances of nutrients may result in an increase in the incidence and severity of physitis, angular limb deformity, wobbler syndrome (wobbles), and osteochondrosis.

NUTRITIONAL FACTORS AS A CAUSE OF DEVELOPMENTAL ORTHOPEDIC DISEASE

Mineral Deficiencies

A deficiency of minerals, including calcium, phosphorus, copper, and zinc, may lead to developmental orthopedic disease. Most commonly fed cereal grains and forages contain insufficient quantities of several minerals. A ration of grass hay and oats supplies only 40% and 70% of a weanling's calcium and phosphorus requirement, respectively, and less than 40% of its requirement for copper and zinc (Table 57-1). The best method of diagnosing mineral deficiencies is through ration evaluation. Blood, hair, and hoof analysis is of limited usefulness.

Mineral Excesses

Horses can tolerate fairly high levels of mineral intake, but excesses of calcium, phosphorus, zinc, iodine, fluoride, and heavy metals, such as lead and cadmium, may lead to developmental orthopedic disease (Table 57-2).

Mineral excesses occur because of overfortification or environmental contamination. Massive oversupplementation of calcium (>300% of required amount) may lead to a secondary

The Role of Nutrition in Developmental Orthopedic Disease: Nutritional Management

Joe D. Pagan

Nutrition may play an important role in the pathogenesis of developmental orthopedic disease in horses. Deficiencies, excesses, and imbalances of nutrients may result in an increase in the incidence and severity of physitis, angular limb deformity, wobbler syndrome (wobbles), and osteochondrosis.

NUTRITIONAL FACTORS AS A CAUSE OF DEVELOPMENTAL ORTHOPEDIC DISEASE

Mineral Deficiencies

A deficiency of minerals, including calcium, phosphorus, copper, and zinc, may lead to developmental orthopedic disease. Most commonly fed cereal grains and forages contain insufficient quantities of several minerals. A ration of grass hay and oats supplies only 40% and 70% of a weanling's calcium and phosphorus requirement, respectively, and less than 40% of its requirement for copper and zinc (Table 57-1). The best method of diagnosing mineral deficiencies is through ration evaluation. Blood, hair, and hoof analysis is of limited usefulness.

Mineral Excesses

Horses can tolerate fairly high levels of mineral intake, but excesses of calcium, phosphorus, zinc, iodine, fluoride, and heavy metals, such as lead and cadmium, may lead to developmental orthopedic disease (Table 57-2).

Mineral excesses occur because of overfortification or environmental contamination. Massive oversupplementation of calcium (>300% of required amount) may lead to a secondary

Table • **57-1**

Mineral Requirements for Weanlings

MINERAL	NUTRIENT CONCENTRATION REQUIRED IN TOTAL DIET (90% DRY BASIS)		GRASS HAY	ALFALFA HAY	OATS	CORN	BARLEY
	MODERATE GROWTH	RAPID GROWTH					
Calcium (%)	0.62	0.70	0.35	1.25	0.08	0.05	0.05
Phosphorus (%)	0.40	0.45	0.20	0.22	0.34	0.27	0.34
Zinc (ppm)	65	65	9	16	6	4	8
Copper (ppm)	22	22	17	28	35	19	17

*Toxic Mineral Levels**

MINERAL	MINERAL LEVEL NEEDED BY YOUNG HORSE (PPM)	TOXIC LEVEL (PPM)
Zinc	60-70	9000
Iodine	0.2-0.3	5
Fluoride	—	50
Lead	—	80
Selenium	0.2-0.3	5
Manganese	60-70	4000
Copper	20-30	300-500
Cobalt	0.1	400
Iron	125	5000

*Adapted from Cunha[1] and 1989 National Research Council.[2]

mineral deficiency by interfering with the absorption of other minerals such as phosphorus, zinc, and iodine. Excessive calcium intake may be compounded by using legume hays as the primary forage source. Iodine and selenium oversupplementation occurs if supplements are fed at inappropriate levels. A ration evaluation is the best way to identify this type of mineral imbalance.

Environmental contamination is a more likely cause of developmental orthopedic disease, because contamination may result in extremely high intakes of potentially toxic minerals. If a farm is experiencing an unusually high incidence of developmental orthopedic disease or if the location and severity of skeletal lesions are abnormal, environmental contamination should be investigated. Blood, feed, and water analysis should be performed. Chemical analysis of hoof and hair samples may reveal valuable information. Farms that are located near factories or smelters are most at risk, although osteochondrosis caused by zinc-induced copper deficiency has been reported on farms using fence paint containing zinc or galvanized water pipes.

Mineral Imbalances

The ratio of minerals may be as important as the actual amount of individual minerals in the ration. High levels of phosphorus inhibit the absorption of calcium and lead to a deficiency, even if the amount of calcium present is normally adequate. The calcium/phosphorus ratio in the rations of young horses should never be below 1:1 and ideally should be 1.5:1. Too much calcium may affect phosphorus status, particularly if the level of phosphorus is marginal. Calcium/phosphorus ratios greater than 2.5:1 should be avoided if possible. Forage diets with high calcium levels should be supplemented with phosphorus. The zinc/copper ratio should be 3:1 to 4:1.

Dietary Energy Excesses

Excessive energy intake can lead to rapid growth and increased body fat, which may predispose young horses to developmental orthopedic disease. A recent Kentucky study showed that growth rate and body size might increase the incidence of certain types of developmental orthopedic diseases in Thoroughbred (TB) foals.[3] Yearlings that showed osteochondrosis of the hock and stifle were large at birth, grew rapidly from 3 to 8 months of age, and were heavier than the average population as weanlings.

The source of energy for young horses also may be important, because hyperglycemia or hyperinsulinemia have been implicated in the pathogenesis of osteochondrosis.[4,5] Foals that experience an exaggerated and sustained increase in circulating glucose or insulin in response to a carbohydrate (grain) meal may be predisposed to develop osteochondrosis.[6]

In a large field trial, 218 TB weanlings (average age 300 ± 40 days, average body weight 300 ± 43 kg) were studied.[6] A glycemic response test was conducted by feeding a meal that consisted of the weanling's normal concentrate at a level of intake equal to 1.4 g non-structural carbohydrate per kilogram of body mass. A single blood sample was taken 120 minutes after feeding to determine glucose and insulin levels. A high glucose and insulin response to a concentrate meal was associated with an increased incidence of osteochondrosis. More research is needed to determine whether the incidence of osteochondrosis can be reduced through feeding foals concentrates that produce low glycemic responses.

RATION EVALUATIONS

The best way to determine whether nutrition is a contributing factor to developmental orthopedic disease is to perform a ration evaluation, which compares the intake of several essential nutrients with the requirements of the horse. Gross deficiencies or excesses of key nutrients then can be identified and corrected. In the past, ration evaluations were time consuming and cumbersome, because much of the mathematical calculation was done by hand. Fortunately computer programs are now available that make ration evaluations quick and easy to interpret. Kentucky Equine Research Inc. (Versailles, Ky.) has developed an equine ration evaluation program called MicroSteed (www.ker.com).

Types of Evaluations

Ration evaluations can be approached in two ways. One way is to add up what is being fed and compare it with the horse's requirements. This may not be easy because most horsemen do not know exactly what their horses are eating. Alternatively, a new ration may be developed.

Protocol

Every nutrition evaluation should include a description of the horse, definition of nutrient requirements, determination of nutrients in feedstuffs, determination of intake of feedstuffs, calculation of nutrient intake, comparison of intake with requirements, and adjustment of the ration to correct deficiencies or excesses.

Describing the Horse

Different classes of horses have different nutrient requirements and each class may eat different amounts of forage and grain. Within each class of horse, it is important to know the horse's current body weight, its age and mature body weight if growing, and its rate of body weight gain or loss.

Defining Nutrient Requirements

Ration evaluations are intended to compare a horse's daily nutrient intake with a set of requirements to determine how well the feeding program meets the horse's nutritional needs. The National Research Council (NRC) publishes a set of requirements for horses, but NRC values generally represent *minimum* requirements for most nutrients. These are the levels of intake that are required to prevent frank deficiency symptoms. No allowances are included to account for factors that may increase the requirement of a nutrient. The bioavailability of nutrients may be different and other substances within a ration may interfere with the digestibility or use of a nutrient.

MicroSteed includes two different sets of nutrient requirements, the NRC and Kentucky Equine Research requirements, based on a combination of NRC numbers, research conducted since publication of the most recent NRC recommendations, and experience in the field. The user has the option of selecting NRC or Kentucky Equine Research requirements or adding a custom set of requirements.

NRC values for digestible energy and protein fairly accurately describe the needs of most horses. These two requirements were primarily developed from direct measurements of growth response and energy balance. Other requirements, such as those for calcium and phosphorus, were developed using more theoretical calculations, involving estimates of endogenous losses and digestibility. Still others were based on values developed for other species or from single experiments that were far from conclusive. Kentucky Equine Research requirements use values ranging from 1.25 to 3 times those recommended by the NRC for most vitamins and minerals. These nutrient requirements are not absolute, but it is assumed that they adequately reflect horses' needs under a wide range of conditions.

Determining Nutrients in Feedstuffs

The accuracy of evaluating the diet depends on proper sampling of feedstuffs. The feeds should be thoroughly mixed and a representative sample taken. Pelleted feeds are fairly uniform, but sampling is more critical for textured feeds and home mixes. If an odd nutrient value is encountered, the clinician should look to sampling error as a likely cause.

A hay core can be used to obtain a representative hay sample for analysis. Pasture analysis is more difficult. Should the entire pasture be systematically sampled or only those areas heavily grazed? Horses tend to be spot grazers; therefore sampling the heavily grazed areas is probably best.

When expressing feed intakes and nutrient composition, air dry values for hay and grain and 100% dry matter values for pasture are used, because hay and grain intakes actually are measured as fed, and pasture intakes tend to be estimated. The moisture content of the pasture is not relevant to the evaluation and only complicates intake calculations.

A number of commercial laboratories analyze forages and feeds. For a typical ration evaluation for young growing horses, the following nutrients should be analyzed or calculated for each forage and concentrate: digestible energy (megacalories [Mcal] or megajoule [MJ], typically estimated), crude protein (percent), lysine (percent, typically estimated), acid or neutral detergent fiber (percent), calcium (percent), phosphorus (percent), zinc (percent), copper (percent), and manganese (percent).

These nutrients usually are included on a standard panel analysis at a reasonable cost. Other minerals, such as selenium and iodine, usually are analyzed separately, and analysis can be expensive. Selenium and iodine are not essential for evaluations that focus on identifying nutritional causes of developmental orthopedic disease.

Determining Intake of Feedstuffs

A common flaw in many ration evaluations is measuring intake inaccurately. A weighing scale should be used to measure the amount of grain and hay offered. A certain degree of hay wastage usually occurs and this should be taken into account when calculating intake. The amount of forage and grain consumed by young horses varies tremendously, depending on its geographical location and forage availability. Typically, horses that are raised in tropical environments depend heavily on grain in the ration. Yearlings raised in temperate areas with abundant forage may eat rations that contain 80% forage.

Calculating Nutrient Intake

Determining pasture intake is the most difficult part of conducting a ration evaluation. Two methods usually are employed to estimate pasture intake. The simplest method is arbitrarily to estimate intake at about 1% to 1.5% of a young horse's body weight. The obtained value is approximate, but it is representative of most young horses at pasture for most of the day. A second and more accurate method is to calculate pasture intake energetically, by subtracting the digestible energy intake from all other feedstuffs from the horse's daily energy requirement. Dividing this number by the calculated energy density of the pasture yields daily dry matter intake. For example, a yearling that weighs 330 kg with an average daily gain of 0.55 kg/day should require 20.4 Mcal of digestible energy per day. If that yearling is eating 3.65 kg of sweet feed (10.8 Mcal of digestible energy) and 2 kg of mature alfalfa hay (3.6 Mcal digestible energy), then the yearling must be consuming around 6 Mcal of digestible energy from pasture. Most grass pastures contain about 2.2 Mcal of digestible energy per kilogram, so this yearling must consume about 2.73 kg of pasture dry matter per day. These intakes can then be used to evaluate the adequacy of the ration for other nutrients. In MicroSteed, pasture intake can be estimated automatically by first entering the other feedstuffs into the ration and then using an estimate key to perform the calculation just described. This method of calculating pasture energy intake works well, provided the horse actually is consuming the intakes of other feedstuffs and the correct energy requirements were selected.

Using the method described previously for estimating pasture intake often yields a negative number. If this occurs, then the digestible energy intake of the other feeds is too high, or the calculated energy consumption is too low. Sometimes horse owners report higher intakes of feeds than actually are eaten, which is particularly true for forages, because hay rarely is weighed and large quantities often are wasted. Grain intake can also be overestimated because the coffee can that is used to measure grain does not hold nearly as much grain as it does coffee. At other times the hay and grain intake may be correct, but the horse may be consuming more energy than calculated. Increased energy intake can occur if the horse is expending extra energy to work or keep warm in cold weather, or a young horse may be growing faster than assumed. For example, a yearling needs about 5 kg of additional grain (16.1 Mcal of digestible energy) per kilogram of gain. If average daily gain is higher than assumed, then the horse may be eating significantly more digestible energy than calculated.

Comparing Intake with Requirements

Rarely will the nutrients supplied by a ration exactly match a horse's requirements, and balancing rations with this type of precision is unnecessary. Instead the key to interpreting a ration evaluation is to identify deficiencies, excesses, or imbalances of nutrients that may affect growth and skeletal soundness. For most nutrients a level of intake in excess of 90% of required is not considered deficient. What is interpreted as excessive varies tremendously among nutrients. For instance, potassium plays only a minor role in skeletal development; a young horse at pasture may consume greater than 300% of its potassium requirement. Most of this potassium comes from the pasture and is perfectly harmless. Even small excesses of other nutrients, such as energy, may play a significant role in the development of skeletal disease. Energy intakes that are 115% of required might trigger mild developmental orthopedic disease, and levels above 130% almost certainly will cause problems in rapidly growing horses.

FEEDING PRACTICES THAT CONTRIBUTE TO DEVELOPMENTAL ORTHOPEDIC DISEASE

Several feeding scenarios may contribute to developmental orthopedic disease. Once identified, most can be corrected easily through adjustments in feed type and intake. Several of the most common mistakes made in feeding young growing horses are explained.

Overfeeding

One of the most common problems of feeding young horses is excessive intake that results in accelerated growth rate or fattening. Both conditions may contribute to developmental orthopedic disease. Unfortunately, there are no simple rules about how much grain is too much, because total intake of forage and grain determines energy consumption. Large intakes of grain are appropriate if the forage is sparse or poor quality, as often is the case in tropical environments. For example, grain intakes as high as 2% to 2.5% of body weight may be necessary to sustain reasonable growth in weanlings that have access to no forage other than tropical pasture. Conversely, grain intakes higher than 1% of body weight may be considered excessive when weanlings are raised on lush temperate pasture or have access to high-quality alfalfa hay.

The surest way to document excessive intake is by weighing and using condition scoring in the growing horse. Based on a system developed by Henneke et al.,[7] condition scoring measures fat deposition. Horses are scored from 1 to 9 (1 denoting extreme thinness and 9 indicating obesity). In a Kentucky study, fillies tended to have higher condition scores than colts, and the difference was greatest at 4 months of age (fillies 6.48; colts 6.0). These condition scores are considered moderate to fleshy according to the Henneke scoring system. By 12 months of age the condition scores of the colts and fillies had dropped to 5.3 and 5.4, respectively. Both sexes increased condition score slightly from 14 to 18 months.

If growth rate cannot be measured, excessive intake can often be assessed by ration evaluation. For example, a 6-month-old TB weanling (250 kg body mass; 500 kg mature body mass) was being fed 4 kg/day of a 16% protein sweet feed and 2 kg of alfalfa hay, with access to high-quality fall Kentucky pasture. To support a reasonable rate of growth (0.80 kg/day), this weanling required about 17 Mcal of digestible energy per day. The hay and grain intake of this foal alone would supply about 17.5 Mcal of digestible energy, which is slightly above the weanling's requirement. If a reasonable level of pasture intake were included (1% body mass or 2.5 kg dry matter), this weanling would be consuming 135% of its digestible energy requirement, a level likely to cause problems.

To reduce intake, the alfalfa hay should be eliminated, if the pasture is indeed adequate. If hay were needed when the weanling was stalled, grass hay would be more appropriate. Grain intake should be reduced to a level of about 3 kg/day. At this level of grain intake the weanling would need to consume about 3.3 kg of pasture dry matter to support a growth rate of 0.80 kg/day, and the ration would be nicely balanced.

Inappropriate Grain for Forage Provided

Occasionally the concentrate offered to a growing horse is incorrectly fortified to complement the forage that is being fed. The problem occurs particularly when the forage is mostly alfalfa or clover. Most concentrates for young horses are formulated with levels of minerals and protein needed to balance grass forage.

For example, a 12-month-old yearling (315 kg body mass; 500 kg mature body mass; 0.50 kg/day average daily growth) is raised without access to pasture, and the only forage available is alfalfa hay, which is fed at a level of intake equal to 1.5% of the yearling's body mass (4.72 kg/day). At this level of forage intake, the yearling would only require about 2.5 kg of grain per day. If a typical 14% protein sweet feed that was formulated to balance grass forage were used, the ration would be inappropriate for a number of reasons. Calcium would be 183% of the yearling's requirement, with a calcium/phosphorus ratio of 2.9:1. This would not be a problem except that phosphorus and zinc are marginal in the ration. Because calcium may interfere with the absorption of these minerals, the yearling may be at risk of developmental orthopedic disease from a zinc or phosphorus deficiency. The solution is to feed a concentrate that is more appropriately balanced for legume hay. For example, a 12% protein feed with 0.4% calcium, 0.9% phosphorus, and 180 ppm zinc would be more suitable.

Inadequate Fortification in Grain

The most common reasons for inadequate fortification are using unfortified or underfortified grain mixes, using correctly fortified feeds at levels of intake that are below the manufacturer's recommendation, or using fortified feeds diluted with straight cereal grains. These errors in feeding can be corrected by incorporating a highly fortified grain balancer supplement.

For example, a 6-month-old weanling (200 kg body mass; 400 kg mature body mass; 0.60 kg/day average daily growth) is fed 3 kg/day of a 10% protein sweet feed that is intended for adult horses. To compound matters, the weanling is also fed grass hay, with an estimated intake of 2.3 kg/day. This ration is deficient in protein, calcium, phosphorus, zinc, and copper. The foal would be prone to a rough hair coat and physitis. There are two ways to correct this problem. A properly formulated 14% to 16% protein grain mix with adequate mineral fortification could be used, or 1 kg of a grain balancer pellet could be substituted for 1 kg of the 10% sweet feed. This type of supplement is typically fortified with 25% to 30% protein, 2.5% to 3.0% calcium, 1.75% to 2.0% phosphorus, 125 to 175 ppm copper, and 375 to 475 ppm zinc. This is an extremely useful type of supplement to correct underfortified rations.

FEEDING SYSTEMS TO PREVENT DEVELOPMENTAL ORTHOPEDIC DISEASE

The nutritional requirements of a broodmare can be divided into three stages. Stage one is early pregnancy, from conception through the first 7 months of gestation. Barren mares and pregnant mares without suckling foals fit into this nutritional category. Stage two encompasses the last trimester of pregnancy, from around 7 months of pregnancy through foaling. Stage three is lactation, which generally lasts 5 to 6 months after

foaling. The most common mistakes are overfeeding during early pregnancy and underfeeding during lactation.

Early Pregnancy

Proper feeding of a mare during pregnancy requires an understanding of how the fetus develops during gestation. Contrary to popular belief, the fetus does not grow at a constant rate throughout the entire 11 months of pregnancy. The fetus is small during the first 5 months of pregnancy. At 7 months of pregnancy the fetus equals only about 20% of its weight at birth. At this stage in pregnancy the fetus equals less than 2% of the mare's weight, and its nutrient requirements are minuscule compared with the mare's own maintenance requirements (Table 57-3). Therefore the mare can be fed essentially the same as if she were not pregnant. Mare owners often greatly increase feed intake after a mare is pronounced in foal, reasoning that she is now eating for two. Increased feeding is unnecessary and may lead to obesity and foaling difficulties, especially if the mare has access to high-quality pasture.

Late Pregnancy

The fetus begins to develop rapidly after 7 months of pregnancy, and its nutrient requirements become significantly greater than the mare's maintenance requirements; therefore adjustments should be made to the mare's diet. Digestible energy requirements increase about 15% over early pregnancy. Protein and mineral requirements increase to a greater extent, because the fetal tissue being synthesized during this time is high in protein, calcium, and phosphorus. During the last 4 months of pregnancy the fetus and placenta retain about 77 g of protein, 7.5 g of calcium, and 4 g of phosphorus per day. Trace mineral supplementation is also important, because the fetus stores iron, zinc, copper, and manganese in its liver for use during the first few months after birth because mare's milk is low in these elements.

New Zealand researchers studied the effect of copper supplementation on the incidence of developmental orthopedic disease in TB foals.[8] Pregnant TB mares were divided into copper-supplemented and control groups. Live foals born to each group of mares were also divided into copper-supplemented and control groups. Copper supplementation of mares was associated with a significant reduction in the physitis scores of the foals at 150 days of age. Foals from mares that received no supplementation had a mean physitis score of 6, whereas foals from supplemented mares had a mean score of 3.7. A lower score means less physitis. Copper supplementation of the foals had no significant effect on physitis scores. A significantly lower incidence of articular cartilage lesions occurred in foals from supplemented mares. However, copper supplementation of the foals had no significant effect on articular and physeal cartilage lesions.[6] Mares in late pregnancy often are overfed energy in an attempt to supply adequate protein and minerals to the developing foal. If a pregnant mare becomes fat during late pregnancy, she should be switched to a feed that is more concentrated in protein and minerals, so that less can be fed per day. This will restrict her energy intake, while ensuring that she receives adequate quantities of other key nutrients.

Lactation

A mare's nutrient requirements increase significantly after foaling. During the first 3 months of lactation, mares produce milk at a rate equal to about 3% of body weight per day. This milk is rich in energy, protein, calcium, phosphorus, and vitamins. Therefore the mare should be fed enough grain to meet its greatly increased nutrient requirements. Mares in early lactation usually require from 4.5 to 6.5 kg of grain per day, depending on the type and quality of forage they are consuming. This grain mix should be fortified with additional protein, minerals, and vitamins to meet the lactating mare's needs. Trace mineral fortification is not as important for lactating mares, because milk contains low levels of these nutrients, and adding more to the lactating mare's diet does not increase the trace mineral content of the milk. Calcium and phosphorus are the minerals that should be of primary concern during lactation. Grain intake should be increased gradually during the last few weeks of pregnancy so that the mare is consuming nearly the amount that it will require for milk production at foaling. A rapid increase in grain should be avoided at foaling, because this may lead to colic or laminitis. Milk production begins to decline after about 3 months of lactation, and grain intake can be reduced to maintain the mare in desirable condition.

Sucklings

If a broodmare has been fed properly during late pregnancy, giving mineral supplements to a suckling is unnecessary until it reaches 90 days of age. At 90 days, moderate amounts of a well-fortified foal feed can be introduced and gradually increased until the suckling is consuming around 0.5 kg of feed per month of age. It is critical that the suckling be accustomed to eating grain before weaning. If the suckling does not become accustomed to eating grain, there is a good chance that its growth rate will decrease dramatically at weaning. When the weanling finally starts eating grain, a compensatory growth spurt occurs that may result in developmental orthopedic disease.

Weanlings

The most critical stage of growth for preventing developmental orthopedic disease is from weaning to 12 months of age, when the skeleton is most vulnerable to disease and nutrient intake and balance is most important. Weanlings should grow at a moderate rate with adequate mineral supplementation. In temperate regions the contribution of pasture to the diet

Table • **57-3**

Expected Feed Consumption by Horses

HORSE	% OF BODY WEIGHT		% OF DIET	
	FORAGE	CONCENTRATE	FORAGE	CONCENTRATE
Maintenance	1-2	0-1	50-100	0-50
Pregnant mare	1-2	0.3-10	50-85	15-50
Lactating mare (early)	1-2.5	0.5-2	33-85	15-66
Lactating mare (late)	1-2	0.5-1.5	40-80	20-60
Weanling	0.5-1.8	1-2.5	30-65	35-70
Yearling	1-2.5	0.5-2	33-80	20-66
Performance horse	1-2	0.5-2	33-80	20-66

often is underestimated, leading to excessive growth rates and developmental orthopedic disease.

Yearlings

Once a horse reaches 12 months of age, it is much less likely to develop many forms of developmental orthopedic disease than a younger horse. Many of the lesions that become clinically relevant after this age probably developed at a younger age. Proper nutrient balance remains important for the yearling, and delaying as long as possible the increased energy intakes that are required for sales preparation is best, because the skeleton is less vulnerable to developmental orthopedic disease as a yearling ages. Normally, increasing energy intake 90 days before a sale is enough time to add the extra body condition that often is expected in a sales yearling. Physitis in the carpus is often a major concern for the sales yearling. The level of trace mineral supplementation should remain high to reduce the incidence of physitis in sales yearlings, and a significant portion of the energy normally supplied from grain should be replaced with fat and fermentable fiber. Sales preparation grain mixes can contain as much as 10% fat. Good sources of fermentable fiber include beet pulp and soy hulls.

NUTRITIONAL MANAGEMENT OF DEVELOPMENTAL ORTHOPEDIC DISEASE

The goal of a feeding program for young horses is to reduce or eliminate the incidence of developmental orthopedic disease. Unfortunately, developmental orthopedic disease still occurs in some foals. Nutritional intervention can help reduce the severity of many forms of developmental orthopedic disease, but not all of the damage resulting from the disease is reversible. However, it is important to alter the feeding programs of foals with developmental orthopedic disease. The type of alteration follows a similar pattern but depends on the foal's age and the type of developmental orthopedic disease. In almost every instance, energy intake should be reduced while maintaining adequate levels of protein and minerals. The rationale for this type of modification is that skeletal growth should be slowed, but adequate substrate should be available to promote healthy bone development.

Physitis

Grain intake should be restricted to a level supplying around 75% of the foal's normal energy requirement. This restriction, however, should not compromise protein and mineral intake, so a different type of feed formulation may be required. For instance, a 6-month-old weanling (250 kg body mass; 500 kg mature body mass; 0.8 kg average daily growth) on a decent fall pasture would normally consume around 3.5 kg of a 16% protein foal feed. If this foal developed physitis, it should be confined and fed grass hay (3 kg/day). Reducing the grain intake to 75% of the foal's normal digestible energy would result in shortages of protein, lysine, calcium, and phosphorus. These shortfalls could be overcome by replacing 1 kg of the 16% sweet feed with a grain balancer pellet. This ration would supply 90% of the foal's normal protein requirement along with a good supply of minerals. As the physitis resolves, intake of the 16% grain mix can be slowly increased and the supplement pellet intake slowly decreased, until the foal returns to its normal ration.

Cervical Vertebral Malformation

A feeding program like the one described previously is also appropriate for a horse with cervical vertebral malformation, except that the degree of exercise and energy restriction may be more severe. In this case a feeding program that combines grass hay (2 kg) with a moderate amount of alfalfa hay (2 kg/day) and 1 kg of balancer pellet would result in a reduction in energy intake equal to 65% of normal intake while maintaining adequate levels of protein and mineral intake.

Osteochondrosis

Once a foal develops osteochondrosis that is severe enough to produce clinical signs, the effect of diet is minimal in solving the existing lesion, but reducing energy intake and body weight while maintaining adequate protein and mineral intake is advised.

CHAPTER • 58

Diagnosis and Management of Osteochondrosis and Osseous Cyst-like Lesions

Dean W. Richardson

The pathogenesis of osteochondrosis, palmar/plantar osteochondral fragments of the proximal phalanx, ununited palmar/plantar eminences of the proximal phalanx, subchondral bone cysts, and other osseous cyst-like lesions is discussed in Chapter 56. In this book the term *subchondral bone cyst* is used for large radiolucent areas in the subchondral bone of the medial femoral condyle; these cysts have a consistent pathological structure with a true fibrous cyst lining. Osseous cyst-like lesions in other locations vary more in structure. This chapter discusses the diagnosis and management of these lesions and other osseous fragments believed to be developmental in origin. The joints most commonly affected include the hock, stifle, fetlock, and shoulder. Although lesions often occur bilaterally in the equivalent contralateral joint, for joints in different anatomical locations to be clinically affected simultaneously is unusual.

Clinical signs of osteochondrosis range from none to severe lameness. Often moderate to severe joint effusion occurs, with minimal or mild lameness. The clinical signs are not necessarily coincident with the development of the lesion. Most osteochondrosis lesions are probably formed before 6 months of age, yet most are diagnosed at a later age. Some radiographic lesions heal, or they at least become stable enough never to cause a clinically apparent lameness. Lesions in racing Thoroughbreds (TBs) and Standardbreds (STBs) are usually recognized by 2 years of age, but in Warmbloods (WBLs) that are older when they begin training, clinical signs may not be seen until the horse is 5 to 6 years of age or even older. Acute, more severe lameness in older horses occurs occasionally when osteochondritic fragments become loose.

Diagnosis is based on typical clinical signs and radiography. Most osteochondritis dissecans flaps have an osseous component and so can be identified using plain radiography. Defects in subchondral bone contours are also easily identified. Radiographic defects in subchondral bone must be interpreted with caution in foals, especially in areas where endochondral ossification occurs later, such as the femoral or talar trochlear ridges. An irregularity in the contour of subchondral bone does *not* mean that an articular defect is necessarily present; the lesion still possibly may heal. Therefore surgical intervention should be delayed until it is clear that either a loose fragment is present or the healing is progressing inadequately. Radiographically apparent lesions must always be interpreted with the clinical signs, because some do not cause clinical signs. If a lesion is identified, the contralateral joint should be examined radiographically, because bilateral involvement (quadrilateral in the fetlock) is common. The presence of bilateral radiographically apparent lesions in a horse that is unilaterally lame is not unusual and further emphasizes the need to evaluate the individual horse fully.

Decisions concerning treatment should consider the age of the horse, its intended use, the severity of the lesions and anatomical location, if the horse is intended for sale through public auction, and if so, the timing of the sale and the conditions of sale. Prophylactic removal of osteochondrosis lesions for economic reasons may be justified in all horses intended for future sale. Most buyers are more willing to purchase horses after an osteochondrosis lesion has been removed and the horse has returned to work.

LESIONS IN THE METACARPOPHALANGEAL AND METATARSOPHALANGEAL JOINTS

Osteochondrosis of the Sagittal Ridge of the Third Metacarpal and Metatarsal Bones

Most foals with osteochondrosis lesions of the sagittal ridge of the third metacarpal (McIII) or third metatarsal (MtIII) bones are not recognized as lame. A variable degree of joint effusion occurs, and the lesions are usually first identified on pre-sale radiographs. Unstable lesions cause lameness and persistent effusion when a horse starts work. Lameness is eliminated by intra-articular or perineural analgesia.

Lesions are more common in MtIII than McIII, but all fetlocks should be examined radiographically if a lesion is recognized in one, using perfectly exposed (or slightly underexposed) flexed lateromedial views (Fig. 58-1). Lesions on the dorsoproximal aspect of the sagittal ridge are easiest to recognize, but lesions may occur farther distally or, less commonly, on the palmar/plantar aspect of the sagittal ridge. The latter can also be seen radiographically on the dorsopalmar (plantar) projection. The larger fragments extend abaxially along the proximal margin of the articular cartilage under the dorsal synovial fold.

Conservative management should always be considered in horses younger than 18 months old, because lesions can show improvement radiographically and presumably heal. Surgery is indicated in young horses with fetlock effusion and lameness. Young horses treated surgically often do well clinically,

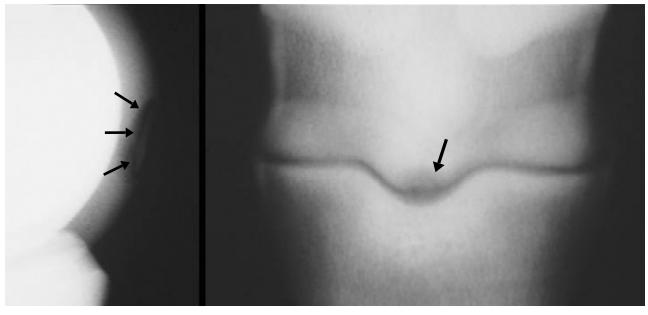

Fig. 58-1 A typical distal sagittal ridge osteochondritis dissecans lesion *(arrows)* of the third metacarpal bone is seen best on a slightly underexposed flexed lateromedial radiographic view *(left)* and well-exposed dorsopalmar view *(right)* of a metacarpophalngeal joint.

but the long-term radiographic appearance is inferior to spontaneous healing. Older horses of training age with unstable fragments are treated by arthroscopic debridement. Proximal lesions are technically easy to approach and debride, but lesions that are more distal can only be exposed by slight or moderate flexion of the joint. The arthroscope portal therefore should be made more distal than usual, and a needle should be used to identify a suitable instrument portal. Debriding a sagittal lesion with a portal placed through the extensor tendon directly over the lesion is easiest. Long reaches across a flexed joint result in undesirable iatrogenic trauma.

The prognosis depends on the size and location of the flap. Probably 90% of horses with typical lesions of the more proximal portion of the sagittal ridge go on to athletic function. Horses with distal lesions in a more weight-bearing location do not do as well as those with flaps at the proximal articular margin, and the radiographic appearance does not improve spontaneously as often.

Osseous Cyst-like Lesions

Osseous cyst-like lesions occur on the weight-bearing surface of the condyles of McIII and MtIII. Most occur in the medial condyle and are diagnosed in horses 1 to 2 years of age. The lesions are easy to recognize radiographically and result in obvious lameness, exacerbated by distal limb flexion. Lameness is improved by perineural or intra-articular analgesia. Lameness associated with an osseous cyst-like lesion sometimes occurs in foals. At the time of onset of lameness no lesion may be identifiable radiographically, or only a subtle defect in the outline of the subchondral bone may be apparent. However, sequential radiographs obtained over the following 6 to 8 weeks may reveal development of an osseous cyst-like lesion. Surgical debridement may be successful,[1] but corticosteroids administered intra-articularly combined with several months of rest also may result in significant improvement in young horses. Although simple debridement of McIII and MtIII osseous cyst-like lesions has been reasonably successful, the intensity of loading on distal McIII/MtIII bones in athletic horses makes these lesions good candidates for future improvements in joint resurfacing techniques.

Palmar/Plantar Osteochondral Fragments of the Proximal Phalanx

Osteochondral fragments arising from the proximal palmar or plantar aspect of the proximal phalanx are common radiographic findings in WBLs, STBs, and TBs, especially in hindlimbs. Palmar/plantar osteochondral fragments and ununited palmar/plantar eminences may not cause clinical signs or merely cause mild discomfort at high levels of performance. Assessment of clinical significance and management are discussed in detail in Chapter 43.

Osteochondral Fragments on the Dorsoproximal Aspect of the Proximal Phalanx

Small, well-rounded osseous opacities on the dorsoproximal aspect of the proximal phalanx are common radiographic findings. Most probably occur as small chip fractures of the developing dorsal rim of the proximal phalanx in foals that subsequently ossify. Whether a true underlying developmental defect in this location exists is unclear. Although fragments in this location do not always cause overt lameness, they often are removed in valuable prospective athletic horses and sales horses. Many of these fragments are loosely tethered along the dorsal rim of the proximal phalanx and can cause damage to the distal McIII/MtIII bones in an intensively exercised horse. Arthroscopic removal is quick and easy, and the prognosis is close to 100% for full function. Horses can be returned to full work within 4 to 6 weeks after removal of these fragments.

LESIONS OF THE PROXIMAL INTERPHALANGEAL JOINT

Lesions in the proximal interphalangeal joint usually cause lameness at a young age, often when the horse is a weanling. Single, discrete, well-defined osseous cyst-like lesions or multiple poorly defined radiolucent lesions may be identified, occurring most commonly in the distal condyles of the proximal phalanx (Fig. 58-2). Surgical access to most pastern osseous cyst-like lesions is difficult, and simple debridement is not usually feasible. Lesions may be advanced when lameness is first recognized, and although occasionally horses spontaneously improve without treatment, horses that are obviously lame usually develop osteoarthritis. Therefore horses that do not respond adequately to corticosteroids administered intra-articularly probably should have an early arthrodesis, especially if a hindlimb is affected. Arthrodesis in young or small horses is readily accomplished with one of the well-described techniques using two or three transarticular 5.5-mm screws placed in lag fashion.[2-5] In larger horses, more stability is afforded by a dorsal four-hole narrow dynamic compression plate combined with two abaxial transarticular 5.5-mm screws. The prognosis for athletic function after pastern arthrodesis appears to depend highly on the desired level of activity. Little doubt exists, however, that the prognosis is far superior in the

Fig. 58-2 Dorsolateral-palmaromedial radiographic view of a proximal interphalangeal joint. The most common manifestation of osteochondrosis in the pastern is an osseous cyst-like lesion *(arrow)* in the distal condyle of the proximal phalanx.

hindlimb than in the forelimb. Most retrospective studies have reported greater than 80% return to athletic function after hind pastern arthrodesis, but forelimb results may be only around 50%. The intensity of the exercise is probably critical. Few successful elite-level athletic horses (racehorses, upper-level dressage, jumping) have fused front pasterns.

LESIONS OF THE DISTAL INTERPHALANGEAL JOINT

Well-rounded osteochondral fragments on the dorsoproximal aspect of the extensor process of the distal phalanx are also believed to be developmental in origin. Small fragments are frequently incidental radiographic findings, and treatment is not necessary unless associated lameness exists. Lameness should be improved substantially by intra-articular analgesia. Nuclear scintigraphy may help definitive diagnosis. Treatment of horses with lesions associated with lameness is arthroscopic removal of the fragment. The prognosis is excellent (>90%) if the fragment is removed before osteoarthritis of the distal interphalangeal joint develops. These fragments are often well imbedded in the extensor tendon insertion, so not all fragments adversely affect joint function. As with many other small osteochondral fragments, removal is sometimes done prophylactically.

Osseous cyst-like lesions of the distal phalanx can be large and associated with dramatic lameness (Fig. 58-3). Apparently the pathogenesis may be similar to that of subchondral bone cysts of the distal femur. An attempt usually is made to manage such lesions with medications administered intra-articularly. If that is unsuccessful, surgical debridement can be attempted, but the lesions are difficult to access, and the outcome after surgery appears to be less than 50% for a return to adequate function.

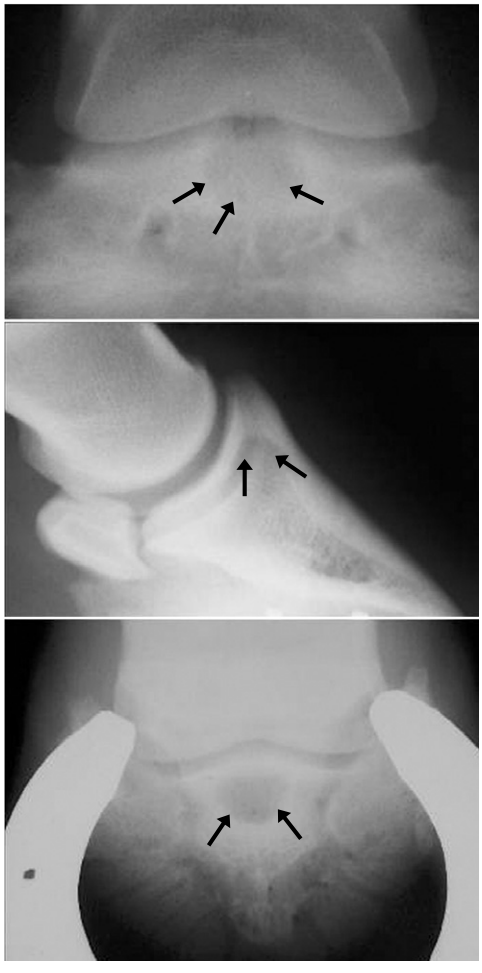

Fig. 58-3 Dorsopalmar *(top)*, lateromedial *(middle)*, and dorsoproximal-palmarodistal oblique *(bottom)* radiographic views of a foal. There is a large osseous cyst-like lesion in the distal phalanx *(arrows)*. Large osseous cyst-like lesions of the distal phalanx are difficult management problems because they are relatively inaccessible to surgical debridement.

LESIONS OF THE SCAPULOHUMERAL JOINT

Osteochondrosis of the scapulohumeral joint may involve the glenoid of the scapula or the humeral head. Humeral head lesions can be solitary, but scapular lesions usually appear with substantial pathological abnormalities of the humeral head in young horses (<2 years old). Lameness can develop insidiously or acutely, presumably after an acute disruption of an unstable osteochondral flap. Recognizing a developing flexural deformity or clubfoot may confuse diagnosis of shoulder lameness in a chronically lame young horse. Occasionally mild lesions are not recognized until a horse starts training. Lameness is improved by intra-articular analgesia but often is not eliminated. Radiographic abnormalities may include poorly defined subchondral radiolucent areas, with or without sclerosis, flattening of the articular surfaces, and modeling of the articular margins, especially the ventral angle of the scapula (see Chapter 41).

Lameness in some young horses improves with rest, and early surgery should not be encouraged in foals younger than 8 to 10 months old unless they are intractably lame. Affected foals should be confined to a stall or small paddock and re-examined clinically and radiographically at 60-day intervals. Intra-articular medication has not been consistently helpful in weanlings and yearlings. The outcome after arthroscopic treatment of osteochondrosis of the scapulohumeral joint is unpredictable and lameness can dramatically worsen after surgery. Radiography may underestimate the severity of lesions, especially those involving the humeral head. It is important to emphasize to an owner before surgery that considerable uncertainty exists about the clinical outcome in any given horse with osteochondrosis in the shoulder. Solitary osseous cyst-like lesions also occur, most commonly in the middle of the distal scapula but sometimes in the humeral head (see Chapter 41).

OSTEOCHONDROSIS OF THE TARSOCRURAL JOINT

Osteochondrosis of the tarsocrural joint is common in many breeds. Obvious joint capsule distention (bog spavin) may precede recognition of any gait abnormality. Effusion may not be recognized in racehorses examined for poor performance associated with osteochondrosis, but in show horses with lameness, effusion almost invariably occurs. Radiographic lesions are not always associated with lameness; therefore diagnosis should be confirmed by intra-articular analgesia or by response to intra-articular medication with corticosteroids. At least four radiographic views should be obtained, because multiple lesions may be present. If osteochondrosis is suspected clinically, but no lesion is identified radiographically, repeating the dorsoplantar view with slightly different angles of projection is worthwhile, because medial malleolar lesions can be difficult to see (Fig. 58-4). Flexed lateromedial views may be necessary to identify lesions involving the plantar aspect of the tarsocrural joint.

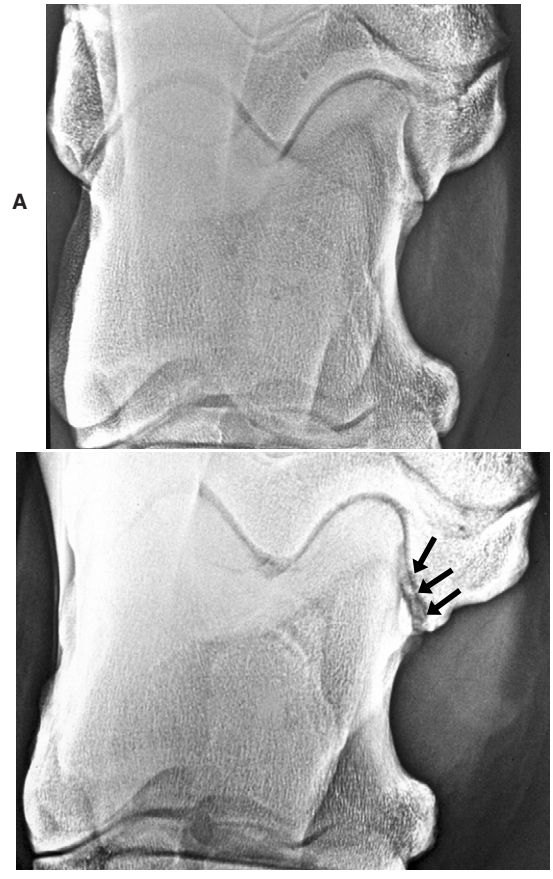

Fig. 58-4 **A,** Dorsoplantar and **B,** dorsal 10° lateral-plantaromedial oblique radiographic views of a hock. Identification of osteochondritis dissecans lesions of the medial malleolus requires well-positioned films. Identifying the lesion on the dorsoplantar xeroradiograph **(A)** is difficult, but a slight alteration in the obliquity **(B)** reveals a large defect *(arrows)*.

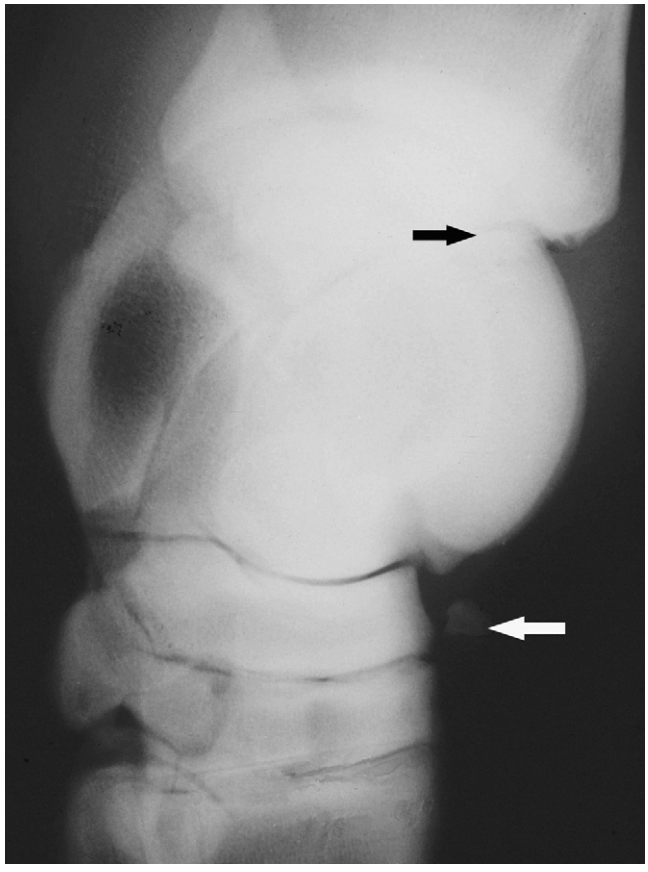

Fig. 58-5 Lateromedial radiographic view of a hock. Osteochondritis dissecans lesions that originate anywhere in the tarsocrural joint and become loose *(white arrow)* frequently lodge in the dorsal aspect of the proximal intertarsal joint. The likely origin of this fragment was the cranial aspect of the intermediate ridge of the distal tibia *(black arrow)*.

Osteochondrosis of the tarsocrural joint is recognized as a common radiographic finding in STBs, TBs, and WBLs, but it is not always associated with lameness. Few of the common osteochondrosis lesions in the hock heal spontaneously after 5 months of age, so surgical removal in young horses, especially sales yearlings, has become commonplace. These lesions are almost always in peripheral, less than completely weightbearing locations, and removal does not seriously compromise joint function. Prognosis is excellent. However, fragments that cause lameness at a later age are a greater problem because the loose fragments and debris often cause extensive cartilage damage. Older show jumpers in particular may dislodge distal tibial osteochondritis dissecans lesions and develop acute clinical signs of effusion and lameness (Fig. 58-5).

The cranial intermediate ridge of the distal tibia is the most common site of lesions (Fig. 58-6). These lesions rarely cause overt lameness unless significant effusion occurs. Arthroscopic removal of the fragment is straightforward and nearly always results in improvement of the lameness and effusion. Lesions may be identified radiographically bilaterally, although only one limb is chronically affected. Loose fragments may become detached in the tarsocrural joint and can become lodged in the communicating proximal intertarsal joint. The opening from the tarsocrural joint into the proximal intertarsal joint at the distal margin of the talar trochlear groove is not patent or is small in young foals or weanlings, but as the opening enlarges in older horses, large fragments can move into the proximal intertarsal joint pouches.[6] If a fragment of bone is found dorsal to (or even on the distal edge of) the central tarsal bone, the fragment is probably one loose in the proximal intertarsal joint that gravitated into that pouch. Fragments associated with lameness should be removed. It is important to recognize that the fragments in the proximal intertarsal joint usually are not easily seen with the arthroscope and often have to be removed blindly with a rongeur guided arthroscopically into the joint pouch.

Lesions of the distal aspect of the lateral trochlear ridge of the talus can be enormous in size and, if loose, may cause acute severe lameness and substantial effusion (Fig. 58-7). This lesion seems to be more common in heavy breeds and STBs. Horses with small, well-attached lesions can be managed conservatively, but any displaced fragment should be removed. The prognosis generally depends on how proximal and axial the lesion extends, but even large lesions can be removed with a good prognosis.

Osteochondritis dissecans lesions of the medial malleolus of the tibia are easily missed, because they are always on the axial rather than the distal (more visible) part of the malleolus (Fig. 58-4). Medial malleolar osteochondritis dissecans lesions usually cause more lameness and more effusion than the more common intermediate ridge lesions. Unless the lesion is unusually large, the prognosis after arthroscopic removal is excellent. Early removal is recommended, because erosive lesions on the medial trochlea of the talus can become severe over time.

Fig. 58-6 Lateromedial radiographic view of a hock. The most common location for osteochondritis dissecans in the tarsocrural joint is the cranial intermediate ridge of the distal tibia *(arrow)*.

Fig. 58-7 Dorsomedial-plantarolateral radiographic view of a hock. Osteochondritis dissecans fragments *(arrow)* arising from the distal lateral trochlear ridge of the talus are often large, but after surgical removal horses have a good prognosis regardless of size of the lesion.

Medial trochlear ridge lesions should be interpreted with caution; most distal medial trochlear ridge lesions are incidental findings and do not require treatment. Unstable lesions may cause lameness (Fig. 58-8). Distal medial trochlear ridge lesions may be on the proximal or distal side of the capsular attachment separating the tarsocrural and proximal intertarsal joints. The fragments wholly within the tarsocrural joint appear to be less stable and more likely to cause lameness. In

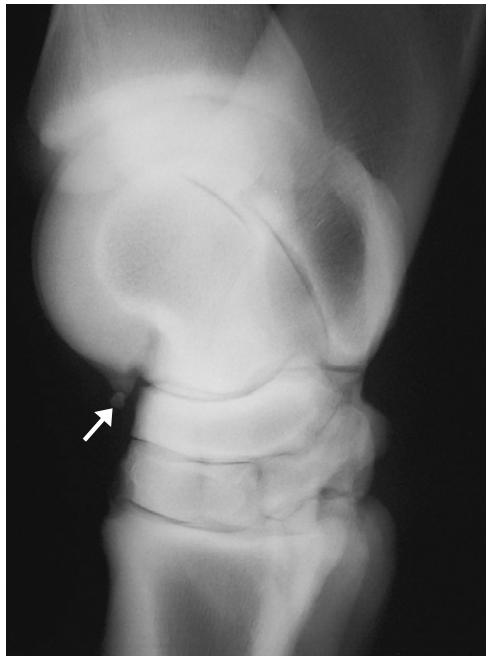

Fig. 58-8 Lateromedial radiographic view of the hock. Small fragments *(arrow)* along the distal dorsal aspect of the medial trochlear ridge of the talus usually do not cause lameness, but some are unstable and induce effusion and lameness, particularly fragments on the proximal side of the proximal intertarsal joint capsule.

all horses the decision for surgical removal should be based on a definitive response to intra-articular analgesia. The arthroscopic removal of the tarsocrural lesions is easy and can be done with minimal dissection. Lesions under the capsular attachment often require sharp dissection of the attachment to expose the fragment. Care should always be taken to dissect the minimal amount of soft tissue, especially because the attachments course abaxially.

More centrally positioned, smoothly outlined depressions in the surface of the medial trochlear ridge of the talus are common in large WBLs, Draft, and Draft-cross horses. The subchondral bone architecture is usually normal, and no associated clinical signs are apparent. These lesions rarely have an unstable chondral or osteochondral flap that can be removed.

Lateral malleolar fragments are usually traumatic (see Chapter 45) and are only rarely (about 1%) osteochondrosis lesions. Unlike the traumatic fractures, lateral malleolar osteochondritis dissecans lesions have irregular diffuse radiolucency within the malleolus instead of a distinctly separated fragment. Arthroscopic debridement of lateral malleolar osteochondritis dissecans lesions is difficult because of the extensive collateral ligament attachments that obscure the structure.

Arthroscopic removal of osteochondritis dissecans lesions from the hock usually can be followed by a short convalescence and rapid return to work. Typically a horse is walked by hand for 4 to 6 weeks and then re-evaluated. If the effusion has resolved and the horse is jogging soundly, the level of exercise can be increased steadily. Intra-articularly administered hyaluronan is given at about the time of suture removal.

Most horses with osteochondritis dissecans of the hock have an excellent prognosis, especially if lesions are removed early, before substantial damage to the joint occurs. The specific location of the osteochondritis dissecans probably makes less difference than the size, because most hock osteochondritis dissecans lesions occur on the peripheral, less than

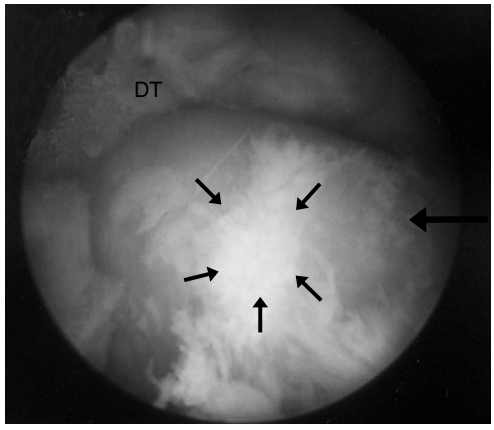

Fig. 58-9 Unlike in most other joints in the horse, full-thickness cartilage erosion of the talus (medial trochlear ridge, *large arrow*) and distal tibia *(DT)* occurs with surprisingly few bony changes such as subchondral lysis or marginal osteophytes. Arthroscopy affords the best means of making the diagnosis. The medial trochlear ridge is nearly devoid of cartilage except for loose and fibrillated cartilage on its summit *(small arrows)*.

fully weight-bearing surfaces of the bones. Controversy remains about the need to remove all hock osteochondritis dissecans lesions, but clearly horses have an excellent (>80%) chance of performing at the expected level after arthroscopic removal of typical lesions.[7-9]

The tarsocrural joint appears to be particularly vulnerable to a form of erosive arthritis that can result in extensive, full-thickness loss of articular cartilage (Fig. 58-9). This occurs in the absence of known trauma or radiographically evident lesions, but most horses with the lesion have a history of intra-articularly administered corticosteroids used to manage an effusion. The exact mechanism of this process in the tarsocrural joint is not known, but corticosteroids should be used cautiously to manage effusions of this joint.

LESIONS OF THE STIFLE

Diagnosis and management osteochondrosis of the femoropatellar joint, subchondral bone cysts in the medial femoral condyle, and other osseous cyst-like lesions are discussed in detail in Chapter 47.

CHAPTER • 59

Physitis

David R. Ellis

Physitis occurs in the horse in three principal forms: infectious physitis and type V and type VI Salter-Harris growth plate injuries.[1] Type V growth plate injury can arise secondary to congenital but persistent angular limb deformities in foals, but these, infections, and type VI injuries are not considered in this chapter. Type V Salter-Harris injuries are considered a manifestation of acquired physitis, one of the group of disorders known as *developmental orthopedic disease*.[2] The inclusion of acquired physitis under the umbrella of osteochondrosis may be more debatable. Jeffcott[3] considered that the condition was better defined as physeal dysplasia, implying a disturbance of endochondral ossification rather than an inflammatory condition. Bramlage[4] outlined two forms of physitis based on radiographic interpretation of the site at which changes were seen. The two forms were those that were seen at the periphery, usually on the medial aspect, and those that were seen in the axial or central section of the growth plate.

Physitis is largely confined to the lighter-boned, faster-growing breeds of horse, particularly Thoroughbreds and Thoroughbred crossbreeds. Milder physitis is relatively common, and rarely does experienced stud management

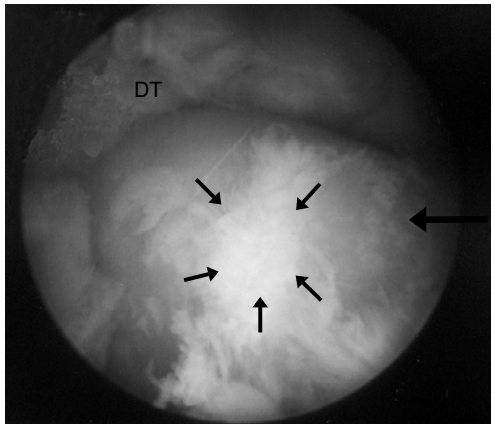

Fig. 58-9 Unlike in most other joints in the horse, full-thickness cartilage erosion of the talus (medial trochlear ridge, *large arrow*) and distal tibia *(DT)* occurs with surprisingly few bony changes such as subchondral lysis or marginal osteophytes. Arthroscopy affords the best means of making the diagnosis. The medial trochlear ridge is nearly devoid of cartilage except for loose and fibrillated cartilage on its summit *(small arrows)*.

fully weight-bearing surfaces of the bones. Controversy remains about the need to remove all hock osteochondritis dissecans lesions, but clearly horses have an excellent (>80%) chance of performing at the expected level after arthroscopic removal of typical lesions.[7-9]

The tarsocrural joint appears to be particularly vulnerable to a form of erosive arthritis that can result in extensive, full-thickness loss of articular cartilage (Fig. 58-9). This occurs in the absence of known trauma or radiographically evident lesions, but most horses with the lesion have a history of intra-articularly administered corticosteroids used to manage an effusion. The exact mechanism of this process in the tarsocrural joint is not known, but corticosteroids should be used cautiously to manage effusions of this joint.

LESIONS OF THE STIFLE

Diagnosis and management osteochondrosis of the femoropatellar joint, subchondral bone cysts in the medial femoral condyle, and other osseous cyst-like lesions are discussed in detail in Chapter 47.

CHAPTER • 59

Physitis

David R. Ellis

Physitis occurs in the horse in three principal forms: infectious physitis and type V and type VI Salter-Harris growth plate injuries.[1] Type V growth plate injury can arise secondary to congenital but persistent angular limb deformities in foals, but these, infections, and type VI injuries are not considered in this chapter. Type V Salter-Harris injuries are considered a manifestation of acquired physitis, one of the group of disorders known as *developmental orthopedic disease*.[2] The inclusion of acquired physitis under the umbrella of osteochondrosis may be more debatable. Jeffcott[3] considered that the condition was better defined as physeal dysplasia, implying a disturbance of endochondral ossification rather than an inflammatory condition. Bramlage[4] outlined two forms of physitis based on radiographic interpretation of the site at which changes were seen. The two forms were those that were seen at the periphery, usually on the medial aspect, and those that were seen in the axial or central section of the growth plate.

Physitis is largely confined to the lighter-boned, faster-growing breeds of horse, particularly Thoroughbreds and Thoroughbred crossbreeds. Milder physitis is relatively common, and rarely does experienced stud management

allow the condition to develop far enough for severe lameness and conformational changes to occur. Only in horses with more extreme or persistent physitis would radiographic examination be undertaken in the United Kingdom. Clinical recognition of enlargement of the growth plate or slight change in conformation usually presumes a diagnosis of physitis and indicates an immediate change of the horse's management as the first line of treatment.

PATHOGENESIS

I consider the pathogenesis of physitis to be consistent with a type V Salter-Harris growth plate injury. This implies a compression lesion that arises medially as a consequence of the greater weight being borne on the medial aspect of the forelimb. Although the medial aspect of the forelimb is the most frequent site, physitis also occurs laterally in a foal with a carpal valgus deformity. Physitis arises at a time in the most active growing phases of young horses, when endochondral ossification is at its peak in the affected physis. It also occurs in the contralateral limb after a chronic lameness, at the fetlock in the younger foal, or the carpus in older foals and yearlings. For example, I have encountered physitis in the contralateral forelimbs of foals with severe acquired flexural deformity of the distal interphalangeal joint (Fig. 59-1). Although physitis may result in an upright conformation of the fetlock joint, probably from off-loading the limb to relieve pain, physitis does not cause other flexural deformity.

Physitis is more common on farms that use rigorous or heavy feeding programs. Owners whose stock live on lush pasture and are supplemented with concentrate feed have a higher incidence of physitis among their horses than those who keep their horses on leaner management. A higher incidence of developmental orthopedic disease is noted in foals and yearlings raised on young (<7 years old) pastures.

I have seen balanced mineral supplementation and withdrawal of concentrates dramatically reduce the incidence of physitis on some farms. Diet and forage analysis can be helpful where high incidence of developmental orthopedic disease is persistent (see Chapter 57), but mineral clearance ratios (creatinine phosphate in particular) are rarely necessary to adjust supplementation. Certain mares may also produce more foals with physitis compared with similarly managed mares, which implies a hereditary predisposition.

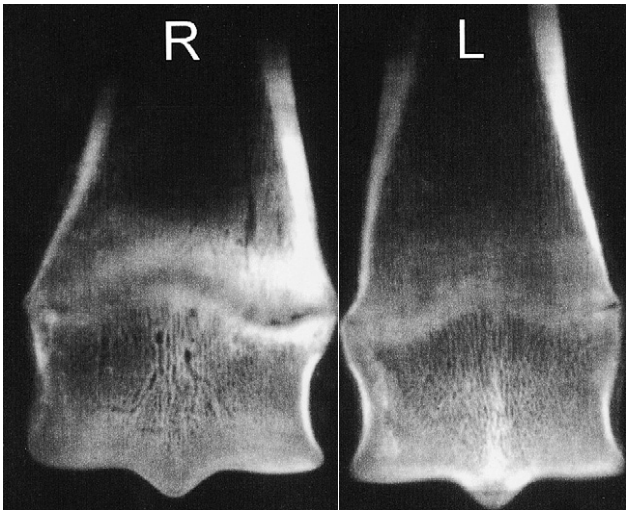

Fig. 59-1 Dorsopalmar radiographic view of frontal sections of the distal third metacarpal bones of a 5-month-old foal with chronic and severe flexural deformity of the left *(L)* distal interphalangeal joint and physitis in the contralateral distal metacarpal physis *(R)*. Note the more intense calcification of the growth plate cartilage and bridging at the medial aspect of the right forelimb, typical of Salter-Harris type V growth plate injury.

CLINICAL SIGNS

Clinical physitis is recognized at three main sites: the distal cannon (metacarpal or metatarsal growth plates), the distal radius, and, less frequently, the distal tibia. During lameness investigations, physitis has been noticed at other sites, such as the distal femur and cervical vertebrae.

Physitis is seen in the fetlock region between the ages of 3 and 6 months and occurs at the distal radius from 8 months to 2 years of age. Clinical signs are characterized by firm, warm, and painful enlargement of the growth plate, most commonly on its medial aspect. The proximal physis of the proximal phalanx also may be enlarged at the fetlock, giving the fetlocks an hourglass shape when viewed from the cranial aspect (Fig. 59-2). Early signs at the distal radial or tibial growth plates include a convex appearance in the medial contour of the metaphysis just proximal to the physis: this should be a straight or slightly concave outline. Swelling also is located around the dorsomedial aspect of the distal radius (Fig. 59-3). This dorsal component can lead the clinician to suspect that the condition has arisen from external trauma. As with the fetlock joint, there is warmth on palpation and tenderness when pressure is applied across the growth plate while the leg is held partially flexed. Full and forced flexion of the fetlock, carpus, or tarsus also may be resented. Most affected horses have changes at the distal medial radius, but a few with pre-existing carpus valgus conformation may develop the condition laterally. Bilateral lameness may be seen as a stilted gait. The conformation may become more upright through the pastern, and fetlock varus deformity may develop

Fig. 59-2 Physitis of the right distal third metacarpal bone (growth plate), with some involvement of the proximal physis of the proximal phalanx, giving the fetlock an hourglass shape.

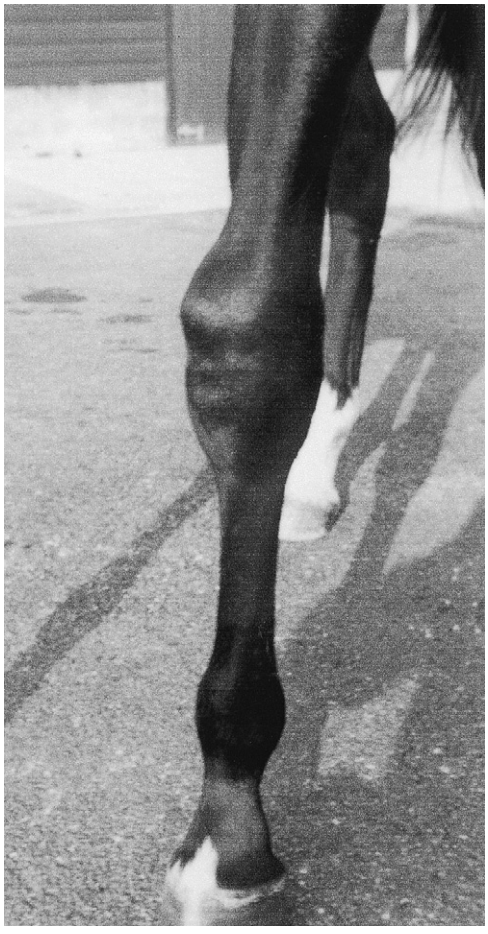

Fig. 59-3 Dorsal view of a left forelimb; lateral is to the right. Physitis of the left distal radial growth plate with characteristic dorsomedial swelling and concavity of the outline of the distal medial metaphysis.

because the horse walks on the outside of the hoof to alleviate pain from pressure on the medial physis. I suspect that foals and yearlings that develop a carpus varus conformation (start to go bandy) are likely to have a subclinical form of physitis that encourages them to bear more weight on the lateral aspect of the forelimbs. If physitis continues unchecked, growth ceases on the medial side, exacerbating the carpus varus deformity, and ultimately, premature closure of the growth plate fixes the abnormal conformation. This chain of events also occurs in horses that develop physitis in the lateral aspect of the distal radius, resulting in a permanent carpus valgus conformation.

TREATMENT

Treatment centers on stable rest. Non-steroidal anti-inflammatory drugs can be helpful, particularly in horses that are very lame or have inflamed and painful growth plates. I have no experience of using corticosteroids or anabolic steroids in horses with physitis. Although body condition and conformation can vary, it is important to assess the nutrition of affected foals and other horses. Reduction of body weight and particularly a reduction in energy content in the diet must be made. Starving these horses completely is unwise, and it is important that mineral intake includes the correct balance of calcium and phosphorus and adequate copper and zinc. The length of rest required varies with the severity of the physitis and is between 2 weeks and 2 months. Corrective hoof trimming must also be undertaken, especially if the horse has developed an angular limb deformity (see Chapter 60). For varus deformity the unworn medial hoof wall must be removed (inside is lowered), and if the angulation is severe, fitting a lateral hoof extension is necessary.

Surgery usually is unsuccessful in horses that develop severe varus limb deformity resulting from physitis. This experience, coupled with the disappointing results obtained when operating on yearlings with congenital angular deformities, has led me to stop recommending periosteal elevation or physeal retardation techniques in these groups of affected horses.

The prognosis for racing or other extreme athletic activities is good, provided the condition was not so severe that the conformation is permanently affected. If carpus varus and bench-knee conformation is significant, then the animal is likely to suffer lameness from splints, carpitis, sesamoiditis, or suspensory branch desmitis when more serious training is undertaken.

CHAPTER • 60

Angular Limb Deformities

DIAGNOSIS AND CONSERVATIVE MANAGEMENT

• Eric J. Parente

Angular limb deformities are considered lateral or medial deviations to the long axis of the limb in the frontal plane. A lateral deviation distal to the carpus, termed *carpus valgus*, is the most common. Tarsus valgus and fetlock varus (a medial deviation) are the next most common, respectively. The toed-in or toed-out appearance that often accompanies an angular deformity is a concurrent rotational deformity and should not be confused with the angular deformity. An outward (external) rotation is usually observed concurrently with a valgus deformity and an inward (internal) rotation is seen with a varus deformity. No confirmed breed or sex predilection is known, but subjectively there may be some genetic predisposition. For a foal to be born with a mild bilateral carpal valgus and toed-out appearance is considered normal by many clinicians, and as the foal grows and the chest widens, the limbs straighten progressively.

Angular limb deformities usually are congenital, but they can be developmental, and have numerous causes. An acquired angular deformity is defined as worsening or failure of correction of the normal slight carpus valgus conformation in the neonatal foal. The cause and the severity and progression of the deformity are vital pieces of information that should be acquired before formulating a treatment plan. Treatment is predicated by these factors. Foals are like molding plastic. The conformation changes slowly with growth. Genetics, nutrition, amount of exercise or weight bearing, and veterinary interventions all influence the conformation of the adult horse. Some of these factors can be influenced as the animal matures and often small adjustments need to be made to the treatment plan as the animal grows. The foal should always be evaluated with the amount of remaining growth in mind and not just its present status. Because the greatest impact on conformation is made during periods of rapid growth, early recognition and regular re-evaluations are extremely important to achieve a positive outcome.

Growth rates are most rapid in the neonate and slow considerably within the first year. Most of the growth from the distal radial and tibial physes is within the first 6 months of age. Most of the growth from the distal third metacarpal (McIII) and metatarsal (MtIII) bones is within the first 3 months of age. Minimal changes take place beyond these times. Radiography alone cannot be used to determine the end of bone growth, because the physis is radiographically apparent long after clinically relevant growth has abated. A normal foal should correct a carpus valgus to within 5° to 7° of normal by 4 months of age and should be almost straight by 8 to 10 months of age.

EXAMINATION OF THE FOAL

It is critical to determine the extent and cause of the deformity before developing a management plan. Foals should be examined while standing and walking and also by radiography. Occasionally foals are assessed in lateral recumbency.

Deformities can be assessed subjectively by visual examination. The foal should stand as squarely as possible, with the foot directly below the proximal part of the limb. Deviations from this stance exacerbate any deformities that truly exist. Because most foals only stand still transiently, repositioning the foal several times to evaluate each limb independently is often necessary. This allows observation of how the foal stands most frequently in a relaxed position. The clinician stands directly in front of the dorsum of the long bones for evaluation of the forelimbs, not necessarily at the front of the toe. The orientation of the toe may be affected by a concurrent rotational deformity, which confounds interpretation. Hindlimbs should be evaluated similarly but directly from behind. The forelimbs can also be evaluated by standing shoulder to shoulder with the foal, looking down the limb toward the ground.

All limbs also should be evaluated with the foal walking away from and toward the clinician. Breakover is determined for each foot, which may be helpful in deciding the most appropriate way to manage the foal. The entire assessment of a foal should be graded and recorded on video or on paper for future reference.

Radiography provides an objective assessment of angular deformity, but sequential radiography may be unreliable if the obliquity varies. Differences in radiographic projection can result in a misinterpretation of worsening or improvement, which is particularly true when trying to quantify small differences in the angle. Long, narrow (18 × 43 cm) cassettes should be used to measure the angle of the deformity, by evaluating the intersection of a line representing the long axis of the proximal and distal long bones from the joint in question. This is more accurate in the carpus and fetlock than the tarsus. Radiography is essential to identify cuboidal injury or malformation. Such a deformity dramatically worsens the foal's prognosis. Foals with angular deformity resulting from cuboidal bone abnormalities usually have compromised range of motion, but this often is detected best with the foal in lateral recumbency.

PERI-ARTICULAR LAXITY

Peri-articular laxity is the major cause of congenital angular limb deformities and often improves dramatically within the first 4 weeks of life, without any intervention, as the peri-articular tissues become less elastic. The improvement is most dramatic in a windswept foal, which has a tarsus valgus of one limb and a concurrent varus of the other. Limited exercise is all that is required for these foals to become normal.

Infrequently the deformity can be so severe, particularly in the fetlock, that the foal is unable to bear weight on the sole of its foot. Immediate treatment is required to establish normal weight bearing. Custom-made glue-on shoes are particularly useful to prevent abnormal breakover and to keep the foot flat on the ground. If the foal has excessive laxity of the lateral collateral ligaments and a tendency to break over on the lateral side of the foot, a lateral extension shoe is used

to maintain appropriate alignment of the limb. The foal should initially be restricted to a stall before turnout in a small paddock or round pen with just the mare. Soft tissues become progressively stronger, and normal activity can be permitted within a relatively short time. Allowing premature excessive exercise can lead to proximal sesamoid bone fractures (see Chapter 37) and other injuries. Glue-on shoes are usually required for several weeks, but they then should be removed to avoid contracture of the foot. External coaptation also should be avoided if possible. Splints are used only to maintain joint alignment if absolutely necessary. Splints are contraindicated to try to pull or push a limb straight. Rigid support from a splint or cast usually leads to greater soft tissue laxity. Trying to support a limb results in continued laxity and soft tissue wounds from bandaging. Every foal must be managed on an individual basis with the goal of achieving normal weight bearing and function while providing the minimal amount of support necessary.

ASYMMETRICAL PHYSEAL GROWTH

Asymmetrical growth of a distal physis is a cause of angular limb deformity. Greater growth from the distal physis of the radius medially compared with growth laterally results in carpus valgus. Continued asymmetrical growth precludes the normal correction anticipated with resolution of peri-articular laxity. Greater growth from the lateral distal physes of the McIII or MtIII bones results in fetlock varus. With time and limited exercise (stall or small paddock turnout, alone with the mare) substantial self-correction occurs for most foals with angular deformities. Radiography can be used to evaluate objectively the degree of deformity and the difference in physeal growth, but it is not always required.

Fetlock varus is often overlooked and affects the left hind fetlock most commonly, possibly because of in utero positioning. Because growth at the distal physis of McIII and MtIII bones terminates within a few months, early recognition of this deformity is critical.

TRAUMA-RELATED DEFORMITIES

Developmental causes of angular deformities are likely secondary to excessive or asymmetrical weight bearing and can be more serious than congenital abnormalities. Incomplete ossification of the cuboidal bones in a foal can result in cuboidal bone crush and a secondary angular limb deformity. The lateral carpal bones most commonly are affected, resulting in carpus valgus. Although the deformity is clearly apparent, the health and function of the joint is most critical. The carpi and tarsi of any premature or dysmature foal should be examined radiographically. Because ossification is incomplete, abnormal cuboidal bones appear round or in other shapes and, if crushing exists, the bones are wedge shaped, overlap opposing bones, or are fractured. If the foal's activity can be managed strictly in a hospital situation, no further support is recommended. Limited, strictly controlled exercise encourages appropriate ossification. If the foal's activity cannot be strictly managed and the foal has moderate strength, sleeve casts are recommended to prevent cuboidal bone crush. Sleeve casts should be changed or removed in 10 to 14 days in a growing foal. Radiographic re-evaluation every 2 weeks helps determine the length of time a cast is required.

Foals can also develop angular limb deformities secondary to lameness in the contralateral limb. If foals become non–weight bearing on a single limb, they adopt a tripod-like stance by bringing the contralateral limb more medial and toeing in. Over several weeks this results in asymmetrical bony growth of the non-lame limb and varus deformity of all joints, with internal rotation of the distal limb. A dorsolateral toe extension can be placed on the foot of the non-lame limb to try to encourage a more abducted stance, but resolution of the primary lameness is the best way to prevent the contralateral limb deformity from occurring. Once the deformity has occurred, correction is improbable.

CONSERVATIVE MANAGEMENT

In most situations, judicious minimal intervention is all that is required to correct angular limb deformities. This includes limited small paddock exercise and careful attention to the foot. Trimming the foot and using shoe extensions can influence a foal's ability to self-correct an angular limb deformity by affecting the weight bearing and tracking of the limb. A foal younger than 4 months of age with mild carpus valgus likely requires no specific intervention. A foal with a moderate carpus valgus, toed-out appearance would benefit from shoes with dorsomedial extensions. This encourages the foal to adduct the limb and turn in more when breaking over. The result is more physiologically normal strain on the limbs, which should result in a straighter limb. A similar external appearance can be achieved by over-trimming the lateral hoof wall, but the effect is not the same. Although trimming the foot in this manner may give the appearance of an immediate benefit, it may have a negative long-term effect of an unbalanced foot, compensating for a limb with a deformity. This method has, however, been used for years with apparent success.

More aggressive intervention is infrequently required. Surgical intervention should be reserved for those foals that are not improving fast enough for the amount of growth potential remaining. Therefore it is critical for frequent re-evaluation of a foal with an angular limb deformity to monitor progress. Surgical intervention has a greater effect on a young foal because of the more rapid growth; thus early surgical intervention should be considered for a foal with a severe deformity.

SURGICAL MANAGEMENT

• José García-López

A high proportion of foals with angular limb deformities are treated successfully conservatively, but surgical intervention is warranted if a deviation is severe, or if deformity persists despite adequate management, including restriction of exercise and corrective farriery. A variety of surgical techniques aimed at accelerating or decreasing the growth on a particular side of the growth plate have been described.[1-6] Surgical technique depends on the age of the horse, the degree of angular limb deformity, the anatomical site, and whether the deformity is varus or valgus (Figs. 60-1 and 60-2).

Before surgery, all the limbs should be assessed from the front, back, and while standing next to the limbs. Good-quality radiographs, which include a substantial length of the bones proximal and distal to the deviation, should be obtained to assess bone structure (Fig. 60-3) and to determine the pivot point and pivot point angle of the deviation. The pivot point is the intersection of two lines drawn parallel to the long axis of the bones proximal and distal to the articulation in question (Fig. 60-4). The pivot point indicates the origin of the deviation and helps to determine whether the cuboidal bones, in the case of the carpus and tarsus, are involved in the deviation, or if deviation is caused by disproportionate physeal growth only. Abnormalities in the structure of these bones can

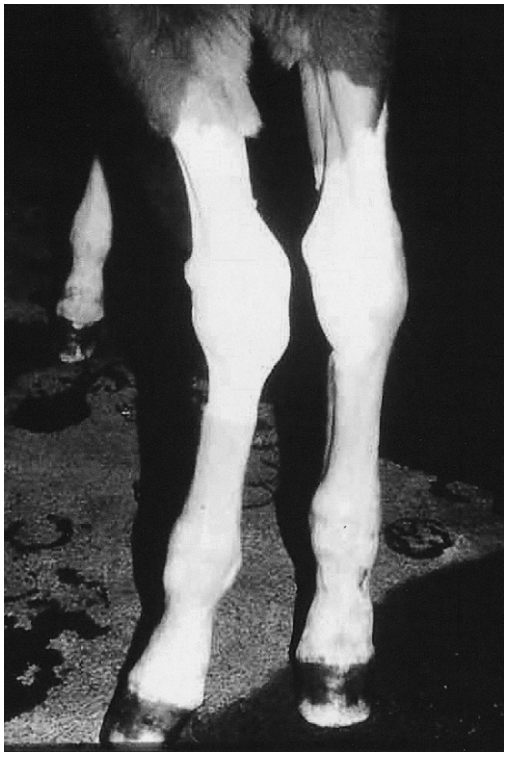

Fig. 60-1 Frontal view of a foal with right carpus valgus.

The point where these lines intersect is known as the pivot point (*PP*), and the angle between them is the pivot point angle (*PPA*).

have a substantial influence on the effect of the procedure and the future athletic potential of the horse. The pivot point angle is the angle formed by the intersection of these two lines and indicates the severity of the condition.[7]

Hemicircumferential periosteal transection and elevation, or periosteal stripping, aims to accelerate growth on the concave side of the limb, laterally for valgus and medially for varus deformities.[1] Previous work on chicken radii had shown that a circumferential division of the periosteum, rather than a longitudinal one, resulted in increased bone growth. The proposal was that the periosteum functioned as a fibroelastic tube, which spanned the diaphysis and provided an even tension between both epiphyses, that was responsible for the regulation of growth.[1,8] A horizontal or circumferential division of the periosteum would result in a release of tension at the level of the growth plate, resulting in the induction of new bone production on the side of the division.

The procedure has been thoroughly described.[4-6] Hemicircumferential periosteal transection and elevation is performed with the foal in lateral recumbency under general anesthesia, with the concave side of the affected limb uppermost. If the procedure is going to be performed bilaterally, dorsal recumbency is recommended. The position of the physis is identified using a 20-gauge needle. For a carpus valgus deformity, a 4- to 6-cm longitudinal incision is made between the common and lateral digital extensor tendons starting just proximal to the physis. The incision is extended through to the periosteum. Using a curved scalpel blade (No. 12), a horizontal incision is made 1 to 2 cm proximal and parallel to the physis, at the distal end of the initial incision (parallel to the skin incision) forming an inverted T. The periosteal flaps are elevated with the aid of a periosteal elevator and then allowed to return to the normal position. It is important to transect the remnant of the ulna, or if the ulna is ossified, it should be removed with the aid of rongeurs. In foals with hindlimb tarsus valgus the veterinarian should bear in mind that a fibular remnant may be present. The incision is closed routinely and the area is bandaged for 10 to 14 days. The foal is kept in a large stall or small paddock until the deformity has been corrected.

Hemicircumferential periosteal transection and elevation has been reported to exert its effects for up to 2 months, but the procedure can be repeated if further correction is needed.[4] There are no reports of over-correction of the deformity. Early reports suggested approximately an 80% success rate[1,3]; however, more recent work indicates less favorable results.[9-11] A large retrospective study in Thoroughbred racehorses investigated racing performance after hemicircumferential periosteal transection and elevation.[9] A lower percentage of treated horses were able to start a race and had a lower starts percentile ranking number compared with half-siblings. Most of the foals appeared to respond favorably to hemicircumferential periosteal transection and elevation based on external appearance of the limbs, but pre-existing conditions, such as abnormal cuboidal bone formation from incomplete ossification or osteoarthritis secondary to abnormal loading of the limb before correction, may have influenced subsequent performance.

Angular limb deformities are probably the most common orthopedic problem affecting Thoroughbred foals.[9,12] Early surgical intervention was previously recommended to take maximum advantage of the growth potential of the physis, to try to provide foals with excellent conformation, and to enhance sale value and possibly potential performance. Based on current knowledge, it now seems likely that a large number of foals with mild angular limb deformities underwent unnecessary surgery. The reported success for correction of angular limb deformities, particularly in the carpus, after hemicircumferential periosteal transection and elevation has been recently challenged. Foals suffering from carpus valgus that underwent hemicircumferential periosteal transection and elevation were no more likely to improve compared with those managed with stall rest and corrective farriery.[10,11] Although the efficacy or need to perform hemicircumferential periosteal transection and elevation when treating foals with mild to moderate carpus valgus deviations is a matter of current debate, the same cannot be said necessarily in other regions of the limb, such as the tarsus and fetlocks, without further investigation.

Transphyseal bridging is performed on the convex side of a deformity to decrease the growth rate on that side of the physis. Traditionally, transphyseal bridging has been performed in young foals with severe deformities or in foals in which most of the growth in a particular physis has subsided. Transphyseal bridging has been performed successfully using cortical screws with cerclage wire in a figure of eight, with a small dynamic compression plate, or with orthopedic staples.[4-6]

The foal is positioned in lateral recumbency under general anesthesia, with the convex side of the affected limb uppermost, or in dorsal recumbency. The position of the physis is identified and checked radiographically using a 20-gauge needle inserted into the physis. Stab incisions are made for placement of cortical screws and cerclage wire; one incision is made in the center of the epiphysis and the other approximately 2 cm proximal to the physis. Once the subcutaneous tissues between both incisions have been bluntly dissected, a 4.5- or 3.5-mm cortical screw is placed through each incision, slightly angled toward the physis. Screw size depends on the size of the foal, but 4.5-mm screws are preferred. Before complete tightening of the screws, a loop of 18-gauge wire is fed through the proximal incision and positioned around the distal screw head. The wire is then tightened over the proximal screw head, forming a figure of eight. Once the wire is tightened, the screws are tightened and the incisions are closed routinely. When performing this procedure in the distal tibia, the clinician should be aware of the contour of the tarsocrural joint, because placing the epiphyseal screw into the joint is possible. The screw should be angled more sharply toward the physis than in the distal radius. Post-operatively the foal should be kept in a large stall and monitored closely. Follow-up radiographs are strongly recommended to assess the amount of correction. Prompt removal of the implants is essential, because over-correction of the deformity is possible.

In foals and young horses with an angular limb deformity that persists after physeal closure, corrective ostectomy or osteotomy can be performed. A step ostectomy (sagittal plane) or step osteotomy (frontal plane) are preferred to closing wedge ostectomy, because limb length is preserved and interfragmentary compression between the bone pieces is better.[4] These techniques are generally considered to be a salvage procedure.

Tarsus valgus deformities frequently go unrecognized by both owners and veterinarians, possibly from lack of observation of the foal from behind and the inherent offset position of the tarsus.[13,14] Early recognition and sometimes more aggressive surgical management of tarsal angular limb deformities are critical to achieve satisfactory results. Although the distal tibial physis has a tremendous growth rate until 4 months of age, foals younger than 2 months of age responded more favorably to hemicircumferential periosteal transection and elevation than older foals. Transphyseal bridging was more effective than hemicircumferential periosteal transection and elevation, especially in foals older than 2 months of age.[13] This is a significant change from the previous perception that hemicircumferential periosteal transection and elevation alone was adequate when managing most tarsus valgus deformities in foals 4 to 6 months of age. Early recognition of incomplete ossification of the tarsal bones (Fig. 60-5) is crucial, because the condition, if unrecognized, leads to collapse of the third or central tarsal bones,

Fig. 60-5 Lateromedial radiographic view of neonatal tarsus with incomplete ossification of the tarsal bones.

resulting in osteoarthritis.[13,14] Of 22 foals with incomplete ossification of the tarsal bones, 73% had tarsus valgus deformities. Only 32% of the foals were able to reach the intended use.[14]

CHAPTER • 61

Flexural Limb Deformity in Foals

Robert J. Hunt

Flexural limb deformity is the inability to extend a limb fully. Generally hyperflexion of a region results from a disparity in the length of the musculotendonous unit relative to the length of the bone. The deformities are categorized as congenital or acquired and may occur during in utero development or at any time after birth. Different anatomical structures may be involved including the flexor tendons, suspensory apparatus, joint capsule, and surrounding fascia, skin, and bone.[1-6]

CONGENITAL FLEXURAL DEFORMITY

Congenital deformities are present at birth and the cause is often unknown. Although uterine malposition of the fetus is often discussed, because of the voluminous nature of the uterus and the ability of the foal to move, uterine malposition is an improbable cause of flexural deformity in most instances. Other documented causes include exposure of the mare to influenza or ingestion of Sudan grass, locoweed, or other teratogenic agents during development of the fetus.[2,3,7] Equine goiter, neuromuscular disorders, and defects in elastin formation or collagen cross-linking may be involved in the pathogenesis.

Congenital flexural deformities most commonly involve the carpus, tarsus, metacarpophalangeal and metatarsophalangeal joints singularly or in combination.[2] Both forelimbs are usually involved and occasionally other variations of skeletal deformities are evident, such as hindlimb deformity (windswept), spinal deformity, rye nose, and cleft palate. Sporadically occurring deformities involving the scapulohumeral, cubital, coxofemoral, or femorotibial joints may occur in combination with other congenital skeletal anomalies. Congenital flexural deformities are a common cause of dystocia in the broodmare, resulting in loss of the foal and subsequent reproductive loss of the mare.

Treatment for congenital flexural deformities varies with the anatomical location involved and severity of the condition. Therapeutic intervention for severe flexural deformities associated with arthrogryposis or gross spinal deformities should be discouraged, and humane destruction is recommended. Surgical transection of the flexor tendons and palmar carpal fascia generally fails to alleviate this deformity. Splinting and casting is also futile, although rare foals have survived with limited athletic potential.

Mild flexural deformity of the carpus or metacarpophalangeal/metatarsophalangeal joints resolves spontaneously if the foal has the ability to stand, nurse, and ambulate on its own. Most foals with mild and moderate deformities respond favorably to physiotherapy, by manually extending the limbs every 4 to 6 hours for 15-minute sessions, or forcing the foal to ambulate (Fig. 61-1). Heavy bandaging, splinting or casting, and the administration of oxytetracycline can be helpful.[2,8] Foals with deformities advanced enough to require assistance to stand respond more rapidly after application of cast, which should be changed every 2 to 3 days (Fig. 61-2). If a carpal deformity severe enough to prevent standing is recognized at parturition, the foal should be heavily sedated, within 30 to 45 minutes, and full-leg casts should be applied with the limbs placed in extension. These should be changed within 24 hours and reset. Generally a rapid response is seen after the first or second application of casts. If the foal incurs any complications with the casts or becomes distressed, casts should be removed. Commercially available articulating braces (Almanza Corrective Boot; Agustin-Almanza@usa.net; Equine Bracing Solutions, Trumansburg, NY) are available, which allow adjusting the degree of extension in a specific region of the limb (Fig. 61-3). As with all splints, caution must be exercised to prevent pressure sores. It is important to assist the foal nursing and to provide supportive care in an intensive neonatal facility, because these are high-risk patients for developing complications with other body systems.

Fig. 61-1 Mild bilateral flexural deformity of the carpus. This degree of deformity is self-limiting.

Fig. 61-2 Moderate to severe bilateral flexural deformity of the carpus. This foal required assistance to stand, external coaptation, and oxytetracycline therapy.

Oxytetracycline (2 to 4 g) administered slowly intravenously is also beneficial, but it should not be used in the neonate until serum creatinine is within normal limits.[8] Oxytetracycline may be given daily or every other day for 3 to 4 treatments. Complications of oxytetracycline administration include renal failure, diarrhea, and, most commonly, excessive laxity of other normal joints. The precise mechanism of action for tendon relaxation remains speculative.

Flexural deformity of the distal interphalangeal joint occasionally is seen at birth but is most often self-limiting if the foal can stand without buckling forward. Bandaging of the lower limb and administration of oxytetracycline hastens recovery. If the foot angle is beyond 90° (i.e., the dorsal aspect of the foot is in front of the vertical), casting or splinting may be necessary.

When splints are used, the clinician must exercise extreme caution to prevent rub sores or pressure sores. Splints should only be applied for brief periods, in a schedule such as 4 to 6 hours on, followed by 4 to 6 hours off. Properly applied casts are more effective, require less maintenance, and result in fewer pressure sores than splints.

Prognosis for future performance as an athlete is good for foals with congenital flexural deformities that progressively respond favorably in the first 2 weeks of life. In general, if the foal is able to stand, nurse, and ambulate without assistance, most congenital flexural deformities are self-limiting and foals warrant a good prognosis. Foals may require several months to stop buckling dorsally at the carpus. Foals with flexural deformity of the metacarpophalangeal or metatarsophalangeal joints typically respond within the first or second week of life. Prognosis for future performance is poor for foals with severe flexural deformity of the carpus, tarsus, or metacarpophalangeal/metatarsophalangeal joints that show no improvement after several days of treatment and have difficulty ambulating without assistance after 1 to 2 weeks of treatment. Foals with congenital flexural deformities involving the scapulohumeral, cubital, coxofemoral, or femorotibial joints have a poor prognosis for future athletic performance.

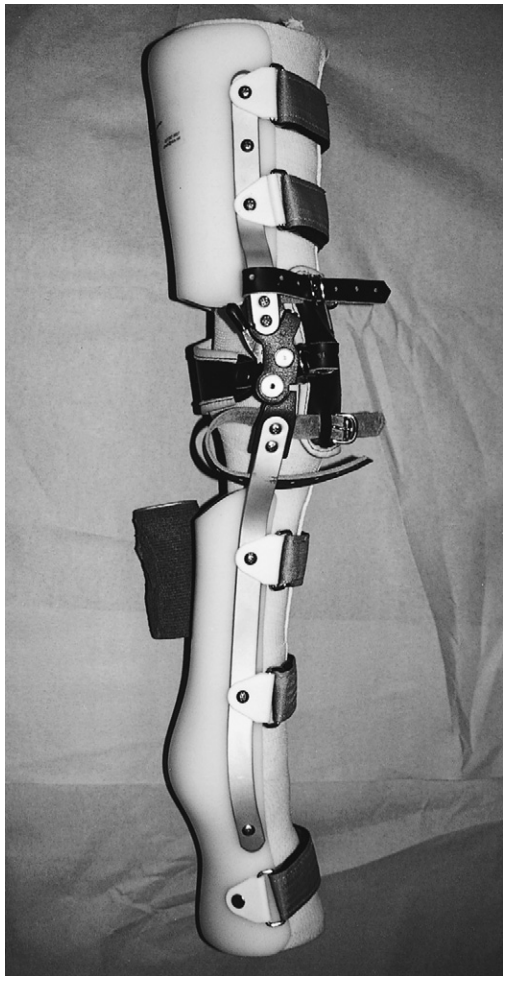

Fig. 61-3 Articulating brace used in foals with flexural deformity of the carpus and the metacarpophalangeal joint.

ACQUIRED FLEXURAL DEFORMITIES

Acquired flexural deformities develop after birth until the second year of life. Commonly involved areas include the distal interphalangeal joint, metacarpophalangeal joint, and carpus. Acquired flexural deformity of the distal interphalangeal joint is recognized between 3 and 6 months of age, carpal flexural deformity is seen between 1 and 6 months of age, and flexural deformity of the metacarpophalangeal joint is recognized later during the yearling or early 2-year-old year (9 to 18 months).[9]

Common causes for flexural deformity of the metacarpophalangeal joint and carpus are believed to include a genetic propensity for rapid growth, over-nutrition, and pain. Relative excess feeding or over-assimilation of nutrients in foals that have an inherent potential for rapid physical development is a frequent finding in foals with acquired flexural deformity, especially involving the carpus and the metacarpophalangeal joint. During periods of rapid bone lengthening the potential for passive elongation of the tendonous unit is limited because of the accessory ligaments and a discrepancy in the length of the bone to tendon unit may result. Another theory is that a pain-mediated response during physeal dysplasia results in altered load bearing on the limbs. This is believed to initiate secondary contraction and shortening of the musculotendonous unit, resulting in limited extension of a region. Any cause of pain resulting in prolonged reduced weight bearing in a limb may result in this syndrome.

Fig. 61-4 **A,** Advanced flexural deformity of the distal interphalangeal joint. The foal's heels do not contact the ground, and the dorsal hoof wall is dish shaped. **B,** Calf-kneed conformation is associated with a clubfoot.

Genetics may be involved with the development of acquired flexural deformity of the distal interphalangeal joints (clubfeet). Other factors include diet and exercise. Protracted lameness from another cause such as osteochondrosis of the upper limb also predisposes to development of acquired distal interphalangeal joint deformity. It is therefore important to isolate an associated source of lameness.

Early clinical signs of acquired flexural deformity of the distal interphalangeal joint consist of a prominent bulge at the coronary band, increase in length of the heel relative to the toe, and failure of the heels to contact the ground after trimming (Fig. 61-4, *A*). Eventually the foot develops a boxy shape with a dish shape along the dorsal hoof wall. This deformity is commonly accompanied by a back-at-the-knee (calf-knee) conformation (Fig. 61-4, *B*).

Treatment for foals with acquired flexural deformity of the distal interphalangeal joint initially entails exercise restriction, frequent lowering of the heels, dietary restrictions, and pain control with non-steroidal anti-inflammatory drugs such as flunixin meglumine. Weaning the foal may be advantageous. If the toe becomes excessively worn, constructing a cap over the toe with one of the commercially available hoof composites may aid in protecting the toe and dorsal sole from bruising and may temporarily serve as a lever arm. Although elevating the heel with a wedge shoe or pad provides comfort for the foal, the deformity gradually worsens and eventually obtaining a normal angle and shape to the hoof is difficult. Glue-on shoes should likewise be used with caution, because they tend to promote a box shape to the foot. Oxytetracycline may be used but exacerbates the back-at-the-knee conformation.

If no improvement is achieved within 1 to 2 months of conservative treatment, surgical intervention with desmotomy of the accessory ligament of the deep digital flexor tendon (ALDDFT) is recommended. When combined with a trimming program, hoof conformation and function will be much improved. The owner should be made aware of the potential for a blemish at the surgical site.

Foals in which the dorsal aspect of the hoof is in front of the vertical (hoof angle >90°) are candidates for deep digital flexor tenotomy, although desmotomy of the ALDDFT has been helpful in some foals when combined with farriery, oxytetracycline, and phenylbutazone therapy. With deformities of this severity, contracture of the joint capsule and surrounding soft tissues often precludes successful management for an athletic future.

Early treatment of foals with flexural deformity involving the metacarpophalangeal and metatarsophalangeal joints consists of eliminating pain through the use of analgesics, exercise restriction, and correction of any underlying nutritional problems. Any extremes in hoof angle should be corrected and the foot should be trimmed at an angle suitable for that individual. If no improvement is achieved with conservative treatment, desmotomy of the accessory ligament of the superficial digital flexor tendon or of the ALDDFT may be helpful in select instances of moderate deformity. If the underlying cause is not addressed, the benefits of surgery will only be transient. Foals with severe deformity resulting in the limb persistently buckled forward rarely respond favorably to conservative or surgical treatment. Transection of both accessory ligaments or of the superficial digital flexor tendon may provide some improvement in horses with advanced deformity.

Treatment for acquired flexural deformity of the carpus is aimed at eliminating the underlying cause, and if the deformity is recognized early, conservative management is generally effective. The nutritional program (see Chapter 57) and growth

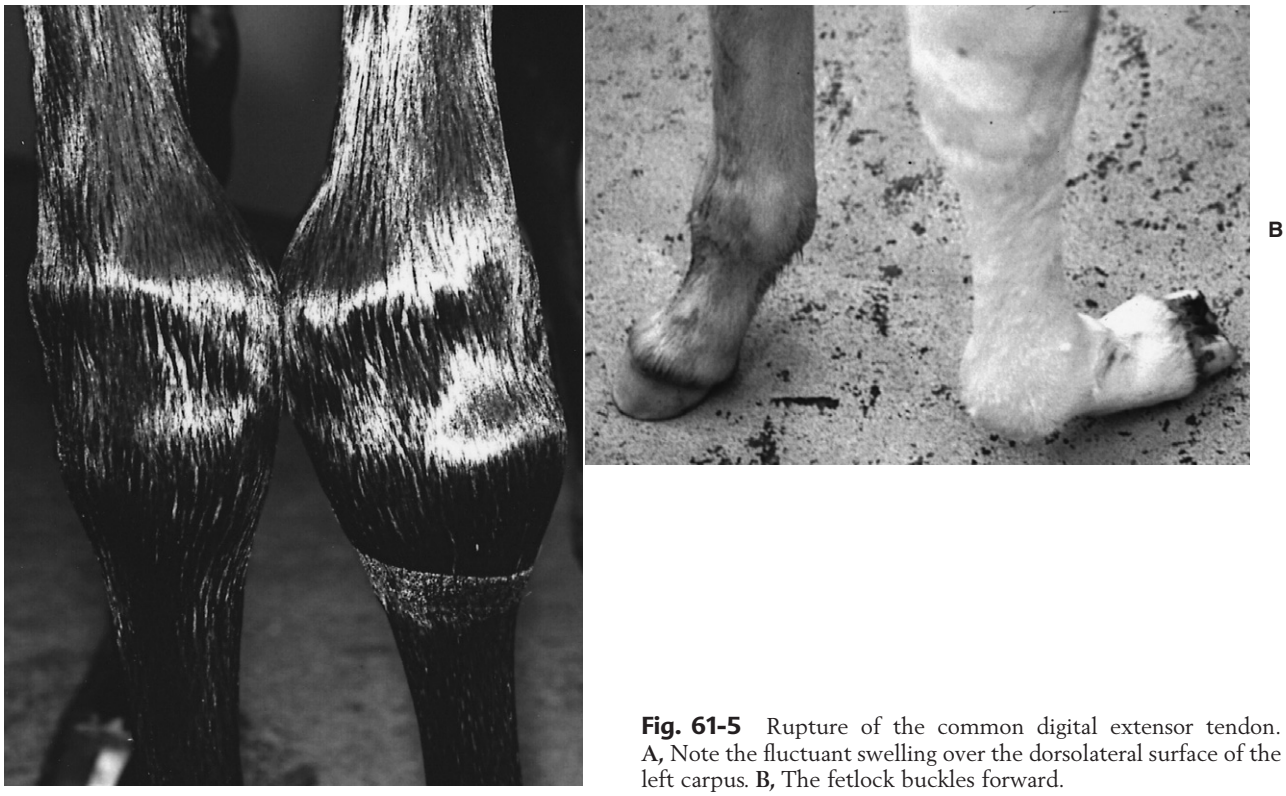

Fig. 61-5 Rupture of the common digital extensor tendon. **A,** Note the fluctuant swelling over the dorsolateral surface of the left carpus. **B,** The fetlock buckles forward.

chart for the foal should be reviewed and errors corrected if found. The nutritional program is often already balanced in some of these foals and treatment is empirical and focused on reducing the energy intake and slowing the growth. Dietary restriction and limitation of turnout schedule and exercise and treatment with non-steroidal anti-inflammatory drugs are currently accepted practice. Grain and other sources high in energy and protein to the mare should be restricted in an attempt to reduce the nutritional quality of the milk and to prevent the foal from ingesting grain while eating with the mare. In foals with severe deformity, limiting access to milk through muzzling the foal and stripping the mare periodically throughout the day may be attempted. However, weaning the foal from the mare to control the diet is generally easier. Acquired carpal flexural deformities may require weeks to months to correct. Splints, bandaging, and oxytetracycline may provide some benefit. These benefits are often short lived if the underlying cause is not addressed.

Rupture of the common or lateral digital extensor tendon is often mistaken for flexural deformity of the metacarpophalangeal joint or carpus because the foal knuckles forward when walking. The disorder may be recognized shortly after birth or generally by 3 to 4 days of life; rarely it may occur in foals up to 3 weeks of age. Diagnosis is based on the characteristic gait of knuckling forward at the fetlock and the presence of a fluctuant swelling over the dorsolateral surface of the carpus (Fig. 61-5). There is usually palpable laxity in the extensor tendons. The limb can be placed in a normal position when the foal is standing. There may be a greater tendency to rupture the extensor tendons in foals with flexural deformities, especially premature contracted foals.

Treatment consists of applying a heavily padded splint over the dorsal or palmar aspect of the lower limb to prevent knuckling forward and traumatizing the dorsum of the pastern and fetlock. Dorsally placed splints are most effective if they do not slip or rotate. Casting may be used but is generally not necessary. Stall confinement is important until the foal develops the ability to use the limb. Foals generally require between 1 week and 2 months of splinting and bandaging before they learn to ambulate properly. The prognosis is invariably good.

CHAPTER • 62

Cervical Stenotic Myelopathy

Bonnie R. Rush

Cervical stenotic myelopathy (wobbler syndrome) is one of the most common spinal cord diseases in young horses. This developmental disorder is characterized by malformation of the cervical vertebrae, stenosis of the vertebral canal, and spinal cord compression.[1] The age of onset is typically 6 months to 3 years, although mature horses (4 to 20 years) are sometimes identified with cervical stenotic myelopathy. Affected horses often demonstrate rapid growth and are more likely to have developmental orthopedic disease of the appendicular skeleton than peers.[2] Male horses are more frequently affected than females by a ratio of 3:1. Cervical stenotic myelopathy has been reported in most light and Draft horse breeds, although Thoroughbreds appear to be particularly predisposed.

CLINICAL SIGNS

Horses with cervical stenotic myelopathy demonstrate upper motor neuron deficits to all limbs, characterized by symmetrical weakness, ataxia, and spasticity.[3] At rest, affected horses may have a base-wide stance and demonstrate delayed responses to proprioceptive positioning. At a walk, weakness is manifested by stumbling and toe dragging. Horses with prolonged clinical signs of cervical stenotic myelopathy may have hooves or shoes that are chipped, worn, or squared at the toe. Ataxia (proprioceptive loss) appears as truncal sway at a walk and is manifested by circumduction and posting (pivoting on the inside limb) of the hindlimbs during circling. Moderate to severely affected horses have lacerations on the heel bulbs and medial aspects of the forelimbs from overreaching and interference. Spasticity, characterized by a stiff-legged gait and decreased joint flexion, is often observed in moderately affected horses. When prompted to back, horses may stand base-wide, lean backward, and drag the forelimbs. In most instances, the hindlimbs are more severely affected than the forelimbs. Occasionally, forelimb ataxia may be more severe in horses with stenosis of the sixth and seventh cervical vertebrae because of compression of the cervical intumescence. The clinical signs of spinal cord compression often progress for a brief period and then stabilize. Owners often report a traumatic incident with the onset of clinical signs of cervical stenotic myelopathy. The traumatic incident may result from mild neurological deficits with the injury exacerbating the clinical signs of spinal cord compression.

Asymmetrical ataxia and paresis may be observed occasionally in horses with dorsolateral compression of the spinal cord caused by proliferative, degenerative articular processes and peri-articular soft tissue structures.[4] Infrequently, clinical signs of nerve root compression are seen, such as cervical pain, atrophy of the cervical musculature, cutaneous hypalgesia, and hyporeflexia of cervical reflexes adjacent to the site of spinal cord compression. These signs are more commonly observed in horses older than 4 years of age with moderate to severe arthropathy of the fifth to seventh cervical vertebrae and result from peripheral nerve compression by proliferative articular processes as the nerve root exits the vertebral canal through the intervertebral foramen.[5]

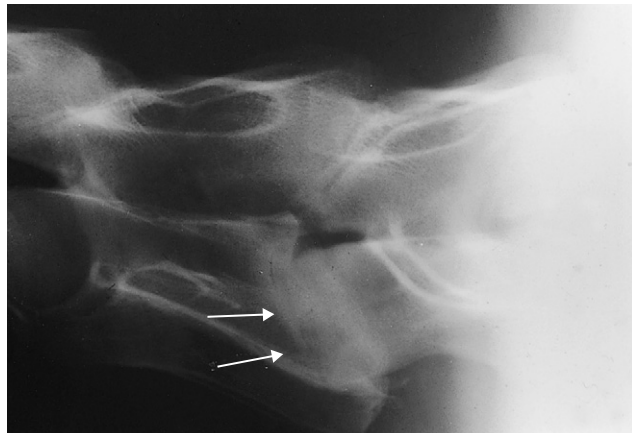

Fig. 62-1 Lateral radiographic view of the caudal neck region of a 4-year-old Paint gelding with cervical pain and spinal ataxia. Cranial is to the left. Note the abnormal intercentral articulation between the sixth and seventh cervical vertebrae *(arrows)*. This represents end-stage diskospondylosis.

In some instances arthropathy of the caudal cervical vertebrae may produce cervical pain and forelimb lameness, caused by peripheral nerve compression, without producing clinical signs of spinal cord compression.[6] Affected horses typically have a short cranial phase of the stride and a low forelimb foot arc and may stand or travel with the head and neck extended (see Chapter 55). Rarely, diskospondylosis of the cervical vertebrae produces a short-strided gait and cervical pain, with or without spinal ataxia (Fig. 62-1). Horses with diskospondylosis or arthropathy of the caudal vertebrae may demonstrate increased rate and depth of respiration with cervical manipulation because of pain.

DIAGNOSIS

Radiographic examination of the cervical vertebrae and cerebrospinal fluid analysis are indicated in horses with symmetrical spinal ataxia. The following neurological disorders should be considered potential differential diagnoses and may produce clinical signs similar to or indistinguishable from cervical stenotic myelopathy: equine protozoal myeloencephalitis (EPM), equine degenerative myeloencephalopathy (EDM), equine herpes virus I myelitis, occipito-atlantoaxial malformation, spinal cord trauma, vertebral fracture, vertebral abscess, and verminous myelitis. Horses with traumatic or infectious cervical vertebral disorders usually demonstrate pain during manipulation of the neck, and the disorders can be differentiated from cervical stenotic myelopathy by standing radiographic examination. Occipito-atlantoaxial malfor-

mation (see Chapter 55) occurs primarily in Arabian horses and is diagnosed definitively by radiographic examination (see Fig. 55-4, *B*). Equine degenerative myeloencephalopathy is a diagnosis of exclusion (unremarkable cerebrospinal fluid [CSF] cytological examination, negative immunoblot analysis for *Sarcocystis neurona*, and negative radiographic and myelographic examination). The veterinarian may suspect EDM during neurological examination (hyporeflexia; forelimbs equally affected to hindlimbs). However, the definitive diagnosis is determined by post-mortem examination. Although most breeds have been reported as having the disease, EDM appears to have a familial predisposition in Standardbred and Appaloosa horses. Horses with equine herpes virus I myelitis may demonstrate urinary incontinence, poor tail tone, and hindlimb weakness. Cytological evaluation of CSF typically reveals xanthochromia and albuminocytological dissociation (high protein, normal cell count) and rising serum antibody titer against equine herpes virus I provides supportive evidence of herpes virus I myelitis. EPM is the most difficult disease to differentiate from cervical stenotic myelopathy. The geographic distribution of EPM is limited to North and South America and to horses exported from these regions. Asymmetrical ataxia, focal sweating, and focal muscle mass loss should direct diagnostic efforts toward EPM. Symmetrical spinal ataxia does not preclude a diagnosis of EPM. EPM-affected horses with symmetrical ataxia are differentiated from those with cervical stenotic myelopathy on the basis of standing radiographic evaluation, CSF immunoblot analysis for *S. neurona*, and myelographic evaluation. It is important to recognize that immunoblot analysis of CSF is frequently positive in horses affected by cervical stenotic myelopathy if they are in a geographic area with a high seroprevalence of EPM. Therefore differentiation of these two conditions should not be determined on the basis of CSF analysis alone. Cytological analysis of CSF is usually unremarkable in horses with cervical stenotic myelopathy, although mild xanthochromia or increases in protein concentration may be observed in horses affected by cervical stenotic myelopathy, with acute spinal cord compression. Myelographic examination is required to confirm a definitive diagnosis of cervical stenotic myelopathy.

Assessment of plain film radiographs of the cervical vertebrae can determine the likelihood of cervical stenotic myelopathy in horses with spinal ataxia.[7] Cervical radiographs should be evaluated for subjective evidence of vertebral malformation and objective determination of vertebral canal diameter. The five characteristic malformations of the cervical vertebrae in horses with cervical stenotic myelopathy are flare of the caudal epiphysis of the vertebral body, abnormal ossification of the articular processes, subluxation between adjacent vertebrae, extension of the dorsal laminae, and osteoarthritis of the articular processes (Fig. 62-2). Osteoarthritis of the caudal cervical vertebrae is the most frequent and severe malformation observed in horses affected by cervical stenotic myelopathy. Nonetheless, degenerative arthropathy occurs in 10% to 50% of non-ataxic horses and is the most frequent and severe vertebral malformation in horses without cervical stenotic myelopathy.[8] Therefore subjective evaluation of osteoarthritis of the articular processes leads to false-positive diagnosis of cervical stenotic myelopathy. Although the presence of characteristic vertebral malformations supports the diagnosis of cervical stenotic myelopathy, subjective evaluation of cervical radiographs does not reliably discriminate between horses affected or unaffected by cervical stenotic myelopathy.[9] Objective assessment of the vertebral canal diameter is more accurate than subjective evaluation of vertebral malformation for identifying horses affected by cervical stenotic myelopathy.

The sagittal ratio technique has been developed for objective determination of vertebral canal diameter in horses.[7] The sensitivity and specificity of the sagittal ratio for identifying

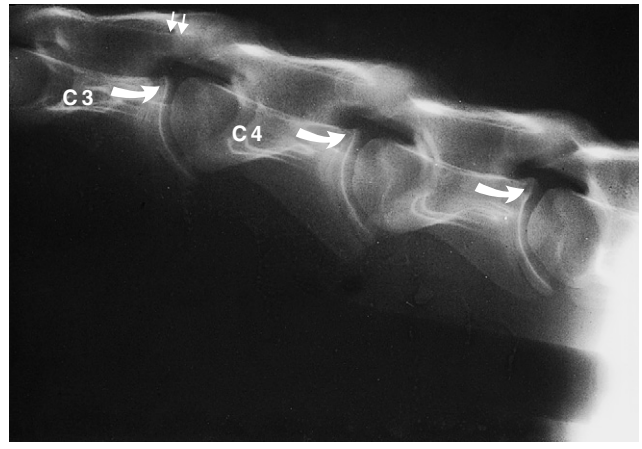

Fig. 62-2 Lateral radiographic view of the mid-neck region of an 8-month-old Quarter Horse colt with spinal ataxia caused by cervical stenotic myelopathy. Bony malformations consistent with cervical stenotic myelopathy include flare of the caudal epiphyses (*curved arrows*), caudal extension of the third cervical vertebra dorsal lamina (*arrows*), and malalignment of the articulation of the third *(C3)* and fourth *(C4)* cervical vertebrae.

horses affected by cervical stenotic myelopathy is approximately 89% for vertebral sites between the fourth and seventh cervical vertebrae.[7] Accuracy of the sagittal ratio technique for identifying horses affected by cervical stenotic myelopathy, without consideration of other bony malformations of the cervical vertebrae, suggests that generalized stenosis of the vertebral canal may be the most important factor in the development of cervical stenotic myelopathy. The sagittal ratio is calculated by dividing the minimum sagittal diameter of the vertebral canal by the width of the vertebral body. The minimum sagittal diameter of the vertebral canal is obtained by determining the narrowest diameter measured from the dorsal aspect of the vertebral body to the ventral border of the dorsal laminae (Fig. 62-3). The vertebral body width is measured perpendicular to the vertebral canal at the widest point of the cranial aspect of the vertebral body. Because the vertebral body is located within the same anatomical plane as the vertebral canal, determination of this proportion negates the effects of magnification resulting from variability in object-film distance. The sagittal ratio should exceed 52% from the fourth to sixth cervical vertebrae and 56% at the seventh cervical vertebrae in horses greater than 320 kg. The clinician should classify the patient into one of the following categories:

1. Low sagittal ratio (<48% for the fourth to sixth cervical vertebrae) and moderate to severe bony malformation: Perform myelographic examination to identify sites of spinal cord compression and to classify lesions as static or dynamic.
2. Marginal sagittal ratio (48% to 56%) and mild to moderate bony malformation: Perform myelographic examination to confirm or exclude cervical stenotic myelopathy.
3. High sagittal ratio (>56%) and minimal bony malformation: Pursue alternative differential diagnoses.

The semi-quantitative scoring system developed by Mayhew et al.[10] should be used in foals younger than 1 year of age to assess cervical radiographs for diagnosis of cervical stenotic myelopathy. The scoring system combines objective measurement of vertebral canal diameter and subjective evaluation of vertebral malformation. Stenosis of the vertebral canal is assessed by determination of the intervertebral and intravertebral minimum sagittal diameter (Fig. 62-3) The interverterbral and intravertebral minimum sagittal diameters

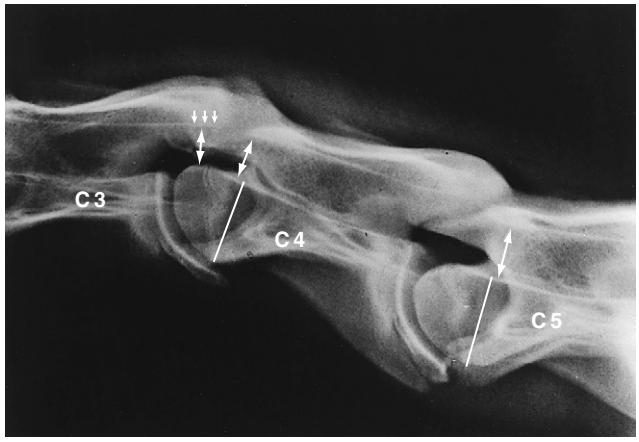

Fig. 62-3 Lateral radiographic view of the third *(C3)*, fourth *(C4)*, and fifth *(C5)* cervical vertebrae of a 2-year-old Thoroughbred colt with cervical stenotic myelopathy. The sagittal ratio is determined by dividing the intravertebral minimum sagittal diameter (*double arrow*) by the width of the vertebral body (*line*). The intervertebral minimum sagittal diameter is measured from the caudoventral aspect of the dorsal lamina of the third cervical vertebra to the craniodorsal aspect of the vertebral body of fourth cervical vertebra (*double arrow below the smaller arrows*). There is caudal extension of the dorsal lamina of the third cervical vertebra (*smaller arrows*), and there is malalignment at the articulation of the third and fourth cervical vertebrae.

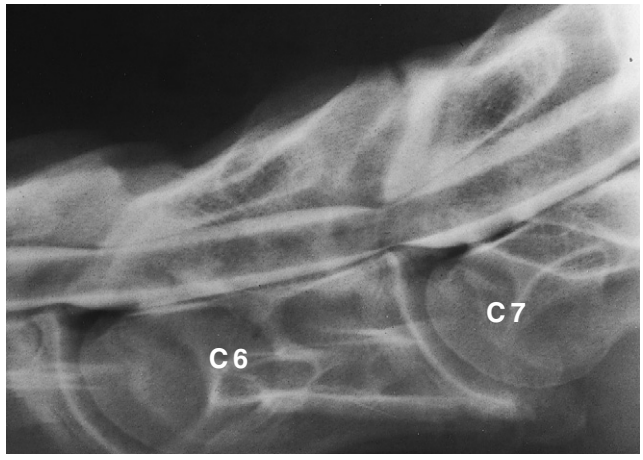

Fig. 62-4 Lateral radiographic view during myelographic examination of the fifth to seventh *(C7)* cervical vertebrae of a 3-year-old Thoroughbred colt with static spinal cord compression. The dorsal and ventral contrast columns are attenuated by more than 50% at the fifth and sixth *(C6)* and sixth and seventh cervical vertebral articulations.

are corrected for radiographic magnification by dividing these values by the length of the vertebral body. The maximum score for cervical vertebral stenosis is 10 points. Cervical vertebral malformation is determined by subjective assessment of five categories: (1) encroachment of the caudal epiphysis of the vertebral body dorsally into the vertebral canal, (2) caudal extension of the dorsal lamina to the cranial physis of the adjacent vertebra, (3) angulation between adjacent vertebral bodies, (4) abnormal ossification of the physis, and (5) osteoarthritis of the articular processes. The maximum score allotted for each category of bony malformation is 5 points. A total score of 12 or higher (maximum total score 35) confirms the radiographic diagnosis of cervical stenotic myelopathy. Stenosis of the vertebral canal and malalignment between adjacent vertebrae are the most discriminating parameters in this semi-quantitative scoring system to differentiate normal foals from those affected by cervical stenotic myelopathy.

Accurate assessment of cervical radiographs requires a precise lateral radiograph of the cervical vertebrae.[11] Obliquity of the cervical vertebrae results in indistinct margins of the ventral aspect of the vertebral canal, producing erroneous values for minimum sagittal diameter and vertebral body width. Obtaining precise lateral radiographs of the cervical vertebrae in recumbent horses is difficult. Plain film radiographs should be obtained in the standing, sedated horse whenever possible.

Although plain film radiography can determine the likelihood of cervical stenotic myelopathy, radiographs of the cervical vertebrae cannot replace myelographic examination for identifying the location and number of affected sites and for classification of spinal cord compressive lesions in horses with cervical stenotic myelopathy. The definitive diagnosis of cervical stenotic myelopathy is defined myelographically by a 50% or greater decrease in the sagittal diameter of the dorsal and ventral contrast columns.[12] The decrease in the contrast column is quantified by comparing it with the mid-vertebral site, cranial or caudal to the compressed site. The ventral column is often obliterated at the intervertebral space in normal studies, particularly in the flexed position. A 50% or greater decrease in opposing dorsal and ventral columns, compared with the adjacent mid-vertebral region, must be present for definitive diagnosis of cervical stenotic myelopathy. I prefer to use less than 2 mm dorsal contrast column as the diagnostic criterion for cervical stenotic myelopathy to reduce the number of false-positive myelographic studies.

In addition to providing the definitive diagnosis of cervical stenotic myelopathy, myelographic examination can differentiate between dynamic and static spinal cord compression.[13] Horses with dynamic spinal cord compression (type I) have obliteration of the dorsal and ventral contrast columns during flexion of the neck, whereas spinal cord compression is not be apparent with the neck in the neutral position. Dynamic spinal cord compression usually occurs in younger horses (<2 years of age) and is associated with instability of the cervical vertebrae, particularly between the third and sixth cervical vertebrae. Dorsal laminar extension, caudal epiphyseal flare, and abnormal ossification patterns often occur in horses with dynamic spinal cord compression. Static vertebral canal stenosis (type II) is characterized by constant spinal cord compression, regardless of neck position (Fig. 62-4). Static compression usually occurs in slightly older horses (2 to 4 years of age) and may occur in considerably older horses. It results from osteoarthritis of the articular processes and proliferation of peri-articular soft tissue structures. A synovial cyst, associated with osteoarthritis of the articular processes, may produce waxing and waning asymmetrical neurological signs. In some horses with static compression, flexion of the neck stretches the ligamentum flavum and relieves spinal cord compression, whereas extension exacerbates compression.

A complete myelographic study should include neutral and stressed (flexed and extended) views of the cervical vertebrae.[12] In horses with obvious sites of spinal cord compression on neutral myelographic views, excessive flexion and extension of the neck should be avoided while obtaining dynamic views to prevent exacerbation of spinal cord injury. Horses should be monitored for 24 hours after the myelographic procedure for depression, fever, seizure, and worsening in neurological status. Worsening of neurological status after myelography may result from spinal cord trauma during hyperflexion, iatrogenic puncture of the spinal cord, or chemical meningitis. Administration of phenylbutazone (4.4 mg/kg PO q24 h) 1 day before through

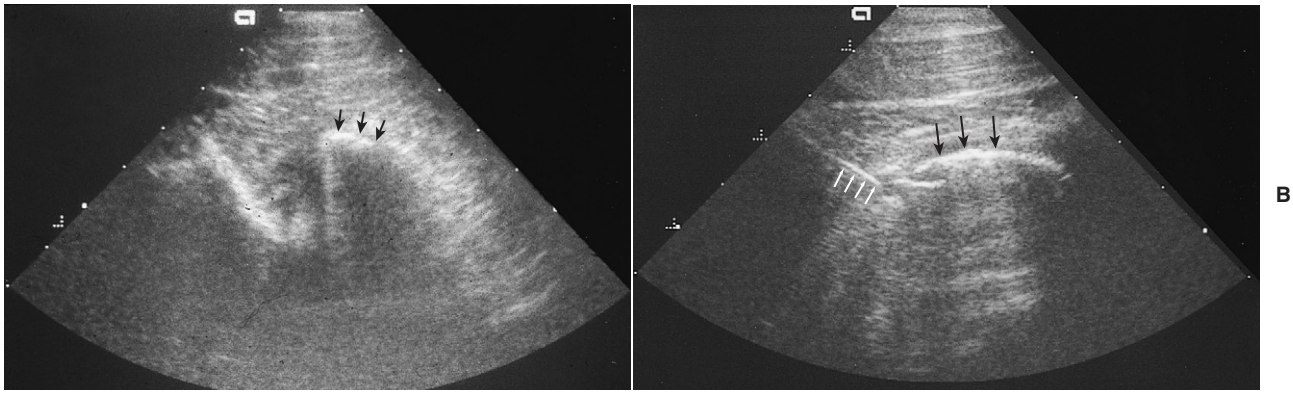

Fig. 62-5 **A,** Ultrasonographic examination of the articulation of the fifth and sixth cervical vertebrae (coronal view). The cranial articular process of the sixth cervical vertebra (*arrows*) is superficial to the caudal articular process of the fifth cervical vertebra. **B,** Ultrasonographic examination during arthocentesis of the articulation of the fifth and sixth cervical vertebrae (transverse view). A 15-cm spinal needle is entering the ventrolateral aspect of the joint (*small arrows*) deep to the cranial articular process of the sixth cervical vertebra (*arrows*).

1 day after myelographic examination attenuates fever and depression associated with chemical meningitis.

CONSERVATIVE MANAGEMENT

Successful conservative management of foals younger than 1 year of age with cervical stenotic myelopathy has been achieved using the paced diet program.[14] The goal of this dietary program is to retard bone growth, enhance bone metabolism, and allow the vertebral canal diameter to enlarge to relieve spinal cord compression. This dietary program is restricted in energy and protein (65% to 75% of National Research Council [NRC] recommendations) but maintains balanced vitamin and mineral intake (minimum 100% NRC recommendations). Vitamins A and E are provided at three times NRC recommendations, and selenium is supplemented to 0.3 ppm. Roughage is provided by pasture or low-quality (6% to 9% crude protein) timothy hay. Dietary regimens are individually formulated according to the age and weight of the foal. Solitary stall confinement is recommended to minimize repetitive spinal cord compression caused by dynamic instability. This program of dietary management and restricted exercise has been successful for preventing neurological signs in foals with radiographic evidence of cervical stenotic myelopathy and treating foals demonstrating clinical signs of cervical stenotic myelopathy.[10]

Anti-inflammatory therapy is indicated in all horses with cervical stenotic myelopathy. Administration of glucocorticoids, dimethylsulfoxide, and non-steroidal anti-inflammatory drugs may reduce edema and provide transient improvement in neurological signs. Spontaneous recovery from cervical stenotic myelopathy without dietary management or surgical intervention is not reported.

Horses with cervical pain and forelimb lameness caused by cervical vertebral arthropathy may benefit from intra-articular administration of corticosteroids or chondroprotective agents. Arthrocentesis of the cervical vertebral articulations (facets) is performed with ultrasound guidance using a 15-cm (6-inch), 18-gauge spinal needle in a standing, sedated horse or a recumbent horse. The cranial facet of the caudal vertebra appears superficial to the caudal facet of the cranial vertebra (Fig. 62-5, *A*). The articular space is accessed at the cranioventral opening of the articular facet, which is angled approximately 60° from the ultrasound beam. The needle should be introduced 5 cm cranial to the facet and inserted at a 30° angle to the skin surface (Fig. 62-5, *B*). Joint penetration should be confirmed by aspiration of synovial fluid. If the neck is extended, the transverse process of the cranial vertebrae may obscure the path to the articulation. Intra-articularly administered triamcinolone (6 mg per joint) or methylprednisolone (100 mg per joint) has produced a reduction in cervical pain in more than 50% of horses with arthrosis of the articular processes.[15] The goal of intra-articular anti-inflammatory therapy should be to improve cervical mobility, reduce cervical pain, and eliminate forelimb lameness. It is unlikely that intra-articular therapy will significantly improve clinical signs of spinal ataxia.

SURGICAL TREATMENT

Surgical intervention is the most widely reported therapeutic approach for horses with cervical stenotic myelopathy. Cervical vertebral interbody fusion was first described in 1979 for horses with dynamic spinal cord compression, and nearly 1000 surgeries have been performed since that time.[16] This procedure fuses adjacent vertebrae in the extended position, which provides immediate relief of spinal cord compression and prevents repetitive spinal cord trauma. Dorsal laminectomy (subtotal Funkquist type-B) is described for horses with static cervical stenotic myelopathy and provides immediate decompression of the spinal cord.[17] Portions of the dorsal lamina, ligamentum flavum, and joint capsule overlying the site of spinal cord compression are removed during dorsal laminectomy. This procedure effectively decompresses the spinal cord. However, it has been associated with significant post-operative complications.[18] Interbody fusion is an alternative to dorsal laminectomy for horses with static compressive lesions. After cervical vertebral fusion, the articular processes remodel and soft tissue structures atrophy, resulting in delayed decompression of the spinal cord over a period of weeks to months.[19] Decompression is immediate with subtotal laminectomy. However, because of its relative safety, interbody fusion is selected by some surgeons as the technique of choice for horses with dynamic and static compressive lesions.

Cervical vertebral fusion improves the neurological status of 44% to 90% of horses with cervical stenotic myelopathy, and 12% to 62% of horses return to athletic function.[18,20] Of the horses that return to athletic function, approximately 60% are

able to perform at the level of intended use, including racing, jumping, and pleasure performance activities. The anticipated magnitude of improvement is one to two neurological grades after cervical fusion. Occasionally, three grades of improvement in neurological status have been achieved. However, it is unusual for a horse with grade IV neurological deficits to become neurologically normal after cervical vertebral fusion. Rarely, a domino effect can occur in horses after vertebral fusion, wherein spinal cord compression develops at the intervertebral site adjacent to the site of fusion. This may result from added forces at the adjacent site or natural progression of the disease.[13] Subtotal laminectomy improves the neurological status of 40% to 75% of horses with static compression.[17]

Fatal post-operative complications have been reported with surgical repair of static compressive lesions of the caudal cervical vertebrae (subtotal laminectomy and interbody fusion). Complications directly related to the surgical procedure include vertebral body fracture, spinal cord edema, and implant failure. Seroma formation is common after cervical vertebral interbody fusion. A pressure bandage is maintained over the surgical site for 2 to 3 weeks to minimize this post-operative complication.[18]

The most important patient factor for determining post-operative prognosis is duration of clinical signs before surgical intervention. Horses with neurological gait deficits present for less than 1 month before surgery are more likely to return to athletic function than are horses with signs of greater than 3 months' duration.[18] The number of spinal cord compressive sites and patient age does not appear to affect the long-term outcome of horses with cervical vertebral interbody fusion. Horses with dynamic compressive lesions appear to have a better post-operative result than those with static compressive lesions. Horses with lesions involving the sixth and seventh cervical vertebrae have a less favorable prognosis than those with lesions affecting the third to fifth cervical vertebrae.

The duration of convalescence and rehabilitation after cervical vertebral interbody fusion is approximately 6 to 12 months. An individualized exercise program dependent on capability, projected use, and neurological status of the horse should be designed to promote muscular strength. Extended exercise at slow speed, including ponying (being led from another horse) and lunging on inclines, is recommended during rehabilitation to build muscular strength. The point at which the horse is competent to return to athletic function after cervical vertebral interbody fusion should be determined by neurological examination. Significant improvement in neurological status occurring after 1 year post-operatively is unlikely.

CHAPTER • 63

Osteoarthritis

John P. Caron

Joints are highly differentiated structures composed of a number of connective tissues including bone, articular cartilage, and peri-articular soft tissues, all of which contribute to normal joint function and undergo changes in structure and metabolism in disease.[1,2] From the point of view of joint diseases, perhaps the most important of these components is articular or hyaline cartilage, composed principally of a precisely organized arrangement of collagens and proteoglycans. This tissue is responsible for the load-distributing functions of the joint and, in health, cartilaginous surfaces glide over one another in a virtually frictionless manner, even when under substantial load. In joint trauma or osteoarthritis the normal structure and function of articular cartilage are deranged, leading to biochemical, structural, and biomechanical abnormalities in all joint tissues. If the trauma is uncorrected, the result is progressive joint destruction, a process likened to organ failure in other body systems. Joint disease is a particularly prevalent cause of lameness and as such is an expensive equine health problem.[3-5] An understanding of the biology and pathobiology of joints enables the clinician better to diagnose joint disease and to provide appropriate treatment and prevention recommendations.

STRUCTURE AND FUNCTION OF NORMAL JOINTS

Synovium and Synovial Fluid

The synovium is a vascular connective tissue lining the inner surface of the joint and consists of the cells of the synovial intima and a subsynovial stroma, the latter comprised of various amounts of fibrous, areolar, and fatty tissues. The synovium covers all articular surfaces, excluding articular cartilage and localized areas of bone. However, synovium is not uniform throughout the joint, and dense connective tissue may be found in its place in areas predisposed to trauma. Because the synovial lining bears neither true epithelium nor conventional basement membrane separating the joint cavity from the synovial vasculature, no true synovial membrane exists. Rather the intima and subsynovial tissues comprise a structural and functional continuum that acts as a macromolecular sieve.

The synovial intima is lined by a diverse population of synoviocytes, which have been classified according to their ultrastructure and with the use of specific antisera.[6-8] The three cell types are type A cells, of macrophage origin; fibroblast-derived type B cells; and type C cells, which appear to be an intermediate between A and B forms.[7,9-11] The most abundant are the type B cells, which synthesize a variety of important macromolecules, including collagen and hyaluronan.[12,13] The viscosity of synovial fluid is largely due to the concentration and degree of polymerization of hyaluronan, which serves a vital function in soft tissue lubrication. Type A cells, comprising only 10% to 20% of the lining cells, are predominately phagocytic. However, apparently some overlap in function between the two principal cell types exists.[14,15] Importantly, synoviocytes synthesize a variety of soluble mediators implicated in the pathogenetic events of osteoarthritis, including cytokines (e.g., interleukin-1),[16-18] eicosanoids (e.g., prostaglandin E_2),[19,20] and proteinases.[21] That the synovial lining is capable of expressing these substances supports a role for the synovium in the pathogenesis of osteoarthritis.

Deep to the synovial lining the subsynovial region possesses a rich blood supply that is essential to generating synovial fluid, facilitates the exchange of nutrients and metabolic wastes of the synovium, and provides the sole source of nutrition to adult articular cartilage. Because of the specialized structure and functions of the synovial lining and subsynovial stroma, synovial blood flow is subject to a complex regulatory system involving extrinsic control and locally produced factors such as angiotensin II, endothelin-1, and nitric oxide.[2]

Peri-Articular Soft Tissues

The peri-articular soft tissues include muscles, tendons, ligaments, and joint capsule. Muscles effect movement and, via complex reflexes, are vital to providing joint stability and protecting the joint from supraphysiological excursion. Muscle mass is more abundant near joints with a wide range of movement, such as the shoulder and the hip, and less so around joints that move in a single plane. Tendons serve as a bridge between muscle and bone, and ligaments provide stability between bones composing a joint. Tendons and ligaments are of similar though not identical composition, consisting mainly of water, an organized array of collagen bundles (predominantly type I), and a sparse population of fibroblasts. Ligaments contain more elastin fibers and have greater elasticity than tendons.[22] Importantly, the molecular composition of these tissues responds to physical stimuli and immobilization elicits catabolic events leading to tissue weakening.[23] The composition of capsular structures parallels that of ligaments. Indeed some ligaments can be recognized only as hypertrophied portions of the joint capsule. The fundamental role of the capsule is to provide stability; however, its specific nature varies with anatomical location and joint position. For example, the caudal capsule of the human knee is lax in flexion but exerts an important stabilizing force when the joint is in extension.[24]

Subchondral Bone

Although subchondral bone is histologically and biochemically similar to bone in other locations, the organization of the subchondral plate is specific. The plate is thinner than cortical bone found at other locations and its haversian systems are oriented parallel to the joint surface rather than parallel to the long axis of the bone.[25] Similarly the organization of subchondral cancellous bone varies between joints, reflecting predominant biomechanical forces and adaptation to exercise.[26,27] The deformability of the subchondral cortical and epiphyseal trabecular bone exceeds that of the diaphyseal cortical shaft by many times and has the important function of force attenuation. As such, possibly the bone stiffening (sclerosis) observed in osteoarthritis contributes to disease progression.[28,29]

Articular Cartilage

Cartilage is the principal working tissue of the joint and allows simultaneous motion and weight-bearing with negligible friction. Cartilage covers the subchondral plate of bones composing the joint, to which the cartilage is firmly attached. Its thickness varies between joints and at different locations within them. Cartilage is composed of water, collagen, and proteoglycans that are present in respective proportions of 65% to 80%, 10% to 30%, and 5% to 10% of its wet weight. Chondrocytes account for less than 2% of its volume in most species. In adults, cartilage is avascular, alymphatic, and aneural, thus cartilage is nourished mainly via the synovial fluid (see the following discussion). Because articular cartilage is aneural, lesions restricted to cartilage are non-painful, and the innervation of the underlying bone and adjacent peri-articular soft tissues is responsible for providing information on joint position.

Cartilage possesses a number of zones or layers including the following:

- The superficial (tangential or gliding) zone, in which the cells are elongated and oriented parallel to the joint surface
- A middle (transitional) zone, in which the cells are rounded and appear randomly distributed
- A deep (radial) zone, containing cells arranged in columns oriented perpendicular to the surface
- A calcified zone, in which cells are heavily encrusted with hydroxyapatite crystals (Fig. 63-1)

The latter two zones are separated by an irregular line, visible on standard histological preparations, called the tidemark, the specific function of which is unclear.[30] The density of chondrocytes in the matrix varies with depth from the articular surface, as does the macromolecular composition of the matrix surrounding the chondrocytes. These regional differences can be identified histologically and have been designated as the pericellular, territorial, and interterritorial regions.

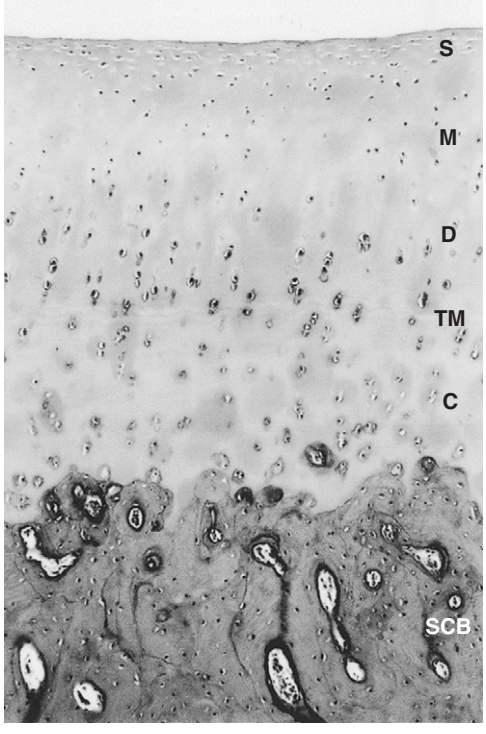

Fig. 63-1 Photomicrograph illustrating regional organization of mammalian cartilage. The four main zones from the articular surface to the subchondral plate include the superficial (tangential) (*S*), the middle (transitional) (*M*), the deep (radial) (*D*), and the calcified (C) zones. The deep and calcified zones are separated by the tidemark (*TM*). Pericellular matrix regions, distinguishable by their histological and ultrastructural differences, and located at progressively greater distances from chondrocyte lacunae, are the pericellular, territorial, and interterritorial regions. (×50.)

The unique functional properties of articular cartilage are reflected in its biochemistry. Articular cartilage is comprised of an abundant, specialized extracellular matrix maintained by the aforementioned sparse population of chondrocytes (Fig. 63-2). Its water content varies with age but may be as high as 80%.[31] This water is freely exchangeable with that in the synovial fluid and is maintained in the matrix in the form of a gel, with matrix collagens and proteoglycans. Water movement is believed to be pivotal to the capacity of cartilage to absorb and distribute compressive load and for its lubrication.

Collagens

The collagens of articular cartilage differ from those found in most other locations in the body. Several collagens, fibrillar and non-fibrillar, are present in this tissue and are thought to provide cartilage with structural support. These proteins also interact with other matrix components to contribute to cartilage architecture and function.[32-34] Collagen fibrils are oriented parallel to the joint surface in the superficial zone and act as a protective layer, whereas larger, radially oriented fibrils in the deeper layers anchor the cartilage to the underlying articular end plate.

Type II collagen is the most abundant in cartilage, accounting for about 90% of the fibrillar network and half of the dry weight of cartilage.[2,35] Type II collagen consists of three identical amino acid chains arranged in a triple helix, is less soluble, possesses a higher proportion of hydroxylysine residues, and is more richly glycosylated than type I collagen.[36,37] Unlike type I, which typically forms fibers, type II collagen is organized in the form of fibrils that are composed of molecules aligned with a 25% overlap or quarter stagger (Fig. 63-3). This structure is stabilized by chemical bonds between specific amino acids in each chain, called hydroxypyridinium cross-links.[38] Fibrils are not uniform in size throughout the matrix; they tend to be larger in the middle and deep zones of the matrix, which reflects regional biomechanical demands.[39] This protein is arranged in arcades, which form the three-dimensional network or skeleton of the cartilage matrix. Type II collagen is produced by the chondrocytes, and whereas significant degradation and resynthesis of fibrils occurs during growth and development, limited turnover occurs in adults.[40,41]

Minor collagens are present in modest amounts in cartilage and the specific roles of these collagens in its structure and function have yet to be defined fully. Type XI is a fibrillar collagen that is found within type II fibrils. Its function is unclear, but likely it plays a role in type II collagen fibril assembly and organization, because a mutation in the type XI gene in mice leads to a disorganized matrix, with abnormally thick collagen fibrils.[42] Type VI is a microfibrillar collagen that may act as a bridge between fibrillar collagen and other matrix components.[43,44] So-called fibril-associated small collagens include collagens IX, XI, and XIV. Type IX collagen molecules bound covalently to the surface of type II fibrils may serve to stabilize the latter.[45] Types XII and XIV collagen also are associated with fibrillar collagen, but the specific functions have yet to be identified.

Proteoglycans

By definition, proteoglycans are composite molecules consisting of protein and glycosaminoglycan (polysaccharide) components. This definition is broad, because some of the aforementioned minor collagens (e.g., type IX) have a single glycosaminoglycan side chain and thus can be designated as proteoglycans. A number of proteoglycans are found in articular cartilage. Aggrecan, the largest and most abundant, has a

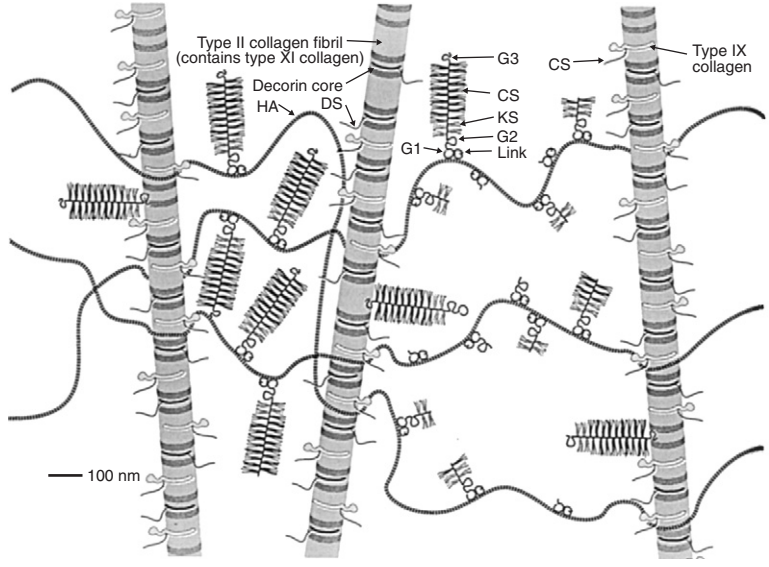

Fig. 63-2 Organization of the major extracellular matrix components in articular cartilage. The principal collagen of cartilage is type II and a network of these fibrils provides much of the tensile strength of the tissue. Aggrecan is composed of a linear protein with three globular domains (*G1* to *G3*) to which are attached numerous glycosaminoglycan chains of chondroitin sulfate (*CS*) and keratan sulfate (*KS*) (see also Fig. 63-4). Supramolecular aggregates are formed by the noncovalent interaction of aggrecan with hyaluronan (*HA*) and stabilized by link protein (*Link*). The negatively charged glycosaminoglycans (*CS* and *KS*) attract several times their weight in water, and this proteoglycan-water composite is responsible for the compressive stiffness of cartilage. Cartilage also has a number of minor proteoglycans and collagens (e.g., decorin and dermatan sulfate [*DS*], the functions of which are not fully characterized). Fragments of aggrecan, remaining bound to hyaluronan, are depicted to illustrate the effects of proteolytic activity in cartilage. (From Koopman WJ, editor: *Arthritis and allied conditions: a textbook of rheumatology,* ed 13, vol 1, Baltimore, 1997, Williams & Wilkins.)

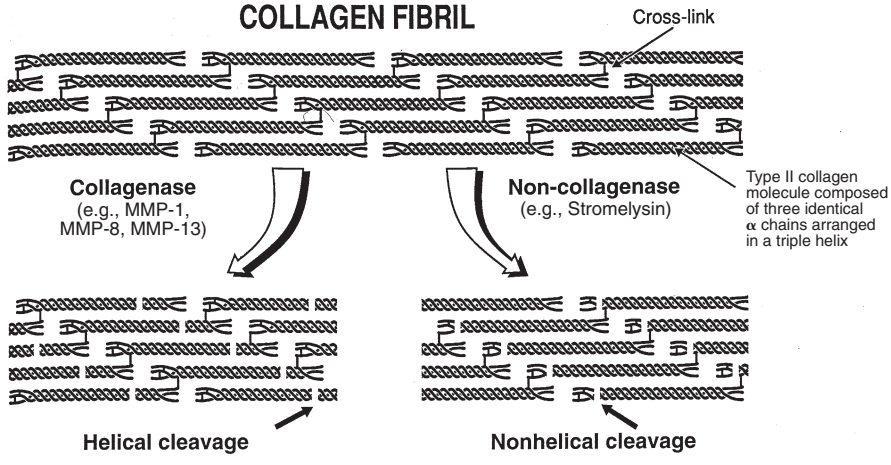

Fig. 63-3 Schematic representation of collagen fibril organization and its proteolytic degradation in cartilage. Cartilage collagen is arranged in fibrils of cross-linked, triple-helical molecules overlapping at regular intervals. Collagenases cleave intact helical collagen and produce characteristic "¾-¼" fragments. Other proteases (e.g., stromelysin) degrade collagen in non-helical regions. (From Koopman WJ, editor: *Arthritis and allied conditions: a textbook of rheumatology,* ed 13, vol 1, Baltimore, 1997, Williams & Wilkins.)

well-defined function in the extracellular matrix; however, the specific roles of the smaller proteoglycans remain to be characterized fully.

Aggrecan is the primary proteoglycan of articular cartilage that interacts with hyaluronan to form aggregates (Figs. 63-2 to 63-4). The individual or monomeric form of this molecule consists of a linear core protein interrupted by three globular domains. The first of these globular domains is designated G_1, exists at the amino-terminal portion of the molecule, and is the site at which the proteoglycan attaches to hyaluronan. As many as 100 aggrecan monomers may be attached to the same hyaluronan chain to form supramolecular aggregates of

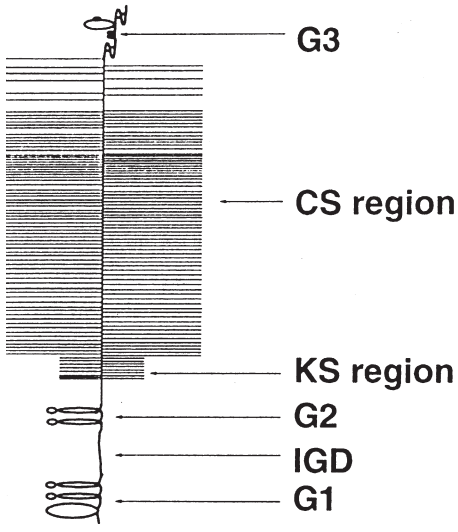

Fig. 63-4 Schematic representation of an aggrecan monomer. Proteolytic cleavage of the molecule in vivo usually first occurs in the G_1 to G_2 interglobular domain (*IGD*). The specific sites involved vary among the enzymes implicated in the process. Keratan sulfate (*KS*) and chondroitin sulfate (*CS*) regions are positioned on the periphery of the moleculte. (From Koopman WJ, editor: *Arthritis and allied conditions: a textbook of rheumatology*, ed 13, vol 1, Baltimore, 1997, Williams & Wilkins.)

micrometer dimensions (see Fig. 63-2).[46] The interaction of aggrecan with hyaluronan is non-covalent but is stabilized by a link protein that binds to the G_1 domain and hyaluronan with equal affinity.[47] Equine link protein recently has been characterized and is similar to that found in human cartilage.[48] The specific functions of the G_2 and G_3 domains are unclear; however, because the G_3 domain is present in only about one third of the aggrecan monomers in adult cartilage, it is unlikely that it plays a pivotal role in the extracellular matrix.[49]

In the region between the second and third globular domains, glycosaminoglycan chains of variable length and composition are attached radially to the protein core (Fig. 63-4). Immediately adjacent to the G_2 domain is a region rich in keratan sulfate and this portion of the proteoglycan, detectable by monoclonal antibodies, has served as a tissue marker of matrix turnover.[50] Farther peripherally on the core protein is the chondroitin sulfate–rich region, where up to 100 chondroitin sulfate chains may be found attached radially to the core protein. These chondroitin sulfate chains vary in length, which is the main reason for heterogeneity in the size of aggrecan. Importantly, these glycosaminoglycan chains contain numerous carboxyl and sulfate groups, so that aggrecan is highly negatively charged and can bind up to 50 times its weight in water.[46,51,52] This highly hydrated matrix gives cartilage its compressive stiffness and ability to dissipate load.

Matrix Proteins

Cartilage, like other connective tissues, contains a number of non-collagenous proteins, many of which are proteoglycans. Among the best characterized of the small proteoglycans are decorin, biglycan, lumican, and fibromodulin, all of which are similar in molecular organization. These proteins have been shown to interact with a number of matrix constituents, including cartilage collagens, and in many cases these interactions involve a number of different collagens and appear to regulate a variety of metabolic processes.[46,52] For example, decorin and fibromodulin inhibit fibrillogenesis of type II collagen, a process that may regulate the size of collagen fibrils in the matrix.[53] Some of these small matrix proteins also may contribute to the anti-adhesive properties of articular cartilage.[54,55]

Cartilage also contains a number of small proteins that are neither collagens nor proteoglycans,[56,57] and most are involved in interactions with a variety of matrix molecules and chondrocytes. For example, anchorin is found on the surface of chondrocytes and within the cell membrane and has a high affinity for type II collagen fibrils. These properties suggest that anchorin may act as a mechanoreceptor, providing chondrocytes with information on changes in stresses experienced by the matrix. Fibronectin is a minor component of cartilage that is thought to contribute to matrix assembly, via interactions with chondrocytes and elements of the extracellular matrix. Fibronectin fragments are present in elevated quantities in osteoarthritis and may contribute to catabolic events in affected cartilage.[58,59] Cartilage oligomeric matrix protein (COMP), also known as thrombospondin-5, is abundant in articular cartilage and is formed by the association of five identical subunits. COMP is most abundant in the proliferative cell layer of growth cartilage where it is thought to regulate cell growth.

Chondrocytes

Studies of cartilage metabolism contradict the seemingly inert histological appearance of this relatively acellular tissue. Despite the fact that chondrocytes represent a small percentage of the volume of cartilage, they are responsible for extracellular matrix synthesis, including all the collagens and proteoglycans. They are also capable of elaborating a variety of proteolytic enzymes effecting degradation of matrix macromolecules. The rate of turnover of the various matrix components is not uniform. At least a portion of the proteoglycan pool is renewed at a relatively rapid rate, whereas the rate of collagen turnover is minimal.[60-62] Chondrocyte metabolism is influenced by intrinsic and extrinsic mechanical influences. For example, cyclic loading and alterations in matrix pressure, as a result of changes in solute content, materially influence proteoglycan synthetic rates.[63,64] Thus the maintenance of the cartilage matrix involves the chondrocyte-mediated processes of synthesis and degradation, and the cartilage loss in osteoarthritis appears to be attributable to a disequilibrium in favor of matrix degradation.

Nutrition

Unlike the cartilage of growing animals, in which articular cartilage receives some blood supply from subchondral vasculature, adult articular cartilage contains no blood vessels. As a result the chondrocyte exists under relatively hypoxic and acidic conditions, with an extracellular pH typically 7.1 to 7.2.[65] Nutrients migrate from subsynovial vessels to the synovial fluid and subsequently penetrate the dense connective tissue matrix of the cartilage, while metabolic wastes are simultaneously cleared in the opposite direction. The density of the matrix appears not to hamper diffusion, because molecules as large as hemoglobin (65 kD) can penetrate normal articular cartilage.[66] The highly charged proteoglycans contained in the matrix do not inhibit the diffusion of small, uncharged molecules.[67] Entry of solutes into the matrix occurs by simple diffusion or may be facilitated by compression-relaxation cycles. Intermittent loading of cartilage is vital to its health, as is evidenced by the deleterious effects of immobilization.[68]

Joint Lubrication

Although several mechanisms for cartilage-on-cartilage lubrication have been hypothesized, two main systems are accepted: a hydrostatic or weeping system that functions at high loads; and a boundary system that functions at low loads.[69] Hydrostatic lubrication of opposing cartilaginous surfaces is effected by a thin film of water liberated from the matrix during cartilage compression. Because little movement of water can occur from cartilage to the subchondral bone, most is squeezed from the opposing cartilages onto the

surface, immediately peripheral to the zone of impending contact.[70] With the release of compressive force, the cartilage expands and water is drawn back into the matrix.

Whereas hydrostatic mechanisms function well under relatively heavy loads, boundary lubrication occurs under low-load conditions. Boundary lubrication is accomplished by specialized materials including lubricin[71] (a glycoprotein of synovial origin) and hyaluronan. These molecules bind to opposing articular cartilage surfaces and prevent the direct contact of these surfaces under low loads. Coefficients of friction were unchanged after hyaluronidase treatment of synovial fluid, suggesting that hyaluronan has no place in cartilage-on-cartilage lubrication.[72,73] However, more recent information indicates that hyaluronan actually does function as a boundary lubricant.[74,75]

Articular soft tissues require lubrication because they contribute most of the frictional resistance to joint movement. Indeed, the energy requirement for the stretching of articular soft tissues is 100 times that of the frictional resistance of opposing cartilage surfaces.[76] The synovium is lubricated by a thin film of synovial fluid, rich in hyaluronan, its principal boundary lubricant.[77]

Intra-Articular Volume and Pressure

Intra-articular volume varies and is influenced by joint position. Specifically, volume and pressure are respectively minimal and maximal near the extremes of flexion and extension.[78-81] This effect is exacerbated in horses with synovial effusion, providing a physiological rationale for diagnostic flexion tests in equine lameness examinations. Moreover, the pointing of an equine limb with a joint effusion likely parallels the observation that in the human knee there is a maximum of intra-articular volume (and minimum of intra-articular pressure and pain) at 30° of flexion.[82,83]

Whereas intra-articular pressure varies during movement, pressure within a normal joint is sub-atmospheric at rest.[84,85] As a result the normal synovial cavity is merely a potential space, the surfaces of which are coated with a thin film of synovial fluid to reduce friction during movement. Although the mechanisms by which this negative pressure occurs remain unclear, the phenomenon contributes measurably to joint stability.[86] Lack of familiarity with the physiological concept of negative intra-articular pressure in normal joints results in the common misconception that the sound of air being aspirated into a joint during arthrocentesis heralds a dry or diseased joint.

Biomechanical Considerations

Articular cartilage remains healthy despite being regularly subjected to considerable normal and shear forces during normal activities. A number of mechanisms exist to facilitate this phenomenon, including the transmission of forces to surrounding tissues by peri-articular soft tissues, the incongruity of cartilage surfaces, and the inherent compliance of cartilage and subchondral bone. Indeed, the capacity for considerable elastic deformation permits normal cartilage to withstand compressive stresses considerably greater than those of body weight alone.[87,88] Nonetheless, cartilage is subject to mechanical breakdown after supraphysiological stresses, and loads exceeding 25 kg/cm^2 are reported to result in matrix damage.[89] Apparently these loads occur in specific areas of cartilage under a variety of clinical circumstances, such as the cartilage degeneration that accompanies the incongruent articular surfaces of a poorly reduced or unstable intra-articular fracture.

At the tissue level the ability of cartilage matrix to resist compression and shear is a function of the interaction of collagen, aggrecan, and tissue fluid. Aggrecan can absorb many times its weight in water, but its complete hydration is restricted by the collagen network. Thus a balance exists between the internal swelling pressure exerted by the association of water with aggrecan (Gibbs-Donnan ionic equilibrium) and the tensile forces of the collagen fibrils. Cartilage under load undergoes a two-phase (viscoelastic) deformation.[90,91] Initially rapid bulk movement of water from the matrix and compression of collagen occur. Subsequently a time-dependent compression occurs, known as the creep phase, in which water flows through the matrix at a slower rate.

These mechanical phenomena have been studied in experiments evaluating the mechanical properties of cartilage after the selective depletion of specific matrix components. The tensile strength of cartilage is a function of its type II collagen content, because strength is reduced in collagen-depleted tissues but is unaffected by proteoglycan removal.[92,93] Proteoglycans (mainly aggrecan) provide the matrix with its compressive stiffness and protect the collagen network from mechanical damage. Trypsin-treated (proteoglycan-depleted) specimens lose the ability to rebound from compressive load and have reduced stiffness.[94]

At rest, opposing articular surfaces are not completely congruent, but when loaded, articular cartilage contact increases, which serves to distribute stress and increase joint stability. This may be a physiological reason why cartilage tends to be somewhat thicker in less congruous joints, such as the hip and stifle.[95] Although cartilage is designed to withstand compressive stress, its ability to act as a shock absorber is finite, largely because it receives its nutrition by diffusion and as a result is of limited thickness. Because its ability to absorb load is limited, cartilage must transmit load to the underlying subchondral bone. As such the articular ends of most bones are flared (less force per unit area) and deform under physiological load to absorb stress.[96] Noteworthy is that the stiffness of the subchondral bone is attributable not only to the cancellous trabeculae, but also to the extracellular fluid content. This was demonstrated in an experiment where subchondral stiffness of canine femoral heads was reduced by 30% after fluid decompression by drilling.[97] When the subchondral bone is unable to accommodate loading, so-called adaptive remodeling failure occurs, in which repetitive subchondral deformation causes trabecular microfractures, which may or may not be accompanied by changes in articular cartilage. Fortunately, when occurring at an acceptable rate, trabecular microfractures undergo a reparative response leading to an orientation of subchondral bone that provides improved strength and shock absorption capacity.[98] Articular surfaces are protected by stress distribution mechanisms beyond those of cartilage and bone. For example, muscles absorb a large proportion of the force experienced during impact loading, leaving the remainder to be cushioned by cartilage and bone. Fine-tuned neuromuscular reflexes are required for this system to work effectively and small failures in these reflex arcs lead to insufficient attenuation of impact loading, which may lead to degenerative changes in cartilage and subchondral bone.[99]

OSTEOARTHRITIS

Etiopathogenesis

Osteoarthritis has been defined as an essentially non-inflammatory disorder of movable joints, characterized by degeneration and loss of articular cartilage and the development of new bone on joint surfaces and margins.[36,100] As in people, equine osteoarthritis is probably not a single disease but reflects a common response of joint tissues to a number of potential causes. Unfortunately the specific contributions and interactions of various mechanical and biological factors contributing to development of osteoarthritis lesions remain unclear.

Three pathogenetic mechanisms are hypothesized for osteoarthritis.[100] The first involves a fundamentally defective carti-

lage, with abnormal biomechanical properties. In this pathway a biomechanically flawed matrix fails under normal loading. In people a recently identified type II collagen defect exemplifies this primary form of osteoarthritis.[101,102] Osteoarthritis attributed to inherently defective cartilage matrix components has not yet been identified in the horse.

A second proposed pathogenetic pathway of osteoarthritis involves physical changes in the subchondral bone.[28,29] Because articular cartilage is too thin to be an effective shock absorber, impact loading must be attenuated by peri-articular soft tissues, muscles, and subchondral bone. Although substantially stiffer than cartilage or joint capsule, cancellous subchondral bone is considered an important shock attenuator. Thus in this hypothesis of osteoarthritis pathogenesis, normal mechanical stresses result in microfractures of the subchondral and epiphyseal trabecular bone. However, when occurring at an excessive frequency, these fractures exceed the rate at which optimal healing and remodeling of the subchondral trabeculae can occur. Bone accretion with healing of these microfractures increases the density of the subchondral plate and adjacent trabeculae, with a concomitant reduction in the ability to absorb repetitive physiological loads. The resulting increase in bone stiffness leads to a state in which the bone-cartilage unit fails to deform normally under load, and the cartilage experiences supraphysiological stresses, resulting in mechanical damage. Subsequent events are those outlined in the following discussion of the third pathogenetic mechanism of osteoarthritis.

To date, a cause-and-effect relationship between subchondral bone plate thickening and cartilage degeneration remains to be established. The hypothesis that subchondral bone and cartilage degeneration are related is supported by the demonstration of microfractures of the subchondral plate and more distant trabeculae in arthritic specimens.[103] Moreover, in mice with osteoarthritis, cartilage degenerates over areas of sclerotic bone but remains intact over areas of normal bone density.[104] However, mathematical models predict that even with considerable increases in subchondral bone stiffness, cartilage stresses are only modestly increased.[105] Collectively these data indicate that subchondral sclerosis contributes to the osteoarthritic process but is probably not a prerequisite to initiate articular cartilage destruction.[106]

The third and most popular hypothesis of the pathogenesis of osteoarthritis is based on the concept of mechanical forces causing damage to healthy cartilage.[36,52,100,107] Matricial or cellular injury by these forces results in metabolic alterations of chondrocytes, leading to the release of proteolytic enzymes that cause cartilage fibrillation and breakdown of the proteoglycan network. Cartilage is remarkably resistant to shear forces but is relatively susceptible to repetitive impact trauma. In people, repetitive trauma is an acknowledged predisposing factor to osteoarthritis in athletes (e.g., metacarpophalangeal joints of boxers) and certain occupations (e.g., shoulder joints of jack-hammer operators). Of many potential causes, repeated microtrauma (use trauma) is probably the most common pathogenetic factor in equine osteoarthritis and the correlation of lesions at defined sites in horses participating in specific sports supports this hypothesis.

Role of the Synovium

Although conventional concepts of osteoarthritis emphasize the direct and predominant involvement of cartilage and bone in osteoarthritis development, it is increasingly recognized that the synovium contributes to the central pathophysiological event of cartilage matrix depletion increasingly. Recent investigations in several species have shown that synoviocytes are a rich source of a variety of inflammatory mediators and degradative enzymes implicated in cartilaginous degeneration, including prostaglandins,[19,20,108-111] cytokines,[112-114] and matrix metalloproteinases.[113-116] These laboratory data are supplemented by the identification of increased levels of these and other inflammatory mediators in the synovial fluid of horses with naturally occurring or experimentally induced synovitis.[117-124] Experiments using synovially conditioned culture media, or co-incubation of synovial tissues with cartilage, support a role of the synovial membrane in cartilage degradation.[125,126] However, determining the specific role of the synovium in the disease process is hampered by the fact that both chondrocytes and synoviocytes are a rich source of the pertinent mediators and enzymes. Thus precise characterization of the relative quantitative and temporal contributions of cartilage and synovium to lesion development has not yet been accomplished.

Role of the Chondrocyte

Of all joint tissues, articular cartilage shows the greatest aberration from normal during disease development, and it is generally considered that metabolic changes in chondrocytes play a primary role in the pathophysiological events of cartilage loss. In normal joints chondrocytes are responsible for maintaining a balance between matrix degradation and repair, and this equilibrium is maintained by a complex interaction between chondrocytes, cytokines, and mechanical stimuli.* In osteoarthritis a disruption of this homeostatic state develops, in which catabolic processes predominate. Though proteoglycan synthesis is greater than normal early in the disease, the rate of matrix digestion is sufficient that the result is a net loss of matrix. With this imbalance toward matrix depletion, cartilage mass is progressively lost and the viscoelastic properties of the remaining tissue become insufficient to withstand normal loads. Subsequently, cartilage fissuring and separation occur (Fig. 63-5). The ultimate result is generalized cartilage loss and secondary remodeling of bone and articular soft tissues (Fig. 63-6).

A number of studies indicate that an important initial biochemical change in osteoarthritis is the loss of aggregating proteoglycans. Up-regulation of chondrocyte proteoglycan synthesis is insufficient to offset enhanced degradation, so that the concentration in the matrix progressively diminishes. In addition to a reduced quantity of proteoglycan, the quality of molecules remaining in the matrix, and newly synthesized replacements, appears to be altered.[128,129] Collagen degradation accompanies proteoglycan loss and is manifested by surface fibrillation (Fig. 63-7). The loss of collagen and changes in collagen fibril size contribute to weakening of the matrix and may account for the increased water content in early cartilage lesions.[130-132]

Whereas the degradation of articular cartilage may occur by the action of a number of mediators, including oxygen-derived free radicals,[133-136] proteolytic enzymes synthesized by chondrocytes are thought to be the major mediators of matrix depletion. Proteinases are classified according to the catalytic mechanism into four main groups, including aspartic proteinases, cysteine proteinases, serine proteinases, and metalloproteinases. Members of each class are synthesized by chondrocytes or synoviocytes and may contribute to cartilage degradation. However, the matrix metalloproteinases and related enzymes apparently are the most active in osteoarthritis.[36,52,137-139]

Matrix-Degrading Enzymes

Matrix metalloproteinases (MMPs) are considered to play a major role in cartilage matrix degradation in osteoarthritis, because this group of proteinases is capable of digesting all major components of the extracellular matrix. The relative contributions of these proteolytic enzymes to the overall process remain to be firmly established; however, a wealth of evidence implicates them in cartilage loss. Specifically, MMPs

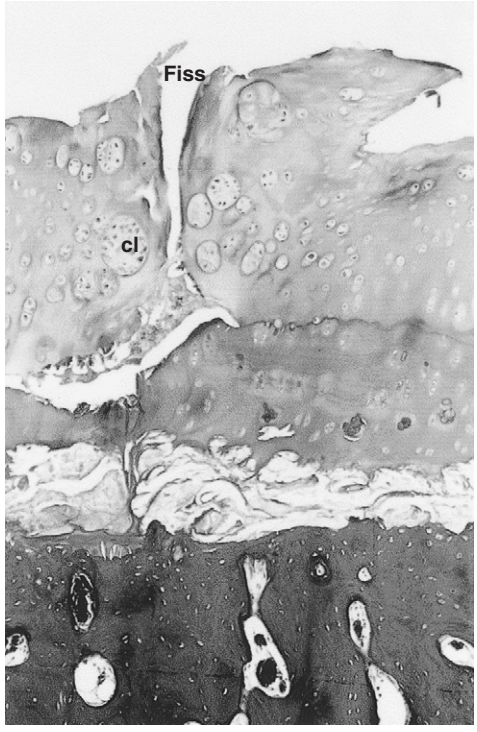

Fig. 63-5 Photomicrograph illustrating the pathological changes associated with cartilage matrix degeneration. Loss of matrix proteoglycans alters the biomechanical properties and ultimately leads to fissures (*Fiss*) in the cartilage, in this case a full-thickness fissure. Chondrocyte clones (*cl*) represent the abortive healing attempts of chondrocytes. (×50.)

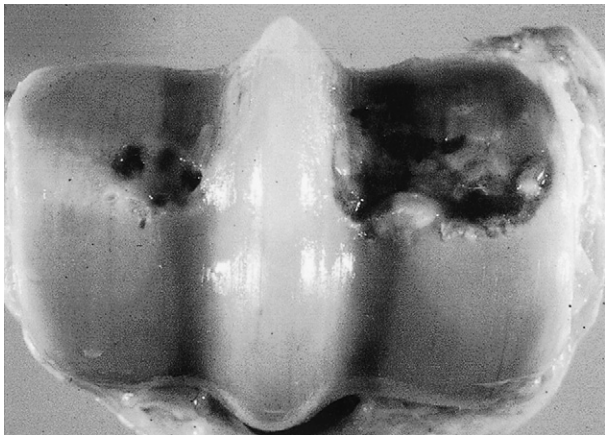

Fig. 63-6 Post-mortem specimen of the distal aspect of an equine third metacarpal bone illustrating partial and full-thickness cartilage loss. Although osteoarthritis affects all articular tissues, degeneration of extracellular matrix of cartilage and its subsequent loss is considered the central event in the disease. Note also the wear lines on the articular cartilage.

are synthesized by synoviocytes and chondrocytes[21,52,140-142] and are present in increased concentrations in diseased cartilage,[143,144] and the topographical distribution and concentration of MMPs in cartilage is correlated with the histological severity of lesions.[144-146] Several types of MMPs are expressed by articular tissues and these are classified as collagenases, stromelysins, gelatinases, membrane-type metalloproteinases, and other MMPs.[142] In addition to other substrates, collagenases degrade intact, helical type II collagen. Stromelysins cleave partially degraded collagen, proteoglycans, and other minor proteins in cartilage. The gelatinases have a diverse range of substrates, including partially degraded type II collagen and types X and XI collagen and elastin. Like collagenases, membrane-type 1-MMP is also capable of digesting fibrillar collagen and a number of other matrix components. MMPs are secreted in an inactive or latent form and require activation through proteolytic cleavage. A variety of enzymes including trypsin, chymotrypsin, plasmin, kallikrein, cathepsin B, and certain MMPs themselves are capable of such cleavage.[52,137,146] The classification and general properties of MMPs are summarized in Table 63-1.

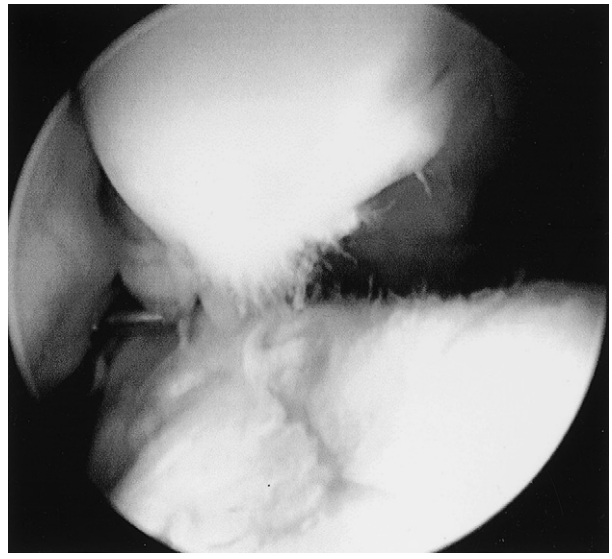

Fig. 63-7 Arthroscopic endophotograph of the middle carpal joint of a Standardbred racehorse with a large osteochondral fragment of the third carpal bone (*top*) and concomitant lesions of the intermediate carpal bone (*bottom*). Cartilage fibrillation is substantial, and its evaluation is greatly facilitated by fluid distention of the joint. Fibrillation indicates damage to the collagenous network of the extracellular matrix.

Recently several members of the ADAM (*a d*isintegrin *a*nd *m*etalloproteinase) family of enzymes have been shown to be expressed by chondrocytes.[147,148] Many of the ADAM enzymes are proteinases and are structurally and functionally related to MMPs. Importantly, certain members of this group cleave aggrecan at a specific site in the interglobular (G_1 to G_2) domain, resulting in aggrecan fragments identical to those found in the tissues and synovial fluids of osteoarthritic animals. These proteinases have been termed *aggrecanase* and share many similarities to typical MMPs, including the inactivation with conventional MMP inhibitors and being inhibited by tissue inhibitor of matrix metalloproteinase-1 (TIMP-1).[149] Recent characterization of aggrecanase has revealed that at least two forms exist and that both are ADAMTS enzymes (ADAM with thrombospondin type 1 motifs).[150,151] The thrombospondin subunits of the protein appear to be critical for the binding and digestion of aggrecan.[152] Aggrecanase is considered pivotal in proteoglycan degradation. Indeed some studies suggest aggrecanase is the principal mediator of proteoglycan depletion in osteoarthritis.[139]

In healthy cartilage the activity of proteolytic enzymes is controlled by a number of mechanisms, one of which is naturally occurring inhibitory proteins. The most important of these inhibitors are the TIMPs.[52,137,142,153] Synthesized by synoviocytes, chondrocytes, and endothelial cells, TIMPs inactivate MMPs by binding to them in a 1:1 non-covalent complex,[154]

Table • 63-1

Matrix Metalloproteinases Implicated in Cartilage Matrix Degradation

PROTEINASE*	MMP†	CARTILAGE SUBSTRATES
Collagenases		
Interstitial collagenase (collagenase 1)‡	MMP-1§	Collagens II and X (not IX and XI), denatured type II, aggrecan, link protein
Neutrophil collagenase‡	MMP-8	Collagen II, aggrecan, link protein
Collagenase 3‡‖	MMP-13§	Collagens II, IV, IX, X; aggrecan; fibronectin
Stromelysins		
Stromelysin 1‡	MMP-3§	Aggrecan, fibronectin; denatured collagen II; collagens IV, IX, X, XI; procollagens; link protein; decorin; elastin; laminin
Stromelysin 2‡	MMP-10	Same as for stromelysin 1
Gelatinases		
Gelatinase A (72 kD)‡	MMP-2§	Denatured collagen II, collagens X and XI, elastin
Gelatinase B (92 kD)‡	MMP-9§	Aggrecan, fibronectin, collagens IX and XI, procollagens, link protein, decorin, elastin
MT-MMPs		
MT1-MMP‡	MMP-14	Aggrecan, collagen II, denatured collagen II, fibronectin, laminin
Others		
Matrilysin (PUMP)‡	MMP-7	Aggrecan
Stromelysin-3	MMP-11	Proteoglycan, denatured collagen II, fibronectin, laminin
Macrophage metalloelastase	MMP-12	Elastin
Novel MMP	MMP-19	Denatured collagen II, collagen IV, aggrecan, fibronectin, laminin

*All except membrane-type 1 MMP are inhibited by some or all of the tissue inhibitors of metalloproteinases 1 to 3.
†*MMP,* matrix metalloproteinase; *MT(1)-MMP,* membrane-type (1) matrix metalloproteinase; *PUMP,* putative metalloproteinase.
‡Expressed by chondrocytes. All are expressed in synovium.
§MMPs characterized in the horse.
‖MMP-13 expression is relatively weak in equine synovium.

Table • 63-2

General Classification of Cytokines and Their Actions on Cartilage Metabolism

CATEGORY OF CYTOKINE	EXAMPLES	ACTIONS
Catabolic (pro-inflammatory) cytokines	IL-1, TNFα*	Promote MMP synthesis Promote nitric oxide and PGE_2 production Inhibit collagen II and aggrecan synthesis
Modulatory (regulatory) cytokines†	IL-4, IL-6, IL-10, IL-13	Stimulate TIMP synthesis Promote IRAP synthesis Inhibit IL-1 synthesis
Anabolic cytokines (growth factors)	IGF-1, TGF-β, bFGF	Promote collagen II synthesis Promote proteoglycan synthesis

**IL,* interleukin; *TNF,* tumor necrosis factor; *MMP,* matrix metalloprotein; *NO,* nitric oxide; *PGE_2,* prostaglandin E_2; *TIMP,* tissue inhibitor of matrix metalloproteinase; *IRAP,* interleukin-1 receptor antagonist protein; *IGF,* insulin-like growth factor; *bFGF,* basic fibroblast growth factor.
†Regulatory cytokines can have mixed actions (e.g., IL-6 amplifies IL-1 effects on MMP synthesis but induces TIMP synthesis).

and these inhibitors are hypothesized to be critical to the longevity of the extracellular matrix of cartilage.[146,155] TIMP exists in at least four forms, the first three of which (TIMP-1, TIMP-2, TIMP-3) are expressed by chondrocytes. Interestingly, each is subject to somewhat different regulatory mechanisms.[156,157] The important role of TIMPs in cartilage matrix health is supported by the observation that imbalances in the ratio of MMP to TIMP synthesis in cartilage is an important determinant of the rate of matrix degradation.[146,158]

Cytokines

Cytokine is a general term to describe a broad array of small regulatory proteins produced by a variety of cells in the body. In joints these mediators exist in a complex balance of activities that regulate the metabolism of the synovial membrane, bone, and articular cartilage in health and disease (Table 63-2).[159,160] Numerous cytokines are involved in articular metabolism and they possess one or more pro-inflammatory (catabolic), anti-inflammatory (regulatory), or anabolic functions. Important in osteoarthritis are the pro-inflammatory cytokines, such as interleukin-1 and tumor necrosis factor-α (TNFα). Chondrocyte receptors for interleukin-1 and TNFα are up-regulated in osteoarthritic cartilage and the activation of these receptors has several deleterious effects on chondrocyte metabolism.[161,162]

A wealth of recent research suggests that interleukin-1 is the most important of the pro-inflammatory cytokines in

osteoarthritis. Early studies using cartilage organ culture provided data supporting a role for interleukin-1 in cartilage matrix degradation,[163] which were supplemented by the identification of elevated levels of this cytokine in synovial fluids of affected patients, including horses.[119,120] Interleukin-1 is involved in the destruction of the extracellular matrix and formation of the functionally inadequate repair tissue in arthritic cartilage. Interleukin-1 decreases the synthesis of proteoglycans and type II collagen and induces the synthesis and secretion of proteolytic enzymes that degrade these matrix macromolecules.[164-174] Decreased synthesis of matrix macromolecules occurs in cartilage exposed to interleukin-1 concentrations substantially less than those required to stimulate matrix degradation.[166] Catabolism is further promoted by inhibition of the synthesis of matrix metalloproteinase inhibitors such as TIMP.[175] In addition, interleukin-1 stimulates the synthesis of prostaglandin E_2 and nitric oxide, the effects of which are outlined in the following discussion.[176-180] Interleukin-1 may also contribute to the proliferative events in the disease. Osteophytosis may be caused, at least in part, by the stimulation of osteoblast-like cells by interleukin-1.[181] Perhaps the most compelling evidence supporting the involvement of interleukin-1 in osteoarthritis is the protective effect of interleukin-1 receptor antagonist protein, which blocks many of the catabolic events typical of interleukin-1 in vitro. This naturally occurring competitive antagonist of interleukin-1 has also been shown to be protective for osteoarthritis-like lesions in arthritis models.[182-184]

TNFα is another pro-inflammatory cytokine that has been implicated in the development of osteoarthritic lesions and is found in elevated concentrations in inflamed and arthritic joints.[185-188] Like interleukin-1, this cytokine stimulates the synthesis of matrix degrading enzymes[172] and inhibits chondrocyte synthesis of proteoglycan and collagen.[173] TNFα appears to be less potent than interleukin-1[189]; however, the effects of interleukin-1 and TNFα are potentiated when combined.[190] TNF appears to stimulate the synthesis of interleukin-1.[191]

The degradative effects of certain cytokines, including interleukin-1 and TNFα, are balanced by inhibitory cytokines (e.g., interleukin-4, interleukin-10, and interleukin-13). Moreover, opposing effects on matrix synthesis are induced by other cytokines, also known as growth factors (e.g., insulin-like growth factor and basic fibroblast growth factor) (see Table 63-2). Using these anti-inflammatory and inhibitory cytokines to control the osteoarthritic process is an active area of research.

Nitric Oxide

Nitric oxide is another mediator of the pathophysiological events in osteoarthritis. This highly reactive, cytotoxic free radical is a by-product of the oxidation of L-arginine to citrulline, catalyzed by a group of enzymes called nitric oxide synthases, which produce large amounts of the mediator when cells expressing this enzyme are activated by mediators such as endotoxins and cytokines.[179,180,192] Early evidence for the involvement of nitric oxide in rheumatic diseases was the observation that nitrite, a stable end product of nitric oxide, was found in elevated concentrations in the synovial fluid and serum of rheumatoid arthritis patients.[193] Subsequently, it has been shown that osteoarthritic cartilage spontaneously produces nitric oxide.[194-196] Nitric oxide may mediate the inhibition of chondrocyte synthetic activities that occur in osteoarthritis. Proteoglycan and type 2 collagen synthesis are inhibited under conditions conducive to nitric oxide formation.[197-199]

Nitric oxide also is hypothesized to mediate in part the augmented expression and activation of MMPs,[200,201] and reduced synthesis of the natural interleukin-1 receptor antagonist protein.[195] However, the specific role of nitric oxide in interleukin-1–induced cartilage matrix depletion is controversial. Early laboratory studies revealed that the MMP activity in interleukin-1 and TNFα-stimulated cartilage cultures was enhanced by adding substrates favoring nitric oxide formation (nitric oxide donors) and this effect was blocked by nitric oxide synthase inhibitors.[200,201] Conversely, cytokine-mediated induction of MMP expression can occur independently of stimulation by nitric oxide,[202] and cytokine-stimulated cartilage explants cultured in the presence of nitric oxide inhibitors had rates of proteoglycan depletion comparable with controls.[203] Nonetheless nitric oxide remains an important area of study, given that in animal models of inflammatory arthritis and osteoarthritis, using compounds that directly or indirectly inhibit nitric oxide synthase activity reduces the severity of lesions.[204-207]

Prostaglandins

Prostaglandins are found in elevated concentrations in inflamed joints,[185,208] and although the specific effects of prostaglandins on joint metabolism are unclear, it is widely held that prostaglandin E_2 contributes to the lesions of osteoarthritis. Prostaglandin E_2 causes synovial inflammation and may contribute to cartilage matrix depletion[209,210] and the erosion of cartilage and bone.[211] Certain data indicate that prostaglandins may actually modulate the release of metalloproteases, such as collagenases and stromelysins.[212,213] Conversely, increasing evidence suggests that cytokine and matrix metalloprotease expression in articular cells is regulated by E-series prostaglandins.[20,214] The net effect of this regulation is unclear, because like corticosteroids, prostaglandin E_2 appears to inhibit TIMP synthesis and MMP synthesis.[215] Moreover, some of the effects of prostanoids may be indirect, acting by promoting the synthesis of other proteins that have unique influences on cartilage metabolism.[216] Thus, although prostanoids are a factor in the signs and certain of the pathophysiological processes of osteoarthritis, the specific role in regulating cartilage depletion and the interactions with other mediators of cartilage lesion development requires elucidation.

Clinical Evaluation of Joint Disease

Joint Pain

Traumatic arthritis and osteoarthritis may be the most common cause of lameness in equine athletes of all types. Unfortunately there is a weak correlation between the magnitude of pain and the severity of articular damage observed.[217-219] The hallmark of osteoarthritis is articular cartilage degeneration, a process occurring in a tissue devoid of sensory innervation. As a result, lameness is typically attributed to involvement of peri-articular soft tissues and bone, the former being relatively richly innervated. In capsular and ligamentous tissues, unmyelinated sensory nerve fibers conduct painful sensations from widely distributed free nerve endings.[220,221] With joint inflammation, these receptors exhibit increased sensitivity. Specifically the threshold for these receptors is reduced by inflammatory mediators such as prostaglandins, and increased receptor activity accompanies physiological joint excursions.[222] Although the severity of soft tissue changes and lameness are related,[223,224] horses with significant peri-articular fibrosis occasionally demonstrate less than the expected degree of lameness. Studies of joint capsule innervation in arthritic specimens have revealed that with time degeneration of neurons is common, which provides a potential reason for the less than expected magnitude of pain in some patients having clearly demonstrable changes in peri-articular soft tissues.

Bone and periosteum also contribute to osteoarthritis pain. The periosteum is well innervated, and the periosteal disruption that accompanies the development of peri-articular osteophytes is a source of joint pain.[225] The subchondral plate and epiphyseal trabecular bone make variable contributions to clinical signs. For example, many, but not all, horses with subchondral cystic lesions demonstrate lameness.[226-228] Inconsistent lameness among horses with similar radiographic signs parallels the weak correlation between pain and radiographic findings of

early osteoarthritis in people.[229,230] Osseous receptor stimulation often accompanies joint movements that cause elevations in intramedullary pressure. People with osteoarthritis of the hip have elevated intra-osseous pressure,[231] which in some people responds favorably to cortical fenestration. Elevation in intramedullary pressure occurs with significant flexion or extension of equine joints and is a likely source of articular pain in some horses. For example, both simulated effusion and metatarsophalangeal joint flexion increase intramedullary pressure in the third metatarsal bone.[232] The concept also is supported by the clinical observation of a favorable response to transcortical decompression in horses with lameness related to osseous cyst-like lesions.

Local Signs

Limited range of motion is a common feature of equine joint disease and is probably caused by a combination of factors, including guarding from pain, synovial effusion and edema, and progressive peri-articular fibrosis. Synovial edema and proliferation and pain are probably the main causes of reduced range of motion in horses with early osteoarthritis, whereas fibrosis is important in chronically affected horses. The specific mechanisms causing peri-articular fibrosis are unclear. However, cytokines and neuropeptides are likely to contribute to fibrosis, given the mitogenic effects on fibroblasts of these substances.[233-235]

Effusion is a common feature of joint disease and is manifested in distal joints as visible or palpable distention of joint pouches. Leakage of protein into the synovial space, because of increased permeability in the capillary endothelium and intercellular spaces of the synovium, which is not matched by compensatory increases in lymphatic clearance, leads to a progressively increased colloid osmotic pressure and augmented synovial fluid volume. Although mild effusion enhances nutrient exchange in the joint,[236] significant effusion results in progressively elevated intra-articular pressure that ultimately destabilizes the joint and causes pain, stiffness, and a reduced range of motion. Increased permeability of the synovium to cells and proteins varies with the degree of synovial inflammation and is reflected in cytological findings in synovial fluid samples.

Synovial Fluid Changes

Reduced viscosity of synovial fluid is a frequent finding in horses with joint disease, particularly in horses with active synovitis. Reduced viscosity has been attributed to a reduced concentration, or depolymerization, of synovial fluid hyaluronan. Substantial reductions in hyaluronan concentration have been documented in the synovia of horses with chronic traumatic arthritis[237]; however, considerable variability exists. In a study comparing the hyaluronan concentration in normal horses with those having lameness that could be eliminated by intra-articular analgesia, normal horses had a mean hyaluronan concentration approximately 50% higher than that of horses with synovitis. However, the variability between horses was sufficient that this difference was not statistically significant.[238] Clinical determinations of hyaluronan concentration are not routine because of this variability and the technically involved procedures required for the quantitative determination of hyaluronan. The mucin clot test is a relatively simple, semi-quantitative test of hyaluronan quantity and quality, but it is not particularly sensitive. Therefore the quality of hyaluronan is often determined clinically by assessing viscosity on gross inspection of synovial fluid obtained during arthrocentesis.

Because increases in cell numbers and protein concentration in osteoarthritis are not dramatic, cytological evaluation of synovial fluid is not used routinely diagnostically. Cytological analysis of synovial fluid is most useful in identifying and monitoring infection and untoward post-injection reactions. Approximate values for cell count and total protein concentrations under a variety of clinical situations are given in Table 63-3. Total protein concentration varies between joints, tending to be considerably higher in the larger, more proximal joints, such as the scapulohumeral joint.

Role of Radiography

Radiography has long been the traditional means of assessing the structural changes of osteoarthritis (see Chapter 15). Radiography has the advantages of availability, convenience, relative safety, and economy. Indeed, it is standard practice for many veterinarians to localize lameness to a particular area of the limb and subsequently to obtain radiographs in an attempt to identify changes to support a diagnosis of osteoarthritis. Unfortunately, although radiography has some merit in characterizing changes in bone that accompany established osteoarthritis, the technique lacks sensitivity and is of dubious value in identifying patients with incipient or focal lesions. It is well known that radiographically undetectable performance-limiting lesions occur in horses.[247,248]

Radiographic findings tend to witness past events in the pathological process and do not consistently reflect ongoing processes. Additionally, in horses, as has been long accepted in people, a lack of correlation exists between lameness or reduced performance and specific osseous structural changes evident on radiographs.[249-253] A lack of correlation with arthroscopically evident degeneration and radiographic findings is also common.[254-257] In addition to this underlying fundamental biological dichotomy, precise quantification of radiographic findings is hampered by difficulties in precisely duplicating conditions from one radiographic examination to the next. Positioning, degree of weight bearing, and radiographic technique contribute measurably to results. Nonetheless, largely because of its aforementioned advantages, radiography remains a principal method of evaluating horses with joint disease.

The radiological features of osteoarthritis mirror the pathological changes occurring in the affected joint (Fig. 63-8). Initially, joint space narrowing, subchondral sclerosis, and osteophytosis occur. With time subchondral lysis, osteochondral fragmentation, and eventually ankylosis may develop (Box 63-1).

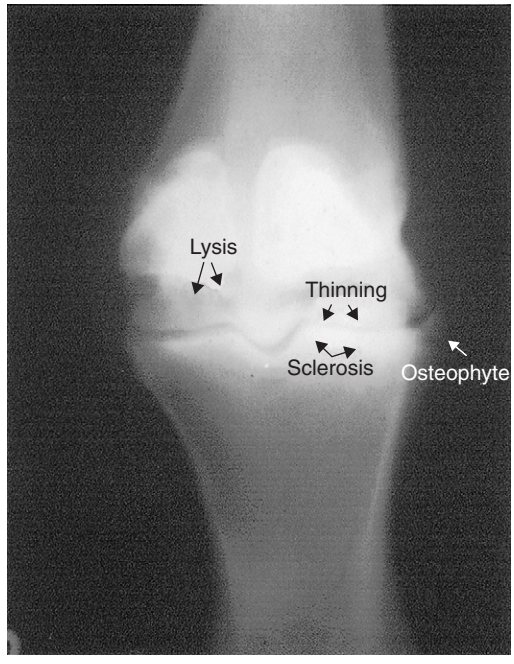

Fig. 63-8 Dorsopalmar radiographic projection of the metacarpophalangeal joint of a horse demonstrating radiographic changes of advanced osteoarthritis. Peri-articular osteophytosis, joint-space thinning, and subchondral sclerosis and subchondral lysis are indicated.

Table • **63-3**

Synovial Fluid Cytology for Various Clinical Conditions and Diagnostic or Therapeutic Manipulations[239-246]*

PARAMETER	NORMAL	MILD SYNOVITIS (e.g., OCD)	OSTEOARTHRITIS	INFECTIOUS ARTHRITIS†	ARTHROCENTESIS‡	BALANCED ELECTROLYTE SOLUTION‡	LOCAL ANESTHETICS‡§	GENTAMICIN‡	DMSO‡ (10% SOLUTION)
Total leucocytes (per µl)	50-500	20-250	≤1 × 10^3	20-200 × 10^3	1-4 × 10^3	6-45 × 10^3 (typically 20 × 10^3)	2-10 × 10^3		8-40 × 10^3

* Listed ranges are approximate. Considerable variability exists in published reports.
† Significant elevations in leukocyte counts and total protein concentration occur within the first 12 hours in experimentally inoculated joints. Values shown represent those observed at 24 hours.
‡ Leukocyte counts and total protein concentrations correspond to the maximum values that typically occur within the first 24 hours.
§ Synovial response to lidocaine and mepivacaine are comparable.

Box • **63-1**

Radiographic Features of Osteoarthritis

Radiographic feature	*Pathogenetic mechanism**
Peri-articular osteophytosis	Endochondral ossification occurring at bony margins of unknown cause. Possible repair attempt modulated by altered cytokine milieu.
(Asymmetrical) Joint space thinning	Cartilage degeneration and loss.† Usually at areas of weight bearing or high stress. May be absent when focal cartilage loss occurs.
Subchondral sclerosis	Deposition of new bone as a response to changes in force transmission and from healing of trabecular microfractures. Corresponds to areas of maximum stress. Significant sclerosis often corresponds to full-thickness cartilage loss.
Subchondral lysis	Less common change of uncertain pathogenesis. Possibly pressure necrosis from synovial fluid gaining access to subchondral plate via fissures, or related to pressure necrosis from trauma to bone.
Osteochondral bodies	Disintegration of joint surfaces or fractured osteophytes. May represent inciting lesions (e.g., osteochondral fracture).
Advanced remodeling/ankylosis	Articular response to advanced degeneration. Environment more consistent with fracture than synovial joint.

*Specific pathophysiological mechanisms and reasons for disproportionate representation of changes among and between joints remain unclear.
†Seldom used as a marker of disease progression because of problems with technical aspects of radiographic positioning and focal-film distance.

In horses substantial differences appear between specific joints respecting the relative degree of these changes. For example, radiographically evident changes tend to be less dramatic and appear later in the disease process in the metacarpophalangeal and metatarsophalangeal joints than in many other articulations.

Other Imaging Modalities

Increasingly available are other imaging modalities for assessing joint diseases. Among them are nuclear scintigraphy, magnetic resonance imaging (MRI), and ultrasonography.

Nuclear scintigraphy. Although more commonly used to detect non-displaced, incomplete fractures and to identify stress-related bone damage in performance horses, nuclear scintigraphy can provide useful information in selected horses with joint disease (see Chapter 19). Whereas radiography (and related techniques, including computed tomography) provide considerable anatomical detail of osseous changes in affected joints, nuclear scintigraphy yields current physiological information on bone metabolism. The main disadvantages of scintigraphy are its relatively poor resolution (isotopes produce much fewer gamma rays than the number of x-rays generated by a cathode tube) and a lack of specificity, because bone responds to most insults by increasing turnover. Owing to the unavailability of a cartilage specific agent, the most common approach to the scintigraphic study of osteoarthritis is using the delayed bone scan images, obtained 3 to 4 hours after injection of the radiopharmaceutical. Currently used agents are the biphosphonates, which bind to the microcrystals of hydroxyapatite in bone. Areas of increased bone modeling have enhanced localization of the radiopharmaceutical, as long as an adequate blood supply exists.

It has long been known that bone-seeking isotopes accumulate rapidly in the bone of osteoarthritis joints.[258] The most intense radiopharmaceutical uptake typically occurs in the subchondral bone and at the osteochondral junctions of osteophytes, although temporal variation in the anatomical distribution of uptake may occur, as has been illustrated in an animal osteoarthritis model.[259] Evidence exists that scintigraphy is useful in predicting the progression of osteoarthritis in the human knee,[260] and scintigraphy apparently may prove useful in diagnosing preclinical joint disease, that is, before the appearance of radiographic abnormalities.[261] Conversely, bone-phase scans may be normal in chronic osteoarthritis joints if the rate of bone turnover returns to normal.

In the equine athlete, scintigraphy has proved useful to document a number of sport-specific lesions among different types of equine athletes.[251,262,263] Unlike the human digit, the size of the bones in the equine skeleton is sufficient that relatively precise anatomical localization of lesions is often possible. Moreover, nuclear scintigraphy has the advantage of allowing a survey of all joints in a single examination. Importantly, as for radiography, close correlation between lameness and scintigraphic findings does not always exist.[251,264]

Magnetic resonance imaging. This imaging method involves detecting alternating electrical current produced when hydrogen protons, predominately found in fat and water, are subjected to pulsed electromagnetic fields applied in a specific manner (see Chapter 21). The rate at which protons change orientation varies among soft tissues and fluids of different composition, which allows the considerable tissue discrimination possible with MRI.

Although to date MRI has played a minor role in assessing joint disease in animals and people, MRI has a number of compelling advantages over many of the existing modalities. Specifically, MRI has the capacity for high-resolution, three-dimensional (tomographic) images of all joint components, obtained in a non-invasive manner. Moreover, advances in equipment and improved imaging sequences provide much greater contrast between articular cartilage and surrounding soft tissues than was previously possible. Indeed, variations in the orientation of collagen in the cartilage matrix provide for images with four laminae corresponding to the histological zones of the tissue. Changes at the tissue level that accompany osteoarthritis include increased water content and matrix swelling, which can be detected by this imaging method.[265] Using specialized techniques to optimize resolution and reduce interference from adjacent fat and fluid, evaluating moderately sized articular cartilage defects with considerable sensitivity and specificity is possible.[266,267] Beyond cartilage

changes, MRI also can be used to characterize the amount and nature of synovial fluid and is a sensitive means of delineating osteophytes and subchondral bone changes.[265] Importantly the identification of subtle lesions requires relatively sophisticated equipment and considerable experience for proper image acquisition and interpretation.

To date, MRI in the horse has been largely limited to anatomical and correlative studies of cadaver specimens.[268-271] In one of the few published reports of using the technique to investigate osteoarthritis in the horse, postmortem magnetic resonance images of the metacarpophalangeal joint correlated well with arthroscopic and necropsy findings.[272] Widespread use of MRI in horses is limited by the expense and the tunnel configuration of currently available equipment. Some time may pass before equipment and software will be available that allows routine use of the technology in equine athletes. Developments in low-field magnets adaptable to the standing horse represent a potential means by which magnetic resonance technology soon may be more readily applicable to horses.[273]

Ultrasonography. Ultrasonographic evaluation of diseased joints represents an additional diagnostic tool that has enjoyed increased use lately (see Chapter 17). Ultrasonography initially was used to assess chronic proliferative synovitis in the metacarpophalangeal joint.[274,275] More recently its use has expanded to include most appendicular (and some axial) skeletal joints.

The principal benefit of ultrasonographic examination over conventional radiography is its superiority in demonstrating soft tissue abnormalities. With experience and an appropriate knowledge of the regional anatomy and acoustic principles, it is possible to identify and localize accumulations of synovial or other fluids, thickened synovial and capsular tissues, damaged intra-articular and peri-articular ligaments, peri-articular osteophytes and entheseophytes, osteochondral fragments, and irregularities in cartilage and subchondral bone. Inherent limitations of ultrasonography preclude its use in areas where the volume of tissue overlying the joint of interest is too voluminous and for structures having a shape or orientation that is not conducive to ultrasonographic evaluation. The principles and techniques of ultrasonographic examination of equine joints were recently the subject of an excellent review.[276]

CHAPTER • 64

Markers of Osteoarthritis: Implications for Early Diagnosis and Monitoring of Pathological Course and Effects of Therapy

David Frisbie

Although joint disease can be diagnosed using routine clinical methods, more accurate and earlier diagnosis may lead to identification of osteoarthritis before irreversible changes occur within joint tissues. Measuring levels of molecular products of tissue turnover, that is, biomarkers, from healthy and diseased cartilage and bone has the potential to achieve early diagnosis and allow a better understanding of osteoarthritis pathophysiology. The potential also exists to monitor disease, especially in response to novel therapeutic agents. Work with biomarkers of articular cartilage and bone in human and equine osteoarthritis patients has yielded promising results. This chapter discusses some of the markers that currently are being evaluated in synovial fluid and serum samples, with a focus on those of potential benefit to the equine industry.

STRUCTURE AND METABOLISM OF ARTICULAR CARTILAGE AND BONE IN HEALTH AND DISEASE

Articular cartilage is a complex tissue with an extensive extracellular matrix. The two main components that define the cartilage matrix are type II collagen and aggrecan (see Chapter 63). A balance of synthesis and degradation orchestrated by the chondrocytes maintains normal populations of these molecules within the cartilage matrix. Osteocytes, osteoblasts, and osteoclasts maintain the structural and functional integrity of bone matrix by regulating synthetic and degradative pathways. Synoviocytes also influence homeostasis in cartilage and bone. Osteoarthritis often is characterized by degradative changes within articular cartilage, bone, and synovium. Direct and indirect factors assault the matrix molecules of these tissues, resulting in degeneration and loss of some macromolecules.

What are direct and indirect molecular markers? Fibrillar collagens, such as types I and II, are synthesized as immature procollagens that undergo proteolytic changes before conversion to mature collagen fibrils. Peptides at either end of the procollagen molecule are cleaved before the procollagen is incorporated into a mature collagen fibril. Estimations of type II collagen synthesis have been obtained from synovial fluid and serum samples by using a specific antibody that recognizes the propeptides cleaved from the carboxy termini.[1] This direct molecular marker specifically identified a known molecular process within a given tissue. Conversely, an indirect molecular marker reflects more general change that is not clearly definable and may represent contributions from several events and tissues. Indirect markers are cytokines, growth factors, and matrix metalloproteinases (MMPs). Osteoarthritis involves changes in subchondral bone and synovium, so assessment of molecular markers from these tissues is relevant.

CHAPTER • 64

Markers of Osteoarthritis: Implications for Early Diagnosis and Monitoring of Pathological Course and Effects of Therapy

David Frisbie

Although joint disease can be diagnosed using routine clinical methods, more accurate and earlier diagnosis may lead to identification of osteoarthritis before irreversible changes occur within joint tissues. Measuring levels of molecular products of tissue turnover, that is, biomarkers, from healthy and diseased cartilage and bone has the potential to achieve early diagnosis and allow a better understanding of osteoarthritis pathophysiology. The potential also exists to monitor disease, especially in response to novel therapeutic agents. Work with biomarkers of articular cartilage and bone in human and equine osteoarthritis patients has yielded promising results. This chapter discusses some of the markers that currently are being evaluated in synovial fluid and serum samples, with a focus on those of potential benefit to the equine industry.

STRUCTURE AND METABOLISM OF ARTICULAR CARTILAGE AND BONE IN HEALTH AND DISEASE

Articular cartilage is a complex tissue with an extensive extracellular matrix. The two main components that define the cartilage matrix are type II collagen and aggrecan (see Chapter 63). A balance of synthesis and degradation orchestrated by the chondrocytes maintains normal populations of these molecules within the cartilage matrix. Osteocytes, osteoblasts, and osteoclasts maintain the structural and functional integrity of bone matrix by regulating synthetic and degradative pathways. Synoviocytes also influence homeostasis in cartilage and bone. Osteoarthritis often is characterized by degradative changes within articular cartilage, bone, and synovium. Direct and indirect factors assault the matrix molecules of these tissues, resulting in degeneration and loss of some macromolecules.

What are direct and indirect molecular markers? Fibrillar collagens, such as types I and II, are synthesized as immature procollagens that undergo proteolytic changes before conversion to mature collagen fibrils. Peptides at either end of the procollagen molecule are cleaved before the procollagen is incorporated into a mature collagen fibril. Estimations of type II collagen synthesis have been obtained from synovial fluid and serum samples by using a specific antibody that recognizes the propeptides cleaved from the carboxy termini.[1] This direct molecular marker specifically identified a known molecular process within a given tissue. Conversely, an indirect molecular marker reflects more general change that is not clearly definable and may represent contributions from several events and tissues. Indirect markers are cytokines, growth factors, and matrix metalloproteinases (MMPs). Osteoarthritis involves changes in subchondral bone and synovium, so assessment of molecular markers from these tissues is relevant.

INDIVIDUAL SKELETAL BIOMARKERS OF ARTICULAR CARTILAGE METABOLISM IN OSTEOARTHRITIS

Anabolic Processes

The carboxy propeptide of type II collagen is a useful measure of the anabolic process of type II collagen synthesis. Levels of carboxy propeptide of type II collagen were significantly higher in synovial fluid from people with osteoarthritis compared with those without osteoarthritis. Levels peaked early in the radiographic progression of the disease and declined in patients with severe radiographic changes.[2,3] This biomarker also has been shown to change significantly in serum samples from people with osteoarthritis and rheumatoid arthritis.[4,5]

Chondroitin sulfate (CS) is a major glycosaminoglycan (GAG) of aggrecan, and measuring specific CS epitopes on newly synthesized proteoglycan (PG) molecules is a useful biomarker for aggrecan synthesis. An epitope called CS-846 that normally is found in fetal, but is almost absent in healthy adult articular cartilage has been measured in many species. Levels of CS-846 epitope are increased in synovial fluid in people after injury or primary osteoarthritis compared with levels in synovial fluid from normal joints. Serum levels also are elevated in joint disease but to a lesser extent than synovial fluid levels.[6,7] Other CS epitopes such as 3B3 and 7D4 were shown to be useful in assessing cartilage injury in animal models and in people with clinical disease.[8] Using arthroscopic evaluation, a negative correlation was found between synovial fluid 3B3 concentrations and gross articular damage that was thought to be caused by decreased normal cartilage volume, or inhibition of synthesis, with increasingly severe lesions. Conversely, in people, increased levels of synovial 7D4 epitope were found in diseased knees compared with contralateral normal knees.[9]

Catabolic Processes

Measuring the degradation of type II collagen is of potential benefit in monitoring osteoarthritis. Antibodies have been developed to identify exposed but previously inaccessible cleaved or denatured type II collagen fragments. Significant elevations in levels of degraded type II collagen were demonstrated in synovial fluid and serum samples from horses, dogs, and rabbits with experimental osteoarthritis.[10,11] Significant increases were detected in the serum of people with osteoarthritis, with a correlation to disease activity.[10]

Keratan sulfate (KS), one of the GAGs found on proteoglycan molecules of aggrecan, has been evaluated extensively. In people, elevations in serum levels of KS were associated with osteoarthritis in some, but not all, studies.[7,12,13] Lack of correlation of serum[14] and synovial fluid[8] KS levels with cartilage damage leads me to question the value of serum KS as a biomarker of joint disease in people. In dogs a specific KS epitope (5D4) was of limited value in experimentally induced and naturally occurring cruciate injury.[15,16] The usefulness of KS in serum and synovial fluid of horses with osteochondral fragmentation is also questionable.[17]

In an initial equine study of molecular markers, carboxy propeptide of type II collagen and the GAG epitopes CS-846 and KS were measured in synovial fluid and serum of horses with and without carpal osteochondral fragments.[17] Synovial fluid and serum CS-846 epitope concentrations were significantly higher in joints with osteochondral fragments compared with normal joints and showed good correlation with grades of cartilage damage. Serum concentrations of carboxy propeptide of type II collagen were elevated in horses with osteochondral fragments, and good correlation between carboxy propeptide of type II collagen concentration and arthroscopic lesion grade was found. A single blood sample assayed for CS-846 and carboxy propeptide of type II collagen levels resulted in 79% accuracy for prediction of an osteochondral fragment.

CS-846, KS, and carboxy propeptide of type II collagen concentrations were measured in synovial fluid from normal joints and those with osteochondrosis.[18] Significantly higher levels of carboxy propeptide of type II collagen and lower amounts of CS-846 and KS epitopes were found in affected joints compared with normal joints.

Cartilage oligomeric protein (COMP) is an abundant non-collagenous protein constituent of cartilage. COMP was once thought to be cartilage-specific, but recently it also has been localized in tendons and synovium. Serum and synovial fluid concentrations of COMP are increased in people with osteoarthritis.[19,20] A positive correlation exists between COMP levels and radiographic grading of osteoarthritis, progression of radiograhpic changes,[21] and results of nuclear scintigraphy.[22] Gene expression of COMP in synoviocytes is up-regulated in osteoarthritis, suggesting that this marker may be useful to indicate synovitis.

Initial work in the horse demonstrated that serum and synovial fluid levels of COMP were significantly lower in diseased joints.[23] Horses with osteoarthritis lesions of the third carpal bone had lower COMP levels in synovial fluid compared with normal joints.[24]

INDIVIDUAL SKELETAL BIOMARKERS OF BONE METABOLISM IN JOINT DISEASE

Anabolic and catabolic cascades exist in bone, but specific markers in normal and disease states are not clearly defined. This section deals only with bone markers thought to be significant in joint disease.

Anabolic Processes

Osteocalcin (OC) is a small non-collagenous protein associated with bone assembly and turnover and has been measured in serum and synovial fluid samples from people with osteoarthritis. Levels of OC correlated with bone scan findings and markers of cartilage metabolism.[22,25] However, because OC levels are higher in serum than synovial fluid, OC in synovial fluid may be derived from peripheral blood and may not reflect local joint disease.[25]

OC levels were measured in horses, and as in people, they appear to vary with age and with the administration of corticosteroids,[25,26] but the effect of gender remains unclear.[26] General anesthesia affects serum OC levels for 4 days.[27]

Bone-specific alkaline phosphatase is an isoform of alkaline phosphatase that is expressed at high levels on the cell surface of the bone-forming osteoblasts and plays an important role in bone formation. In a recent equine study a correlation was found between synovial fluid levels of bone-specific alkaline phosphatase, KS-5D4 epitope, and total GAG, and between all three biomarkers, and the amount of joint damage defined arthroscopically.[28] This supports a putative role for altered subchondral bone metabolism in equine osteoarthritis.

Catabolic Processes

Type I collagen C-telopeptides (CTX) may be useful markers of bone resorption. CTX levels in people with rheumatoid arthritis were positively correlated with indices of disease activity and joint destruction.[29,30] The marker was influenced by the administration of corticosteroids. CTX is present in equine serum, although its usefulness as a marker of pathological processes is unknown.[31]

Human bone sialoprotein is found only in adult bone, and levels are seven times higher at the interface of cartilage and bone compared with other locations in bone.[32] Serum levels are elevated significantly in people with clinical osteoarthritis

and those with bone scans consistent with osteoarthritis.[32,33] Detection of equine bone sialoprotein has not been reported, although development of an assay is currently under way. The hope is that this will be useful in identifying subchondral bone damage in horses with osteoarthritis.

FUTURE OF BIOMARKERS IN OSTEOARTHRITIS

Limited data are available regarding using biomarkers to diagnose and monitor equine joint disease. Factors influencing levels of biomarkers include liver and kidney clearance, circadian rhythms, intestinal peristalsis, exercise level, age, breed, diet, sex, drug administration, surgery, and general anesthesia. Methods of sample collection and storage also may be influential.

Although biomarkers may have a role in diagnosis and monitoring equine joint disease, a combination of markers likely will be required, especially because so many factors influence activity. Preliminary results from our ongoing study indicate that serum levels of OC, GAG, and a type I/II collagen degradation product, a biomarker of collagen cleavage, are significantly elevated in horses with an experimentally induced osteochondral fragment in the middle carpal joint. A prospective study is currently under way to investigate whether serum levels of bone and cartilage markers can predict important musculoskeletal injuries in Thoroughbreds in training.

ACKNOWLEDGMENT

I thank Dr. R. Clark Billinghurst for his insight and review of this chapter.

CHAPTER • 65

Models of Equine Joint Disease

Chris E. Kawcak

Animals have been used extensively as models of joint disease to represent clinical conditions in people. However, veterinary researchers have the luxury of using experimental animals from species that are clinically relevant. Unlike human research, one has no need to assume similarity in findings between species. Equine models of joint disease have been used for several decades to test the effects of drugs and various treatments on joints and to evaluate the pathogenesis of certain diseases. Joint disease can be assessed in horses with clinical disease; however, large numbers are needed for each treatment group to see significant differences in the face of great variation among individual horses. Owner compliance, differing treatment protocols between clinicians, and variability between horses in response to disease and treatment (such as conformation, limb use, and size) all contribute to this variation. Furthermore, clinical studies take a long time, not only to perform, but also to see the effects of treatment. Consequently, in vitro and in vivo models have been developed to give researchers better controlled studies that can be done in a relatively short period of time.

The model to be used should be designed to answer a question by using a testable hypothesis. Variability should be reduced as much as possible so that the question can be answered with little outside influence. However, as more and more variables are eliminated, the model becomes less representative of the clinical situation. For instance, the efficacy of oral joint supplements in reducing joint disease cannot rely solely on results from in vitro studies. The drugs must be tested in vivo to determine if and how they work. However, to determine the effects of a drug or chemical on articular cartilage matrix metabolism, a quick, relatively inexpensive in vitro test can be conducted. Therefore the type of model to be used depends on the question to be answered.

Two types of models are used to study equine joint disease. In vitro models can be used to study various treatments in cell lines and tissue cultures and involve using cells, cell lines, or tissues harvested from joints to test usually one specific pathological pathway or treatment scheme. In vivo systems can be used to test drugs and to determine the pathophysiological response to an insult. Unlike in vitro studies, in vivo studies involve the entire joint, allowing researchers to assess the whole organ to determine truly the clinical efficacy of a drug.

In this chapter the complexity of joint disease and the use of joint models are discussed. The difficulties in modeling joint disease, the rationale for selecting specific models, specific examples of models used for the study of the joint disease, and the current status and future use of equine models of joint disease are considered.

COMPLEXITY OF JOINT DISEASE

The joint can be considered an organ because it comprises several different types of tissues, which biomechanically and biochemically interact with each other. Joint disease can result from several factors. First, the disease has a direct biochemical effect on all tissues. For instance, with synovitis, inflammatory mediators can be released into the joint space and put the articular cartilage into a catabolic state.[1-4] Second, the pain produced by joint disease can result in a change in the character of the gait.[5,6] Consequently this change in joint loading alters biomechanical inputs on all tissues, resulting in a biochemical change in the response by tissues.[7,8] Third, disease of one tissue can result in a change in the mechanical input on another tissue. For instance, articular cartilage degeneration, which can result in increased stress to subchondral bone, can induce a sclerotic response.[9] As another example, subchondral bone sclerosis, which commonly occurs in racehorses, can lead to increased stress on overlying articular cartilage.[10] Therefore in the live animal all tissues are affected by one another.

Because several factors can influence joint disease, researchers have attempted to control these influences in experimental studies. However, not all of the factors can be controlled. For instance, several mechanical factors play a role in joint disease: specifically, mechanical input can vary with horse size, exercise intensity, conformation, neurological control, and lameness. Consequently, differences in the stress to joints can result in changes in biochemical pathways in those tissues. For instance, ponies are one third to one half the size of horses and have little naturally occurring joint disease. Therefore, they may not be the best equine models of joint disease for joint healing studies and exercise studies because of lower imposed stresses. However, they are still good models if imposed stresses do not play a role in the specific disease

Models of Equine Joint Disease

Chris E. Kawcak

Animals have been used extensively as models of joint disease to represent clinical conditions in people. However, veterinary researchers have the luxury of using experimental animals from species that are clinically relevant. Unlike human research, one has no need to assume similarity in findings between species. Equine models of joint disease have been used for several decades to test the effects of drugs and various treatments on joints and to evaluate the pathogenesis of certain diseases. Joint disease can be assessed in horses with clinical disease; however, large numbers are needed for each treatment group to see significant differences in the face of great variation among individual horses. Owner compliance, differing treatment protocols between clinicians, and variability between horses in response to disease and treatment (such as conformation, limb use, and size) all contribute to this variation. Furthermore, clinical studies take a long time, not only to perform, but also to see the effects of treatment. Consequently, in vitro and in vivo models have been developed to give researchers better controlled studies that can be done in a relatively short period of time.

The model to be used should be designed to answer a question by using a testable hypothesis. Variability should be reduced as much as possible so that the question can be answered with little outside influence. However, as more and more variables are eliminated, the model becomes less representative of the clinical situation. For instance, the efficacy of oral joint supplements in reducing joint disease cannot rely solely on results from in vitro studies. The drugs must be tested in vivo to determine if and how they work. However, to determine the effects of a drug or chemical on articular cartilage matrix metabolism, a quick, relatively inexpensive in vitro test can be conducted. Therefore the type of model to be used depends on the question to be answered.

Two types of models are used to study equine joint disease. In vitro models can be used to study various treatments in cell lines and tissue cultures and involve using cells, cell lines, or tissues harvested from joints to test usually one specific pathological pathway or treatment scheme. In vivo systems can be used to test drugs and to determine the pathophysiological response to an insult. Unlike in vitro studies, in vivo studies involve the entire joint, allowing researchers to assess the whole organ to determine truly the clinical efficacy of a drug.

In this chapter the complexity of joint disease and the use of joint models are discussed. The difficulties in modeling joint disease, the rationale for selecting specific models, specific examples of models used for the study of the joint disease, and the current status and future use of equine models of joint disease are considered.

COMPLEXITY OF JOINT DISEASE

The joint can be considered an organ because it comprises several different types of tissues, which biomechanically and biochemically interact with each other. Joint disease can result from several factors. First, the disease has a direct biochemical effect on all tissues. For instance, with synovitis, inflammatory mediators can be released into the joint space and put the articular cartilage into a catabolic state.[1-4] Second, the pain produced by joint disease can result in a change in the character of the gait.[5,6] Consequently this change in joint loading alters biomechanical inputs on all tissues, resulting in a biochemical change in the response by tissues.[7,8] Third, disease of one tissue can result in a change in the mechanical input on another tissue. For instance, articular cartilage degeneration, which can result in increased stress to subchondral bone, can induce a sclerotic response.[9] As another example, subchondral bone sclerosis, which commonly occurs in racehorses, can lead to increased stress on overlying articular cartilage.[10] Therefore in the live animal all tissues are affected by one another.

Because several factors can influence joint disease, researchers have attempted to control these influences in experimental studies. However, not all of the factors can be controlled. For instance, several mechanical factors play a role in joint disease: specifically, mechanical input can vary with horse size, exercise intensity, conformation, neurological control, and lameness. Consequently, differences in the stress to joints can result in changes in biochemical pathways in those tissues. For instance, ponies are one third to one half the size of horses and have little naturally occurring joint disease. Therefore, they may not be the best equine models of joint disease for joint healing studies and exercise studies because of lower imposed stresses. However, they are still good models if imposed stresses do not play a role in the specific disease

being studied, such as induced synovitis models. Tissue material properties also have an influence on joint disease. For instance, weaker tissues undergo greater biomechanical changes than those that are stronger. Forces that control material properties of tissues include genetics, loading history, and age of the animal. The tissue remodeling status and the ability of animals to remodel articular cartilage, subchondral bone, and soft tissues can also influence joint disease, which is also affected by age, loading history, and genetics. The inflammatory response can also change the joint environment. Specifically, differences in the immune system at the time of disease can greatly influence the inflammatory response to the joint and influence the concentration of cytokines released into the joint.

Variables such as age, size, conformation, and neurological status can be controlled in experimental in vivo studies. However, loading history and the presence of subclinical disease are virtually impossible to control. With the advent of more sophisticated imaging equipment, such as computed tomography (CT), more information on loading history and subclinical disease can be obtained. For instance, subchondral bone density is indicative of loading history.[11] Therefore, researchers in the Equine Orthopaedic Research Laboratory (EORL) at Colorado State University are starting to perform pre-study CT examinations to determine subchondral bone density as an indicator of loading history. Another benefit of CT is that some subclinical diseases may be more easily detectable. Researchers in the EORL laboratory are also initiating a controlled exercise program on a high-speed treadmill before starting the study. The hope is that this can normalize the loading histories of experimental animals. Equally important as loading history and subclinical disease is the biomechanical and biochemical status of the articular cartilage, which at this time is difficult to assess non-invasively at the beginning of a project. With the advent of magnetic resonance imaging (MRI) and pressure probes, articular cartilage and bone matrix structure can be assessed more readily.

TYPES OF MODELS

In Vitro Models

Several types of models have been used to study joint disease. In vitro models have been used and are increasing in use for several reasons. Researchers in university settings are constantly driven to develop in vitro studies to reduce the use of live animals and to address the humane issues that surround live animal research. In vivo models at this time are essential for testing new drugs. However, animal care and use committees at universities critically evaluate in vivo research projects to be sure that they are necessary. These committees are under constant pressure to assure that research animal use falls within ethical guidelines. In vitro systems for studying joint disease can be performed on cells from the tissues of joints. Culture systems can be created for cells such a synoviocytes and chondrocytes in two-dimensional and three-dimensional matrices. Isolated cells also can be evaluated, within the individual matrices, or within artificial matrices. Isolated cells are used to evaluate cellular response to therapeutics agents. Specific outcomes are analyzed to determine cell metabolism and proliferation. Some cell cultures are allowed or stimulated to produce the matrix, and specific cell matrix interaction and matrix metabolism can be studied. Cells are often cultured within artificial matrices to evaluate cell-matrix interactions and cell proliferation within the matrix.

Tissues from living systems are also used for in vitro study of joint diseases. The advantages of such a system over isolated cells are that cells can be maintained within the natural matrix and the experiments are relatively easy to perform. However, tissues must equilibrate in the culture medium to a steady state. This metabolic state may not truly reflect the in vivo state, because no axial load exists and the tissue edges are unconfined. The change in stress patterns and bathing in artificial media then influence articular cartilage matrix metabolism, often leading to increased articular cartilage matrix degradation. Tissues are harvested from cadavers and specimens are placed within media, which is changed every 24 to 48 hours. These tissues then can be manipulated for study, and the media and tissue can be evaluated. Media collected during the study can be analyzed for release or degradation of matrix components and inflammatory mediators. Tissues can be assessed for changes in cell proliferation, matrix synthesis, and characteristics of matrix degradation.

Two types of tissue cultures are available. Single tissues can be studied to determine biochemical, molecular, mechanical, and histological changes that occur with certain influences.[12,13] However, co-culture systems also can be evaluated to determine interactions between tissues. Investigators in the EORL have studied synovium–articular cartilage and articular cartilage–subchondral bone co-culture systems. Exposure of articular cartilage matrix to subchondral bone caused a significant reduction in articular cartilage matrix metabolism.[14] Furthermore similar findings also were seen in the synovium–articular cartilage co-culture systems, in that exposure of articular cartilage matrix to subintimal tissues and vessels led to a significant reduction in articular cartilage matrix metabolism.[15] From these studies one can conclude that exposure of various depths of synovium and subchondral bone to articular cartilage can lead to release of mediators that can change articular cartilage metabolism. However, unlike the equilibration period for in vitro experiments, this change in metabolism is severe and long lasting.

In vitro experiments are relatively straightforward to perform and allow large numbers of repeats. Consequently the numbers are strong for statistical analysis. However, only one small portion of the disease process usually can be evaluated. Furthermore, the more tissues are removed from the natural joint environment, the greater the change in matrix metabolism and response to treatment.

In Vivo Studies

In vivo studies have been used for decades to study equine joint disease. The advantages of in vivo systems are that the cells and matrices are kept within the native environment and can be studied without the influence of harvest and culturing, and normal interaction between tissues can be maintained. The disadvantages are that live animals are sacrificed, and the costs can be prohibitive. In vivo studies are used for evaluating medications, articular cartilage healing techniques, and determining pathological responses to disease. An understanding of the clinical disease and an appreciation for strict experimental design are needed to produce useful in vivo models.

Various inciting mechanisms can be used to induce experimental joint disease. For instance, synovitis models are used to evaluate the sequence of events that occurs with synovitis and the influence of various drugs and medications. Change in gait, measurement of inflammatory mediators, assessment of articular cartilage matrix metabolism, and various clinical tests have been studied. Examples of these studies include injection of lipopolysaccharide,[1,16] interleukin-1,[17] sodium monoiodoacetate,[18,19] filipin,[2,20] polyvinyl alcohol foam particles,[21] carrageenan,[22] and amphotericin[6] into joints. Of these models, those that use the natural inflammatory mediators, such as lipolysaccharide and interleukin-1, seem to me to be the best for promoting the natural cycle of events in inflammation. The advantages of such studies are that they are quick, relatively well studied, and replicate a common clinical problem.

Instability models also have been studied in horses. The purposes of these studies have been to determine the sequence of events that occurs within tissues because of instability and to induce osteoarthritis.[15,23,24] Once osteoarthritis is induced, various treatments can be examined. An example of an instability model includes cutting the collateral and collateral sesamoidean ligaments in the metacarpophalangeal joints of horses.[24] Unlike the dog, complete surgical transection of the cranial cruciate ligament in horses has not resulted in progressive osteoarthritis.[25] Mild osteophyte formation occurred in these joints, but no progressive articular surface changes or lameness were appreciated. The results are unlike horses with naturally occurring cranial cruciate damage, in which some horses are lame and substantial articular cartilage damage may result. Unlike synovitis models, instability models are relatively long-term and represent an example of chronic, progressive disease.

Forced exercise can also lead to changes in joint environment. Examples include evaluation of osteochondral tissues in response to various levels of exercise. Significant changes were found in articular cartilage matrix biochemical and biomechanical properties in exercised horses compared with horses not exercised.[26] Strenuous exercise led to significant increases in calcified cartilage thickness, significant decreases in articular cartilage mechanical properties, and significant increases in fibronectin at the sites of degradation.[26-28] Treadmill exercise led to significant increase in clinical disease in the metacarpophalangeal joints of horses. This was detected grossly and using various imaging techniques.[29] Currently several studies are ongoing to evaluate the effects of exercise to determine the level of exercise most appropriate for protecting the tissues of the musculoskeletal system. For instance, researchers in the EORL are comparing horses with experimentally induced osteochondral disease to young normal horses that are exercised, in the hope of differentiating clinical and diagnostic results in horses with joint disease from those that are undergoing exercise-induced adaptation. Researchers also have shown a recent interest in the effects of exercise on foals, weanlings, and yearlings in the hope that early exercise will lead to stronger musculoskeletal tissues.

The osteochondral fragment model is a blend of in vivo models and involves inducing a clinically relevant disease through creation of an osteochondral fragment and imposed exercise. Researchers at the EORL have used this model extensively. Various medications have been studied, including betamethasone,[30] intravenous hyaluronan,[31] triamcinolone acetonide,[32] methylprednisolone acetate,[33] and gene therapy for joint disease.[34] The researchers are currently using the model to determine differences in diagnostic tests between adaptation to exercise and disease. The model is clinically relevant and induces progressive osteoarthritis, yet it is benign enough to induce grade 1 to grade 3 lameness.[35]

Models of disuse also have been shown to induce osteochondral damage. Disuse is a clinically relevant problem that induces articular cartilage and subchondral bone atrophy. Examples include a significant reduction in articular cartilage matrix metabolism in horses with a lower limb cast.[36] Furthermore, researchers[37,38] showed that application of a cast for 7 weeks, followed by treadmill exercise, led to a significant increase in lameness in the limb with a cast and significant decrease in bone formation.[37,38] Therefore disuse models are important, because casts are used clinically and can lead to substantial problems after removal. Often the race is between healing and the degradative changes caused by disuse.

Models of articular cartilage healing have been studied extensively because of the need to test various modes of treatment in vivo. These models also have been stimulated by the cutting edge research being done by several equine research laboratories around the world and the fact that the horse is becoming more accepted as a model of articular cartilage healing for people. If an implant or technique can stimulate and maintain articular cartilage healing in a horse, then the thought is the implant or technique should work in people. Several equine models are used to study joint healing. Besides the type of treatment that is tested, the models vary in the depth and size of articular cartilage defect formation. Partial-thickness and full-thickness articular cartilage, articular and calcified cartilage, and osteochondral defects have been evaluated in vivo and treated with various techniques.

The size and location of osteochondral lesions appear to have an effect on healing.[39] Small lesions in weight-bearing areas healed better than large lesions and lesions in non–weight-bearing areas. The physical characteristics of the lesions also affect healing. For instance, subchondral cystic lesions formed in horses with linear articular cartilage lesions but not in horses with elliptical lesions.[40] The subchondral defects did not fill in with bone. Trauma to the subchondral bone led to cyst formation.[41] The presence or absence of calcified cartilage also plays a role in articular cartilage healing. Calcified articular cartilage reduced defect filling compared with defects without calcified cartilage present.[42] However, the conclusion from this study and others was that calcified cartilage may provide support for improved healing. Consequently the influence of calcified cartilage on healing is currently being studied.[43]

Various articular cartilage resurfacing treatments have been tested in vivo. Periosteal grafts,[44,45] sternal cartilage grafts,[46,47] mosaicplasty,[48] subchondral micropicking,[42] and cell-based grafting have been evaluated.[45] Sternal cartilage grafts showed promise in the short term. However, significant degradation occurred after 4 months, with subchondral cyst formation.[46,47] Mosaicplasty also has shown promise; however, harvest sites are needed to obtain tissue for implantation.[48] Subchondral bone micropicking also has shown promise in improving healing of osteochondral defects and is simple to perform.[42] Cell-based grafting also has shown promise, but it requires special equipment and advanced training to perform.[49]

Models of infectious arthritis also have been studied (see Chapter 66). For instance, studies have aimed at identifying the ability of certain medications to potentiate infection when injected along with a sub-infective dose of bacteria. This work proved the clinical impression that polysulfated glycosaminoglycans increased the chances of infectious arthritis unless given with antibiotics.[50,51] Comparison of various treatment methods used to treat infectious arthritis also have been studied.[52,53]

Biomechanical Models

Computerized models currently are being developed to study joint disease not only in people, but also in horses and other animals. Specifically, these models are derived from the geometry of the joints, the forces imparted by limb loading and muscle force, and the material properties of tendons, ligaments, and articular cartilage. Consequently, joint disease can be imitated on the computer and the resulting change in joint forces determined. These models also can be used to determine changes in loading in clinical patients. Surgical procedures can be inserted into the program and resulting forces evaluated.

In vivo work will not be replaced in the near future, because it is the best means of evaluating tissue response to disease and treatment. However, newer in vitro systems and computer models are becoming more precise and better accepted by the research community and clinicians.

CHAPTER • 66

Infectious Arthritis

Alicia L. Bertone

Classic clinical signs of infectious arthritis are heat and swelling and rapid development of non–weight-bearing lameness, often in less than 24 hours. The suspicion of joint infection increases if a predisposing risk factor is evident, such as prematurity, high sepsis score, or multisystemic disease in a foal[1] or preceding joint injection in an adult horse. Fracture and non-articular infection (cellulitis or foot abscess) need to be differentiated from infectious arthritis, because in these diseases, acute, severe lameness also develops.[2,3]

CAUSES

Musculoskeletal infection was reported to cause death in 5.2% of 2468 foals.[4] Yearly morbidity was 27.4% (677 foals), and morbidity attributed to musculoskeletal infection was 2.1%. Septicemia was the second most common cause of death, and hematogenous spread was the most common cause of infectious arthritis.[5] The risk of infection was highest in the first 30 days post partum and was lowest in practices that assessed the efficacy of transfer of passive immunity. Isolation of *Salmonella* species from synovial fluid and systemic disease were associated with an unfavorable prognosis for survival.[1]

In two retrospective studies of 153 mature horses[6,7] the most common causes of synovial infection were traumatic wounds (36.5% for joints and 55% for tendon sheaths), injections (34.1% and 22%), post-operative infection (19.8% for joints), and idiopathic causes (9.5% and 22%).[7,8] The Standardbred and the tarsocrural joint were over-represented in adult horses with joint infection, reflecting a greater number of joint injections in this breed and joint.

Of 424 bacterial isolates from 233 horses with joint, sheath, or bone infection, 91% were aerobic or facultative anaerobes. The most common organisms were Enterobacteriaceae (28.8%), followed by streptococci (13%) and staphylococci (11.8%).[9] In foals, Enterobacteriacae including *Escherichia coli* and *Staphylococcus* species[1,10] were more likely to be isolated. Staphylococci, specifically *Staphylococcus aureus*, is the most common organism isolated from infections occurring after surgery or injections. Foals or horses with infectious arthritis secondary to penetrating wounds are likely to have multiple bacterial infections. *Clostridium* species were the most common anaerobes isolated and were most common from wounds near the hoof. Fungal organisms were a rare cause of infectious arthritis but can be considered pathogens if identified in pure culture more than once.[11] Reactive arthritis in foals with septicemia from *Rhodococcus equi* can be confused with infectious arthritis, but lameness usually is not prominent, and synovial fluid nucleated cell counts are often within normal limits.[12]

EXAMINATION AND INITIAL MANAGEMENT

Potential infectious arthritis must be considered an emergency and is treated most effectively with early diagnosis. A systematic approach should include hematological examination, measurement of plasma fibrinogen, synovial fluid analysis, including cytological examination, Gram stain, and synovial fluid culture (up to 5 ml of synovial fluid in a broth culture bottle), and radiography.[3] In foals, particularly those with abnormal sepsis scores, blood culture should be performed

CHAPTER • 66

Infectious Arthritis

Alicia L. Bertone

Classic clinical signs of infectious arthritis are heat and swelling and rapid development of non–weight-bearing lameness, often in less than 24 hours. The suspicion of joint infection increases if a predisposing risk factor is evident, such as prematurity, high sepsis score, or multisystemic disease in a foal[1] or preceding joint injection in an adult horse. Fracture and non-articular infection (cellulitis or foot abscess) need to be differentiated from infectious arthritis, because in these diseases, acute, severe lameness also develops.[2,3]

CAUSES

Musculoskeletal infection was reported to cause death in 5.2% of 2468 foals.[4] Yearly morbidity was 27.4% (677 foals), and morbidity attributed to musculoskeletal infection was 2.1%. Septicemia was the second most common cause of death, and hematogenous spread was the most common cause of infectious arthritis.[5] The risk of infection was highest in the first 30 days post partum and was lowest in practices that assessed the efficacy of transfer of passive immunity. Isolation of *Salmonella* species from synovial fluid and systemic disease were associated with an unfavorable prognosis for survival.[1]

In two retrospective studies of 153 mature horses[6,7] the most common causes of synovial infection were traumatic wounds (36.5% for joints and 55% for tendon sheaths), injections (34.1% and 22%), post-operative infection (19.8% for joints), and idiopathic causes (9.5% and 22%).[7,8] The Standardbred and the tarsocrural joint were over-represented in adult horses with joint infection, reflecting a greater number of joint injections in this breed and joint.

Of 424 bacterial isolates from 233 horses with joint, sheath, or bone infection, 91% were aerobic or facultative anaerobes. The most common organisms were Enterobacteriaceae (28.8%), followed by streptococci (13%) and staphylococci (11.8%).[9] In foals, Enterobacteriacae including *Escherichia coli* and *Staphylococcus* species[1,10] were more likely to be isolated. Staphylococci, specifically *Staphylococcus aureus*, is the most common organism isolated from infections occurring after surgery or injections. Foals or horses with infectious arthritis secondary to penetrating wounds are likely to have multiple bacterial infections. *Clostridium* species were the most common anaerobes isolated and were most common from wounds near the hoof. Fungal organisms were a rare cause of infectious arthritis but can be considered pathogens if identified in pure culture more than once.[11] Reactive arthritis in foals with septicemia from *Rhodococcus equi* can be confused with infectious arthritis, but lameness usually is not prominent, and synovial fluid nucleated cell counts are often within normal limits.[12]

EXAMINATION AND INITIAL MANAGEMENT

Potential infectious arthritis must be considered an emergency and is treated most effectively with early diagnosis. A systematic approach should include hematological examination, measurement of plasma fibrinogen, synovial fluid analysis, including cytological examination, Gram stain, and synovial fluid culture (up to 5 ml of synovial fluid in a broth culture bottle), and radiography.[3] In foals, particularly those with abnormal sepsis scores, blood culture should be performed

simultaneously. In adult horses, systemic blood examination is less rewarding than in foals, particularly in the early phases of clinical signs. In horses with experimental infectious arthritis, elevations in leukocyte count, total protein, and fibrinogen levels took several days to develop and were changed significantly from baseline values for individual horses, but they remained in the normal range for all horses.[13] Before performing arthrocentesis, surgical scrub materials, sterile gloves, needles, syringes, broth culture bottles, ethylenediamine tetraacetic acid (EDTA) or heparin tubes for cytological examinations, smear slides for Gram stain, and a dose of antimicrobial agents to instill directly into the joint after sampling should be available (see the following discussion).

Adult horses should be sedated. Foals can be placed in lateral recumbency with administration of an α_2-agonist and synthetic narcotic combination. Although data suggest that aseptic preparation of unclipped hair may be adequate and significantly decrease bacterial counts on the skin,[14] clipping the site for arthrocentesis is strongly recommended. In horses with peri-articular wounds, arthrocentesis should be performed well away from the wound to avoid the risk of joint contamination, if the joint is not contaminated already from the wound. To determine if a joint and wound communicate, the clinician should infuse 50 to 200 ml of balanced electrolyte solution into the joint after a synovial fluid sample has been obtained for culture and cytological examination. The clinician should watch closely for leakage of fluid from the wound. This is easier than using blue dye injections or contrast radiography. The joint should be drained and antibiotic instilled into the joint after samples have been obtained and any lavage or injection of fluid completed. Samples should be submitted immediately for evaluation.

If the joint fluid is grossly cloudy, turbid, or flocculent, broad-spectrum antibiotics initially should be given intravenously, and ingress and egress or through-and-through lavage of the joint should be performed until diagnosis of infectious arthritis can be confirmed. Antibiotic should be instilled into the joint after lavage is completed.

DIAGNOSIS

Gross evaluation of the synovial fluid can be informative. If newspaper print cannot be read through the fluid sample, it probably has a cell count of 30×10^9 nucleated cells/L. Fluid from infected joints is usually turbid, cloudy, and watery. Flocculence develops in chronically infected joints or joints that have been invaded with a needle or surgery. Blood contamination makes gross assessment of synovial fluid difficult, and determining if infection is present without clinicopathological analysis is often impossible. Serosanguineous fluid commonly is obtained from infected joints (Fig. 66-1). An estimate of the amount of blood (packed cell volume or red blood cell count) can be made to correct for the number of nucleated cells contaminating the sample (hemorrhage from arthrocentesis or leakage of blood from the infection):

$$\frac{\text{PCV (\%) of synovial fluid}}{\text{Actual or estimated PCV (\%) of blood}} = \frac{\text{X (WBC} \times 10^9\text{/L in synovial fluid)}}{\text{Actual or estimated WBCs} \times 10^9\text{/L blood}}$$

where PCV is packed cell volume and WBC is white blood cell.

Synovial fluid nucleated cell count, differential cell count, and total protein concentration are the most useful parameters to evaluate in diagnosing infectious arthritis. Synovial fluid nucleated cell counts in excess of 30×10^9/L cells, with >80% neutrophils, or total protein concentration in excess of 40 g/L are considered consistent with infection, particularly if these synovial fluid parameters correlate with clinical signs and predisposing circumstances.[3] The likelihood of isolating the causative organism is correlated positively to the nucleated cell count, that is, higher nucleated cell counts have greater isolation rates.[15] Approximately 25% of samples from horses suspected of having infectious arthritis demonstrate bacteria on Gram stain, confirming infection and offering the added benefit of assisting with identifying the organism and the initial selection of an antimicrobial agent.

Fig. 66-1 At post-mortem examination, hemorrhagic synovitis associated with acute joint infection is seen in this tarsocrural joint.

For horses that do not meet obvious criteria for infectious arthritis, assessment of all parameters is necessary to conclude that the joint is infected. Importantly, joints can be infected with nucleated cell counts less than 30×10^9/L. Infection should be suspected if nucleated cell counts are between 10×10^9/L and 30×10^9/L and fluid is not serosanguineous, clinical signs of substantial lameness exist, fluid is flocculent (coagulating cells may falsely lower the measured cell count), a predisposing cause for infection is present (septicemia, surgery, or joint injection), and protein concentration exceeds more than 40 g/L. Previous intra-articular treatment with corticosteroids may delay onset of clinical signs and confuse interpretation of nucleated cell counts and total protein concentration in the acute phase.[16,17]

Synovial fluid protein levels continue to increase in chronically infected joints to more than 60 g/L in some horses.[13] Few other differential diagnoses, other than infection, produce significant elevations in total protein (>50 g/L). Isolation of a pure culture of a single organism, particularly a known pathogen, such as a coagulase-positive *Staphylococcus*, almost always indicates infection is present, even if the nucleated cell count is low.

In horses with chronic infectious arthritis refractory to aggressive treatment, nucleated cell counts can be low (5 to 10×10^9/L), but organisms, usually *Staphylococcus*, can still be isolated. In these horses the synovial fluid protein values are often high (>50 g/L) and other clinical signs of infectious arthritis (lameness, effusion, and heat) persist. In my experience these are horses that developed infectious arthritis after injection with a corticosteroid, were treated with systemic antibiotics and lavage, but not aggressive drainage, have a nidus of infected subchondral bone that keeps seeding the joint, or have a joint with severe cartilage erosion.

The distribution of nucleated cells in synovial fluid is an important aid to diagnosis. In horses with early infectious arthritis, almost always nucleated cells comprise more than 80% neutrophils and commonly more than 90% neutrophils.

The neutrophils usually appear healthy and not degenerate, although in overwhelming or aggressive infection, degeneration of neutrophils is seen. If synovial fluid has less than 75% neutrophils, infection is usually resolving.

Techniques that may be useful clinically in the future for diagnosis include polymerase chain reaction (PCR) analysis for detecting base pairs of bacterial or viral DNA in the synovial fluid[18,19] and determining enzyme and cytokine release that may be specific for infection.[20,21] Benefits of PCR include rapid (<24 hours), sensitive testing that can detect selected species of bacteria in the presence of antimicrobial drugs. PCR diagnostic techniques are sensitive because they amplify small quantities of bacterial DNA. Inherent in high sensitivity, however, is a possible high false-positive rate, because of skin contamination or contamination with bacteria at the time of arthrocentesis. Future clinical use and evaluation of this technique is expected.

Identification of enzyme/cytokine ratios or quantity may be specific for infection, because infection is the largest joint challenge that exists. Knowledge of the presence and interaction of mediators and inhibitors in joints is growing rapidly and is an active area of research. For further information on this aspect of joint infection, the reader is referred to other texts.[20,22]

It is important to determine whether bone or physeal involvement is concomitant, particularly in foals with refractory infectious arthritis. In most foals with bone involvement, radiolucent changes occur rapidly and are often detectable within 1 week after onset of clinical signs. In most bones radiographic changes may be apparent in 7 to 10 days, but if the small cuboidal bones of the carpus or tarsus are involved, the clinician may face an even greater diagnostic challenge. Infarction associated with infection may slow bone resorption, and evidence of radiolucency may lag for several days.

Nuclear scintigraphy may be useful to locate foci of infected bone, particularly in identifying involvement of subclinical sites of infection in polyarthritic foals, but the technique has practical restrictions. Normal bone scans or radiolabeled white cell studies can be performed. The foals become radioactive, and handling of the foal, blood samples, and synovial fluid samples becomes a small risk to attendants. Additionally, if the joints surrounding the small bones are infected, the resolution of the scan may be inadequate to identify specific bone involvement. Magnetic resonance imaging offers promise of improved identification of osteomyelitis[23,24] and often can be arranged for foals at facilities used for imaging people. Osteomyelitis is present in up to 59% of foals with infectious arthritis, but a favorable prognosis still can be achieved with treatment,[1] although the prognosis for athletic function is reduced when adjacent bone is involved or infectious arthritis is protracted.

ANTIMICROBIAL THERAPY

Systemic Therapy

Intravenous antimicrobial therapy should be initiated immediately, before bacterial culture results are available. Systemic administration of broad-spectrum antimicrobial drugs should be combined with the local administration of antimicrobial agents. Most common combinations include penicillin with an aminoglycoside or a third-generation cephalosporin such as ceftiofur sodium. In a retrospective study of equine musculoskeletal infections, gentamicin and amikacin were effective against 85% and 95% of equine isolates, respectively, indicating they are good choices for initial combination therapy.[9] Antimicrobial drugs given orally should be reserved for infection that is resolving, because gastrointestinal absorption is erratic, and blood and tissue levels are lower. Oral enrofloxacin is used to treat chronic bone and synovial infections in mature horses without reported incident, but enrofloxacin is not currently approved for use in horses. Enrofloxacin (Baytril 100) administered intravenously at 5 mg/kg once daily is effective and safe in mature (3 years and older) horses.[25] Enrofloxacin may cause lameness and cartilage lesions in foals and should not be used.[26] Enrofloxacin should not be administered to lactating mares, because the milk may concentrate the drug and subject the foal to chondrotoxic dosages.

Antimicrobial drugs should be given intravenously and in general at a dosing interval that maximizes peak serum levels and sustains trough levels that are at or above the MIC for the isolated organism. Serum antimicrobial peak and trough measurements should be periodically checked to maximize effectiveness and minimize toxicity (see the following discussion).

Aminoglycoside dosing three times a day was originally designed to achieve peak serum concentrations (5 to 10 μg/ml) and trough serum concentrations (0.5 to 2.0 μg/ml) to balance optimal clinical efficacy and to minimize toxicity.[27] However, once daily dosing may be more effective. The larger the serum aminoglycoside concentration to minimum inhibitory concentration (MIC) ratio, the greater the bactericidal effect. The aminoglycoside post-antibiotic effect (duration of sustained antimicrobial killing) is concentration dependent. With a single daily dose, trough levels could be lowered, thus lowering the risk of toxicity. Using in vivo models of infectious osteomyelitis, improved efficacy of gentamicin was demonstrated using once daily dosing (6.6 mg/kg body mass IV) compared with three times a day dosing (2.2 mg/kg body mass IV). In normal horses, gentamicin (administered at 6.6 mg/kg body mass once daily for 10 days) did not induce signs of nephrotoxicity and prolonged the post-antibiotic effect.[28] Therefore gentamicin and other aminoglycosides should be administered once daily in horses. However, the pharmacokinetics of aminoglycosides are altered in septic and premature hypoxic foals.[29] Serum drug concentrations should be measured to adjust dosing intervals. Sepsis score and creatinine concentration are inversely correlated to amikacin clearance in foals and could be useful indicators of altered drug disposition and delayed clearance.[30] The dosing interval may need to be lengthened beyond 24 hours in these foals to avoid toxicity (higher trough concentrations). In septic neonatal foals, administration of gentamicin at 3.3 mg/kg twice daily intravenously produced peak serum concentrations of more than 6 μg/ml and trough concentration less than 2 μg/ml in all foals without toxicity or development of new sites of infection.[31]

The drug must have excellent diffusion into the joint.[6] Most antimicrobial drugs penetrate the synovium in therapeutic concentrations when administered systemically at recommended dosages.[3] Concentrations of aminoglycosides actually may be greater in inflamed joints compared with normal joints.[32] If systemic blood trough levels drop below MIC for that antimicrobial, synovial fluid concentrations may also drop below MIC. Local antimicrobial administration (intra-articular), used to sustain high drug concentrations at the site of infection, may be most effective in both killing bacteria and penetrating organic debris.

Most positive synovial fluid cultures will be so within 24 hours after onset of infection, and a Gram stain can be immediately helpful. An additional 24 hours is usually needed to confirm the identity and susceptibility pattern of the organism. In my opinion, a broad-spectrum antimicrobial drug should be administered initially and continued at least until clinical signs begin to resolve substantially. Some joints may contain single or several organisms that were not isolated, particularly if infection was caused by a wound or by septicemia. Joints may be open, or repeatedly invaded during treatment, or a foal may be at risk of continued showers of bacteremia,

thereby increasing the risk of a shift in causative organism in the middle of treatment.

Local Therapy

For years local administration of antimicrobial agents was considered taboo, because solutions varied in pH and were believed to be injurious to tissues. The deleterious effects of local antibiotic administration were greatly overemphasized, and one of the most substantial advances in the management of horses with infectious arthritis and osteomyelitis has been the implementation of local antimicrobial therapy. High tissue concentration of antimicrobial agents causes rapid elimination of joint and bone infections.[33,34] Many innovative methods are being explored to provide high local antimicrobial drug levels. Administration of systemic antimicrobial agents remains an important adjunctive therapy, but it is recognized that tissue concentrations at the site of infection may be considerably lower than those achieved with local administration of drugs (at or below MIC for the organism) and therefore less effective.[35]

Direct Local Infusion of Antimicrobial Drugs

Intra-articular injection of antimicrobial drugs into the infected joint every 24 hours is currently the most common therapy for early infectious arthritis. Intra-carpal administration of 150 mg gentamicin maintained synovial fluid gentamicin concentrations well above the MIC for most equine pathogens (2 µg/ml) for 24 hours.[33,36] Most antimicrobial drugs, including penicillin, the cephalosporins, and aminoglycosides, are minimally irritating.

Appropriate intra-articular dosages of antimicrobial drugs are not scientifically identified, but anecdotally up to 500 mg gentamicin, 250 mg amikacin, 1×10^6 units of sodium penicillin, 500 mg cefazolin, and 500 mg ceftiofur sodium have been used without reported difficulties. Fluoroquinolones should not be used because at high concentrations the drugs are toxic to chondrocytes.[37]

Topical lavage of an infected joint or osteomyelitic bone is beneficial for the removal of infected organic debris, destructive enzymes, and neutrophils, but the inclusion of antimicrobial or antiseptic compounds in the lavage solution is still of questionable benefit. An increase in the local antimicrobial drug concentration is expected after lavage with antimicrobial drugs, but most of the drug leaves the joint with the lavage solution. Injection of antimicrobial drugs at the termination of lavage is probably more efficient. Use of antiseptics and potentiated antiseptics (EDTA and Tris buffer) in lavage may kill surface bacteria, but sustained killing is expected to be limited.[38] Even dilute antiseptic compounds such as 0.05% chlorhexidine can be irritating to equine joints.[39]

Antimicrobial-Impregnated Polymethylmethacrylate

One of the most practical methods for maintaining slow but effective release of antimicrobial agentss in bone and joint infections is the intra-articular insertion of impregnated polymethylmethacrylate (PMMA) beads.[40] In a study of 1085 open limb fractures in people, the post-operative infection rate was significantly reduced from 12% to 3.7% when aminoglycoside PMMA beads were inserted at surgery.[41] In horses, PMMA impregnated with aminoglycoside and cefazolin was used in horses with open fractures and with bone, implant, and joint infections, and survival rate was about 60%[42,43] (Fig. 66-2). In 12 horses with infectious arthritis treated with gentamicin-impregnated PMMA beads and lavage, including six with osteomyelitis, 92% survived.[44] Several antimicrobial drugs were shown to elute from PMMA in active concentrations, including aminoglycosides such as amikacin and gentamicin, and fluoroquinolones such as ciprofloxacin.[34,44,46] Use of fluoroquinolones in PMMA is not currently recommended in joints, because the concentrations expected to be released with local therapy may be toxic to equine chondrocytes.[37]

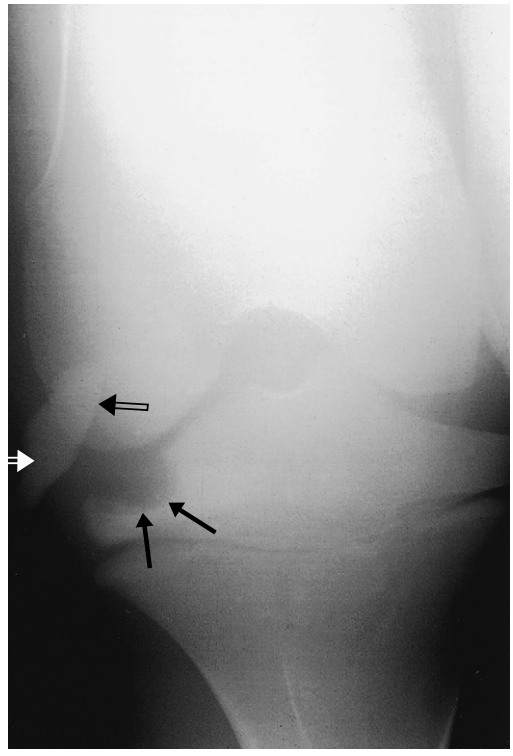

Fig. 66-2 Craniocaudal radiographic view of a foal's stifle joint demonstrating osteolysis of the medial tibial plateau *(solid black arrows)* that was debrided arthroscopically and a singular polymethylmethacrylate bead *(open arrows)* placed intra-articularly.

Preparation of implants (beads) can be performed in the operating room or beads can be gas sterilized and stored for future use. The antimicrobial compound (1 or 2 g of powder or liquid) is mixed thoroughly with 20 to 40 g of PMMA (medical grade) and shaped as desired. Beads can be placed on suture material to assist with retrieval from the joint. The beads can be placed into the joint through an arthrotomy, which is usually left open to drain. If infection recrudesces, existing beads can be exchanged with fresh ones or with those impregnated with different antimicrobial agents. Small beads (4 × 6 mm) can be placed through arthroscopic portals or cannulas, thus avoiding arthrotomy. Arthotomy, however, can also assist with joint drainage if left open to heal by contraction and epithelialization. In my experience, if infection is rapidly eliminated, the beads can be difficult if not impossible to retrieve. Beads frequently migrate to a joint pouch and become enveloped by synovium. If the arthrotomy heals quickly, the beads need to be removed surgically. Occasionally beads well removed from articular surfaces can be left in place permanently. Long-term sequelae appear minimal, but studies to date have not been performed. Complications with PMMA implants include the use of too many or too large beads, causing soft tissue trauma and pain, failure to exchange beads in unresolving infection and placement of beads under tendons and on articular cartilage. If osteomyelitis exists, lesions can be debrided and lavaged, and beads can be implanted directly into the bone bed. Beads placed directly into bone lesions are usually removed without difficulty.

Addition of antimicrobial compounds to PMMA alters the biomechanics of PMMA, particularly when using liquid forms. For purposes of treating joint infection, accuracy in drug elution and biomechanical properties of the PMMA are not critical. Use of the PMMA in orthopedic implants may require more precise preparation of implant material. The

elution rate of antimicrobial drugs varies with size and shape of the implant, the amount of antimicrobial agent impregnated, and the type and form of antimicrobial drug selected and depends on thorough and even mixing of the formulation.

Antimicrobial-Impregnated Biodegradable Drug Delivery Systems

Although PMMA offers advantages for local antibiotic delivery, its permanency is not ideal, particularly for certain tissue types. Many biodegradable compounds have been investigated as possible implants for antimicrobial drug delivery, most notably collagen,[47] DL–lactide-glycolide copolymers, polyanhydrides, polylactide, sebacic acid, tricalcium phosphate and calcium carbonate bone cement, and plaster of Paris.[48-53] Because of the ongoing degradation a greater amount and duration of antimicrobial drug release can be achieved. In a study using rabbits with infectious osteomyelitis, bacterial counts were significantly lower in those treated with gentamicin/polyanhydride implants than in those treated with gentamicin/PMMA implants.[50]

In horses, 50:50 DL–lactide-glycolide copolymers and poly(DL)lactide impregnated with gentamicin that eluted for 10 days eliminated infection of synovial explants in vitro without significant detrimental effects on synovial cell function (hyaluronan acid production), morphology, or viability.[48] In horses with experimentally induced *Staphylococcus* joint infection, intra-articular treatment with C44 fatty acid-sebacic acid (1:1) beads impregnated 20% with gentamicin as the sole treatment effectively eliminated joint infection in 33% of joints by day 3 and 66% of joints by day 13.[52] Lameness significantly improved. Gentamicin concentration peaked at 82 µg/ml at 24 hours after insertion of beads and remained higher than 10 µg/ml for 12 days (range of 5 to 41 times the MIC for the organism).[52] Currently these implants are being investigated for clinical use, but they are not yet commercially available. Plaster of Paris beads may offer a practical option for degradable implants, but biocompatibility studies should be performed.[54]

Regional Perfusion

Regional perfusion can be used to deliver high concentrations of antimicrobial agents to a selected region of the limb, usually using the venous system for drug administration. With horses under anesthesia, drugs also can be administered using an intra-osseous route. In either case a tourniquet is applied proximal to the infected bone or joint. Concentrations of gentamicin obtained in synovial fluid ranged from a peak of 589 µg/ml immediately after regional perfusion and declined to 4.8 µg/ml at 24 hours.[54] This technique was used to decrease white blood cell numbers in infected synovial fluid in experimentally induced equine arthritis and is most practical if applied when the horse is anesthetized for other treatment of infection, such as debridement and lavage, when intra-osseous infusion can be performed simultaneously.[55] Practically the technique is not commonly used for sustained high concentrations of antimicrobial agents, simply because daily general anesthetic procedures are costly and time consuming. Intravenous infusion can be performed in some standing, sedated horses. Limitations include the need for a tractable horse, minimal peri-articular swelling for ease of vein identification, and the horse must tolerate the pain of a tourniquet and infusion of antimicrobial drugs. Perineural analgesia can be performed (Editors). Intra-articular antimicrobial drug concentrations using intravenous regional infusion are not as high as those obtained with direct intra-articular injection.[36]

In contrast to joint concentrations, bone concentration of antimicrobial agents is expected to be higher after regional perfusion, because bone is also perfused. Therefore in foals with infectious arthritis and adjacent osteomyelitis, regional perfusion offers an advantage, because daily intra-articular administration of antimicrobial agents may not yield high concentrations of the drug in bone. Intra-articular administration relies on drug diffusion through cartilage or local blood supply to reach bone. Confirmation of bone antimicrobial concentrations after regional perfusion is warranted. Caution should be used when applying tourniquets in foals, because even short durations of application can induce clinical signs of distal limb ischemia. In foals with compromised bone blood flow from swelling and toxic effects of infection, this may be detrimental. I have seen two foals develop severe osteonecrosis after repeated regional perfusion procedures, a complication attributed to tourniquet application.

JOINT DRAINAGE AND DEBRIDEMENT

Joint lavage and drainage are vital for the effective management of infectious arthritis.[1,3,5,6,44] Ideally arthroscopic evaluation should be performed to remove foreign material and fibrin and to assess cartilage health. Removal of angry, infected synovium may reduce bacterial count and a source of infection. Healthy synovium should not be removed, because it may help combat the infection and may normalize joint health. In horses, maximal synovectomy was no better than open arthrotomy for management of infectious arthritis.[56] After synovectomy villous structures may not be regained for many months.[57-60] Repeated through-and-through lavage using needles placed on opposite sides of a joint can be effective in eliminating infection in some horses, but the lavage fluid may completely bypass some areas of a joint, allowing the infection to persist. Arthroscopy permits more thorough lavage of the entire joint, and together with a form of continued joint drainage, provides the most complete and rapid method to remove infective material and to estimate the extent of damage.[6,44]

Arthroscopic portals can be enlarged to function effectively as open arthrotomy incisions for continued drainage, or closed suction drainage can be initiated. The goal of either technique is continued joint decompression and drainage. I prefer open arthrotomy because it is simple and avoids the complications that can occur with drains, including drain breakage, ascending infection, joint irritation, and clogging. Arthrotomies usually heal without complication and with minimal scarring. With continued infection, arthrotomies stay open and may develop excessive granulation or fibrous tissue, but this complication may occur with other methods of chronic drainage as well. Open drainage in joints that cannot be bandaged, such as the stifle, can be performed by tying up the horses using cross ties or an overhead wire. Adhesive bandages applied using ether can be used to cover open drainage sites. I have not seen substantial permanent complications associated with arthrotomy and open drainage. Open arthrotomy can be used to insert PMMA beads for treatment of osteomyelitis or in horses with refractory infection.

Properly managed closed suction drainage is useful for large joints such as the tarsocrural and scapulohumeral joints, using a flat, fenestrated, latex drain. The drain should be tunneled under the skin to exit at a site removed from the joint. Negative pressure is applied using a large syringe, with a large guarded needle passed through the syringe to keep the plunger retracted.[60] The syringe is evacuated several times a day, and the drain is left in place until only small volumes of fluid are collected or the fluid appears relatively normal grossly and cytologically, and lameness improves. If the suction system fails, the drain is removed.

After initial debridement, lavage, and establishment of drainage, the joint can be flushed and local antimicrobial drug therapy applied daily, usually for 3 days. If clinical improvement is dramatic, further lavage is optional, but local antimicrobial injection should continue for 3 days. If clinical improvement continues, local antimicrobial therapy is discontinued. The joint is then rested for 24 hours and the synovial

fluid is reassessed. Ideally, follow-up synovial fluid contains fewer than 15×10^9 nucleated cells/L, but irritation from aggressive lavage and intra-articular antimicrobial compounds can result in higher cell counts.

Clinical improvement is assessed by evaluating rectal temperature, lameness, and heat over the joint surface. The synovial fluid nucleated cell counts should decline slowly over the next 7 days if infection remains under control. If nucleated cell counts rise again or if lameness recurs, lavage and local antimicrobial therapy can be re-instituted. Having to perform two series of lavage procedures (3 days each time) in foals is typical.

Articular Osteomyelitis

Fifty percent of foals with infectious arthritis also have osteomyelitis or bone necrosis.[1,6,7,10] Usually bone is infected, but bone infarction can also occur. These lesions are best treated using arthroscopic debridement and joint infection usually clears within days of removing infected bone. The importance of arthroscopic debridement cannot be overemphasized. In young foals with severe joint distention, lesions that would not normally be amenable to arthroscopic evaluation and debridement become accessible, such as those involving the tibial plateau (Fig. 66-2), caudal humeral head, or coxofemoral joint. In my experience those involving infection or necrosis of the tarsal bones and some aspects of the carpal bones are the most difficult to treat, because they are not directly accessible using arthroscopy. Insertion of PMMA beads close to the distal tarsal joints and prolonged systemic antimicrobial administration may be successful.

In adult horses with articular osteomyelitis it is critical to debride the infected bone as soon as the condition is recognized radiographically (Fig. 66-3). In chronic, progressive, infectious osteomyelitis in adult horses, arthrodesis or stimulated ankylosis with a bone graft may be the only way to eliminate joint pain.[61-63] Infection of implants does not always occur.[61] Bone infection can resolve with prolonged antimicrobial drug therapy, but joint immobilization is important to assist with elimination of infective organisms.

Fig. 66-3 Dorsolateral-palmaromedial radiographic view of a carpus of a Standardbred racehorse with infectious osteomyelitis and necrosis of the dorsomedial aspect of the third carpal bone. The infection occurred subsequent to an intra-articular injection.

PAIN MANAGEMENT

Non-Steroidal Anti-Inflammatory Drugs

In a rabbit staphylococcal model of infectious arthritis, use of NSAIDs with antimicrobial drugs significantly reduced joint swelling, prostaglandin E_2 release, and collagen joint destruction compared with the administration of antimicrobial drugs alone.[64] In mature horses phenylbutazone administration (4.4 to 8.8 mg/kg body mass daily) is commonly used to reduce pain and joint inflammation. Risk of laminitis in the supporting limbs of lame horses is an important consideration when treating infectious arthritis. Cyclooxygenase II inhibitors are currently being approved for use and seem promising at reducing the risk of toxic side effects, such as gastrointestinal ulcers and nephrotoxicity, seen with currently marketed NSAIDs. Cyclooxygenase II inhibitors reduce the production of inducible prostaglandin E_2 without suppressing the constitutive form of prostaglandin E_2 that protects epithelial mucosa homeostasis. Administration of NSAIDs in horses with infectious arthritis must be titrated to allow for the accurate assessment of joint pain as an indicator of clinical response to treatment. Most currently available NSAIDs marketed for use in horses, or used off label in horses, have been demonstrated to suppress equine synovial membrane inflammation and prostaglandin E_2 release in culture experiments.[65,66]

Dimethylsulfoxide (DMSO) solution (10% to 40%) has been used experimentally to treat synovitis and clinically to treat infectious arthritis in horses.[3] Lavage or intra-articular injection of up to 40% DMSO does not appear to have significant negative effects on articular cartilage. DMSO is a free radical scavenger, antiseptic, and analgesic and may inhibit chemotaxis of inflammatory cells. Practically, DMSO can be used in lavage fluid, particularly in the last liter of lavage. Because of the high solubility of DMSO, some residual drug probably is absorbed into the synovium during lavage.

Epidural Narcotics

Placement of indwelling epidural catheters and chronic infusion of α_2-agonists and narcotics such as morphine have been useful in alleviating hindlimb lameness and in horses with severe pain secondary to infectious arthritis (see Chapter 86).[67,68] In horses with chronic osteomyelitis or refractory infectious arthritis this technique may be useful in preventing recumbency or supporting limb laminitis.

TOPICAL TREATMENT, BANDAGING, AND ALTERNATIVE THERAPY

DMSO applied topically to horses with experimentally induced carpal synovitis significantly reduced synovial fluid nucleated cell counts.[14] DMSO was detectable in the synovial fluid of five of six horses and in the plasma of one of six horses, indicating its penetration of the tissues from topical application.[69] Topical application over infected joints may reduce synovitis.

Pressure bandages applied to reduce swelling also can reduce joint pain. Edema formation can be overwhelming in infected joints and produce stiffness, discomfort, elevated synovial fluid production (joint pressure), and poor joint clearance of infected material through the lymphatic system. Pressure bandages should be sterile, particularly when covering open arthrotomy incisions.

Once acute inflammation has resolved, passive flexion is indicated to enhance lymph flow, improve drainage, reduce edema, and enhance joint range of motion. Capsulitis associated

with infection can be a significant complication, and physiotherapy to restore joint function can be critical to improving long-term outcome and joint motion.

PROGNOSIS

Adult horses with infectious arthritis have a good prognosis for survival and for return to athletic function, provided that infection is recognized early. In most patients infection is eliminated.[2,6,7,44] Pre-existing osteoarthritis and articular cartilage damage are the most common reasons for failure to return to performance. Prompt recognition, aggressive drainage and lavage, and early treatment with local antimicrobial drugs have steadily improved prognosis to >80%[6] and, we hope, will achieve success rates close to 100%. Aggressive surgical debridement and use of implantable elution materials for chronic administration and multiple site delivery of antimicrobial agents have improved prognoses. The prognosis in foals is more guarded. Septicemia, osteomyelitis, and hypogammaglobulinemia result in a lower prognosis for life in foals, and infection is eliminated in only 50%.[7] Elimination of infection was achieved in 70%,[1,6] 50% survived,[6,10] and 30% reached racing performance.[1]

FUTURE TREATMENTS

Newer biodegradable polymers impregnated with antimicrobial drugs for direct joint insertion through an arthroscopic portal could greatly enhance the process of sustained drug delivery. Arthroscopic instrumentation can be used to insert the beads into the joints of standing horses.

Medical therapies for intra-articular drug therapy in the future may focus on prevention of *S. aureus* adhesion. A prominent feature of *S. aureus* virulence is the production of a bacterial surface marker that recognizes adhesive matrix molecules in collagen, precipitating bacterial adherence.[70,71] Monoclonal antibody, receptor antagonists, and vaccination challenges reduce the risk of obtaining infection with *S. aureus* in experimental animals.[70-72] These therapies may also be useful in the horse, since *S. aureus* is the most common cause of joint infection in adult horses.

CHAPTER • 67

Non-Infectious Arthritis

Alicia L. Bertone

Non-infectious arthritis is characterized by pain, heat, swelling (effusion), erythema, and lameness. Joint structure and function, aspects of diagnosis and management of joint disease, and osteoarthritis are discussed in Chapters 63 and 64. This chapter focuses on normal and abnormal joint physiology and other specific non-infectious joint diseases.

JOINT PHYSIOLOGY

Fluid flow from the vascular space into the interstitium and joint space (third compartment space) and out into venules and lymphatics is tightly governed by Starling forces, which are a balance of arterial and venous pressures and colloid osmotic forces across the joint. The resultant fluid flow through the joint is modified by permeability of the synovium (osmotic reflection coefficient) and the vessel surface area available for fluid transport (filtration coefficient). Even in normal joints these forces are influenced by gravity (joint dependency), motion (exercise), and structure (joint compliance).[1-7]

Horses are unique in needing joint motion to maintain isogravimetric states of the joints (no fluid gain or loss), especially in peripheral joints.[1] In normal stationary equine limbs, lymphatic drainage from joints approximates zero until joint pressure exceeds 11 mm Hg for the fetlock joint (transitional microvascular pressure). In standing animals without counter forces, such as motion or external bandages to increase lymph flow forces, gravitational pressures increase arterial pressure to the joint and venous and lymphatic pressure from the joint. The result is tissue edema and joint effusion.

JOINT PATHOPHYSIOLOGY (SYNOVITIS)

The balance of these forces is altered in horses with synovitis because of the increased blood flow, altered synovial permeability, structural joint capsular changes, and loss of joint motion because of pain.[1,3,5,8,9] These factors profoundly affect joint physiology, contribute to clinical signs, and result in damage to the synovium and articular cartilage. Early signs of effusion that precede clinical detection of inflammation are related to changes in the hemodynamics of the joint, including increased blood flow and reduced joint motion.[8,9]

In chronic arthritis, capsular thickening, fibrosis, and altered synovial function likely influence fluid dynamics. Capsular fibrosis and joint enlargement produce decreased tissue compliance and an increase in intra-articular pressure occurs, even with slight increases in joint effusion. Articular cartilage is avascular and depends on synovial fluid for nutrition, so alteration in fluid flux affects nutritional exchange between the articular cartilage and synovium. Reduced nutrition exchange to articular cartilage exacerbates articular surface fibrillation and degenerative changes.[10,11]

JOINT PATHOLOGICAL CONDITIONS ASSOCIATED WITH ARTHRITIS

Effusion

Increased blood flow and capillary leakage occur early and contribute to increased fluid volume in the joint interstitium and synovial fluid, recognized as effusion. The condition is stimulated by vascular changes and neurotransmitter release, particularly β_2-adrenergic stimulation.[2,8,9] Because of low intra-articular pressures in normal equine joints (–5 mm Hg[6]; –1.25 mm Hg[12]), effusion precedes interstitial edema, until intra-articular pressure is greater than 11 mm Hg.[1] These physiological circumstances make detection of effusion one of the most sensitive indicators of early joint stress. Effusion, although common, is not normal and alters joint function. Congruent motion of joint surfaces depends on normal negative pressure and is important in decreasing shear force (side to side, sloppy movement).[7] Effusion is not painful as long as capsular tension is normal. Through the phenomenon of creep-relaxation, capsular tension is reduced in distended joints. Normal joints are relatively compliant and can accommodate fairly large changes in fluid volume with minimal increase in pressure, but elastance profiles of these joints may be permanently altered.[13] Joints with high structural congruence, such as the tarsocrural joint, are less affected biomechanically by joint effusion than are less congruent joints.[7]

High synovial fluid volume becomes more important during joint motion. Joint pressure profiles are profoundly altered by joint angle.[6,7,13] With effusion, as initial intra-articular pressure is increased, the capacity to accommodate rapid changes in pressure goes down, causing a rapid rise in intra-articular pressure and capsular wall tension at extreme joint

Non-Infectious Arthritis

Alicia L. Bertone

Non-infectious arthritis is characterized by pain, heat, swelling (effusion), erythema, and lameness. Joint structure and function, aspects of diagnosis and management of joint disease, and osteoarthritis are discussed in Chapters 63 and 64. This chapter focuses on normal and abnormal joint physiology and other specific non-infectious joint diseases.

JOINT PHYSIOLOGY

Fluid flow from the vascular space into the interstitium and joint space (third compartment space) and out into venules and lymphatics is tightly governed by Starling forces, which are a balance of arterial and venous pressures and colloid osmotic forces across the joint. The resultant fluid flow through the joint is modified by permeability of the synovium (osmotic reflection coefficient) and the vessel surface area available for fluid transport (filtration coefficient). Even in normal joints these forces are influenced by gravity (joint dependency), motion (exercise), and structure (joint compliance).[1-7]

Horses are unique in needing joint motion to maintain isogravimetric states of the joints (no fluid gain or loss), especially in peripheral joints.[1] In normal stationary equine limbs, lymphatic drainage from joints approximates zero until joint pressure exceeds 11 mm Hg for the fetlock joint (transitional microvascular pressure). In standing animals without counter forces, such as motion or external bandages to increase lymph flow forces, gravitational pressures increase arterial pressure to the joint and venous and lymphatic pressure from the joint. The result is tissue edema and joint effusion.

JOINT PATHOPHYSIOLOGY (SYNOVITIS)

The balance of these forces is altered in horses with synovitis because of the increased blood flow, altered synovial permeability, structural joint capsular changes, and loss of joint motion because of pain.[1,3,5,8,9] These factors profoundly affect joint physiology, contribute to clinical signs, and result in damage to the synovium and articular cartilage. Early signs of effusion that precede clinical detection of inflammation are related to changes in the hemodynamics of the joint, including increased blood flow and reduced joint motion.[8,9]

In chronic arthritis, capsular thickening, fibrosis, and altered synovial function likely influence fluid dynamics. Capsular fibrosis and joint enlargement produce decreased tissue compliance and an increase in intra-articular pressure occurs, even with slight increases in joint effusion. Articular cartilage is avascular and depends on synovial fluid for nutrition, so alteration in fluid flux affects nutritional exchange between the articular cartilage and synovium. Reduced nutrition exchange to articular cartilage exacerbates articular surface fibrillation and degenerative changes.[10,11]

JOINT PATHOLOGICAL CONDITIONS ASSOCIATED WITH ARTHRITIS

Effusion

Increased blood flow and capillary leakage occur early and contribute to increased fluid volume in the joint interstitium and synovial fluid, recognized as effusion. The condition is stimulated by vascular changes and neurotransmitter release, particularly β_2-adrenergic stimulation.[2,8,9] Because of low intra-articular pressures in normal equine joints (–5 mm Hg[6]; –1.25 mm Hg[12]), effusion precedes interstitial edema, until intra-articular pressure is greater than 11 mm Hg.[1] These physiological circumstances make detection of effusion one of the most sensitive indicators of early joint stress. Effusion, although common, is not normal and alters joint function. Congruent motion of joint surfaces depends on normal negative pressure and is important in decreasing shear force (side to side, sloppy movement).[7] Effusion is not painful as long as capsular tension is normal. Through the phenomenon of creep-relaxation, capsular tension is reduced in distended joints. Normal joints are relatively compliant and can accommodate fairly large changes in fluid volume with minimal increase in pressure, but elastance profiles of these joints may be permanently altered.[13] Joints with high structural congruence, such as the tarsocrural joint, are less affected biomechanically by joint effusion than are less congruent joints.[7]

High synovial fluid volume becomes more important during joint motion. Joint pressure profiles are profoundly altered by joint angle.[6,7,13] With effusion, as initial intra-articular pressure is increased, the capacity to accommodate rapid changes in pressure goes down, causing a rapid rise in intra-articular pressure and capsular wall tension at extreme joint

angles, resulting in sharp pain during maximal joint excursion and simultaneous reduction in synovial perfusion.[14] These effects could be present even if synovitis is not recognized clinically. The influence of intermittent synovial ischemia is not elucidated fully, but it may be important in diseases of synovial proliferation.

Inflammation

Inflammation causes a humoral (vascular) and a cellular response. In early arthritis, cells are up-regulated to produce inflammatory mediators. Gene transcriptional profiles may be unique to certain forms of arthritis and potentially could be used in the future to recognize and prevent arthritis. Up-regulation of genes causes protein production, initiation of the inflammatory cascade, and further release of inflammatory mediators. Important mediators include cytokines interleukin-1, interleukin-6, and tumor necrosis factor.[2-4,15,16] Secondary mediators such as the eicosanoids (prostaglandin E_2 and leukotrienes),[2-4,15] free oxygen radicals,[17] substance P,[3] and nitric oxide[3,4] are also pro-arthritic and amplify pain.

Cellular influx causes effusion and subsequent clinical recognition of synovitis. The degree of synovitis and articular cartilage damage are directly proportional to synovial fluid nucleated cell count in infectious and non-infectious arthritis. Neutrophils are highly migratory and can move into joint fluid within 3 hours after a chemotactic stimulus, such as interleukin-1, paclitaxel, or endotoxin.[2,8,9,15,18] These cells are damaging to surrounding tissue because they have destructive enzymes and alter synovial fluid environment. In non-infectious arthritis, nucleated cell count is usually less than 30,000 nucleated cells per microliter,[15] but values greater than 100,000 nucleated cells per microliter occur in autoimmune arthritis,[19] endotoxin-induced arthritis,[16,20] and early in reactive arthritis.

Ischemia

Intra-articular pressures greater than 30 mm Hg cause significant reduction in the perfusion of the synovium and fibrous layer of the joint capsule.[14] Pressures of this magnitude occur in horses with palpable effusion of the fetlock joint and are present when synovitis is prominent.[12] Pressures greater than 60 mm Hg can reduce blood flow profoundly, and pressures approximating 100 mm Hg can cause capsule joint rupture (carpus and fetlock[21]). Clinically, joint rupture is uncommon but was hypothesized to contribute to dorsal fetlock capsular thickening.[12] I have seen this as a rare occurrence in the plantar pouch of the tarsocrural joint and the palmar pouch of the antebrachiocarpal joint. Intra-articular pressure can reach high levels during maximal flexion and extension, particularly in horses with resting pressures greater than 30 mm Hg.[6] Ischemia has been hypothesized to be a component of synovitis particularly in the proliferative form.[22] Low oxygen tension stimulates angiogenesis and granulation tissue formation, resulting in fibrosis. In chronically inflamed joints, clubbed and thickened synovial membrane often is seen during arthroscopic surgery, supporting the concept of synovial ischemia.

Synovial Fluid Lubrication: Hyaluronan

Synovial cells produce hyaluronan. A protective layer of high concentration hyaluronan remains close to the surface of the synovium and the remainder diffuses into the joint space, creating the unique viscosity of synovial fluid.[3,7] Adequate hyaluronan concentration is critical to provide lubrication of synovial soft tissues, particularly synovial villi. During inflammatory synovitis, lubrication of the soft tissues is reduced because of dilution of hyaluronan and a reduction in hyaluronan production. Swollen, edematous villi cause an elevated coefficient of friction. In horses with mild effusion, hyaluronan concentration can be normal because increased production by synovial cells matches elevation in synovial fluid volume.[23] When inflammation increases, synovial cell production decreases and degradation of hyaluronan increases. In horses with severe joint inflammation or hemarthrosis, hyaluronan concentration may be negligible.

Pain in Arthritis

Sensory and motor innervation help maintain joint stability, and in the absence of these protective reflexes, severe arthropathy may develop.[24] When activated, the peripheral nervous system can initiate the major features of acute inflammation, such as vasodilation and effusion, and lower the threshold for pain.[25] The C and A nerve fibers responsible for pain sensation in arthritis are activated by amines (such as serotonin) and neuropeptides (calcitonin gene-related peptide and substance P) that also act locally to exert pro-inflammatory effects on synovium. A role of substance P in joint pain is supported by the clinical effectiveness of the substance P depleting substance, capsaicin. Capsaicin initially activates C fibers, resulting in substance P release and pain, but subsequently desensitizes or causes degeneration of C fibers.[26]

The contribution of neuropeptides may be different in acute and chronic inflammatory arthritis. Edema formation in denervated limbs may indicate that loss of sensory innervation could play a role in acute arthritis.[27] Increased edema formation and decreased permeability to macromolecules were observed in denervated limbs subjected to interleukin-1 induction of synovitis.[2] The role of innervation in chronic arthritis is complex, because the neuropeptide substance P and calcitonin gene-related peptide were increased in sciatic nerve, dorsal root ganglia, and peri-articular tissues but were decreased in synovium.

The therapeutic implications are intriguing. Intramuscular gold or topically applied capsaicin could selectively destroy C fibers, thus lowering substance P levels, and these have been found to be clinically useful. Non-steroidal anti-inflammatory drugs (NSAIDs) decrease prostanoid production, and intra-articular corticosteroids inhibit the arachidonic acid cascade, thus having direct and indirect effects.[28] In addition, stimulation of primary afferent nociceptive fibers causes release of glutamate and substance P from central spinal pathways. This nociceptive input can be inhibited by stimulation of proprioceptive and tactile type I and II fibers. Stimulation of these fibers can be accomplished by high-frequency, low-intensity transcutaneous neural stimulation, frequently used in physiotherapy.

AUTOIMMMUNE-MEDIATED ARTHRITIS

Rheumatoid arthritis is a steroid-responsive arthritis, associated with high synovial nucleated cell counts, progressing to bone erosion and pannus formation. To establish a diagnosis of rheumatoid arthritis, an autoimmune component and production of rheumatoid factor must be documented. According to these criteria rheumatoid arthritis has not been reported in horses. In human systemic lupus erythematosus (SLE), systemic disease is also present and auto-antibodies are directed toward nuclear cellular material. An SLE-like disease was described in a young horse.[29] In horses, anti-collagen type II antibodies and immune complexes were identified in synovial fluid of horses with osteoarthritis and joint trauma. However, these immune complexes are much less common in horses with mild synovitis and have been found in sera. Relationship of cause and effect of these immunological findings is unclear, because immune complexes were found in many disease types. Although these auto-antibodies may be associated with equine diseases, it is unlikely that they initiate arthritis in horses.[30] They may develop after exposure to type II collagen,

after articular cartilage trauma or wear. Specific assays of synovial fluid for immunoglobulin M–rheumatoid factor (a feature of rheumatoid arthritis), antibodies to heat-shock protein, and anti-nuclear antibodies (ANA), a feature of SLE, revealed only modestly low levels of rheumatoid factor without correlation to disease and no ANA.[31]

IMMUNE-MEDIATED ARTHRITIS

The presence of synovitis and immunoglobulin G complex deposition in the synovium of foals has been reported.[32-34] This form of synovitis is called immune-mediated arthritis and may be associated with circulating immune complexes formed as a result of systemic disease.[32] Using specific monoclonal antibody techniques, immune-mediated arthritis was diagnosed in a 6-week-old pony foal infected with equine herpes virus-4.[33] Three horses were hyperimmunized with *Streptococcus* equine M protein vaccine and subsequently injected intra-articularly with purified streptococcal M protein. Severe suppurative synovitis developed, and synovial fluid nucleated cell counts were greater than 100,000 cells per microliter.[34] Eosinophils were prominent in the synovial fluid and synovial membrane in two horses.

A clinical syndrome of polysynovitis and vasculitis secondary to high circulating M protein (after streptococcal infection), or associated with *Rhodococcus equi* infections, is recognized and thought to be caused by immune-mediated arthritis. Seventeen (35%) of 48 foals with *R. equi* pneumonia infection had chronic active non-infectious arthritis. Pathogenesis involves immunocomplexes in the synovium. The hallmark of immune-mediated arthritis in foals is effusion in one or more joints but minimal lameness.[35] Synovitis often resolves in several weeks with or without treatment. Foals should be restricted to box rest, but no other specific treatment is necessary. Corticosteroids are contraindicated, because bacterial infection may be perpetuated.

REACTIVE SYNOVITIS

Reactive synovitis may occur after intra-articular injection of any product. Any intra-articular injection incites at least mild synovitis. The activated drug or a product in the solution may chemically induce reactive synovitis. Endotoxin contamination of multiple-dose vials or even single-dose products may cause reactive synovitis. In the case of a multiple-dose vial, a suspicion of endotoxin contamination should be high if more than one horse shows clinical signs within a short period. Horses are exquisitely sensitive to endotoxin, and concentrations above 0.125 ng per joint incite synovitis.[36] After intra-articular injection of methylprednisolone acetate, inflammatory cells surrounding vehicle crystals were identified in synovium 6 weeks later.[37] Reactive synovitis associated with methylprednisolone acetate may be most common in the distal interphalangeal joint. Although unusual, within a few hours after injection, horses can show severe lameness. Steroid arthropathy may be a form of reactive synovitis. The distal interphalangeal and tarsocrural joints appear most at risk to develop reactive arthritis after intra-articular injection of polysulfated glycosaminoglycans.[38]

Reactive synovitis must be distinguished from early infectious arthritis. Distinguishing features of reactive arthritis include early onset after injection (about 24 hours), synovial nucleated counts less than 30,000 cells per microliter, and resolution within 1 to 3 days. Lameness ranges from mild to severe, and in some horses distinguishing reactive arthritis from infectious arthritis may be difficult, and prompt management with intra-articular lavage, systemic and local antimicrobial drug administration, and anti-inflammatory therapy should be instituted. Culture and susceptibility testing should be performed if any suspicion exists that a bacterial infection is present, if synovitis does not resolve quickly, or in horses in which lameness persists.

Eosinophilic synovitis is rare and may represent an allergic reaction to an injected product, or to parasite migration, or could be truly idiopathic.[34,39] Joint lavage to assist in removing foreign material, and the administration of non-steroidal anti-inflammatory medication and anthelmintic treatment are indicated.

Foreign bodies rarely may be present within a joint or tendon sheath and incite chronic reactive synovitis. Broken needles, plant or seed awns or thorns, and debris from nearby wounds can cause reactive synovitis. Radiographic and ultrasonographic examinations can be helpful to identify the nature of the foreign material.[40] Cellulitis close to a joint may cause reactive synovitis that resolves with successful treatment of the primary infection.

TRAUMATIC SYNOVITIS

Primary traumatic synovitis is an early form of osteoarthritis. Horses at risk are usually in active sports training. Lameness usually is managed by intra-articular and systemic medication. Early medical intervention and appropriate joint rest and physiotherapy are critical to prevent loss of glycosaminoglycan from articular cartilage and permanent joint wear. Early loss of articular cartilage proteoglycan is reversible with medication and joint rest. If training is continued, some horses will develop proliferative synovitis, chip fractures, intra-articular ligament injury, and osteoarthritis. Intermittent hemarthrosis (see below) may be detected with primary traumatic synovitis, but often it indicates injury to subchondral bone, such as chip fracture or cartilage elevation.

PROLIFERATIVE (VILLONODULAR) SYNOVITIS

Chronic traumatic synovitis and continued exercise result in a painful thickening of the synovium, proliferative synovitis, particularly in areas of compression trauma.[41-45] The most common location is the dorsal fibrous pad (synovial pad) of the metacarpophalangeal joint, directly under the broad, flat common digital extensor tendon and joint capsule.[41] At maximal extension and flexion, pad compression results in intrasynovial hemorrhage, granulation tissue formation, fibrosis, and mineralization. Diagnosis and management are discussed in Chapter 37.

Chronic proliferative synovitis is a frequent finding in the carpal and tarsocrural joints during arthroscopic examination. Diffuse proliferative synovitis can be seen in horses that have had frequent intra-articular injections and have continued in exercise. Capsular fibrosis and loss of fine villous architecture occur. I do not recommend radical synovectomy, but removal of fibrotic tufts of capsule and synovium prone to pinching or demonstrating signs of internal hemorrhage and edema is warranted.

See Chapters 56 and 58 for a discussion of osteochondrosis.

IDIOPATHIC ARTHRITIS

Synovitis can occur without any known cause or associated trauma and can be truly idiopathic, although synovitis may be related to circulating toxins, including endotoxin, streptococcal cell wall, M protein, and viruses. In people, bacterial and viral deoxyribonucleic acid and bacterial peptidoglycans have been located in joints of patients with early rheumatoid and other non-infectious arthritides.[46,47] In horses synovitis can be associated with vasculitis, such as that seen with equine viral arteritis.

HEMARTHROSIS

Bleeding into a joint (hemarthrosis) causes joint capsule distention, severe pain, and lameness.[48] Draining the blood from the joint usually results in rapid relief of clinical signs. The cause of hemorrhage may be trauma to proliferative hemorrhagic synovium, an intra-articular fracture, or tearing of an intra-articular ligament. Hemorrhage may occur on a single occasion or may be recurrent. Diagnosis of hemorrhage is simple, by arthrocentesis, but identification of the primary cause can be more difficult. In the absence of radiological abnormalities, exploratory arthroscopy is warranted in a horse with recurrent episodic severe lameness associated with hemarthrosis. Hemorrhage associated with proliferative synovitis may be managed successfully by subtotal synovectomy.

LYME DISEASE

Although strictly speaking an infectious disease, Lyme disease is discussed in this section because it should be considered a differential diagnosis in tick-endemic areas in a horse with shifting limb lameness associated with synovitis in several joints.[49,50] However, many clinically normal horses have antibody titers to *Borrelia burdorferi*, and high titers are not synonymous with clinical disease. True Lyme disease is poorly documented in the horse, and definitive diagnosis would require identification of significantly raised titers in paired serum samples.

CHAPTER • 68

Other Joint Conditions

Chris E. Kawcak and Gayle W. Trotter

Several types of joint diseases are rare and have been presented only in case reports or small retrospective studies. This makes generalizations about these diseases difficult and searching for information a tedious process.

DISEASES OF SOFT TISSUES OF THE JOINT

Soft tissue structures serve to support the joint, and disease can result in abnormal stresses to the articular cartilage and hence chronic progression of articular cartilage degeneration and osteoarthritis (see Chapter 63). Preoperative diagnosis of some soft tissue injuries is difficult, often leaving the surgeon with little to do other than evaluate the injury and debride fibrillated tissue during arthroscopic surgery. With the advent of newer diagnostic techniques such as magnetic resonance imaging (see Chapter 21) and increased use of ultrasonography (see Chapter 17), soft tissue injuries can be characterized better preoperatively.

Most soft tissues of joints, such as ligaments, menisci, and joint capsule, function to support joints. Joint ligaments maintain alignment of opposing and adjacent bones in joints. They form a connection between opposing bones (such as the tibia and femur in the stifle) and between adjacent bones in more complex joints (such as between the carpal bones in the carpus). They function to maintain alignment and allow for movement of the joint. The meniscal cartilages function as cushions between the tibia and femur of the femorotibial joints. Proper material characteristics are necessary for maintenance of the joint environment. Joint capsule is also responsible for maintaining joint support and provides a barrier for synovial fluid. Because the capsule surrounds the entire joint, appropriate elasticity is needed to maintain joint flexibility (see Chapter 67).

Ligament Injuries

Joint ligament injury can be an incidental finding during surgery or a devastating cause of lameness. For instance, medial palmar intercarpal ligament damage can be an incidental finding during arthroscopic surgery and has been seen incidentally in necropsy specimens (see Chapter 39).[1]

Injury to cruciate ligaments and menisci of the stifle usually cause significant pain (see Chapter 47), but cutting the cranial cruciate ligament in an attempt to create a model of osteoarthritis did not lead to osteoarthritis in horses. Therefore further destabilization of the joint beyond cruciate injury must usually occur, with possible damage to other soft tissue structures, including the joint capsule.

Collateral ligament injury caused by a bad step or laceration can result in subtle or severe lameness. We have seen low-grade lameness in a horse that had complete tearing of the medial collateral ligament of the metatarsophalangeal joint (Fig. 68-1). Laxity of the joint was detected by manipulation and stressed radiographs. The joint was immobilized in a cast for 6 weeks, followed by a splint for an additional 6 weeks. Reinjury occurred after splint removal and the joint was recast. After immobilization for 16 weeks the injury healed well enough for trail riding.

Ligament injuries usually heal slowly, and gradual return to function is needed to strengthen the tissues. The conse-

CHAPTER • 68

Other Joint Conditions

Chris E. Kawcak and Gayle W. Trotter

Several types of joint diseases are rare and have been presented only in case reports or small retrospective studies. This makes generalizations about these diseases difficult and searching for information a tedious process.

DISEASES OF SOFT TISSUES OF THE JOINT

Soft tissue structures serve to support the joint, and disease can result in abnormal stresses to the articular cartilage and hence chronic progression of articular cartilage degeneration and osteoarthritis (see Chapter 63). Preoperative diagnosis of some soft tissue injuries is difficult, often leaving the surgeon with little to do other than evaluate the injury and debride fibrillated tissue during arthroscopic surgery. With the advent of newer diagnostic techniques such as magnetic resonance imaging (see Chapter 21) and increased use of ultrasonography (see Chapter 17), soft tissue injuries can be characterized better preoperatively.

Most soft tissues of joints, such as ligaments, menisci, and joint capsule, function to support joints. Joint ligaments maintain alignment of opposing and adjacent bones in joints. They form a connection between opposing bones (such as the tibia and femur in the stifle) and between adjacent bones in more complex joints (such as between the carpal bones in the carpus). They function to maintain alignment and allow for movement of the joint. The meniscal cartilages function as cushions between the tibia and femur of the femorotibial joints. Proper material characteristics are necessary for maintenance of the joint environment. Joint capsule is also responsible for maintaining joint support and provides a barrier for synovial fluid. Because the capsule surrounds the entire joint, appropriate elasticity is needed to maintain joint flexibility (see Chapter 67).

Ligament Injuries

Joint ligament injury can be an incidental finding during surgery or a devastating cause of lameness. For instance, medial palmar intercarpal ligament damage can be an incidental finding during arthroscopic surgery and has been seen incidentally in necropsy specimens (see Chapter 39).[1]

Injury to cruciate ligaments and menisci of the stifle usually cause significant pain (see Chapter 47), but cutting the cranial cruciate ligament in an attempt to create a model of osteoarthritis did not lead to osteoarthritis in horses. Therefore further destabilization of the joint beyond cruciate injury must usually occur, with possible damage to other soft tissue structures, including the joint capsule.

Collateral ligament injury caused by a bad step or laceration can result in subtle or severe lameness. We have seen low-grade lameness in a horse that had complete tearing of the medial collateral ligament of the metatarsophalangeal joint (Fig. 68-1). Laxity of the joint was detected by manipulation and stressed radiographs. The joint was immobilized in a cast for 6 weeks, followed by a splint for an additional 6 weeks. Reinjury occurred after splint removal and the joint was recast. After immobilization for 16 weeks the injury healed well enough for trail riding.

Ligament injuries usually heal slowly, and gradual return to function is needed to strengthen the tissues. The conse-

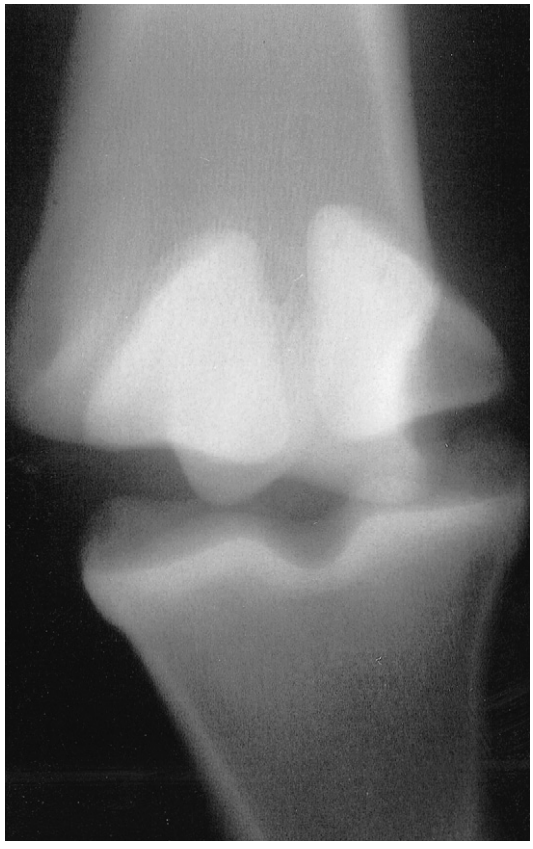

Fig. 68-1 A 3-year-old Paint gelding had acute swelling on the medial aspect of the metatarsophalangeal joint. A stressed dorsoplantar radiograph shows subluxation of the metatarsophalangeal joint caused by complete rupture of the medial collateral ligament.

Fig. 68-2 A synovial hernia on the dorsum of the carpus.

quences of collateral ligament injury depend on the severity of damage to the ligament, contamination in the joint, and damage to other structures in the joint and may be difficult to predict at the time of injury. Long-term instability may place abnormal stresses on the joint and lead to progressive osteoarthritis. Cutting the lateral collateral and lateral collateral sesamoidean ligaments of the metacarpophalangeal joint resulted in lameness, increased joint circumference, decreased range of motion, and osteophyte formation in 8 weeks, resulting in osteoarthritis.[1]

Hygroma

A hygroma is an adventitious or acquired bursa on the dorsum of the carpus caused by trauma from falling, getting up and down, or hitting a fence; or by chronically pawing and hitting the dorsum of the carpus.[2-4] Non-painful, fluctuant, uniform soft tissue swelling occurs on the dorsal aspect of the carpus. Pressure does not induce swelling in any associated joints or tendon sheaths. Range of motion of the carpus may be reduced, but lameness is unusual. Injection of radiopaque contrast agent into the hygroma confirms its extra-articular position.

Spontaneous resolution of hygromas may occur, but treatment is often necessary. Drainage and injection of anti-inflammatory agents has been used with varying success; in many horses repeated injection is necessary.[3,4] We have seen spontaneous resolution after injection of the contrast agent. Injection of atropine (7 mg) may resolve the swelling. Owners should be warned that bandaging is an essential component of treatment and that long-term chronic thickening may occur.

Other treatments include incisional drainage; injection of irritants, such as iodine or Lugol's solution; and blistering,[3,4] but contrast radiography should be performed to ensure that the hygroma is an isolated structure. Although preoperative contrast radiographs may show no communication between a hygroma and a joint or tendon sheath, one might exist in the form of a one-way valve from the joint into the mass.[5] Drainage of the mass with a Penrose drain and bandaging has been used successfully for treatment of recurrent hygromas. Drains usually are removed once drainage stops, 2 to 7 days after placement.[6] Surgical excision can be performed in horses with chronic hygroma and is best accomplished if the fluid sac is left intact and dissected from the other tissues (see Chapter 39).[7] Soft tissue and skin closure are routine, and a splint can be used to prevent flexion for better healing. Prognosis for resolution of hygroma is often good, although some degree of thickening usually persists.

Synovial Hernia

A synovial hernia is a defect in a joint capsule or tendon sheath through which the synovial membrane can protrude. The condition rarely causes lameness but is a cosmetic blemish. A well-defined, round, soft tissue mass can be palpated over a joint, and with palpation fluid often can be moved between the hernia and the underlying joint or tendon sheath (Fig. 68-2). The hernia may disappear with joint flexion. Contrast agent injected into the hernial sac is detected in the underlying joint or tendon sheath, although a one-way valve may be present, limiting movement of contrast material. If the synovial hernia is of cosmetic concern, surgical excision can be performed, with a good prognosis for soundness provided no other joint diseases are present.[8]

Ganglion

A ganglion is defined as a fluid-filled structure that connects to a joint or tendon sheath through a one-way tract from the joint into the mass.[2] Unlike a synovial hernia, the mass lacks a synovial lining and often is filled with mucin. Ganglions are rare in

the horse, but common in people, and they have been reported around the stifle and the carpus.[2] A ganglion adjacent to the fetlock was associated with lameness that was alleviated by regional analgesia and after surgical excision of the mass.[9] However, communication with the tendon sheath and joint was not demonstrable by ultrasonography. Demonstrating connection between a ganglion and an adjacent joint by injection of radiographic contrast agent into the mass may or may not be possible.[6]

Synovial Fistula

Synovial fistulae are communications between two synovial structures, usually a joint and tendon sheath. They have occurred between the antebrachiocarpal joint and the common digital extensor tendon; the middle carpal joint and the extensor carpi radialis tendon sheath or the common digital extensor tendon sheath; the proximal interphalangeal joint and long digital extensor tendon sheath; and the extensor carpi radialis tendon sheath and a carpal hygroma.[5,10-12] Additional joint damage is often present in association with the fistula, causing lameness referable to the area.

Swelling in the joint and nearby tendon sheath occurs, and fluid is often movable between the structures (Fig. 68-3). Radiography may reveal additional joint or tendon sheath damage, and contrast agent injected into one of the structures is visible in the other.[10]

Fig. 68-3 Dorsal view of carpus with effusion of the antebrachiocarpal joint and common digital extensor tendon sheath. A synovial fistula was seen during arthroscopic surgery.

Occasionally a fistula can be seen during arthroscopic surgery, but closure of the fistula requires an arthrotomy. However, arthroscopic surgery for treatment of a primary problem, without repair of the fistula, has resulted in resolution of lameness, without resolution of the swelling. We do not close these fistulae unless a cosmetic effect is important, if the swelling itself is impeding performance, or if medical therapy fails to alleviate lameness.

NEOPLASIA

Joint-associated tumors in horses are rare and consequently behave unpredictably, and relying on treatment information from other species is difficult. Soft tissue tumors in horses are vascular, fibrous, or synovial in origin. Benign vascular masses such as hemangiomas have been seen in carpal and digital tendon sheaths of horses.[2] The tendon sheaths were distended with blood-stained fluid, but no associated lameness occurred, and surgical excision of the masses was curative.

Fibromas may occur as slow-growing masses near the tarsus, stifle, and distal radius. These masses are rarely erosive to associated bone. Complete surgical excision may be curative, but incomplete excision can result in recurrence.[11,13] A fibroma on the proximal lateral aspect of the tarsus was incompletely resected, and over a 4-month period the mass regrew to larger than its original size.[14]

Villonodular (proliferative) synovitis is a common traumatic injury on the proximal dorsal aspect of the metacarpophalangeal joints of racehorses and is not a tumor (see Chapters 36 and 67). Keratinization of a villonodular synovitis was associated with severe lameness.[15] It was suggested that this was a form of epidermal inclusion cyst, the result of inadvertent introduction of epidermal tissue into the joint after repeated arthrocentesis for previous infectious arthritis, resulting in a foreign body reaction. Surgical resection resulted in resolution of lameness. Pigmented villonodular synovitis has occurred in the metatarsophalangeal and femoropatellar joints resulting in chronic lameness in a mule.[16]

Synovial cell sarcomas have been identified in the antebrachium,[14] a digital sheath,[17] and proximal interphalangeal joint associated with soft tissue swelling and variable lameness. The masses had infiltrated the soft tissues and caused localized inflammatory bone loss because of pressure. Recurrence may occur after surgical excision.[18] Chondrosarcomas are rare, but they have been described in a metacarpophalangeal joint[19] and the carpal region,[20] associated with expansible radiolucent lesions.

A hemangiosarcoma occurred in the tarsal sheath, and surgical excision resulted in relief of lameness.[21] A secondary melanosarcoma in a shoulder joint caused severe lameness.[22]

OSTEOCHONDROMATOSIS

Synovial chondromatosis and osteochondromatosis describe pieces of uncalcified and calcified hyaline cartilage, respectively. Synovial chondromatosis is a disease in which hyaline cartilage can occur in the joint in pedunculated form, within the synovial membrane, or free within the joint. Osteochondromatosis results when endochondral ossification of the mass occurs, often making it difficult to differentiate from osteochondral fragmentation. Osteochondromatosis has occurred in the femorotibial joint.[2,23] Secondary osteochondromatosis also occurs within joints with osteoarthritis. The condition is often painful in people, and surgical removal is indicated. Osteochondromatosis has occurred incidentally in horses without lameness.

CALCINOSIS CIRCUMSCRIPTA

For a discussion of calcinosis circumscripta, see Chapter 47.

CHAPTER • 69

Pathophysiology of Tendon Injury

Roger K.W. Smith

FUNCTIONS OF TENDONS AND LIGAMENTS

Tendons passively *transfer force* generated by muscle to bony attachments on the opposite side of a joint, or joints, to provide movement. In contrast the function of a ligament is to resist distraction of its two bony attachments (e.g., collateral ligaments and suspensory ligament [SL]). Although this function is true for most tendons and ligaments, the horse has evolved its digital flexor tendons and SL to exhibit additional functions. These tendons and ligaments, situated on the palmar aspect of the equine distal limb, receive large weight-bearing loads because of the hyperextended metacarpophalangeal and metatarsophalangeal joints. As a result the tendons and ligaments on the palmar aspect act to *support* the metacarpophalangeal and metatarsophalangeal joint during normal weight bearing.

In addition, the equine digital flexor tendons exhibit considerable elasticity that is used to *store energy* for energy-efficient locomotion.[1] In the case of the superficial digital flexor tendon (SDFT), its muscle is highly pennate (the muscle fibers are arranged at an oblique angle to the line of pull of the muscle, which maximizes power and minimizes contraction distance) and is unable to contract by more than a few millimeters. Therefore the action of the muscle, together with its accessory ligament, is largely passive to fix the origin of the SDFT in space. Although the muscle contracts only a short distance, its action, together with the tendon elasticity, also provides *shock absorption*. The gait of a horse at speed can be compared with a weight (the horse's body) bouncing up and down on elastic springs (the digital flexor tendons) in a similar fashion to a pogo stick.[2] This arrangement allows horses to reach and maintain high speeds while minimizing energy expenditure.

FUNCTIONAL CHARACTERISTICS

Biomechanical Properties

Stress-Strain Curves

Stress-strain curves for the tendon in which the force per unit area (stress) is plotted against the percentage of elongation (strain) can be used to provide values for the elastic modulus of tendon. Variation in the slopes between tendons and tendon sites occurs, but Fig. 69-1 shows a simplified stress-strain curve for tendon. The curve has four regions:

1. The toe region, where stretch to the tendon is nonlinear. This is associated with the elimination of the undulating pattern of the collagen fibrils (known as *crimp;* see the following discussion).
2. Linear deformation, which is this area of the curve from which the modulus of elasticity is determined and that characterizes the elastic stiffness of the tendon. The mechanism for this elongation is unclear, but it involves elongation of the collagenous network, with possible movement of collagen fibrils or fascicles relative to one another. A tendon is not homogeneous, and what parts of the tendon are responsible for this linear deformation is unclear.
3. Yield region, in which irreversible lengthening of the tendon occurs at these strains, possibly arising from covalent cross-link rupture and slippage of collagen fibrils.
4. Rupture, in which the stress falls quickly to zero as the collagen cross-links or fibrils sequentially rupture.

Biomechanical Parameters

A number of simple biomechanical parameters can be ascribed to tendons that are derived from its stress-strain characteristics: ultimate tensile stress (force per unit area at the point at which the tendon breaks), ultimate tensile strain (the percentage extension of the tendon at its breaking point), and the modulus of elasticity (E, a constant determined from the ratio of stress to strain for the linear part of the stress/strain curve). Some of the values of these parameters for the palmar supporting structures of the distal limb are shown in Table 69-1. A parameter not frequently calculated, but probably more relevant to the in vivo situation, is the force/stress at the yield point, after which irreversible damage is occurring.

Ultimate tensile force/stress. The SDFT receives in excess of 1 metric ton of weight (10 kN) at maximum weight bearing on a structure only about 1 cm^2 in cross-sectional area. The ultimate tensile stress (force at failure per area) for the SDFT (rupturing at the mid-metacarpal region) in the horse is therefore close to 100 MPa, which is at the upper limit of previously documented figures for other species (45 to 125 MPa).[3,4]

However, within any population of horses, large variation occurs in the ultimate tensile force, with up to a twofold dif-

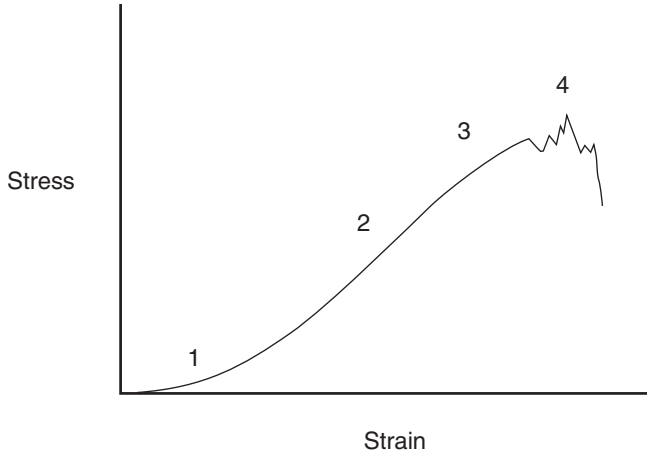

Fig. 69-1 Simplified stress-strain curve for tendon. *1*, Toe region; *2*, linear deformation; *3*, yield, *4*, rupture. (From Goodship AE, Birch HL, Wilson AM: The pathobiology and repair of tendon and ligament injury, *Vet Clin North Am Equine Pract* 10:323, 1994.)

ference between the weakest and strongest tendons.[5] This variation also exists for ultimate tensile stress,[6] indicating that the variation is not just due to differences in cross-sectional area. It is hypothesized that the horses with weaker tendons are more prone to tendon injury.

Modulus of elasticity/stiffness. The structural stiffness of a tendon is the force required to extend it by a unit length. This material property, the modulus of elasticity, is derived from the linear portion of the stress-strain curve for tendon, and for the SDFT it is about 1000 Mpa. It is normally correlated with ultimate tensile stress, so that the stronger the tendon, the stiffer it is.

Ultimate tendon strain. In vitro testing of equine flexor tendons indicates that they usually extend by 10% to 12% of the original length before they rupture, although values of up to 20% have been reported.[7] However, the ultimate tensile strain reflects only the final strain before rupture and includes that yield portion of the stress-strain curve that represents irreversible damage to the tendon tissue (Fig. 69-1). In addition the ultimate tensile strain is not constant along the length of the SDFT in vitro,[8] with the highest ultimate tensile strain in the metacarpal region (the region most frequently injured).

In vivo, the normal strains in the digital flexor tendons (in ponies) are about 2% to 4% at the walk and 4% to 6% at the trot.[9] At the gallop in the Thoroughbred, maximum strains in the metacarpal region of the SDFT can reach 16%.[10] Such strains are far greater than usually expected in tendons from most species and reflect the highly specialized nature of the equine digital flexor tendon. If these high strains are truly representative of the strains within the tendon, they indicate that equine tendon is operating at or close to its ultimate tensile strain. This suggests little tolerance in the system, which would explain the high incidence of injury in this structure. However, some caution in the interpretation of in vitro measurements is necessary, because studies have shown different results obtained between in vivo and in vitro tests.[9]

Hysteresis

Hysteresis refers to the energy loss between the loading and unloading cycles of tendon (Fig. 69-2), determined from the area between these two curves. Hysteresis is usually about 5% in equine tendons.[11] Some of this energy is responsible for the rise in temperature within the tendon core associated with repeated loading (as in an exercising horse), which has been suggested as a causative factor in equine superficial digital flexor tendonitis[12] (see the following discussion).

Classification of Tendons and The Relationship to Function

Recent research has demonstrated that tendons possess different properties depending on function. The tendons in the horse, like those in people, can be divided into two broad categories: those with the primary function of withstanding the weight of the horse (weight-bearing tendons) and those with the primary function of flexing, extending, or rotating joints (positional tendons). Weight-bearing tendons, such as the equine digital flexor tendons, are more elastic than positional tendons (e.g., the equine digital extensor tendons), which reflects the function of the digital flexor tendons as elastic energy stores. Positional tendons require stiffness for accurate positioning of the limb or digit. Human finger tendons are stiff for such a purpose, and although equine digital extensor tendons are not required for accurate placement of the digit, they nevertheless resemble this category of positional

tendons.[13] These differences in biomechanical properties are reflected in the anatomical features of the tendons.

ANATOMICAL STRUCTURE

Morphology of Tendons

Tendon is composed of a hierarchical structure of subunits. To the naked eye, in cross-section the tendon substance is divided into a number of fascicles, which are in turn composed of ever decreasingly sized subunits: fibers and then fibrils.

The fascicles are held together by the loose connective tissue, the endotenon, which is confluent with the outside of the tendon, the epitenon. The endotenon contains vascular and neural elements and separate cell populations, which may be a source of pluripotential cells. In regions where the tendons are not surrounded by a tendon sheath, a thick fibrous layer, the paratenon, further surrounds the tendon.

Crimp

In longitudinal section, under the light microscope, the collagen fibers in tendon have a wavy appearance known as crimp. This pattern is responsible in part for the elasticity of the tendon, and the toe region of the stress-strain curve when the mechanical behavior of the tendon is non-linear. A generalized reduction in the crimp angle occurs with aging, with a differentially greater reduction in the central fibers.[14,15] As the tendon stretches, the central fibers straighten first and therefore receive differentially greater load than the peripheral fibers, which may explain the site of pathological damage in those horses with centrally positioned core lesions. The reason for lesions situated peripherally at the tendon is less clear, unless these are also focal regions of the tendons that have developed atypically straightened fibers. Lesions involving the entire cross-section of the tendon represent a more generalized disruption of the tendon matrix.

Collagen Fibril Diameter

The collagen fibrils are composed of many triple helical collagen molecules arranged in a quarter stagger, which gives a characteristic banding pattern on electron microscopy. These collagen molecules are secreted through pores in the cell membrane as triple helical procollagen, which is subsequently assembled into fibrils extracellularly, by covalent intermolecular cross-linking (see the following discussion). Fusion of adjacent fibrils is responsible for the increasing size of collagen fibrils with age.[16,17] Foals at birth already have a bimodal or trimodal pattern of fibril diameters, and in the adult the fibrils can be grouped into two or three populations: small (40 nm), medium (120 nm), and large (>200 nm).[7]

Associated Structures

Blood Supply

Tendons obtain nutrients from two primary processes: perfusion and diffusion. Diffusion of nutrients from compartments other than blood occurs predominantly where the tendon is enclosed in a sheath, the synovial fluid playing an important role in tendon nutrition.

The principal blood supply in tendon arises from three sources: proximally, the musculotendonous junction; distally, the osseous insertion; and between these two, the tendon is supplied by intratendonous and extratendonous vessels. The extratendonous supply arises from the paratenon in extrasynovial tendon and from mesotenon attachments within synovial tendon sheaths (such as the vinculum between the fetlock annular ligament and the SDFT). The predominance of either source in the mid-tendon region depends on the species and the tendon. In the equine SDFT, two major parallel vessels run longitudinally in the lateral and medial borders of the mid-metacarpal tendon accompanied by an extensive anastomosing network of vessels.[18] These vessels anastomose with paratenon blood vessels, although removal of the paratenon blood supply in the horse failed to produce gross pathological damage. However, ligation of the intratendonous supply in the mid-metacarpal region produced ischemic pathological damage, demonstrating the importance of the intratendonous supply. The deep digital flexor tendon (DDFT) also has an anastomosing vascular network, except for its dorsal aspect as it passes over the metacarpophalangeal joint, where it has a more fibrocartilagenous phenotype to resist the compressive forces in this region.[19]

Tendon has been shown to have a good blood supply based on a number of techniques, usually involving clearance measurements of various radionuclides injected intratendonously (most commonly ^{133}Xe and ^{24}Na). The SDFT appears to have good blood supply similar to that of resting skeletal muscle, although findings have been inconsistent between studies and between animals on successive measurements. The large variation in the blood flow under different circumstances may indicate that external factors, as yet undefined, influence blood flow on a day-to-day basis.

Differences in blood flow between tendons are affected by age, exercise, and injury (Fig. 69-3).[20] The SDFT has a slightly higher blood flow than the DDFT, which reflects its good vascular anatomy (see the previous discussion). However, studies have shown similar functional blood flow throughout the metacarpal region of the SDFT although, histologically and microangiographically, the mid- and distal regions are less well vascularized.[21] However, not surprisingly, the DDFT in the metacarpophalangeal joint region has a significantly lower blood flow, associated with its fibrocartilagenous phenotype, with few blood vessels because of the high compressive forces in this region, which would limit any blood flow.

The blood flow appears to be considerably higher in foals than in adult horses, with a gradual decline in blood flow to the adult level by 3 years of age.

Exercise induces an increase in blood flow (about 200%), although this increase is delayed in animals not previously trained. The tendon blood supply therefore appears to exhibit a fitness memory.

Injury provokes a considerable increase in blood flow (>300%), which occurs in the clinically affected and the clinically unaffected limb, consistent with the bilateral nature of tendonitis in the horse, even though one limb is more severely affected than the other. Other measurements carried out in injured tendons have yielded variable results, which have been interpreted as representing the coexistence of fibrous tissue with low blood flow and hyperemic areas of acutely inflamed tendon.

Cellular Components

Although the biomechanical characteristics of tendon are determined by the composition and organization of the extracellular matrix, tenocytes are essential for the formation and maintenance of tendon tissue. At least three different populations of tenocytes are identifiable within normal equine tendon and ligament[7,22] (Fig. 69-4):

- Type I: Cells with thin, spindle-shaped nuclei
- Type II: Groups of cells with more rounded, thick, cigar-shaped nuclei
- Type III: Cartilage-like cells with round nuclei and visible nucleoli

The proportion of these cells varies between tendons and ligaments, with tendon site, and with age. Young tendon has considerably larger numbers of type II cells arranged between the collagen bundles. With aging, type I cells predominate, whereas in the areas subjected to compressive forces, type III cells can be identified.

The activity of these different cell types is unknown. The different cell types identifiable histologically may represent different cell lines or different states of extracellular matrix

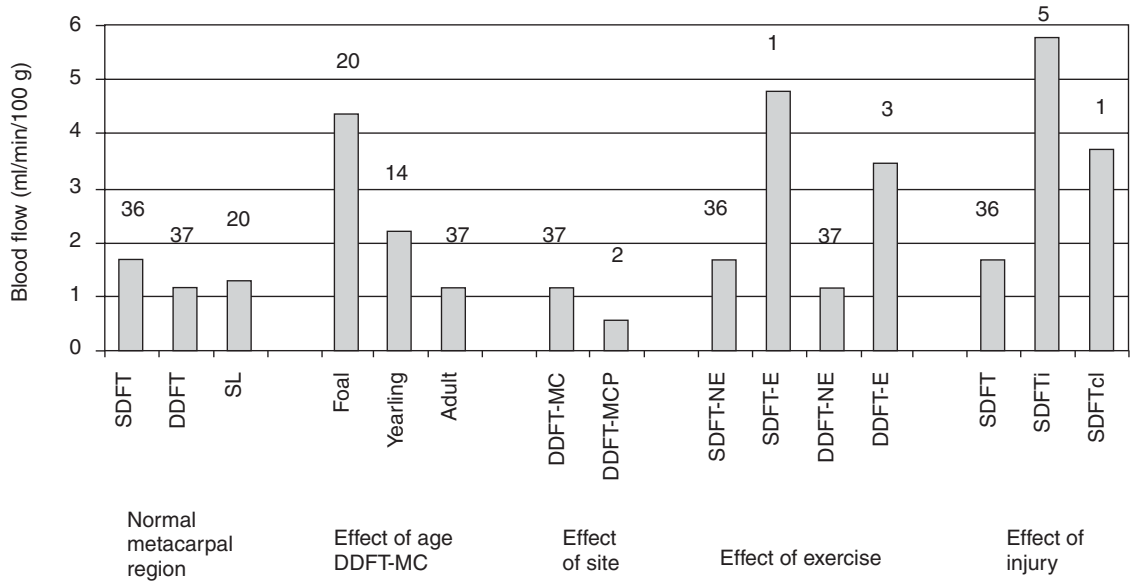

Fig. 69-3 Absolute blood flow in equine digital flexor tendons derived from ^{133}Xe clearance half-times. Numbers above the columns indicate the numbers of tendons evaluated. *DDFT,* Deep digital flexor tendon; *E,* exercised; *MC,* metacarpal region; *MCP,* metacarpophalangeal region; *NE,* not exercised; *SDFT,* superficial digital flexor tendon; *SDFTcl,* contralateral "normal" SDFT; *SDFTi,* superficial digital flexor tendonitis. production. A reasonable assumption is to suppose that type II and III cells are metabolically more active and are responsible for maintaining the tendon extracellular matrix, although the metabolic activity of the type I cells cannot be discounted.

Ligament has a much higher cell population, with a predominance of type II cells arranged in columns. In the SDFT of the horse, which has greater numbers of cells during growth, total tendon cell numbers remain relatively constant after skeletal maturity. However, acellular areas develop, especially in the center of the SDFT in the metacarpal region, although the degree of acellularity is not particularly related to age.[23] More active, type II cells can be found surrounding the fibrils in these regions. Chondroid metaplasia can also be identified associated with these areas. Other areas, typified by the DDFT in the metacarpophalangeal region, also have acellular regions associated with a fibrocartilagenous phenotype (type III cells and cartilage-like matrix) as a result of concurrent compressive forces as the tendon wraps around the metacarpophalangeal joint. Other cells are associated with the tendon, namely the paratenon, epitenon, and endotenon fibroblasts and the synovial-like cells of the epitenon within the tendon sheaths. These cell populations may also play important roles in maintaining tendon tissue, especially because the endotenon harbors certain growth factors, such as transforming growth factor-β (TGF-β) (Fig. 69-5).[24]

The regulation of tenocyte metabolism still is not understood fully but probably relies on a combination of mechanical and cytokine stimuli. Tenocytes have been shown to sense and react rapidly to mechanical stimuli in vitro.[25] However, equine tenocytes in culture require the addition of a suitable growth factor to initiate a synthetic response to load.[26] Recently, the use of confocal microscopy has provided an insight into the relationship between tenocytes. Staining with a membrane dye has revealed extensive cytoplasmic extensions from tenocytes, which form a complex meshwork around the collagen bundles. Gap junctions have been shown to exist between these cytoplasmic extensions, which would provide an ideal arrangement for the coordinated biosynthetic reactions to mechanical stimuli.[27]

Of the multitude of growth factors having effects on connective tissues, TGF-β and insulin-like growth factor 1 have been investigated the most in equine tendon.[28,29] The synthesis and distribution of TGF-β isoforms in equine digital flexor tendon vary with age. The highest levels are observed in young equine digital flexor tendon, especially within the endotenon.[24] Levels decline after skeletal maturity, especially in the tendon fascicles themselves, and this may result in a relative lack of tenocyte synthetic activity after skeletal maturity. However, it is not yet clear which are the most fundamental growth factors in equine tendons and how the growth factor milieu acts to cause tendon matrix synthesis and repair.

Molecular Composition of Tendon Matrix

Tendons are composed predominantly of extracellular matrix, within which is a wide array of proteins, organized and interacting to produce the mechanical properties of tendon. The tendon extracellular matrix is composed predominantly of water (about 65% wet weight), collagen (about 30% wet weight), and non-collagenous glycoproteins (about 5% wet weight).

Collagen

About 80% of the dry weight of the tendon is collagen, of which the predominant collagen type is type I (>95%).[7] Type III collagen is present in the endotenon and appears to increase as the animal ages. Type II (the collagen of articular cartilage) is likely to occur at the same sites in the horse as described in other species; namely, tendon insertions and where tendons develop fibrocartilage-like tissue associated with a change in the direction of pull around bony prominences (e.g., at the metacarpophalangeal joint).

Collagen fibrils are strong, but the bonds formed between these fibrils and the higher order subunits are more likely to determine the strength of the tissue. The major covalent cross-link of type I collagen in tendon is between hydroxylysine and lysine residues.[30] Lysine and hydroxylysine are converted to the respective aldehydes by the action of the enzyme lysyl oxidase, which is inhibited by β-aminopropionitrile fumarate, a chemical that has been used in the treatment of equine

The acellular areas are visible between the regions of chondroid metaplasia. **E,** Suspensory ligament branch showing the lines of type II cells (*arrows*) characteristic of ligament.

tendon injuries. These lysine and hydroxylysine aldehydes then can form a number of different types of cross-links: reducible (e.g., dihydroxylysinonorleucine and hydroxylysinonorleucine) or non-reducible (hydroxylysylpyridinoline). The reducible cross-links become reduced with age so that at maturity their level is less than 10% of the level in the foal.[31]

Non-covalent cross-links (electrostatic in nature) are provided by the proteoglycans and other glycoproteins, especially the small proteoglycan decorin, which coats the collagen fibril. Although individually these cross-links are less strong than the covalent cross-links, the high number and involvement in the higher order organization of the collagen network

make them potentially major determinants of tendon mechanical properties.

Non-Collagenous Glycoproteins

Cartilage oligomeric matrix protein. The large cartilage oligomeric matrix protein (COMP) consists of five subunits, bound via disulfide bonds at their N-termini to form a five-armed protein, with a bouquet of arms with globular C-terminal domains that can interact with other matrix components[32,33] (Fig. 69-6). Although initially thought to be restricted in distribution to cartilage, COMP subsequently has been found largely in tissues whose function primarily is to resist load. Thus COMP is found in significant amounts in tendon, ligament, cartilage, intervertebral disk, and meniscus. In equine digital flexor tendons COMP shows large variation with site and age.[34] Levels are low at birth but accumulate rapidly associated with weight bearing. Levels peak in the metacarpal region of the SDFT (at about 3% dry weight of tendon) at skeletal maturity and subsequently decline (Fig. 69-7). Levels peak at a lower level in the metacarpophalangeal regions and in the DDFT but are maintained in the former.

The function of COMP has not yet been elucidated completely, but COMP is known to bind fibrillar collagens (I, II, and IX),[35,36] and a mutation in the human COMP gene is responsible for pseudoachondroplasia, characterized by lax tendons and ligaments, short stature, and early-onset osteoarthritis.[37,38] Although COMP may have a structural role, present research data suggest that it also may also act to bring collagen molecules together to form fibrils, and it may assist in the organization of the collagen network. This role may explain the decline in COMP levels after skeletal maturity in the metacarpal region, because the collagen matrix has been formed and limited remodeling occurs in the adult. Preliminary data on equine SDFT show a significant correlation between ultimate tensile stress and COMP levels at skeletal maturity.[39] Thus high levels of COMP during development potentially enable the formation of a high-quality tendon matrix.

Proteoglycans. Proteoglycans are a group of molecules that possess a protein core and a side chain of sugars (glycosaminoglycans, or GAGs). The sugar side chains are highly variable in type and length so that great diversity exists even within a given tissue. Work on a variety of soft tissues, especially articular cartilage, has demonstrated a large number of different proteoglycans that are vital to maintaining the structural integrity of the tissue by playing structural roles or by regulating the metabolism of the tissue.

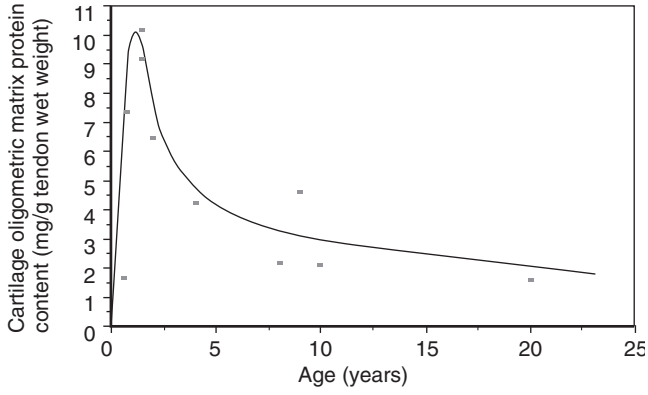

Fig. 69-7 The variation of cartilage oligomeric matrix protein levels with age in the metacarpal region of the superficial digital flexor tendon. (Modified from Smith RK, Zunino L, Webbon PM, et al: The distribution of cartilage oligomeric matrix protein (COMP) in tendon and its variation with tendon site, age and load, *Matrix Biol* 16:255, 1997.)

Proteoglycans are largely divided into two broad categories, the large and small proteoglycans. The large proteoglycans are exemplified by the major proteoglycan of cartilage, aggrecan, and the fibroblast-derived large proteoglycan, versican. These molecules possess a large number of GAG side chains and can form aggregates with hyaluronic acid. With the repulsion of the negatively charged GAG chains, this molecule has a bottle-brush shape and can trap large quantities of water. The swelling potential for this molecule, when restrained by the collagen network of cartilage, produces a structural matrix ideally suited to resisting compression. In tendon, areas subjected to compressive forces develop a matrix rich in these large proteoglycans, such as in the DDFT and SDFT in the metacarpophalangeal region.

The small proteoglycans such as decorin, biglycan, fibromodulin, and lumican usually have only one or two GAG side chains. Many of these proteoglycans have wide tissue distribution and have been shown to have structural and regulatory roles. A number of these proteoglycans bind to other members of the extracellular matrix. Thus decorin, the most common proteoglycan in tensional tendon (e.g., metacarpal region of the digital flexor tendons), has been shown to bind to fibrils of type I collagen.[40] Decorin is thought to be respon-

sible for regulating collagen fibril diameter and, together with the other small proteoglycans, may be responsible for providing electrostatic cross-links between fibrils, thus being also an important determinant of tendon strength. Targeted disruption of the genes for some of these small proteoglycans has confirmed a suggested role in maintaining tissue structural integrity. Deleting or knocking out the decorin gene results in variably sized collagen fibrils and poor mechanical strength in skin,[41] whereas targeted disruption of the fibromodulin gene causes altered collagen fibril morphology and reduced mechanical strength in tendon.[42]

Furthermore the small proteoglycans have been shown to bind various growth factors, especially TGF-β,[43] which may be important in regulating tendon homeostasis, adaptation, and response to injury.

Other non-collagenous glycoproteins. A number of other non-collagenous glycoproteins have been described in tendon, including elastin (not thought to be important for tendon elasticity in the horse),[31] fibronectin (which is upregulated after injury), thrombospondin 4, PRELP (*p*roline a*r*ginine-rich *e*nd *l*eucine-rich repeat *p*rotein), and tenascin-C. However, the functions of these, and others that have yet to be characterized, have not been determined fully.

Types of Tendon Injury

Tendons can suffer intrinsic (strain) or extrinsic (percutaneous) injury or displacement. The most common injury in the horse is the intrinsic injury of the SDFT in the metacarpal region. Recent epidemiological data have indicated an incidence of 43% in National Hunt horses in training.[44] Much of our understanding of tendon physiology (as described previously) and pathogenesis relates to this tendon. Insertional injuries, although common in the human athlete, are rarer in the horse and most commonly are seen associated with the SL rather than the SDFT.

Clinical superficial digital flexor tendonitis varies in severity from individual fibril or fiber slippage to individual fibril or fiber rupture and ultimately to complete rupture of tendon with progressive involvement of more groups of fibers and fascicles. Many horses with clinical tendonitis are believed to be preceded by subclinical degeneration of the tendon matrix. This is based on a number of observations. First, post-mortem examination of tendons of horses euthanized for reasons other than tendonitis revealed low-grade pathological damage ranging from acellular areas, chondroid metaplasia, and cyst formation.[23,45] Second, tendonitis is frequently a bilateral disease, although one limb is more severely affected than the other. Although bilateral changes sometimes can be difficult to identify clinically, ultrasonography invariably confirms some degree of bilateral involvement. Thirdly, recent research has identified a number of changes that occur within tendons associated with aging and exercise.

Mechanisms of Tendon Injury: Effect of Aging and Exercise

A number of controlled exercise studies in adult and young horses (Table 69-2) has provided considerable information on the effect of exercise on normal equine tendons. In none of these studies was there any indication of clinical tendonitis induced by the exercise protocols.

Regional differences in collagen fibril diameter were seen in long-term exercised older horses, but not in the short-term exercised, or younger horses.[46] Within the central region of the SDFT there was a higher proportion of smaller fibrils in comparison with the controls (Fig. 69-8). The higher proportion of small fibrils did not correlate with new collagen formation and thus appears to result from disassembly of the larger diameter fibrils, rather than the formation of new collagen, which would indicate an adaptive response. The reduction in crimp pattern seen with aging was accelerated by the exercise protocols in the adult.[47]

Changes in molecular composition also occurred in the long-term exercise studies, with a reduction in GAG content and an accelerated loss of COMP in the center of the tendon.[48,49] In contrast, molecular analysis of tendons recovered post mortem with central discoloration but no prior diagnosis of superficial digital flexor tendonitis demonstrated an increase in type III collagen and GAG.[50] Because these tendons appear to be enlarged significantly and have central hypoechoic lesions when examined by ultrasonography in vitro (Fig. 69-9), these molecular changes probably more reflect a reparative response rather than a degenerative change associated with aging and exercise.

In young growing animals, removal of load from tendon results in a lack of COMP accumulation in tendon, whereas removal of load after COMP has accumulated does not alter its levels in the tendon. Because recent data have shown an association between COMP levels and tendon strength at skeletal maturity,[39] too little exercise may inhibit the ability of the tendon to develop quality tendon matrix. However, exercise studies during skeletal development indicated that tendons are more easily damaged if the exercise level is too high.[51]

Table • **69-2**

Studies Aimed at Investigating the Effect of Exercise of Equine Digital Flexor Tendons

POPULATION	STUDY NAME	AGE OF ANIMAL AT ONSET OF EXERCISE	DURATION OF EXERCISE	NATURE OF EXERCISE	AGE AT ANALYSIS	REFERENCES FOR PROTOCOL
Thoroughbred	Bristol, long-term study	21 months	18 months	Treadmill	3 years 3 months	46, 49
Thoroughbred	Bristol, short-term study	19 months	4½ months	Treadmill	23½ months	49
Warmblood	Utrecht study	1 week	19 weeks (high intensity) followed by 6 months (low intensity)	Over ground	5 months (first group) 11 months (second group)	68

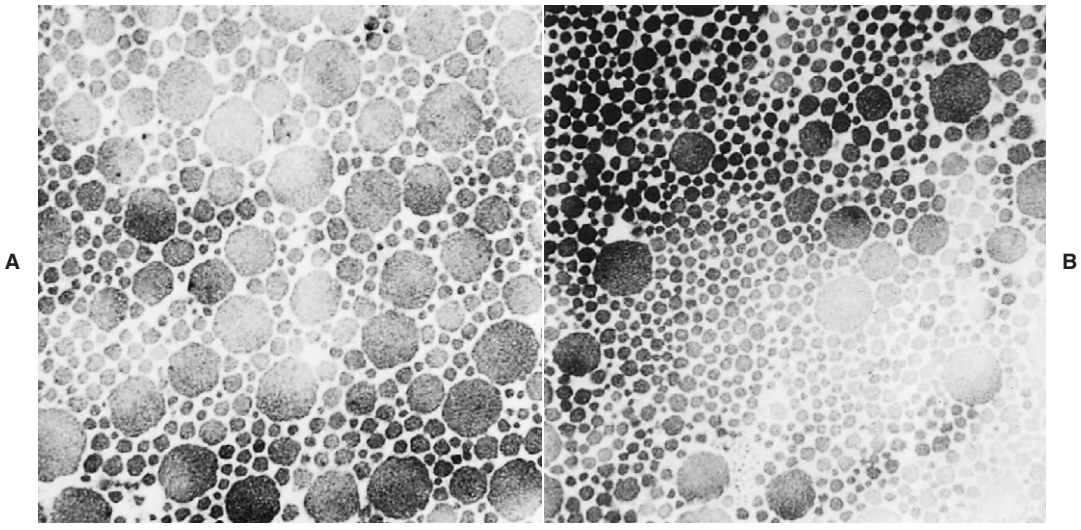

Fig. 69-8 Difference in collagen fibril populations in control and treadmill-exercised yearlings. **A,** Control. **B,** Treadmill exercised. Note the increased proportion of small-diameter fibrils compared with the non-exercised cohort (**A**). (From Patterson-Kane JC, Firth EC, Parry DAD, et al: Comparison of collagen fibril populations in the superficial digital flexor tendons of exercised and nonexercised thoroughbreds, *Equine Vet J* 29:121, 1997.)

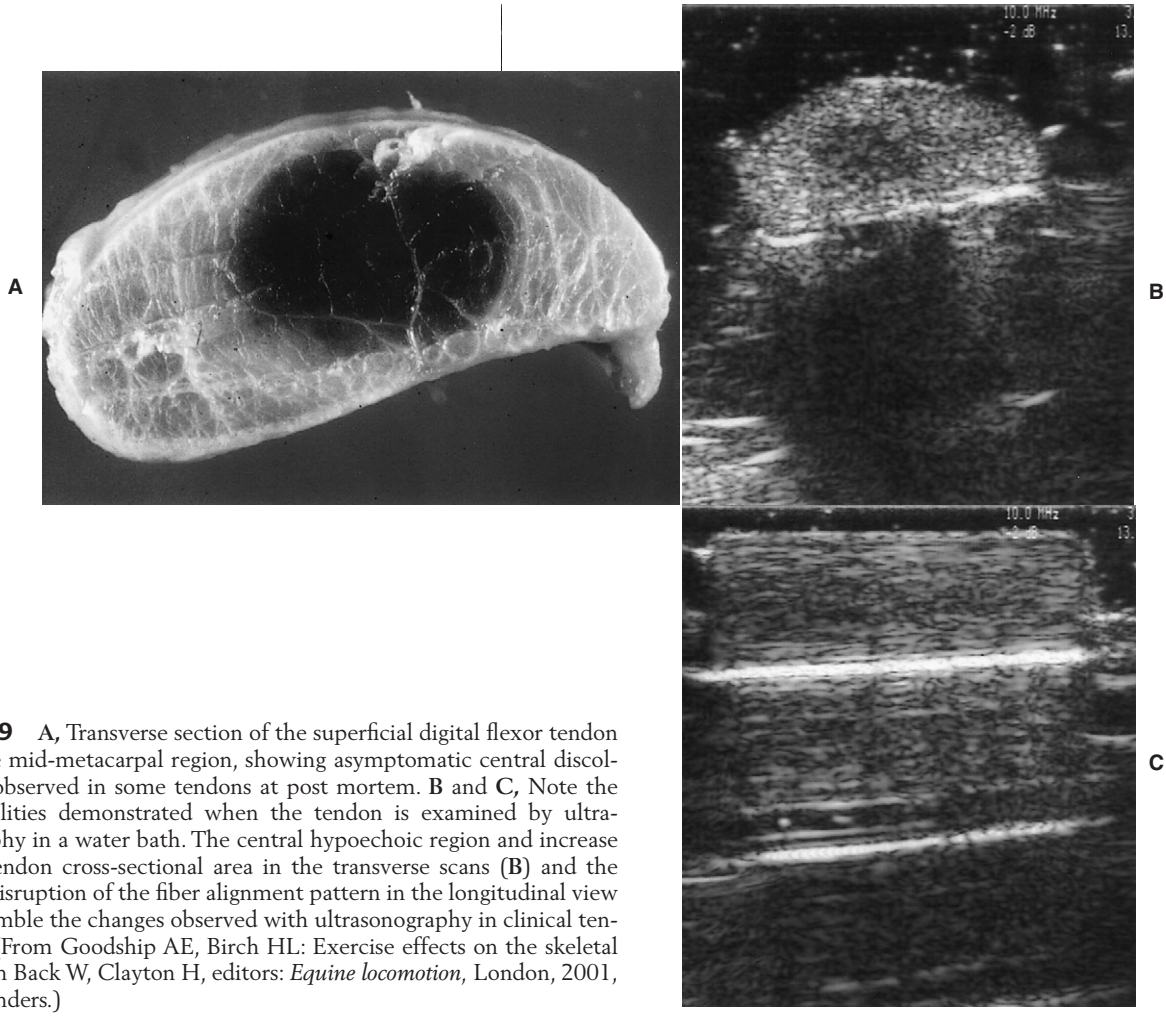

Fig. 69-9 **A,** Transverse section of the superficial digital flexor tendon from the mid-metacarpal region, showing asymptomatic central discoloration observed in some tendons at post mortem. **B** and **C,** Note the abnormalities demonstrated when the tendon is examined by ultrasonography in a water bath. The central hypoechoic region and increase in the tendon cross-sectional area in the transverse scans (**B**) and the central disruption of the fiber alignment pattern in the longitudinal view (**C**) resemble the changes observed with ultrasonography in clinical tendonitis. (From Goodship AE, Birch HL: Exercise effects on the skeletal tissues. In Back W, Clayton H, editors: *Equine locomotion*, London, 2001, WB Saunders.)

These controlled exercise studies have demonstrated that exercise accelerates a degenerative change that occurs inevitably with aging. Thus the research data would suggest that after skeletal maturity the tendon has limited ability to adapt. Instead, cumulative fatigue damage weakens the tendon matrix and allows the initiation of clinical tendonitis when loading overcomes the resistive strength of the tendon. Epidemiological studies have supported a strong association of age and exercise with the incidence of tendon injury in horses and people.[44,52]

Further confirmation of cellular activity during growth, but not after skeletal maturity, has been provided by studies of matrix turnover and gene expression. The turnover of collagen has been determined for experimental animals, but no definitive data are present for the horse. In experimental animals, collagen turnover is high in the neonate and growing animal, but it declined to low levels in the adult.[53] In bovine digital flexor tendons matrix gene expression, as determined by in situ hybridization, was easily detectable in young, growing animals, but no gene activity was present in the metacarpal region in the adult.[54] Interestingly, gene activity did persist in the metacarpophalangeal region, which may explain the relative resistance to injury of this region, because of its capability to remodel microdamage. In support of this hypothesis, COMP levels in this region of the equine SDFT and DDFT do not decline after skeletal maturity. The absence of gene activity in the metacarpal region may be from a lack of appropriate growth factors or cellular senescence. Certainly in these studies investigating TGF-β in equine tendons, young equine tendon had high levels, but amounts declined after skeletal maturity.[24]

In contrast, young growing tendon does appear to be sensitive to the effects of loading and exercise. The adaptive response of the growing animal may not be constant, and research data suggest that response may be pronounced most early in life and decline with growth. The level and amount of work necessary to induce this response is unknown and currently is being evaluated. However, by analogy with bone remodeling in response to load, high strain rates may be the most effective. An interesting note is that the natural exercise performed by a group of young foals at pasture includes a large amount of jumping activity at play, which is perfectly suited to these high strain rates on the digital flexor tendons.

Thus, as with other skeletal tissue development, such as cartilage, a window of opportunity apparently may be exploited to optimize conditioning of tendons for athletic performance (Fig. 69-10). The large variation seen in the mechanical properties within a population could be accounted for by variation in tendon development, caused by environmental factors, or genetic determinants.

From these observations a strategy for preventing tendonitis can be proposed. Maximizing the quality of tendon before skeletal maturity with the early introduction of controlled exercise may be possible, thereby reducing the incidence of tendon injury in subsequent racing and competition (Fig. 69-11).

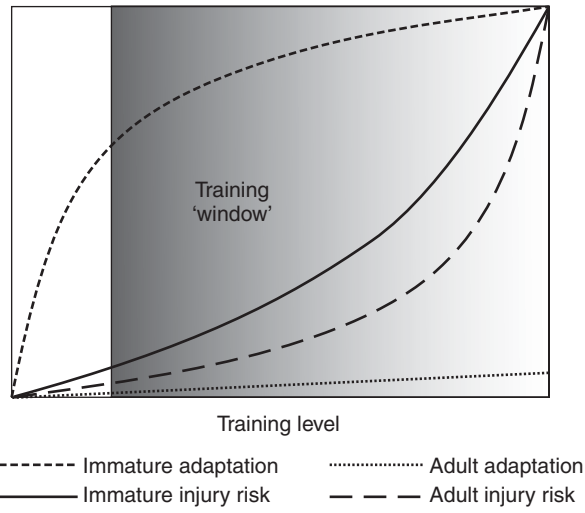

Fig. 69-10 Hypothesized schematic representation of the adaptive response and injury risk for growing (immature) and adult (>2 years of age) equine digital flexor tendons. (Modified from Goodship AE, Birch HL: Exercise effects on the skeletal tissues. In Back W, Clayton H, editors: *Equine locomotion*, London, 2001, WB Saunders.)

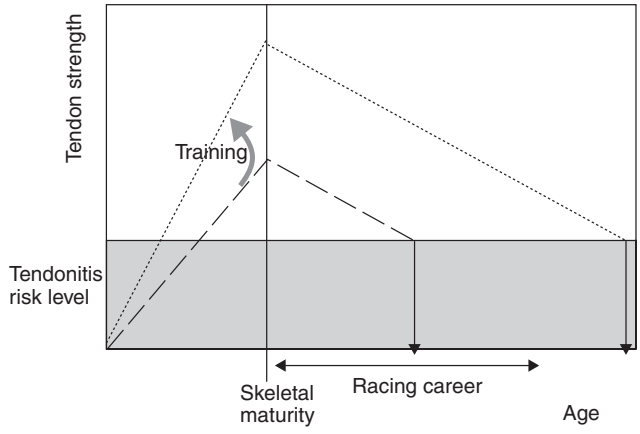

Fig. 69-11 Strategy for the prevention of tendonitis in the horse. The *dotted line* refers to a horse that develops strong tendons, whereas the *dashed line* represents a horse with poor-quality tendons at skeletal maturity (which appears to be at about 2 years of age). The latter suffers tendonitis during its racing/competitive career because of inevitable and cumulative fatigue damage to the tendon, whereas the former, although suffering the same degeneration, starts from a stronger point and therefore does not suffer tendonitis. The early introduction of exercise during development potentially improves tendon quality (*arrow*), thereby subsequently reducing the incidence of tendonitis.

Hypothesized Mechanisms of Tendon Degeneration

Mechanical Influences

Sudden over-extension of the metacarpophalangeal joint causes mechanical disruption of the tendon. Although this may be the mechanism of certain tendon injuries, such as deep digital flexor tendonitis, direct low-grade mechanical forces, such as experienced under maximal loading, could be responsible for the cumulative fatigue microdamage of the tendon matrix. Subsequent clinical tendonitis is initiated by similar, or sudden supra-maximal, loading after the accumulation of microdamage.

Physical Influences: Exercise-Induced Hyperthermia

Because of the hysteresis loop, when a tendon is loaded and unloaded, a loss of stored energy as heat results in temperature increases within the equine digital flexor tendons. Thermocouples have been placed inside the SDFT, and these have recorded temperatures of up to 45° C during periods of galloping.[12] Such temperatures are used to kill neoplastic cells therapeutically and so it was hypothesized that these temperatures would interfere with tenocyte metabolism and possibly destroy the cells. However, in vitro experiments have shown that tenocytes are much more resistant to these temperature increases in comparison with other fibroblast-like cells.[55] Interestingly, tenocytes tolerate such temperature increases even in utero, suggesting a genetically determined, rather than acquired, characteristic. Although

the cells remain viable with such temperature increases, hyperemia may still influence tendon matrix quality. A reduction in the normal synthetic activity of tenocytes or a direct denaturing effect on tendon extracellular matrix still may occur.

Vascular Theories

Blood flow through tendon is a complex issue and its relevance to clinical injury is still unsubstantiated. Under maximal loading, blood flow is limited or abolished within the tendon because of the compressive forces generated by the lengthening of the tendon, and this may give rise to relative hypoxia. Some areas of equine flexor tendon are relatively poorly perfused (e.g., the dorsal portion of the DDFT in the metacarpophalangeal joint region), and this level (but not just the dorsal surface) is a site predisposed to deep digital flexor tendonitis. However, this area also shows histological adaptation to the relatively ischemic environment, with fewer cells and increased amounts of the compression-resisting extracellular matrix components. Furthermore the tendon may receive some of its nutrition at this site by diffusion from the digital sheath synovial fluid. Similar alterations in the extracellular matrix composition are seen at the corresponding positions in the SDFT, and one could assume that the forces on this tendon would be similar to those of the DDFT at the same site. Therefore, a reduced blood flow would also be expected at this level, and yet clinically this region is invariably spared injury in all but the most severe tendonitis.

Equine tendon cells do rely at least in part on oxidative metabolism, although blocking aerobic metabolism does not prevent normal cell proliferation.[56] Based on studies in other species, tenocytes may be more resistant to hypoxia than other similar fibroblast-like cells.

Laser Doppler flowmetry has suggested that a change in blood supply is not the initiating cause in human Achilles tendonitis,[57] in contrast to the previously proposed hypoxic cause for tendonitis based on electron microscopic investigations of normal and diseased Achilles tendons.[58]

Another result of poor perfusion under loading is the generation of toxic free radicals when perfusion is restored. Such reperfusion injury also has been proposed as a causative factor for tendonitis through the destruction of tenocytes or tendon matrix by the free radicals, although this at present remains a speculative mechanism.

Proteolytic Enzymes

Various stimuli, including those mentioned previously, could result in the synthesis, release, or activation of proteolytic enzymes. Relatively little information is available on the constitutive or induced expression of proteases in tendon, although activity of procollagenase and aggrecanase has been described in human and bovine tendon explants in vitro.[59,60] An imbalance between the matrix synthesis and degradation of various extracellular matrix proteins is a possible mechanism whereby the tendon can be weakened and predisposed to clinical tendonitis.

Factors Affecting the Loading of the Superficial Digital Flexor Tendon and Initiation of Clinical Tendonitis

Peak SDFT forces are responsible for initiating clinical tendonitis. When the tendon has been weakened sufficiently by the preceding degenerative change, factors that increase the peak loading of the SDFT therefore also act to increase the risk of clinical tendonitis.

The SDFT is loaded preferentially at the early stage of the stride,[7,9,61] which represents the time of highest injury risk. External factors, such as the rider's weight or hard ground, increase these peak forces, although possibly only in certain tendons.[9] Recent data have suggested that landing from a jump increases the peak forces in the SDFT but not the SL.[62] The greater the height and number of fences jumped at Grand Prix–level show jumping would explain the higher incidence of injury in these horses to those competing at a lower level (see Chapters 70 and 116).

Foot conformation is also critical for affecting the loading of the SDFT (and SL). The lowering of the toe with respect to the heels, or the raising of the heels with respect to the toe, results in reduced loading of the DDFT and increased loading of the SL (and possibly the SDFT), often only detectable at the trot.[10,63,64] As a corollary to this, the long-toe, low-heel conformation characteristic of the Thoroughbred may actually protect the horse from superficial digital flexor tendonitis.[64]

The ground surface also influences the loading of the SDFT. Soft ground may predispose to increased strains in the SDFT by allowing the toe to sink. However, using sand has been shown largely to have little effect on the strains in the SDFT and DDFT.[9] The effect of ground surface on the incidence of tendonitis is probably more related to determining the speed of the horse. Speed is correlated with strains in the SDFT and also has been correlated with the incidence of SDFT tendonitis in racehorses (see Chapters 70, 107, 108, and 113). Thus ground surfaces that slow the horse tend to be protective of SDFT tendonitis, whereas the driest and hardest racecourses are associated with the highest incidence of tendonitis.

Many horses suffer tendonitis toward the end of a race or event when horses are fatigued. Fatigue will cause greater incoordination, which can result in increased peak loads on the SDFT, thereby increasing the risk of tendonitis.

Because tendon degeneration appears to be related to the number of loading cycles, the greater the exercise history and age, the more at risk the horse becomes. This certainly explains the strong association between age and tendonitis and may explain why older, sedentary horses still can develop tendonitis.

Because the subclinical phase of tendon degeneration affects both limbs similarly, clinical superficial digital flexor tendonitis is frequently bilateral. Changes are frequently observed with ultrasonography on both limbs, although one limb is usually more severely affected than the other.

Pathological Conditions and Phases of Tendon Healing

Tendonopathy can be divided into four phases. The subclinical phase of tendon degeneration, described previously, is difficult to identify clinically at present by palpation or ultrasonographic examination, because it causes minimal, if any, inflammatory reaction. In the future, serological assays, currently being developed to detect matrix proteins released from the tendon, may prove useful for detecting and monitoring this phase.

The clinically detectable pathological condition is divided into three phases: the acute inflammatory phase, the subacute reparative phase, and the chronic remodeling phase.

The acute inflammatory phase begins with the onset of the clinical injury and lasts usually only 1 to 2 weeks, although this is in part determined by the severity of the injury and the anti-inflammatory therapy initiated. This phase is characterized by substantial inflammation, with intratendonous hemorrhage, increased blood supply and edema, and the infiltration of leukocytes, initially neutrophils, but followed by macrophages and monocytes. The pronounced inflammation, if unchecked, results in the release of proteolytic enzymes, which, although directed at removing necrotic collagen, also digest relatively intact tendon collagen, which may cause the expansion of the lesion in the few days after the onset of the clinical tendonitis.

The sub-acute reparative phase begins within a few days of the injury, overlapping with the acute phase, and peaks after about 3 weeks.[65] This phase is characterized by a strong angiogenic response and the accumulation of fibroblasts within

the damaged tissue. These fibroblasts probably are derived from a number of sources including the resident tenocytes, endotenon and paratenon cells, and monocytes of vascular origin. These cells are then responsible for synthesizing scar tissue (tendon tissue is not regenerated), characterized by haphazardly arranged collagen, predominantly type III. The scar tissue formed is initially weaker than tendon tissue and hence healing tendon is predisposed to re-injury at the injury site. Such episodes of re-injury perpetuate the first two phases and increase the amount of damaged tendon and hence the severity of the injury.

The absence of a paratenon and an externally derived blood supply within a tendon sheath may explain the relative poor response in healing in these areas. The formation of adhesions within tendon sheaths, although responsible for limiting the movement of the tendons subsequently, provide a method of allowing angiogenesis and the infiltration of cells into damaged tendon tissue within a tendon sheath. Hence, although adhesions have deleterious effects on the function of tendons, they are a normal response to encourage tendon healing in this region.

During the chronic remodeling phase, which begins several months after the injury, the scar tissue slowly remodels over a number of months. This remodeling process is associated with a conversion of type III collagen to type I collagen, the major component of normal tendon. However, in spite of this conversion the tissue never becomes normal tendon tissue, although it is probably more functional. Controlled loading (exercise) during this phase may help promote this conversion and, even more importantly, align the collagen fibrils in the direction of force, which further improves the mechanical properties of the scar tissue. This aspect of the remodeling process is followed by assessing the fiber alignment score on ultrasound (see Chapter 70).

Re-injury is unfortunately common, even after healing is complete, in the same tendon, the contralateral tendon, or other supporting structures of the metacarpophalangeal joint. As the injured tendon remodels, it becomes stronger, so that fully healed tendon (15 to 18 months after injury) is frequently stronger than normal tendon.[66] However, remodeled tendon has poor elasticity, resulting in increased strain in adjacent, relatively undamaged regions of the tendon. Therefore if re-injury occurs in the same tendon, it frequently occurs at adjacent or remote sites to the original injury. Subsequent injury to the contralateral tendon is also effectively a re-injury because of the bilateral nature of the preceding degeneration and clinical tendonitis. Subsequent injury to the SL may be the consequence of some loss of support of the metacarpophalangeal joint, caused by significant lengthening of the SDFT, which can occur with severe superficial digital flexor tendonitis. The SL may also suffer cumulative microdamage, which would increase further its susceptibility to injury.

CHAPTER • 70

Superficial Digital Flexor Tendonitis

The first two sections of this chapter consider the general clinical manifestations of tendonitis and then the specific surgical management of tendonitis in racehorses. The third section discusses some of the variable clinical presentations in other competition horses and factors influencing treatment and prognosis.

SUPERFICIAL DIGITAL FLEXOR TENDONITIS IN RACEHORSES

• Joan S. Jorgensen and Ronald L. Genovese

Superficial digital flexor tendon (SDFT) injuries significantly compromise athletic performance and may culminate in a career-ending injury. The incidence of SDFT injuries in Thoroughbred (TB) racehorses ranges from 7% to 43%,[1,2] and such horses are most at risk because of high racing speeds or high speeds associated with jumping (steeplechase racing, see Chapter 113).[3] Other performance horses, including upper-level event horses (see Chapter 118), have an increased risk of SDFT injury (see page 639). Horses used for dressage, high-level show jumpers (see Chapter 116), racing Arabians (see Chapter 112) and Quarter Horses (see Chapter 111) , polo ponies (see Chapter 120) , and fox hunters incur SDFT injuries less frequently.[3-5] SDFT injury from athletic use in racehorses commonly is seen because of repetitive speed cycles over distance and possibly genetic predisposition to SDFT injury.[6] We are aware of several TB racehorse mares and at least one TB stallion and one Standardbred (STB) stallion that are known to have progeny with an increased susceptibility to SDFT injury compared with the normal racehorse population. Additional factors that may predispose a horse to SDFT injury include conformation, working surfaces, shoeing, training methodology, and the relationship between the level of physical fitness and the current exercise.

SDFT injury also occurs spontaneously in sedentary or lightly used horses more than 15 years of age. These tendon injuries often are severe and generally involve the proximal metacarpal region and the carpus and extend to the musculotendonous junction in the antebrachium. Many of these injuries result in overt lameness, tendon thickening, and carpal sheath effusion. Sometimes, however, the only presenting sign is lameness, with little palpable thickening. These injuries occasionally can be difficult to diagnose, requiring local analgesia and ultrasonography.

SDFT injuries from athletic use occur in the forelimb far more frequently than in the hindlimb. In one American study of 143 TB racehorses, 58% of SDFT injuries occurred in the left forelimb and 42% in the right forelimb.[7] Bilateral injury is common and has been recognized more frequently since veterinarians have been examining both limbs routinely by ultrasonography.

Most injuries in the SDFT caused by athletic use occur in the mid-metacarpal region (zones 2B to 3B), but injuries also occur at the musculotendonous junction of the antebrachium, in the carpal canal and subcarpal region, and in the pastern (see Chapter 83). The plantar hock region is the most common site of SDFT injury in hindlimbs, especially in the STB racehorse (see Chapters 79 and 109). Occasionally this injury extends into the mid-metatarsal region. Infrequently, a subtle SDFT injury is associated with tenosynovitis of the digital flexor tendon sheath (DFTS) in hunters, jumpers, and dressage horses.

Racehorses with SDFT injuries in racehorses traditionally have been regarded as having a guarded to poor prognosis for return to racing, although the prognosis for other athletic disciplines is more optimistic. Before ultrasonography was used routinely, documentation of SDFT injury was limited. Diagnosis was based on gait evaluation and palpation of a swollen or thickened tendon. The injury was referred to as a bowed tendon, and morphological abnormality and severity of injury were little appreciated.

Recently, substantial progress has been made in understanding the nature of tendon injury and the mechanisms of healing. During repair, injured elastic tendon fibers are replaced with modified fibrous scar tissue, resulting in a tendon repair that is never totally normal. The quality of repair can vary greatly. Some tendon injuries repair and resolve with enough mature collagen so that they return to nearly normal size, with sufficient remodeling that results in approximately parallel alignment of the repair tissue. Other injuries develop a scar, with an overall increase in tendon size, poor or random fibrous tissue alignment, and peritendonous fibrosis.

Many of the proposed therapeutic approaches are directed at maximizing the chances for a more physiologically functioning tendon. Therapy requires a multifaceted approach

CHAPTER • 70

Superficial Digital Flexor Tendonitis

The first two sections of this chapter consider the general clinical manifestations of tendonitis and then the specific surgical management of tendonitis in racehorses. The third section discusses some of the variable clinical presentations in other competition horses and factors influencing treatment and prognosis.

SUPERFICIAL DIGITAL FLEXOR TENDONITIS IN RACEHORSES

• Joan S. Jorgensen and Ronald L. Genovese

Superficial digital flexor tendon (SDFT) injuries significantly compromise athletic performance and may culminate in a career-ending injury. The incidence of SDFT injuries in Thoroughbred (TB) racehorses ranges from 7% to 43%,[1,2] and such horses are most at risk because of high racing speeds or high speeds associated with jumping (steeplechase racing, see Chapter 113).[3] Other performance horses, including upper-level event horses (see Chapter 118), have an increased risk of SDFT injury (see page 639). Horses used for dressage, high-level show jumpers (see Chapter 116), racing Arabians (see Chapter 112) and Quarter Horses (see Chapter 111) , polo ponies (see Chapter 120) , and fox hunters incur SDFT injuries less frequently.[3-5] SDFT injury from athletic use in racehorses commonly is seen because of repetitive speed cycles over distance and possibly genetic predisposition to SDFT injury.[6] We are aware of several TB racehorse mares and at least one TB stallion and one Standardbred (STB) stallion that are known to have progeny with an increased susceptibility to SDFT injury compared with the normal racehorse population. Additional factors that may predispose a horse to SDFT injury include conformation, working surfaces, shoeing, training methodology, and the relationship between the level of physical fitness and the current exercise.

SDFT injury also occurs spontaneously in sedentary or lightly used horses more than 15 years of age. These tendon injuries often are severe and generally involve the proximal metacarpal region and the carpus and extend to the musculotendonous junction in the antebrachium. Many of these injuries result in overt lameness, tendon thickening, and carpal sheath effusion. Sometimes, however, the only presenting sign is lameness, with little palpable thickening. These injuries occasionally can be difficult to diagnose, requiring local analgesia and ultrasonography.

SDFT injuries from athletic use occur in the forelimb far more frequently than in the hindlimb. In one American study of 143 TB racehorses, 58% of SDFT injuries occurred in the left forelimb and 42% in the right forelimb.[7] Bilateral injury is common and has been recognized more frequently since veterinarians have been examining both limbs routinely by ultrasonography.

Most injuries in the SDFT caused by athletic use occur in the mid-metacarpal region (zones 2B to 3B), but injuries also occur at the musculotendonous junction of the antebrachium, in the carpal canal and subcarpal region, and in the pastern (see Chapter 83). The plantar hock region is the most common site of SDFT injury in hindlimbs, especially in the STB racehorse (see Chapters 79 and 109). Occasionally this injury extends into the mid-metatarsal region. Infrequently, a subtle SDFT injury is associated with tenosynovitis of the digital flexor tendon sheath (DFTS) in hunters, jumpers, and dressage horses.

Racehorses with SDFT injuries in racehorses traditionally have been regarded as having a guarded to poor prognosis for return to racing, although the prognosis for other athletic disciplines is more optimistic. Before ultrasonography was used routinely, documentation of SDFT injury was limited. Diagnosis was based on gait evaluation and palpation of a swollen or thickened tendon. The injury was referred to as a bowed tendon, and morphological abnormality and severity of injury were little appreciated.

Recently, substantial progress has been made in understanding the nature of tendon injury and the mechanisms of healing. During repair, injured elastic tendon fibers are replaced with modified fibrous scar tissue, resulting in a tendon repair that is never totally normal. The quality of repair can vary greatly. Some tendon injuries repair and resolve with enough mature collagen so that they return to nearly normal size, with sufficient remodeling that results in approximately parallel alignment of the repair tissue. Other injuries develop a scar, with an overall increase in tendon size, poor or random fibrous tissue alignment, and peritendonous fibrosis.

Many of the proposed therapeutic approaches are directed at maximizing the chances for a more physiologically functioning tendon. Therapy requires a multifaceted approach

that reduces the acute inflammatory response and hemorrhage in the acute phase and improves fiber alignment during the long rehabilitation phase. The ultimate goal of any treatment and management programs is to maximize the chances for a tendon to repair with adequate strength and elasticity for a return to a similar level of performance with the lowest risk of re-injury.

It is important to recognize the variables that may affect the ultimate prognosis when managing SDFT injuries. Not all tendon injuries are the same, and case management depends on the specific injury, medical factors, and other non-medical factors.

CLINICAL SIGNS

Clinical signs of SDFT injury in racehorses vary considerably depending on the location of the primary injury, type of injury, severity, and the timing of the examination. Occasionally, clinical signs may be delayed by days or weeks. Furthermore, a lack of correlation may exist between the severity of the injury and the severity of tendonitis in any given individual, especially in the more common core tendon injuries experienced by TB racehorses. In contrast, STB racehorses more often experience lateral and medial border tendon injuries that result in significant swelling but less severely injured tendon fascicles. Identification of subtle, yet significant, re-injury by clinical evaluation may be difficult because of previous tendon thickening. Thus ultrasonographic imaging is essential to confirm clinical signs and to evaluate the extent of injury to the SDFT.

Lameness

In our experience the degree of lameness associated with a tendon lesion in the mid-metacarpal region is correlated with the severity of the injury. Slight to high-slight (category II to IV) injuries generally are not associated with any appreciable lameness, whereas mid-moderate to high-moderate (category V) injuries cause only transient lameness. Most severely injured tendons (category VI), or total rupture of the SDFT, result in at least transient lameness, which may be severe. In contrast, lesions in the carpal canal or proximal metacarpal region (zones 0 and lA) consistently are associated with lameness.

Swelling

For assessing tendon injuries, swelling is defined as subcutaneous or peritendonous fluid accumulation. Digital palpation reveals a soft or semi-firm, diffuse or focal fluid accumulation that may prohibit exact palpation of the SDFT. Subcutaneous swelling can be associated with tendon injury, especially in the acute stage of injury. Careful digital palpation of the limb held in a semi-flexed position may reveal slight crepitus in an acutely injured tendon. However, subcutaneous inflammation or hemorrhage is not associated invariably with tendon injury. Examples of focal edema or hemorrhage without significant SDFT injury include swelling associated with cording of the mid-metacarpal region secondary to a malpositioned bandage or subcutaneous swelling in the proximal or distal metacarpal region caused by malpositioned tendon boots or stable (stall) bandages. An example of diffuse swelling is pitting edema (see Chapter 14), occasionally caused by external blistering. Diffuse filling also may reflect a sub-solar abscess or cellulitis.

Thickening

Thickening, or enlargement specifically indicates SDFT swelling secondary to injury or a thickened end-stage repair from a previous injury. In this context, subcutaneous swelling is not appreciable, but a palpable enlargement of the SDFT occurs. In many slightly and diffusely injured tendons thickening may be difficult to appreciate and careful comparison to the normal contralateral limb may be required to identify SDFT enlargement. In more severely injured tendons examined in the subacute phase, enlargement generally can be felt. Two clinical situations in which assessing SDFT thickening is difficult are a focal SDFT injury in the sub-carpal region, where the tendon is enveloped by the retinaculum, especially in colder climates when limb hair is long, and instances of SDFT injury within the DFTS that also is associated with tenosynovitis. Tenosynovitis makes distinguishing between tendon thickening and sheath fibrosis difficult.

When palpating the SDFT, one should always determine if the medial and lateral borders of the SDFT can be separated clearly from the accessory ligament of the deep digital flexor tendon and the tendon itself. If both digital flexor tendons are slightly enlarged, detection of abnormality is more difficult; however, frequently the margins of both tendons are more rounded than normal. Assessing the flexibility of the SDFT also is useful, because abnormal stiffness usually reflects previous injury.

Heat

Increase in surface temperature often can be the earliest and most subtle clinical sign of SDFT injury or re-injury. Digital appreciation of an increase in skin temperature, or thermography, often can indicate tendon inflammation. Because extensive use of liniments and daily bandaging in racehorses also increases skin temperature, one must be careful when making this assessment.

Sensitivity to Direct Digital Palpation

A painful response to direct digital palpation is often a reliable clinical test for tendon injury. Examination is best performed by holding the limb in a semi-flexed position and palpating with the thumb and forefinger systematically from proximal to distal in the metacarpal region in an effort to elicit a painful response. When a sensitive area is palpated, the horse generally flinches. The examination has many caveats. If a sensitive response is elicited bilaterally, the horse may merely be hyperresponding to increased pressure and possibly has no injury. Not all horses with tendon injury have a painful response. Horses with blistering of the skin, adverse local drug reaction, infection, or cording are also hyper-responsive and more reactive than those with a tendon injury. In addition, extreme sensitivity to direct palpation coupled with focal or diffuse swelling may indicate a problem not related to the tendon.

Tendon Profile

Evaluation of the tendon profile with the limb in a full weight-bearing position can provide valuable information. In a normal limb the metacarpal region has a straight palmar profile. A normal SDFT should be superficial and parallel to the deep digital flexor tendon. It is important to examine the profile from all possible angles. With a slight injury, the tendon often has a normal profile when viewed from the lateral aspect and a convex or bowed profile from the medial aspect, or vice versa. In an acute total rupture, little swelling and thickening may be present if the leg is examined within 2 hours of the injury. However, with the limb in full weight-bearing position, one may note hyperextension of the metacarpophalangeal joint. In this case, digital palpation along the palmar aspect of the tendon reveals a 1- to 2-cm defect in the SDFT. Digital palpation with the limb in a semi-flexed position also reveals laxity and excessive mobility of the tendon.

Tenosynovitis of the Carpal Sheath or Digital Flexor Tendon Sheath

Tenosynovitis may be associated with a tendon injury or may be a clinical entity without tendon injury (see Chapters 75 and 76). Ultrasonographic evaluation is required to appreciate tendon injury in the presence of tenosynovitis.

Tendon Injury Limited to the Pastern

Injury to one or both of the SDFT branches of the pastern generally is associated with branch thickening and a painful response to direct digital pressure (see also Chapter 83). This is best appreciated with the limb held in a semi-flexed position and direct pressure placed on the branch with the clinician's thumb. Injury to the SDFT branch(s) may be associated with tenosynovitis.

MANAGEMENT OF THE ACUTE PHASE OF TENDON INJURY IN RACEHORSES

In most horses with sub-total SDFT injuries in the acute phase, anti-inflammatory and supportive management are instituted. A variety of treatment regimens are available. For the most part, systemic non-steroidal anti-inflammatory drugs (NSAIDs) such as phenylbutazone (4.4 mg/kg per day) for 7 to 10 days and a single dose of systemic corticosteroids such as dexamethasone (0.04 mg/kg) are included in the initial therapy. Perilesionally administered corticosteroids are considered contraindicated in tendon injuries, especially long-term usage, because they are thought to delay collagen formation. However, some clinicians use a single perilesional dose of triamcinolone (6 to 9 mg) or methylprednisolone acetate (40 mg) (dystrophic mineralization occasionally has been associated with methylprednisolone therapy) in horses with slight, peripheral tendon injuries in STB racehorses, especially when associated with a curb (see Chapter 79). Practitioners often administer a course of polysulfated glycosaminoglycans (PSGAGs; 1 vial per week for 4 weeks) in the acute stage.

Physical therapy is indicated, and we recommend icing for 1 to 2 hours once or twice a day, with application of a poultice, or simple support bandaging for subtotal injuries. Casting may be indicated for total ruptures. Exercise generally is restricted to stall (box) rest or limited hand walking. In horses with subtotal injuries, we prefer to keep the injured limb shod in a fully grooved bar shoe, with a straight hoof-pastern axis, so that the metacarpophalangeal joint position is normal in a standing position. We do not advocate raising or lowering the heel to an exaggerated position. We perform an ultrasonographic examination within the first few days and then again 3 to 4 weeks later. Sometimes tendon splitting is advised for small core lesions.

INJURY ASSESSMENT AND GOALS FOR ATHLETIC OUTCOME

Qualitative assessment combines the physical findings and a subjective ultrasonographic appraisal. This gives an accurate diagnosis, but we also strongly encourage the use of quantitative ultrasonographic evaluation. This includes data such as cross-sectional area (CSA) and echogenicity and fiber alignment scores (see Chapter 16).

Optimal healing of SDFT injuries depends on managing a number of variables including the personality of the horse, its age, sex, athletic use, conformation, injury episode number, maximal level of exercise attained, and severity of the injury. For instance, a 4-year-old TB gelding racehorse that has an upright conformation, has never raced, and suffers a severe (category VI) SDFT injury after one gallop has a poor prognosis with any treatment. If this horse sustained a small core lesion of the SDFT, its prognosis would be more guarded because of its conformation and the exercise level at which injury occurred compared with a similar injury in a well-conformed, seasoned racehorse.

Athletic outcome of a racehorse may be divided into three categories: successful, meaning completion of five or more races (I); partially successful, completion of one to four races (II); and failure, meaning re-injury occurred before the first race was completed (III). Successful horses can be further subdivided into those with re-injury or no re-injury. Partially successful can be further subdivided into those suffering re-injury or those injuring the contralateral SDFT or a forelimb suspensory ligament.

ULTRASONOGRAPHIC EVALUATION AND CATEGORIZATION OF INJURIES

If clinical evaluation indicates a possible SDFT injury, ultrasonography should be used to confirm the diagnosis and objectively assess the severity of injury. Sequential examinations provide a guide to controlled exercise management and are used to assess progress of repair and attempt to establish an optimal time to return to full work.

The acquisition and assessment of accurate ultrasonographic data requires high-quality images, and it is important to develop a rigid, standardized technique (see Chapter 16). The ultrasonographer must take primary responsibility for image interpretation. For a second person to give an opinion on images previously obtained by someone else is often difficult.

Quantitative ultrasonographic data includes CSA, percentage of CSA occupied by a lesion, grade of echogenicity of a lesion (type or echo score, TS), and assessment of fiber bundle alignment in longitudinal images (fiber alignment score, FAS). Each of these data points is assessed at every defined level of the limb (zone) and then summed to provide total scores. These scores then can be used to categorize an injury as minimal (category III), slight (category IV), moderate (category V), or severe (category VI) (see Chapter 16). The following comments apply to forelimb and hindlimb injuries, although reference is only made to the metacarpal region.

Initial Evaluation

Early examination of a suspected new injury of the SDFT may not reveal any anechoic or hypoechoic lesions. However, if the CSA of a single zone is more than 39% larger than the contralateral limb, or if the total of 6 of 7 zones is more than 14% larger than the contralateral limb, then tendonitis should be suspected (category II). If tendonitis cannot be substantiated by ultrasonography, despite soft tissue swelling, then conservative management is indicated. The horse should be restricted to walking exercise for at least 72 hours and then re-evaluated clinically and by ultrasonography. Symptomatic therapy includes systemic NSAIDs, daily icing, and mild leg liniments or sweats with limb bandaging. One must recognize that sometimes a lesion(s) cannot be appreciated by ultrasonography for at least several days or longer.

Within 7 days of injury a hypoechoic or anechoic lesion may represent tendon fascicle damage, hemorrhage, or inflammatory exudates and is most likely a combination of all three. Distinguishing the relative contributions of each or determining accurately the severity of injury, which may be underestimated or overestimated, is not possible. Initially, damaged collagen fibers may be grossly intact but non-functional, resulting in reflecting echoes. Ongoing enzymatic degradation and further injury caused by pressure necrosis may result in a lesion deteriorating over 3 to 4 weeks. In contrast, infrequently the hemorrhage and inflammatory exudates resolve over the following 3 to 4 weeks and result in a great improvement of the lesion, and the injury to fiber bundles may not be as serious as initially indicated.

Baseline Evaluation

If an initial examination is done within 1 to 7 days of a new injury or a re-injury, we strongly advise that a second ultra-

sonographic evaluation be performed 2 to 4 weeks (preferably 4 weeks) later to obtain baseline data about the severity of injury (see Chapter 16).

SUBACUTE PHASE TREATMENT AND LONG-TERM REHABILITATION

History of Treatment in Racehorses

A wide variety of short-term and long-term treatment programs for superficial digital flexor tendonitis have been used, sometimes implemented regardless of the severity of the injury or re-injury, and with or without prolonged rest or controlled exercise. No comprehensive reports comparing various treatments of similarly injured tendons are available, and therefore proposing specific recommendations that will give the best prognosis for return to racing is difficult.

A comprehensive retrospective study of TB and STB racehorses currently is being performed to compare the rate of return to racing between a variety of therapeutic regimens for minimal (category III), slight (category IV), moderate (category V), and severe (category VI) tendon injuries documented by ultrasonography. Therapies include pasture turnout, external blistering, internal blistering, intralesional therapies (excluding β-aminoproprionitrile fumarate [Bapten]), or a combination of these. In addition, the amount of layup time is being considered for each category of injury. If all therapeutic regimens are combined (Fig. 70-1), preliminary data indicate that few racehorses successfully return to racing without re-injury (athletic outcome I, completed five or more races), especially with severe injuries.[8] In addition, these data demonstrate that few racehorses are able to return to racing and not experience re-injury of the SDFT, sustain injury to the contralateral SDFT, or injure the suspensory apparatus (subcategories IB and IC). Ultimately, we hope that this research helps to determine optimum therapy for specific lesions and better equip the veterinarian to provide accurate prognostic information.

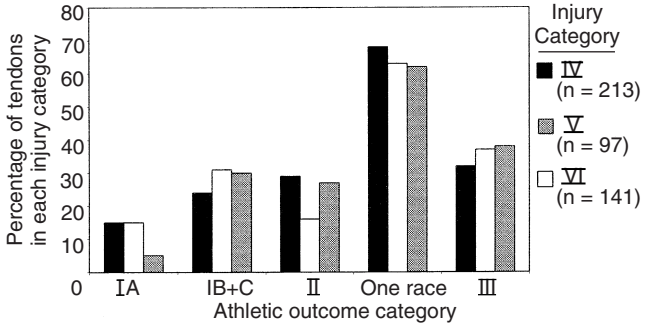

Fig. 70-1 A successful return to racing becomes increasingly difficult as the severity of tendon injury increases. Treatments for slight (category IV), moderate (category V), and severe (category VI) superficial digital flexor tendon injuries including pasture turnout, external or internal blistering, intralesional injections (excluding β-aminoproprionitrile fumarate), or a combination of these were assessed for their success in return to racing. Athletic outcome categories (AOCs) were separated into five groups. AOC IA refers to those horses that have successfully raced at least five times with no re-injury. AOC IB + C includes those that have raced at least five times but have re-injured the same tendon (group B) or the contralateral tendon (group C). AOC II includes those that have raced successfully one to four times and includes tendons that have been re-injured, whereas horses with tendon injuries in AOC III have never raced successfully. An additional group of all those that completed at least one race was included. Data are represented as the percentage of tendons in each injury category that resulted in the ultimate AOC.

Symptomatic Treatment with Continued Exercise

If the decision is made to treat a horse with an injured tendon symptomatically and continue exercise (racing), serial ultrasonographic examinations should be performed, because changes in size or echogenicity may be detected before clinical signs are obvious. If the ultrasonographic examination demonstrates progressive injury or instability and the horse is not athletically (economically) productive, stopping racing and considering long-term rehabilitation would be wise. Naturally, any racehorse racing with an injured tendon is risking more serious injury.

A retrospective study of 209 tendons from 207 TB racehorses was performed to determine if quantitative ultrasonographic assessment could aid in accurately defining a SDFT injury and provide evidence for determining a prognosis for racing in patients that underwent symptomatic treatment with continued exercise. Eighty-eight percent of horses that had no or minimal injury (categories I and III) started more than three races, whereas 12% failed. Thirty-five percent of horses with slight (IV), moderate (V), or severe (VI) injuries started more than three races, but 82% had recurrent injury.[7] Ultrasonography is therefore helpful to determine the prognosis for returning to racing. Symptomatic therapy while continuing to race is a viable therapeutic option for minimal tendon injuries.

Consider a 3-year-old TB gelding racehorse with a swollen left front SDFT after a race (Fig. 70-2). Quantitative ultrasonographic analysis revealed a total lesion area of 13%, TS of 7, and total FAS of 7, indicating a mildly injured (category IV) tendon. The horse was treated symptomatically with anti-inflammatory medication and continued to race. After 4½ months and 6 races the horse was racing well, having earned more than $34,000. After two additional races, the total lesional area increased and the horse's performance decreased. Long-term therapy with time off was instituted. STB racehorses are generally more successful than TBs in continued performance with a tendon injury.[8]

A retrospective study of pre-training (exercise level 5) ultrasonographic data from 106 injured racehorses provided four criteria that we use as a guideline for an optimum return to racing[9]:

1. At least a 60% decrease in category IV total lesional area, or <12% total hypoechogenic fiber bundles for all categories of severity of injury
2. At least a 10% to 15% decrease in total CSA from baseline for all categories of injury (a relatively greater decrease in more seriously injured tendons)
3. At least a 70% decrease in the total TS (ideally <4; the closer to zero the better).
4. At least a 75% decrease in the total FAS (ideally <4; the closer to zero the better) before advancing to exercise level 5.

After grouping the criteria, the horse should meet at least three of the four, with only minimal failure of the other criterion. Horses that met all criteria or failed only one had a 50% chance to be successful as defined by completing five races. If a horse failed more than one criterion, the chance of re-injury before racing one race was 85%. Horses that failed all criteria had a 100% failure rate.

Ultrasonographic evaluation is used to monitor tendon stability during training. For example, ultrasonographic examination of a right front SDFT 11½ months after the baseline scan and after 6 weeks of galloping indicated stable total CSA values but increased hypoechogenic tendon fascicles in zones 3B and 3C (Fig. 70-3). Clinically, increased heat and swelling in the distal metacarpal region were found, which indicated

Zone	Structure Size (mm^2)	Lesion Size (mm^2)	Fiber Alignment Score	Type/Echo Score	Clinical Findings
1A	87	—	—	—	Lameness: 0/5
1B	82	11 (14.25%)	—	1	Swelling: 2/5
2A	88	5 (6.18%)	—	1	Thickening: 1/5
2B	108	16 (14.84%)	1	1	Sensitivity: 2/5
3A	139	14 (10.47%)	3	2	Heat: 2/5
3B	**123**	**36 (29.19%)**	**3**	**2**	Tendon sheath involvement: 1/5
					Fetlock sinking: 0/5
Totals	627	82 (13%)	7	7	Fetlock flexion: Negligible

Bold type indicates maximal injury zone.

Fig. 70-2 Data derived from an initial computerized scan of a 3-year-old Thoroughbred racehorse actively racing with a category IV injury (<15% tendon lesion). The type (or echo) score and fiber alignment score are similar, indicating a new lesion. Zone 3B was determined to be the maximal injury zone with a 29% increase in size compared with the contralateral limb.

Zone	Structure Size (mm^2)	Lesion Size (mm^2)	Fiber Alignment Score	Type/Echo Score	Clinical Findings
1A	109	—	—	—	Lameness: 0/5
1B	95	—	—	—	Swelling: 1/5 (zone 3C)

Fig. 70-3 Data derived from a computerized scan of a right forelimb superficial digital flexor tendon injury 11½ months after the baseline scan and 6 weeks after galloping was resumed. Before galloping, the total cross-sectional area was 975 mm^2, which decreased to 961 mm^2. However, new hypoechoic lesions were documented in zones 3B and 3C, indicating an unstable healing process.

tendon instability at the current exercise level and a high risk of re-injury with continued training. The trainer was unwilling for economic reasons to pursue another long-term treatment program and decided on an intermediate program of 30 days of ponying (leading the horse from another horse) and swimming. Six weeks later significant re-injury of the SDFT occurred in the distal metacarpal region (Fig. 70-4). Using serial ultrasonographic monitoring is discussed in detail elsewhere (see Chapter 16).

Common Long-Term Treatment Programs

Controlled Exercise and Time Out of Training

A graded exercise program has been used based on severity of the injury and the ultrasonographic progress during rehabilitation.[10] Turnout in a large paddock was not permitted. The time out of training ranged from 9 to 12 months, depending on the initial severity of the injury and ultrasonographic progress. Twenty-eight TB racehorses were managed in this manner and 20 (71%) of the 28 returned to racing. Only two (25%) of eight horses treated with time off and large pasture exercise were successful. Currently no consensus exists on the treatment of choice for superficial digital flexor tendonitis in racehorses, but most treatment regimens are combined with a controlled exercise program and serial ultrasonographic assessment. Most horses with category II (tendonitis without lesions perceptible by ultrasonography) or III (total echogenicity score less than 3) lesions have a reasonably favorable prognosis for successful return to racing (defined as five or more races [athletic outcome I]) if they are confined to controlled exercise for sufficient time.

External/Internal Blistering, Pin Firing, and Time Off for Long-Term Rehabilitation

The most common therapeutic regimen in the United States for rehabilitating racehorse SDFT injuries includes some sort of counterirritation (see Chapter 89), plus controlled exercise

Zone	Structure Size (mm^2)	Lesion Size (mm^2)	Fiber Alignment Score	Type/Echo Score	Clinical Findings
1A	88	—	—	—	Lameness: 0/5
1B	116	—	—	—	Swelling: 0/5

*Evidence of focal instability of echogenicity near the metacarpophalangeal joint.

Fig. 70-4 Data derived from a computerized scan of the same limb in Figure 70-3. After 16 days of continued exercise, significant re-injury is documented by an increase in total cross-sectional area to 1022 mm^2, worsening type score and fiber alignment score in zones 3B and 3C, and an increase in the total percentage hypoechogenic volume of the injury. These findings illustrate the importance of quantitative analysis in monitoring tendon healing and predicting responses to an aggressive treatment program.

or turnout into a large pasture. Many counterirritation options exist, including external blistering agents such as a variety of iodine-based liniments, internal peritendonous injection of 2% iodine in almond oil (internal blister), and pin firing. Several reasons exist for the persistent use of these treatment regimens, in spite of limited research suggesting that external blistering, and especially pin firing, have no beneficial effect on tendon injury repair.[11] No alternative therapeutic regimens result in a consistent return to racing without re-injury or injury to another soft tissue structure. Tradition is strong, and most newer surgical and medical treatment regimens are expensive, even though the prognosis remains guarded.

Counterirritation promotes angiogenesis and when used, exercise is restricted. In a retrospective study of 54 TB and STB racehorses treated with pin firing or external blistering and given more than 6 months out of training, 23 (43%) returned to race at least once.[12] Ten (19%) of these horses returned to racing without experiencing re-injury to the tendon. These data indicate that racehorses treated by counterirritation can return successfully to racing, and so counterirritation will continue to be used until alternative methods prove to have significant and consistent improved athletic outcomes. If counterirritation is the treatment option selected by the trainer or owner, athletic outcomes may be improved if treatment is combined with a controlled exercise program and serial ultrasonographic examinations. We recommend re-examination every 2 months to evaluate the quality of repair and to determine if the current exercise program is excessive for any given stage of healing.

Intralesional β-Aminoproprionitrile Fumarate and Controlled Exercise

β-Aminoproprionitrile fumarate is a toxic substance found in the seeds of the plant *Lathyrus odoratus* (sweet pea). If β-aminoproprionitrile fumarate is injected into an injured tendon 30 to 90 days after injury, it binds to the enzyme lysyl oxidase and inhibits the deamination of lysine. This temporarily blocks cross-linking between collagen fibers and improves the quality of repair, if combined with controlled exercise, to generate piezoelectric forces and encourage axial alignment of the repairing collagen fibers. In a naturally healing tendon the collagen fibers may be aligned randomly, whereas treatment with β-aminoproprionitrile fumarate may encourage parallel alignment of the fibers, resulting in a stronger, more physiological repair. Treatment with β-aminoproprionitrile fumarate combined with a controlled exercise program resulted in superior healing, with more type I collagen fibers and improved longitudinal fiber alignment compared with those treated without exercise.[13] β-Aminoproprionitrile fumarate does not increase tenocyte formation and only affects the orientation of the scar and does not hasten repair. Theoretically intralesionally administered β-aminoproprionitrile fumarate is indicated for horses with moderate to severe injuries, when a large volume of the tendon will be repaired by scarring.

β-Aminoproprionitrile fumarate is administered 30 to 90 days after injury and is used at a rate of 1 ml (0.7 mg) per 3% total lesional area, up to a maximum of 10 ml (7 mg). Pretreatment quantitative ultrasonographic evaluation is important for establishing the anatomical extent of the lesion to be treated and the dose required.

Several clinical trials with β-aminoproprionitrile fumarate have been performed. Genovese reported an improvement in quantitative ultrasonographic morphology.[14] In a study in the United Kingdom, six of seven TB flat racehorses failed to complete one race,[3] but a trial in the United States determined that 50% of treated horses returned to racing and completed at least five races.[15] Clinical trials performed in Ohio compared the results of β-aminoproprionitrile fumarate treatment (75 horses) with a placebo (10 horses). All horses followed a similar exercise program. In phase 1, horses were out of training for less than 6 months, but the rate of re-injury was high. In phase 2, convalescence was increased, based on the ultrasonographic grading of the severity of the injury. Horses with a category IV lesion had at least 6 months out of training; this was extended to 8 months for category V lesions, and 10 months for category VI injuries. In phase 2 the success rate increased (Fig. 70-5).

Thirty-seven percent of treated horses with moderate (category V) or severe (category VI) injuries returned to racing without recurrence of injury; 57% failed to race once. None of the placebo group returned to racing without recurrent injury

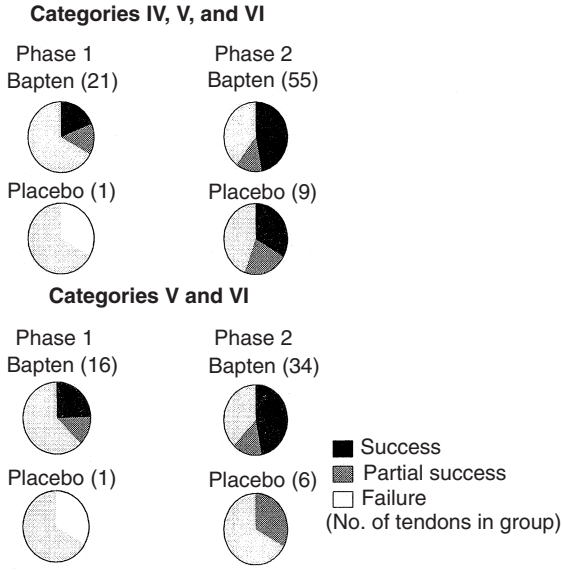

Fig. 70-5 Superficial digital flexor tendon injuries treated with Bapten were compared with placebo groups in two phases of the study. Phase 1 required less than 6 months of layup time, whereas phase 2 studies increased the convalescent time to at least 6 months for category IV injuries, 8 months for category V, and 10 months for category VI injuries. The percent of the total number of tendons was divided into three groups: success (raced at least five times after injury), partial success (raced one to four times), and failure (never raced). In phase 1, injuries including mild (category IV), moderate (category V), and severe (category VI) were grouped together to determine outcome; in phase 2 only moderate and severe categories were grouped.

and 71% failed to race once. Although slight (category IV) and moderate (category V) tendon lesions may appear healed clinically and by ultrasonography (with qualitative and quantitative assessment) 4 to 5 months after treatment, the strength of repair is inadequate to permit return to full training, and further time is essential for collagen maturation and remodeling.

Improvements in management have resulted in increased success with the use of β-aminoproprionitrile fumarate. Racehorses with career-ending category VI injuries also have been rehabilitated for low-level dressage or eventing, or as show hunters or show jumpers.

Intralesional or Perilesional Administration of Hyaluronan

Hyaluronan is a component of the ground substance of the tendon, directly influences collagen fibril formation and aggregation, and stimulates fibrillogenesis of type 1 collagen. Hyaluronan may decrease adhesion formation during tendon repair. In a clinical field trial, treatment of horses with acute anechoic tendon lesions with a single intralesional injection of high molecular weight hyaluronan (Hylartin-V) was compared with a saline placebo. Ultrasonography showed 60% of lesions resolved in the hyaluronan group compared with 24% resolved in the placebo-treated group, but athletic outcome results were not reported.[16] A separate long-term study comparing re-injury rate up to 2 years after treatment with intralesional high molecular weight hyaluronan combined with a controlled exercise program or controlled exercise alone found no significant difference in recurrence of injury. Neither study reported any adverse reaction to intralesionally administered high molecular weight hyaluronan.[16,17]

Corticosteroids

Repeated treatments with corticosteroids may impair tendon healing, but many veterinarians have anecdotally reported that low doses of corticosteroids combined with hyaluronan can be used successfully to manage category III/IV peripheral SDFT lesions in STB racehorses. This practice seldom is used in TB racehorses because of the concern of acute breakdown, an uncommon occurrence in the STB racehorse. A single perilesional injection of 6 to 9 mg triamcinolone with 10 to 20 mg hyaluronan is suggested. Methylprednisolone is not recommended, because it may be associated with development of dystrophic mineralization. It is important to note that continued exercise during this treatment may lead to more serious injury. Therefore close clinical and ultrasonographic monitoring, modification of training schedules (downscaled), and spaced, selected races for optimal results are recommended.

Intralesional and Systemic Administration of Polysulfated Glycosaminoglycans

PSGAGs are reported to inhibit macrophage activation and collagenase and metalloproteinase activity and therefore may be useful in the acute stage of tendon injury or re-injury.[2] The suggestion has been made that PSGAG may stimulate tenocyte repair. However, in a long-term clinical study, no significant difference was found in the recurrent injury rate of tendons treated with systemic or intralesionally administered PSGAGs compared with controlled exercise alone.[17] However, because tendon injuries are potentially career threatening, one author (R.L.G.) often recommends weekly systemic administration of PSGAGs for 4 to 6 weeks for horses with acute injuries of less than 8 weeks' duration. This is combined with other long-term rehabilitation procedures.

Physical Therapies

Physical therapeutic approaches for long-term rehabilitation of a tendon injury, such as therapeutic ultrasound, low-frequency laser, extracorporeal shock wave therapy, cryotherapy, and electromagnetic field therapy frequently are used by owners, but no clinical studies document their therapeutic value over conservative, controlled exercise management.

Other Proposed Long-Term Treatments

Use of insulin-like growth factor-1 and transforming growth factor β-1 are two intralesional hormonal treatments proposed to stimulate intrinsic healing of tendon injuries, with the overall goal to stimulate tenocyte replication and production of type 1 collagen. Clinical trials in racehorse tendon injuries have not been reported. Research in these areas is promising and is greatly improving the biochemical understanding of tendon injury and the biomechanics of repair.

SURGICAL MANAGEMENT OF SUPERFICIAL DIGITAL FLEXOR TENDONITIS

• Mike W. Ross

TRANSECTION OF THE ACCESSORY LIGAMENT OF THE SUPERFICIAL DIGITAL FLEXOR TENDON

Since Bramlage first described transection of the accessory ligament of the superficial digital flexor tendon (ALSDFT), also known as superior or proximal check desmotomy, as a novel surgical treatment for tendonitis of the SDFT, there has been controversy regarding efficacy of the procedure.[1-6] Early, optimistic results were reported in TB racehorses and included 32 of 36 horses (89%) that returned to racing and 25 horses that competed at a level equal to or above the pre-injury level.[3] The results of that study were criticized because criteria for success, defined as completing two races and starting a third, were lenient, and horses developing contralateral limb lameness, including tendonitis, were excluded. Recently, results from a larger group of TB racehorses, using a more strict definition of success, revealed that 97 of 137 horses raced (71%), 70 horses (51%) made more than five starts after surgery, but average earnings decreased in 58% of horses. In that study the mean time from surgery to first start was 353 days.[4] The proposal was that the ALSDFT heals after transection but in an elongated fashion, causing an increased length of the bone-ligament-tendon-bone (radius-ALSDFT-SDFT-proximal and middle phalanges) construct.[5] In a smaller, separate study evaluating the long-term effects of transection of the ALSDFT and other treatments, 53% of flat racehorses, 58% of steeplechasers, and 73% of hurdlers competed in five or more races after surgery.[6] Clearly, with more strict definition of success, earlier results have been downgraded, but do appear superior to results from unmonitored conservative therapy alone. For instance, one estimate claims that only 20% of TB racehorses will compete three or more races after injury.[7] In a separate study of TB horses treated without surgery, 52% returned to racing, but 48% had recurrent tendonitis.[8] More recently, 20 of 28 (71%) TB racehorses were managed successfully with careful rehabilitation (controlled exercise, no turnout), serial ultrasonographic examinations, and a minimum of 8 to 9 months of rest.[9] Clearly, controlled exercise and careful clinical and ultrasonographic examinations are important components of any rehabilitation program. In contrast to other reported results a recent study found no difference in prognosis in TB racehorses treated with transection of the ALSDFT compared with conservative management and in fact found horses that underwent surgery to be at risk to develop suspensory desmitis.[10]

In the STB racehorse, results after transection of the ALSDFT are clearly superior to those achieved in the TB racehorse and published results in horses receiving only conservative management. In our study, 35 of 38 horses raced after surgery (92%), and 33 horses (87%) started more than five races, but tendonitis recurred in six horses.[11] Using a strict definition of success, 71% of horses started five or more times after surgery without recurrence of tendonitis, median earnings per start decreased significantly, and mean time from surgery to first start was 237 days. Suspensory desmitis developed in five horses, all of which had bilateral transection of the ALSDFT.[11] In a similar study, 82% of STB horses raced after transection of the ALSDFT, and 69% competed in five or more starts. In that study, horses that raced before injury had a better prognosis.[5] Published results of conservative management in STB racehorses are scant, but in one retrospective study, 31 (75%) of 41 STB racehorses completed two races and started a third, but tendonitis recurred in 43% of these horses.[12]

In summary, transection of the ALSDFT is clearly beneficial in the STB racehorse. Results of transection of the ALSDFT in other types of sport horses have not been published, but I suspect hunters, jumpers, event, and dressage horses have a prognosis somewhere between that published for the TB and STB racehorse. Unpublished results in the Three Day Event horse suggest that transection of the ALSDFT may be of limited value, although reasons for this are not known.[13] In a study of 33 horses in which 22 were non-racehorses, tendon splitting under ultrasound guidance combined in some horses with transection of the ALSDFT, resulted in 68% return to previous level of competition.[14] In the TB racehorse, results of transection of the ALSDFT may be superior to those achieved with intratendonous injections and uncontrolled rehabilitation, but are not as favorable as conservative management with controlled exercise.

Surgical Procedure

Currently, I prefer conventional surgery using a transthecal approach through the flexor carpi radialis tendon sheath.[3] Compared with the original description of transection of the ALSDFT, this modified approach allows the surgeon to close the incision in three layers, providing a much more secure closure. Transection of the ALSDFT is performed in a caudal location where the ligament is well defined. The surgical procedure is performed using a medial approach, with the horse in lateral recumbency (repositioned if bilateral transection of the ALSDFT is performed) without tourniquet application. The initial incision is made directly over or just cranial to the cephalic vein. The vein is carefully dissected free from underlying antebrachial fascia and retracted caudally. The cranial approach to the vein is less vascular than is the caudal approach, and in most horses a vein penetrating the antebrachial fascia is clamped and ligated. It is important to sever the ALSDFT completely, because incomplete division does not allow immediate transfer of load to the muscle and intuitively would promote faster healing of the structure after

surgery and reduce the possibility the ligament would heal in elongated fashion. To sever the ligament completely, carefully dissecting the proximal fibers from the nutrient artery and vein often is necessary, and in some horses these structures are cut inadvertently, or division is necessary. Division of the vessels causes no known clinical problem, but the vessel ends should be ligated to prevent edema and seroma formation.

Often, the proximal aspect of the carpal canal is penetrated, because the ALSDFT is attached to this structure distally. In horses undergoing transection of the ALSDFT an occasional complication is inadvertent transection of the nutrient artery. Although ligation of the vessel ends has no adverse clinical consequence, swelling in the SDFT seems to abate quickly after surgery, suggesting that hemorrhage may be an important factor early after injury. Complications with the surgical procedure are unusual, but the clinician should be aware of what normal healing of the surgical site entails. Nearly all sites develop diffuse swelling within 1 to 3 days after surgery, and in some horses hematoma or seroma formation occurs. The tendon region is vascular, and swelling is common and expected. If necessary, fluid can be evacuated, but this is seldom necessary. Firm, fibrous tissue forms at the surgical site by 4 to 6 weeks after surgery and may persist for several months. However, in most horses it is difficult to see residual swelling by 6 to 8 months after surgery, and cosmetic appearance is acceptable, if not normal, thereafter.

Transection of the ALSDFT can be accomplished using an endoscopic approach through the carpal sheath. A lateral approach is preferred, but the surgical procedure could be done with the horse in dorsal recumbency if bilateral transection of the ALSDFT was necessary.[15] The ALSDFT can be seen through the sheath and severed, but problems with hemorrhage from transection of the nutrient vessel can be encountered, and whether the entire ligament has been transected is sometimes unclear. Some surgeons prefer the endoscopic approach to avoid swelling that occurs with conventional surgery, but I feel this concern is overrated. Although this approach may be considered more elegant than conventional surgery, I prefer the conventional approach described previously.

How Transection Works

Originally, transection of the ALSDFT was thought to reduce tendon strain, thereby reducing the risk of recurrence of tendonitis. If a gap remained in the ALSDFT after transection, one could reasonably assume load was transferred to the superficial digital flexor muscle. In this case the muscle rather than the inelastic scar within the tendon could stretch, thereby protecting the healed portion of tendon. Experimental evidence in cadaver specimens suggests that after transection of the ALSDFT, load is transferred immediately to the muscle, but tendon strain increases because of a decrease in the metacarpophalangeal joint angle (hyperextension).[16] It has been proposed that the ALSDFT likely heals after transection, but in an elongated fashion, allowing increased length of the bone-ligament-tendon-bone axis, rather than replacing this load bearing axis with muscle. This in theory would increase elastic limit of the damaged tendon and negate the intrinsic loss of elasticity found in healed but scarred tendon.[5] I was initially skeptical of the mechanical effects of transection of the ALSDFT, but immediately after surgery horses may exhibit back-at-the-knee conformation (calf knee). Circumstantially the fact that suspensory desmitis occurs in horses after transection of the ALSDFT implicates a shift in distribution of load from the SDFT to the suspensory ligament.[10,11] Although suspensory desmitis is a serious soft tissue injury and possibility of suspensory injury has altered recommendations for transection of the ALSDFT, I do not consider the risk of suspensory desmitis after surgery a reason to abandon the procedure in certain sport horses.

When Transection Should Be Performed

I used to perform transection of the ALSDFT with the assumption that the procedure was useful in preventing recurrence of tendonitis, and no attempt was made to perform surgery immediately after discovery of tendonitis. However, my current recommendation is that the procedure be done as early as possible after injury. Obvious, visible reduction in tendon size occurs in the first 5 to 10 days after surgery, and although I cannot substantiate this claim, the procedure may be important in limiting or reducing inflammation and thus improve the quality of early healing. Immediate reduction of load on the damaged tendon may explain decreased swelling, but possibly transection of the ALSDFT may function to decompress the injured tendon or may alter blood flow. Reduction in tendon swelling is most marked in horses undergoing transection of the ALSDFT and annular desmotomy.

Patient Selection for Transection

Racehorses with mild, diffuse tendonitis or those with core lesions involving less than or equal to 10% of the CSA of the tendon likely will heal with conservative management and generally are not considered surgical candidates, unless injury is recurrent. Racehorses with recurrent diffuse tendonitis, severe diffuse tendonitis, or core lesions involving 10% to 15% or more of the CSA of the tendon are surgical candidates. In other sport horses, transection of the ALSDFT is recommended in the affected limb in upper-level performance horses using similar guidelines as racehorses, but in lower-level horses conservative management of more severe injuries is often successful.

Bilateral Transection

Bramlage's early results using transection of the ALSDFT in TB racehorses were complicated by the development of superficial digital flexor tendonitis in the contralateral limb.[2,3] In any racehorse, bilateral tendonitis is not uncommon. Ultrasonographic evaluation of young racehorses with obvious tendonitis in one limb often reveals mild tendonitis in the contralateral limb, and I suggest that both limbs be examined carefully before surgery. These facts led me to consider performing transection of the ALSDFT in racehorses bilaterally, even when the procedure was done prophylactically. However, horse's age, existence of concomitant suspensory desmitis in the contralateral limb, gait (in STB racehorses), type of sport horse, and cause of tendonitis play a role in decision making. Bilateral transection of the ALSDFT is recommended in horses with bilateral tendonitis, young 2- or 3-year-old TB or STB racehorses with unilateral tendonitis in which the contralateral limb is operated on prophylactically, or in horses with subtle ultrasonographic evidence of contralateral tendonitis. Unilateral transection of the ALSDFT (surgical procedure performed in affected limb only) is recommended in show horses; in young racehorses, particularly STB racehorses with suspensory desmitis in the contralateral limb; or in horses with tendonitis caused by direct trauma (tendonitis is unlikely to occur in the contralateral limb), such as a bandage bow. In older STB racehorses I often recommend contralateral transection of the ALSDFT in pacers, but not in trotters, because the prevalence of superficial digital flexor tendonitis is much lower in trotters.

Aftercare

Horses are given 2 weeks of absolute stall rest, followed by 6 weeks of stall rest with an increasing hand walking program, beginning with 10 to 15 minutes twice daily. After 8 weeks, an additional hand walking program, walking in the jog cart (STB racehorses), or swimming physiotherapy is recommended for an additional 8 weeks. Turnout exercise is not permitted. Horses then are placed back into early training by trotting and light galloping (TB) or by walking and light jogging (STB).

Serial ultrasonographic examinations should be performed each time an incremental increase in exercise is planned or when clinical evidence of mild inflammation exists. Time to first start varies considerably but in TB and STB racehorses is between 11 and 12 months and 8 and 9 months, respectively.

Large, full-limb support bandages are considered important in limiting motion and swelling at the surgical site(s) and are maintained and changed as needed for a minimum of 14 days. Once bandages are removed, swelling inevitably occurs at the site(s) of transection of the ALSDFT. An inner, lighter bandage is covered by a heavy cotton, full-limb dressing. Concomitant systemic use of PSGAGs or hyaluronan is controversial, and clear benefits have not been demonstrated, but the use of these medications makes sense to me theoretically. Eight weekly injections of PSGAGs are recommended. Dramatic clinical improvement in tendon size occurs when transection of the ALSDFT is combined with other surgical procedures, or in horses in which peritendonous injection of corticosteroids or a combination of corticosteroids and other anti-inflammatory products is used adjunctively with surgery. Phenylbutazone (4.4 mg/kg, intravenously or PO, twice daily for 10 to 14 days) administration appears useful in reducing swelling and improving comfort after surgery.

ANNULAR DESMOTOMY

Recently in equine literature much attention has been given to transection of the ALSDFT and tendon splitting, but little to no mention has been made of annular desmotomy. This procedure remains a most useful surgical treatment, usually combined with transection of the ALSDFT, to manage distal tendonitis of the SDFT. Two distinct clinical situations occur in which annular desmotomy is recommended. The most successful is adjunct use of annular desmotomy in horses with superficial digital flexor tendonitis. The palmar annular ligament (PAL) is a passenger in the disease process, which results in annular constriction of the SDFT. As the SDFT enlarges, the PAL impedes gliding function of the tendon. Further tendon enlargement and inflammation may cause thickening of the PAL, but the primary disease process involves the SDFT, not the PAL or DFTS. The PAL often becomes thickened and adheres to underlying DFTS and SDFT. Once the PAL impedes SDFT function, lameness, continued swelling, and inflammation occur. Annular desmotomy usually is combined with transection of the ALSDFT but can be a career-saving procedure when done alone. Annular desmotomy provides immediate decompression and improved gliding function of the SDFT, which are important, time-honored surgical principles to follow. The decision to transect the PAL is based on clinical observations. Typically a notch appears along the palmar aspect of the limb when viewed from the side, at the location of the PAL. Even if impingement is not severe, I recommend annular desmotomy. Viewed with ultrasonography the PAL may be normal to moderately thickened and adhesions may exist, but actual evidence of PAL desmitis is lacking. The SDFT is abnormal. After annular desmotomy a reduction in tendon size is seen within 5 to 10 days, and clinically initial swelling appears to redistribute proximal to the PAL and distal to the level of the surgical site. The PAL likely reforms in an elongated fashion after surgery but well after tendon size has decreased. Adhesion formation between the PAL, DFTS, and SDFT may occur after surgery, and inadvertent damage to the edge of the SDFT is possible, but the benefits appear to outweigh the risks of the procedure.

The second and less successful clinical situation in which annular desmotomy is used is in horses with chronic tenosynovitis without tendonitis of the SDFT, in horses with tendonitis of the deep digital flexor tendon, or in those with rarely seen primary palmar annular desmitis (see Chapter 75).

I prefer a minimally invasive conventional surgical approach. A 1.5-cm stab incision is made medially (when used with transection of the ALSDFT) just proximal to the PAL through skin, subcutaneous tissues, and DFTS, but care should be taken to avoid incision of the medial (lateral) aspect of the SDFT. A curved bistoury (Sontec Instruments, Englewood, CO) or one blade of a straight Mayo scissors is inserted deep to the PAL, superficial to the SDFT. The PAL is incised in its entirety, and care must be taken to transect the distal aspect completely. Reversing the bistoury or scissors and transecting the fibers of the PAL and thickened DFTS proximal to the incision may be necessary. The small incision then is closed using subcutaneous and skin sutures. Occasionally a larger incision is necessary in horses with severe and chronic tendonitis, because adhesions preclude accurate insertion of the bistoury. Care after surgery is the same as described for transection of the ALSDFT when the procedures are done simultaneously, but if annular desmotomy is performed alone, an accelerated exercise program often is advised. Long stall rest periods after annular desmotomy may promote earlier healing of the severed PAL and adhesion formation. After an initial 2-week period of stall rest, hand walking is given for 2 weeks and the tendon is re-evaluated. Acceleration of the exercise program at this point may be recommended depending on factors such as horse's value, class of racing, time of season, and owner's and trainer's proposed schedule.

Other surgical approaches, including an extended open approach or an open approach without entering the DFTS, have been described, but I do not recommend them. The approach described previously can be done with horses in the standing position or while they are under general anesthesia. Endoscopic examination of the DFTS and transection of the PAL have been described elegantly (see Chapters 24 and 75). This is a novel visually pleasing surgical procedure, but in my hospital it is expensive and time consuming to perform.[17] Complications with any approach include incisional dehiscence, delayed healing, infection, and damage to the ipsilateral edge of the SDFT. Horses with severe tendonitis in which the SDFT is severely enlarged and those with extensive adhesions and thickening of the annular desmotomy and DFTS are at most risk for complications.

TENOSCOPY OF THE DIGITAL FLEXOR TENDON SHEATH AND CARPAL SHEATH

See Chapter 24 for a discussion of tenoscopy of the digital flexor tendon sheath and carpal sheaths.

PROXIMAL METACARPAL FASCIOTOMY/CARPAL RETINACULAR RELEASE

For horses with proximally located superficial digital flexor tendonitis an effective method to decompress the damaged, enlarged SDFT and improve gliding function is to transect the proximal metacarpal fascia and carpal retinaculum. Clinical diagnosis in horses with only proximal superficial digital flexor tendonitis can be challenging because swelling and pain can be easily missed during palpation. Lameness is often inappropriately severe based on the minimal clinical signs present, horses often stand with an over-at-the-knee conformation (bucked knee), a positive response to carpal flexion is manifested, and horses may have mild carpal tenosynovitis. Horses with severe mid to distal superficial digital flexor tendonitis may have proximal involvement, and fasciotomy/carpal retinacular release appears beneficial. Old horses with inexplicably severe superficial digital flexor tendonitis often have extension of tendonitis to the region of the carpal canal and may have moderate to severe carpal tenosynovitis. Carpal retinacular release is

described for use in horses with carpal tenosynovitis, but it can be useful in horses with superficial digital flexor tendonitis in which transection of the metacarpal fascia is done concomitantly. This procedure most often is performed in combination with transection of the ALSDFT but can be combined with annular desmotomy also. Prognosis in horses with superficial digital flexor tendonitis in which transection of the ALSDFT and fasciotomy/carpal retinacular release are performed is guarded to good. Prognosis in old horses requiring transection of the ALSDFT, fasciotomy/carpal retinacular release, and in some annular desmotomy is better than expected, because swelling and lameness are often severe in these horses. Substantial reduction in tendon size and lameness score after surgery can be expected, and some horses have returned to light riding or field hunting.

Fasciotomy/carpal retinacular release is done using conventional surgical techniques and usually via a medial approach, because the procedure often is combined with transection of the ALSDFT. A 2- to 3-cm incision is made through skin and subcutaneous tissues just dorsal to the cephalic vein at the level of the proximal aspect of the second metacarpal bone. Because underlying tendonitis is present, bleeding can be excessive. A 1-cm incision is made in the dense, underlying metacarpal fascia, and a straight Mayo scissors is used to extend the fasciotomy proximally, through carpal retinaculum to the level of the distal aspect of the accessory carpal bone and distally to the mid-metacarpal region. No distinction is perceivable, between fascia and retinaculum because the tissues blend together. Subcutaneous tissues and skin are closed routinely. Bandaging and care after surgery are the same as given for transection of the ALSDFT, because the procedure usually is performed in combination.

TENDON SPLITTING

Interest in tendon splitting as an adjunct method to manage superficial digital flexor tendonitis has been renewed. Originally the procedure was developed to promote vascularization of the tendon in horses with chronic tendonitis, and early results showed promise.[18] Experimental studies questioned the value of tendon splitting, and the conclusion was that splitting induced excessive granulation tissue and slow healing of areas of tendon necrosis.[18,20] Clinical use of the technique then fell out of favor, but renewed interest was sparked by reports of combined use of splitting with transection of the ALSDFT in a clinical study and improved healing and revascularization of acute collagenase-induced tendon injuries in an experimental study.[21,22] The collagenase model produces severe tendonitis with extensive necrosis, and I question the value of this model in mimicking the naturally occurring disease. Various authors have reported clinical experiences with tendon splitting used with other procedures, but clinical studies using splitting alone are lacking.[4,5,11,14] Tendon splitting currently is used in horses with core lesions early in the disease process rather than in horses with chronic tendonitis, the group for which the procedure was designed originally. Tendon splitting, done to decompress areas of hemorrhage, or to provide vascular access channels early after injury, makes theoretical sense for horses with anechoic lesions, but it is of questionable value if done once granulation tissue has formed or mature collagen fibers exist. The rationale given for use in early lesions is to decompress the area of hemorrhage and to provide vascular access channels to improve vascularization by vessel ingrowth. Soon after injury areas of hemorrhage become granulation tissue in which the value of decompression would be minimal. The surgical procedure would have to be performed before granulation tissue develops (3 to 5 days, but certainly before 2 weeks) and should be reserved for horses with anechoic lesions. Damage caused to peritendonous tissues and surrounding intact tendon fibers must be considered and may outweigh any benefit. However, the procedure has been done apparently successfully or at least without outward harmful effects.

In clinical practice I use the procedure when requested by referring veterinarians or in TB racehorses with anechoic core lesions. The percutaneous technique is preferred, and using a double-edged tenotome or a No. 11 scalpel blade is recommended. The procedure seldom is used in the STB racehorse, and in our report detailing results of transection of the ALSDFT in this racing breed, tendon splitting was done in only one horse.[11] In STB racehorses managed with transection of the ALSDFT, I recommend annular desmotomy, but not tendon splitting. Currently I recommend that the procedure be done in TB racehorses or other non-STB sport horses with transection of the ALSDFT. Needle decompression of anechoic lesions early after injury may be of value to provide early decompression, but creation of vascular access channels using this method appears implausible.

COMBINED SURGICAL PROCEDURES

Because superficial digital flexor tendonitis is career limiting in many sport horses, early and aggressive surgical management should be considered. Potentially, injection of growth factors, liquid bone marrow, or other substances used with surgery and strict rehabilitation may offer the best hope for a successful outcome. Combined surgical management using transection of the ALSDFT and annular desmotomy; transection of the ALSDFT, annular desmotomy, and fasciotomy/carpal retinacular release; or in some horses various combinations with tendon splitting has been successful even in horses with severe tendonitis. In my experience, using transection of the ALSDFT without annular desmotomy in horses with distal superficial digital flexor tendonitis often results in failure, as does using transection of the ALSDFT without fasciotomy/carpal retinacular release in those with lesions involving the proximal aspect of the tendon.

The ideal management program for horses with superficial digital flexor tendonitis has yet to be discovered but should rely on the principles of tendon healing, including minimizing peritendonous scar tissue formation, minimizing the effect of hemorrhage and subsequent granulation tissue formation and disorganized fiber alignment, maximizing gliding function within and external to the SDFT, reduction of load and protection of inelastic scar tissue by increasing the length of the bone-ligament-tendon-bone construct, and an exercise regimen that allows healing and maturation of collagen fibers without deleterious effects of uncontrolled exercise. Surgical management preserves many of these time-honored principles and has proved useful in many types of sport horses.

Treatment of tendon injuries in racehorses is a challenge to clinicians and researchers. Return to racing is associated with a high rate of recurrent injury. However, much progress has been made in the past 2 decades in diagnostic identification and classification of injury, and the biochemical and biomechanical aspects of tendon injury. Treatment and management programs by necessity depend heavily on economics and trainer decisions relative to continued exercise or long-term rehabilitation. Of vital importance is accurate injury severity categorization, controlled exercise in long-term rehabilitation programs, and ultrasonographic monitoring at all levels of treatment. Improved athletic outcome results gradually evolve as continued basic science research and clinical investigations of past and proposed therapeutic regimens unfold.

SUPERFICIAL DIGITAL FLEXOR TENDONITIS IN EVENT HORSES, SHOW JUMPERS, AND DRESSAGE HORSES

• Sue J. Dyson

Superficial digital flexor (SDF) tendonitis is a potentially career-limiting injury in event horses and Grand Prix–level show jumpers. Although the incidence of SDF tendonitis is much lower in dressage horses, it is also an important injury. The clinical manifestations vary considerably.

SUPERFICIAL DIGITAL FLEXOR TENDONITIS IN EVENT HORSES

Clinical Signs

Although all event horses are at risk of injury of the SDFT, the incidence of injury is highest in horses competing at advanced or international level, especially those competing in Three Day Events. This is probably due to the combination of galloping long distances and jumping on very variable terrain and footing. After training or competing, riders commonly apply a proprietary clay to the forelimbs and bandage the limbs at least overnight. This practice may result in early warning signs of impending tendon damage being missed. Because lesions frequently occur bilaterally, subtle changes in limb temperature may be missed except by the most astute and vigilant riders or grooms.

The clinical signs associated with tendon damage vary markedly. A horse may pull up lame after the cross country phase of an event and rapidly develop peritendonous soft tissue swelling and pain on palpation of the tendon. In some horses the degree of pain is severe and the horse may be distressed and reluctant to bear weight on the limb. If lesions occur bilaterally, the horse may be reluctant to move and its behaviour may mimic the appearance of a horse that is tying up. These horses may require both analgesia and sedation to relieve the distress. Clinicians should be aware that a horse may appear very lame, but it may not be possible to elicit pain by palpation of the tendon, although the tendon may feel abnormally soft.

In contrast a horse may complete the cross country phase and appear sound, with lameness developing several hours later. Although soft tissue swelling may develop, in some horses there may be absolutely no clues as to the cause of lameness (i.e., no heat, pain, or swelling). This may persist for many days, and then suddenly enlargement, subtle or obvious, of the SDFT may be seen despite resolution of lameness.

In other horses, lameness is never present. The horse initially may exhibit poor performance and clinical examination may reveal that the SDF tendons are slightly enlarged. Alternatively, the horse may have localized heat and pain on pressure applied to the SDFT, with no history of lameness. Some horses have obvious clinical signs of SDF tendonitis after the first training gallop, cross country schooling, first event, or following a period of reduced work for some months after a Three Day Event. It seems highly likely that these horses sustained damage to the SDF tendon(s) at the Three Day Event without associated detectable clinical signs.

Clinical signs and the severity of the tendon injury are not necessarily correlated. The clinical signs of SDF tendonitis can easily be masked. I have examined a number of horses at events when the horses have finished lame and had clinical signs compatible with SDF tendonitis. The horses have been treated by application of a modified Robert Jones bandage and systemic NSAIDs. Ultrasonographic examination after 5 to 7 days has been recommended. The horse has then been examined by the owner's regular veterinary surgeon, who has been unable to detect any palpable abnormality after removal

of the bandage and therefore elected not to perform an ultrasonographic examination. Return to work has been recommended by the second veterinary surgeon with catastrophic consequences. Some horses that have completed the speed and endurance phase of a Three Day Event and sustained a tendon injury can be managed to pass the final horse inspection and complete the show jumping, without marked deterioration of the tendon injury.

Diagnostic Ultrasonography

In my opinion, whenever unexplained lameness occurs in an event horse, the SDF tendons should be examined ultrasonographically. I also recommend routine ultrasonographic examination 10 to 14 days after the horse completes a Three Day Event. Ultrasonographic examination should be mandatory for any horse with a history of slight heat or filling in the metacarpal region, unless there is an obvious cause (Fig. 70-6). However, it is equally important to recognize the constraints of ultrasonographic examinations, due both to the skill of the veterinarian and limitations of the resolution of ultrasonographic images. If a SDF tendon appears normal ultrasonographically, but the clinical signs are suspicious of injury, the horse should be treated as if it had a tendon injury, with repeat examination after a further 7 to 14 days.

In horses with early subtle tendonitis the only abnormality detectable may be slight, localized enlargement in CSA of the tendon, therefore area measurements and comparisons with the contralateral limb can be extremely valuable. If the injury is bilateral, subtle enlargement in both SDF tendons is easily missed. It is important to examine the relative sizes of the superficial and deep digital flexor (DDF) tendons and to be aware of the way in which a normal SDF tendon changes shape from proximally to distally in the metacarpal region (see Chapter 16).

It is also important to look carefully at the echogenicity of the SDFT and compare it with the DDFT and more proximal and distal sites within the SDFT. Subtle lesions often result in a slight diffuse reduction in echogenicity of part or all of the CSA of the tendon, but only in a localized region. Such lesions are easily missed, especially if the gain controls of the ultrasound machine are set too high or if the limb is examined without fine clipping of the hair coat. Detection of these early injuries is very important, because a horse can make a relatively rapid complete recovery at this stage, whereas continued work may result in a much more severe, career-limiting injury. In these early injuries, longitudinal images of the tendon often appear normal. Both forelimbs should be examined routinely.

Because lesions may be very localized, it is important to carefully and systematically examine the tendon from proximally to distally. Although gross core lesions of the SDFT are relatively easily identified without fine clipping of the hair coat, image resolution is inferior. Application of mineral oil helps to improve resolution, but this can destroy the ultrasound standoff pad. Subtle lesions will be missed unless the hair is clipped, although shaving is unnecessary. Owners may be reluctant to allow the limbs to be clipped, suggesting that this may jeopardize the horse's evaluation at an inspection at a forthcoming Three Day Event if the limbs actually appear normal and the horse is unable to compete. Owners must be persuaded that it is essential to clip the limbs and that only a narrow strip is necessary; the clinician should suggest that if the horse is fit to compete, the entire horse is then clipped.

Treatment

Management of SDF tendonitis in the event horse is difficult. Individual horses' capacities to recover from tendon injuries vary considerably. In some horses a marked improvement is

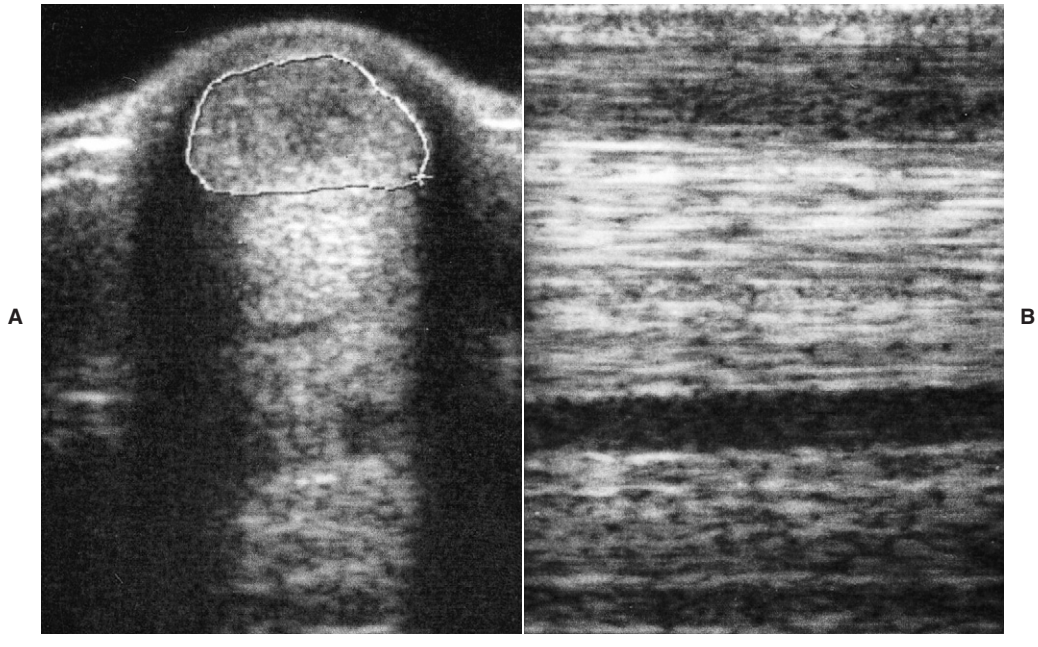

Fig. 70-6 **A,** Transverse ultrasonographic image of the palmar aspect of the right forelimb of a 9-year-old advanced event horse; the scan was obtained at 16 cm distal to the accessory carpal bone. Medial is to the left. The horse initially had slight heat in the metacarpal region but no lameness. The superficial digital flexor tendon (SDFT) is enlarged (cross-sectional area 1.2 cm^2), and there is a diffuse reduction in echogenicity with an acentric, more hypoechogenic region. The lesion extended from 12 to 24 cm distal to the accessory carpal bone. **B,** Longitudinal ultrasonographic image of zone 2B; proximal is to the left. There is diffuse reduction in echogenicity of the SDFT with loss of long linear echoes.

seen in the clinical and ultrasonographic appearance of the tendon within 3 months of first injury, whereas little progress is seen in other horses with a similar injury. In almost all horses a convalescent period of 1 year after injury is required. In some horses, normal echogenicity is never restored and a fairly obvious central hypoechoic area persists ultrasonographically. These horses may be able to withstand one day events, but frequently sustain re-injury at a Three Day Event. Lesions in the distal one fourth of the metacarpal region (zones 3B and 3C) are particularly at risk to re-injury. Even in those horses in which relatively normal echogenicity is restored, it is relatively unusual for them to be able to complete more than one or two Three Day Events without re-injury.

Most published studies of the treatment of SDF tendonitis relate to the racing TB and STB. It is generally accepted that the rate of re-injury is high, especially for horses competing in Three Day Events. Although a horse may be managed successfully to complete one Three Day Event after injury, the risks of subsequent injury are very high.

Of 23 event horses treated with a controlled exercise program alone, 57% were able to return to full athletic function without recurrent injury in a 2-year period after resumption of full work,[1] compared with 56% of 25 horses that received intralesional hyaluronan and the same controlled exercise program and 58% of 31 horses that received intralesional PSGAGs administered intralesionally, systemically, or by both routes. Almost all horses with a unilateral injury re-injured the same tendon.

The results of intralesional treatment with β-aminopropionitrile fumarate appear superficially to be slightly worse; in a 2-year follow-up period after return to full work, only 12 (52%) of 23 horses competed without re-injury.[2] Five (22%) horses re-injured the same SDFT. However, an additional 6 horses competed successfully and then injured either the SDFT of the contralateral limb (5) or the ALDDFT in the ipsilateral limb (1). Eight of the 12 successfully treated horses have completed three or more Three Day Events at championship level without recurrent injury. A further 6 (of 6) horses have been competing successfully for 12 to 18 months after treatment. Overall, in my experience, this treatment seems to offer the best long-term prognosis for event horses with moderate to severe injuries of the SDFT. After treatment, horses are walked for 30 to 60 minutes daily for 4 months and are then re-examined ultrasonographically. Successfully treated horses had a remarkably good strength of fiber pattern in longitudinal ultrasonographic images 4 months after treatment. This feature appears to be a good prognostic indicator. Work intensity is slowly and progressively increased thereafter, with horses generally reaching full work by 12 months after treatment.

Desmotomy of the accessory ligament of the SDFT has been less successful in the management of SDF tendon lesions in event horses than in the racehorse, and the disappointing results achieved in the author's clinic have led to this technique being abandoned. It has also fallen from favor in the United States.[3,4] Tendon splitting has been used for anechoic central core lesions, combined with a controlled exercise program with successful results, but the number of treated horses does not compare with the studies described previously.[2]

Regardless of the method of management, serial ultrasonographic examinations during the convalescent period seem to be the most accurate predictors of the final outcome. If the echogenicity and fiber pattern have improved markedly by 4 months after injury, then the longer-term prognosis is much better than in those horses where improvement is only slight. The strength of the fiber pattern when full work is resumed is a good predictor of whether the horse will sustain re-injury.[1] It does appear that some horses have an innately better ability to repair tendon lesions than others.

Pastern Lesions

Injury to the medial or the lateral branch of the SDFT in the pastern region occurs most commonly in forelimbs but also occasionally in hindlimbs (see Chapter 83). Such injury can occur as an isolated acute lesion or as a sequel to previous tendonitis in the metacarpal region. There is usually acute-onset, moderate lameness. In some horses, soft tissue swelling is immediately apparent on the palmar aspect of the pastern, but in others, obvious swelling may take several days to develop. In these horses, perineural analgesia may be required in the acute stage to localize the source of pain. Lameness is alleviated by perineural analgesia of the palmar nerves at the level of the proximal sesamoid bones. Diagnosis is confirmed ultrasonographically. The affected branch is usually enlarged with poor demarcation of its margins and diffuse or focal areas of reduced echogenicity. Horses with acute lesions with no preceding tendonitis have a fair prognosis for complete recovery after adequate rest for at least 6 months. However, horses with lesions secondary to tendonitis in the metacarpal region have a more guarded prognosis.

SUPERFICIAL DIGITAL FLEXOR TENDONITIS IN SHOW JUMPERS

Injury to the SDFT is comparatively unusual in show jumping horses, except those competing at international level, or horses approximately 15 years of age or older. Injury to the SDFT is most commonly unilateral. It may occur as a primary lesion or as a sequel to previous desmitis of the ALDDFT. Injuries occur most frequently during competition and may result in an acute, severe lameness with the horse abruptly stopping during a round. Alternatively, the horse may finish lame. Clinical signs of heat, swelling, and pain may or may not be obvious at the time. In some horses, SDF tendonitis is insidious in onset, with development of swelling and localized heat without recognition of any gait abnormality (Fig. 70-7, *A*). Occasionally traumatic injuries occur to the SDFT within the carpal sheath after the horses has sustained a fall (see Chapter 76).

Injuries restricted to the proximal one third of the metacarpal region are common, and there appears to be a tendency for the development of peritendonous adhesions and recurrent lameness. Horses with these lesions have been difficult to manage successfully, as are those with lesions that extend proximally into the carpal canal. However, horses with lesions restricted to the metacarpal region, without peritendonous adhesions, can be rehabilitated and returned to competition with judicious, symptomatic management relatively quickly compared with event horses with a comparable injury. Some horses can withstand return to full work, despite persistence of quite obvious ultrasonographic abnormalities of the SDFT. However, the tendon must be monitored carefully, because some horses continue to sustain recurrent low-grade injuries, which result in the tendon becoming progressively larger and wrapping around the DDFT and becoming contiguous with the ALDDFT. Severe injuries predispose to the development of secondary desmitis of the ALDDFT (see Chapter 72).

Desmitis of the ALDDFT may occur as a primary lesion. Severe lesions predispose to the development of secondary SDF tendonitis. Horses with these injuries are difficult to manage successfully. Marginal tears of the SDFT within the DFTS occur occasionally, presenting as an acute-onset lameness associated with distension of the DFTS (Fig. 70-7, *B*).

Fourteen (93%) of 15 show jumpers with unilateral SDF tendonitis that were treated conservatively after a controlled exercise program were able to return to full athletic function for at least 2 years without recurrent injury, compared with 4 (80%) of 5 horses treated with intralesional hyaluronan and

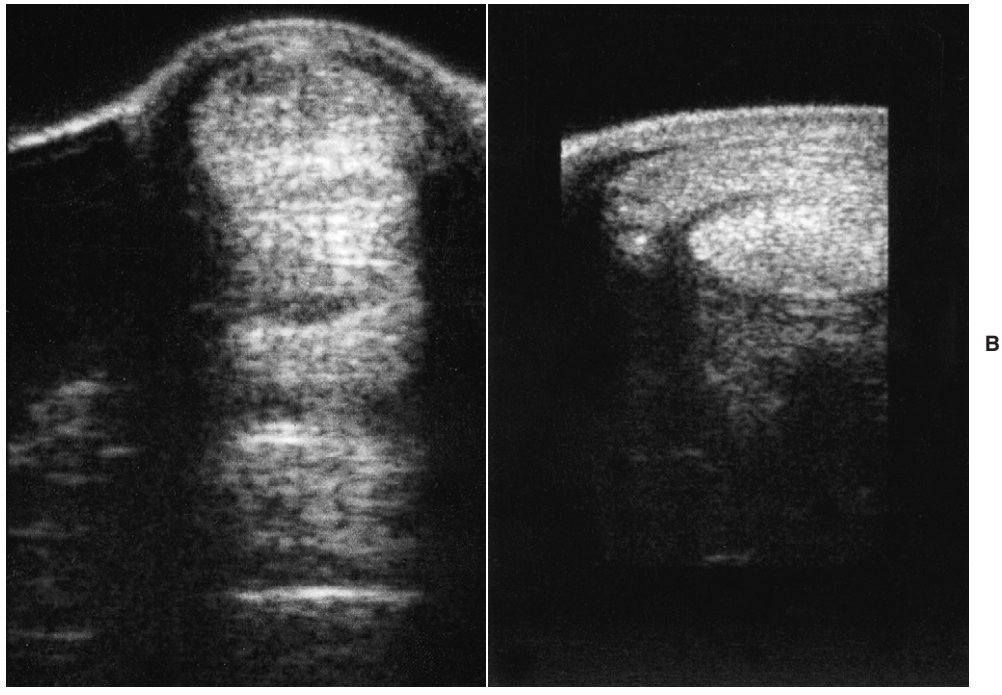

Fig. 70-7 **A,** Transverse ultrasonographic image of the palmar aspect of the left forelimb of a 13-year-old Grand Prix show jumper; the image was obtained at 11 cm distal to the accessory carpal bone. The horse initially had localized heat and swelling but no lameness. A focal hypoechoic lesion is seen on the palmar margin of the superficial digital flexor tendon (SDFT). The lesion extended less than 1 cm proximodistally. The horse's condition was managed symptomatically and the horse continued to compete successfully for 6 months with no change in the lesion; the horse then developed acute lameness with exacerbation of the injury. **B,** Transverse ultrasonographic image of the palmar aspect of the distal metacarpal region of a 14-year-old Grand Prix show jumper with acute-onset, severe lameness associated with distention of the digital flexor tendon sheath. Medial is to the left. The medial aspect of the superficial digital flexor tendon is enlarged, its margin is irregular, and there are focal anechoic lesions.

3 (75%) of 4 horses treated with PSGAG.[1] Five horses with severe lesions that had not responded adequately to conservative management were subsequently treated with β-aminoproprionitrile fumarate, and all have withstood return to international competition without recurrent injury.[2]

Older horses (>15 years of age) with SDT tendonitis generally carry a more guarded prognosis. Some of these injuries appear to be progressive degenerative lesions, which deteriorate despite rest.

SUPERFICIAL DIGITAL FLEXOR TENDONITIS IN DRESSAGE HORSES

SDF tendonitis is not a common injury in dressage horses but it does occur occasionally (Fig. 70-8). Most lesions occur either in the proximal one third of the metacarpal region or in the distal metatarsal and pastern regions of hindlimbs. Mild lesions in the distal two thirds of the metacarpal region are less common but are easily managed. The horse is restricted to stall rest and controlled exercise and usually resumes work after resolution of localized heat, pain, and peritendonous swelling. Lesions in the proximal one third of the metacarpal region are much more difficult to manage, and clinical signs resolve very slowly regardless of the method of management. Hindlimb lesions have been restricted to the DFTS and are sometimes bilateral. They often are associated with adhesion formation within the DFTS and tend to result in chronic lameness.

Some marginal tears of the SDFT are only recognized during exploratory tenoscopy of a distended DFTS. Concurrent tears of the manica flexuria have also been identified during tenoscopic evaluation. The results of debridement of marginal tears of the SDFT within the DFTS in dressage horses have been rather disappointing. Although lameness has often improved, minor career-limiting gait abnormalities have persisted.[2]

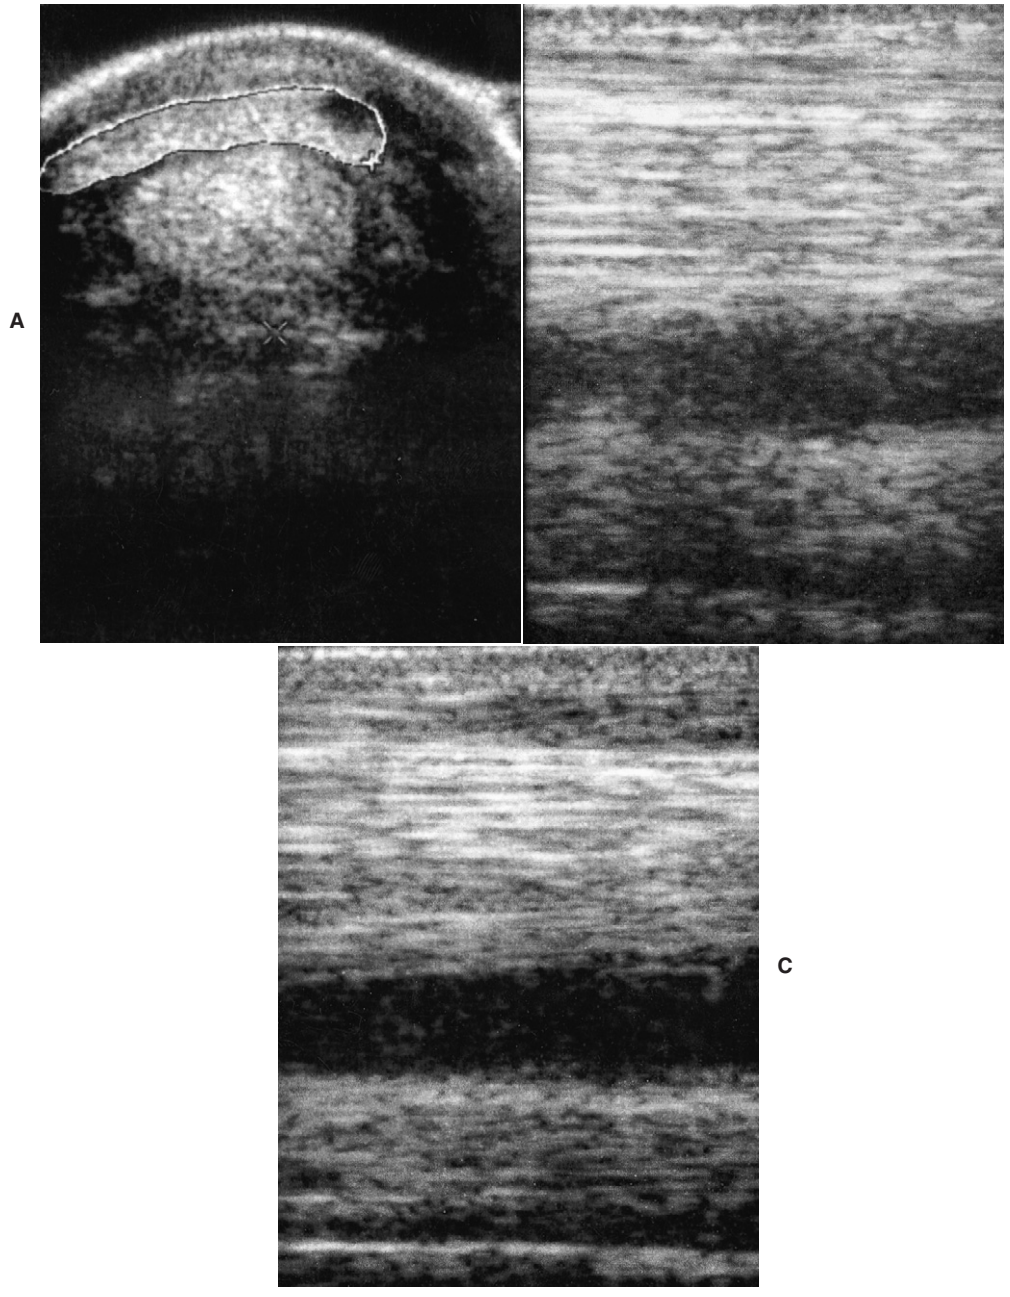

Fig. 70-8 **A,** Transverse ultrasonographic image of the palmar aspect of the left forelimb of a 12-year-old Grand Prix dressage horse. The image was obtained at 22 cm distal to the accessory carpal bone; medial is to the left. The horse had exceptionally extravagant forelimb paces and acute-onset, moderate lameness. There is a focal hypoechoic lesion on the lateral aspect of the superficial digital flexor tendon (SDFT). The lesion extended from 16 to 26 cm distal to the accessory carpal bone. At this level the tendon is slightly enlarged (cross-sectional area 1.2 cm^2), but at all other levels it was of normal size. **B,** Longtitudinal ultrasonographic image of zone 3A obtained from the palmar midline; proximal is to the left. The SDFT appears normal. **C,** Longitudinal ultrasonographic image of zone 3A obtained from the palmarolateral aspect of the metacarpal region shows reduced echogenicity of the SDFT.

CHAPTER • 71

The Deep Digital Flexor Tendon

Sue J. Dyson

ANATOMY

In the forelimb the deep digital flexor tendon (DDFT) has three heads: the humeral head, the largest, and the smaller radial and ulnar heads.[1] The tendon of the humeral head develops 8 to 10 cm proximal to the antebrachiocarpal joint, but muscular tissue persists until the level of the antebrachiocarpal joint, where the ulnar and radial heads join. The merged tendon is triangular in cross-section within the carpal canal but becomes more rounded in the metacarpal region. The accessory ligament of the DDFT (ALDDFT) merges with the DDFT in the middle third of the metacarpal region.

In the hindlimb the DDFT is formed by a large lateral digital flexor tendon and a smaller medial digital flexor tendon. The lateral digital flexor tendon incorporates the caudal tibialis tendon and passes over the sustentaculum tali within the tarsal sheath. The medial digital flexor tendon passes over the proximal tubercle of the talus, on the medial aspect of the talus, in its own synovial sheath. These two tendons fuse in the proximal metatarsal region. In the proximal metatarsal region the DDFT is a large oval-shaped structure that becomes smaller farther distally. The ALDDFT in the hindlimb varies in size and is generally comparatively smaller than in the forelimb.

At the fetlock region the DDFT becomes wider, elliptical, and fibrocartilaginous and is enclosed within the digital flexor tendon sheath (DFTS). In the pastern region the tendon becomes bilobed. At the level of the proximal part of the middle phalanx the dorsal part of the tendon becomes a fibrocartilaginous pad. Distally the DDFT is molded to the palmar/plantar aspect of the navicular bone. The DDFT is broad and has a terminal fan-like expansion containing cartilage and inserts on the facies flexoria of the distal phalanx, delineated dorsally by the semilunar line and the adjacent surface of the ungular cartilage.

The DDFT has a high modulus of elasticity (1585 MPa) and a considerable strength to rupture (approximately 1700 daN).[1] The ALDDFT has a low modulus of elasticity (490 MPa) and a moderate strength to rupture (approximately 490 daN). The DDFT limits carpal and fetlock extension under high loads. In the fetlock region the DDFT is under tension and compression. It is therefore fibrocartilaginous in this region and in the pastern, where the tendon is under pressure from the tuberositas flexoria, a transverse prominence on the proximal palmar aspect of the middle phalanx. In the digit the DDFT facilitates flexion of the proximal interphalangeal joint during weight bearing and stabilizes the distal interphalangeal joint.

The position of the DDFT and the navicular bone varies considerably during the stance phase. In the full weight-bearing position the DDFT is only in close contact with the distal border of the navicular bone, but during propulsion it comes into full contact with the palmar aspect of the bone. The tendon is stretched maximally as active contraction of the muscle bellies and the elasticity in the tendon result in elevation of the fetlock and extension of the distal interphalangeal joint. During the swing phase of the stride the DDFT relaxes. The DFTS facilitates displacement of the flexor tendons during flexion and extension.

DEEP DIGITAL FLEXOR TENDONITIS ASSOCIATED WITH RECURRENT DESMITIS OF THE ACCESSORY LIGAMENT OF THE DEEP DIGITAL FLEXOR TENDON

Injuries of the DDFT in the carpal or metacarpal region, proximal to the DFTS, are rare except in association with chronic desmitis of the ALDDFT (see Chapter 72). Recurrent desmitis may be accompanied by pathological lesions of the DDFT.[2] Because of the close proximity of the DDFT and its accessory ligament, it is difficult by palpation to assess each structure accurately, especially with chronic enlargement of the ALDDFT, which may wrap around the borders of the DDFT. Ultrasonographic examination may reveal slight enlargement of the DDFT. The dorsal border may be less well defined, and diffuse hypoechogenic regions may occur within the DDFT, extending a variable distance proximodistally. These injuries usually result in recurrent lameness.

It has also been noted that in association with substantial enlargement of the superficial digital flexor tendon (SDFT) because of chronic tendonitis, the DDFT becomes smaller in cross-sectional area.[3] With chronic enlargement of the ALDDFT, the DDFT may also reduce in size.

I have not examined a horse with primary deep digital flexor tendonitis in the proximal metacarpal region, but a single case was recorded by Genovese and Rantanen[4] in an 8-year-old Quarter Horse used for English pleasure riding. Occasionally traumatic injuries of the DDFT have been seen within the carpal sheath.

DEEP DIGITAL FLEXOR TENDONITIS IN THE CARPAL SHEATH SECONDARY TO SOLITARY OSTEOCHONDROMA

Lesions of the DDFT within the carpal sheath are an unusual cause of lameness except secondary to irritation by a solitary osteochondroma. An osteochondroma is an exostosis continuous with the cortex of the bone and is covered by cartilage. The osteochondroma develops immediately proximal to the distal radial physis, often medial to the midline. Lameness is sudden in onset and usually is accentuated by carpal flexion. Invariably distention of the carpal sheath occurs. An osteochondroma is readily identifiable radiographically. Ultrasonographic examination from the medial aspect of the distal antebrachium also reveals the abnormal bone contour, an abnormal amount of fluid within the carpal sheath, and an irregular dorsal contour of the DDFT. Treatment is by surgical removal of the osteochondroma and debridement of any torn fibers of the DDFT. The prognosis for return to athletic function is excellent.

DEEP DIGITAL FLEXOR TENDONITIS WITHIN THE DIGITAL FLEXOR TENDON SHEATH IN THE FETLOCK REGION

Some enlargement of the DFTS is common in hindlimbs, often unassociated with lameness, but occurs less frequently in forelimbs. Sudden-onset lameness associated with distention of a DFTS in a forelimb or a hindlimb may be caused by a variety of different lesions, but deep digital flexor tendonitis always should be considered[5,6] (see Chapter 75). It is rare to identify lesions of the DDFT within a DFTS that is not distended. Some horses develop deep digital flexor tendonitis *after* long-term chronic enlargement of the DFTS.

Lameness associated with DDFT lesions within the DFTS occurs more frequently in hindlimbs than in forelimbs and in horses from a variety of disciplines. The condition usually occurs unilaterally, although it has been seen bilaterally in the hindlimbs of several Warmblood dressage horses.[3]

Lameness varies from mild to moderately severe. Distention and thickening of the DFTS may make accurate palpation of the DDFT difficult. In some horses pain can be elicited by palpation of the margins of the tendon or by firm pressure being applied to its palmar (plantar) aspect. The tendon should be assessed throughout its length, proximal and distal to the fetlock. In the acute stage there may be localized heat. Passive flexion of the lower limb may induce pain. If forelimb lameness is only mild in straight lines, it may be exaggerated on the lunge on a soft surface, especially in medium and extended trot. Distal limb flexion often accentuates the lameness.

Intrathecal analgesia of the DFTS usually results in significant improvement but rarely alleviates lameness. Better improvement is seen after low palmar/low plantar perineural analgesia. In horses in which the metacarpophalangeal (metatarsophalangeal) joint capsule also is distended, performing intra-articular analgesia may be necessary to be sure that distention is not contributing to pain.

Definitive diagnosis requires ultrasonographic examination. Four types of lesions involving the DDFT have been identified: enlargement and change in shape of the tendon, focal hypoechoic lesions within the tendon or on its border, mineralization within the DDFT, and marginal tears.[5-7] The first three are readily diagnosed using diagnostic ultrasonography, but the marginal tears are much more difficult to identify. Surgical exploration may be required for definitive diagnosis.[8] Acute-onset focal hypoechoic areas generally are not seen with pre-existing adhesion formation, although any of the other lesions may be.

The normal DDFT changes in its shape and cross-sectional area from proximally to distally, but it is usually bilaterally symmetrical. The normal DDFT is uniform in its echogenicity, and its margins are clearly defined. Hypoechoic artifacts are induced readily in the distal fetlock and pastern regions if the ultrasound transducer is not perpendicular to the tendon, and in these regions evaluating the SDFT and DDFT simultaneously is difficult. Echogenic synovial plicae (mesotendon) extend medially and laterally from the DDFT to the DFTS wall in the proximal recess of the DFTS (Fig. 71-1, *A*). These are seen much more obviously when the tendon sheath is distended and should not be mistaken as marginal tears or adhesions. With chronic tenosynovitis, these plicae may become thickened. Distal to the fetlock is an echogenic palmar (plantar) synovial fold that should not be confused with an adhesion (Fig. 71-1, *B*). The ergot on the palmar (plantar) distal aspect of the fetlock prohibits ultrasonographic evaluation at this level and lesions of the DDFT may be missed.

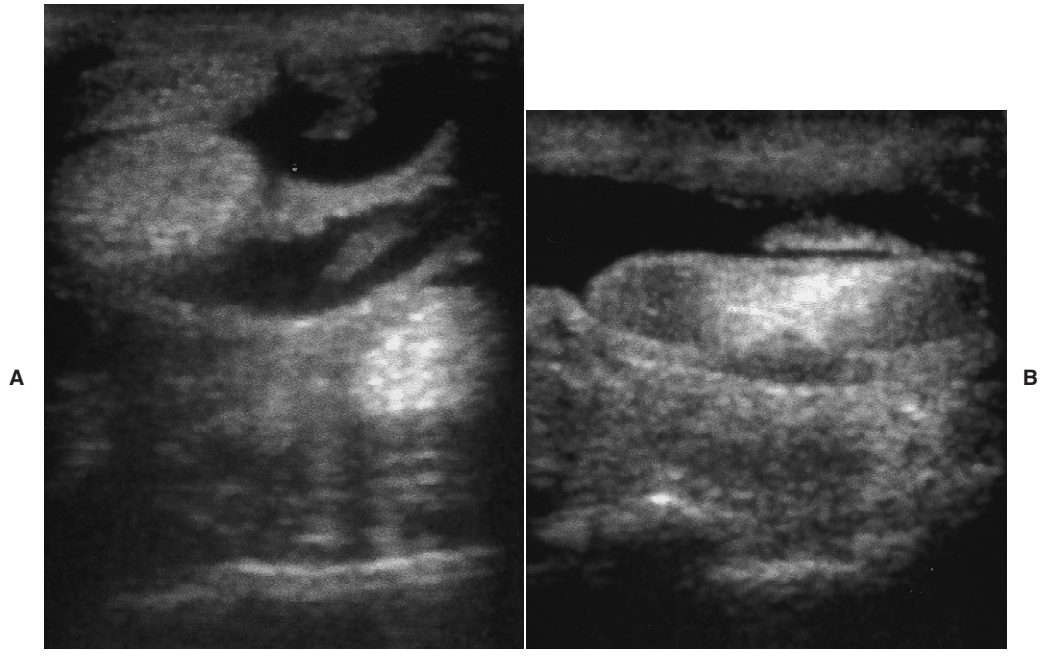

Fig. 71-1 Transverse ultrasonographic images of the digital flexor tendon sheath in (**A**) the distal metacarpal region and (**B**) the pastern. Medial is to the left. **A,** An abnormal amount of fluid is within the digital flexor tendon sheath, but the deep digital flexor tendon appears normal. Note the prominent synovial plica extending from the lateral aspect of the deep digital flexor tendon. This plica also is thickened slightly, and other echogenic material is within the anechogenic synovial fluid, but the horse had no associated lameness. **B,** Note the abnormal amount of fluid within the digital flexor tendon sheath, and a synovial plica is on the palmar aspect of the deep digital flexor tendon. These are normal anatomical structures that are visible most readily when the digital flexor tendon sheath is distended.

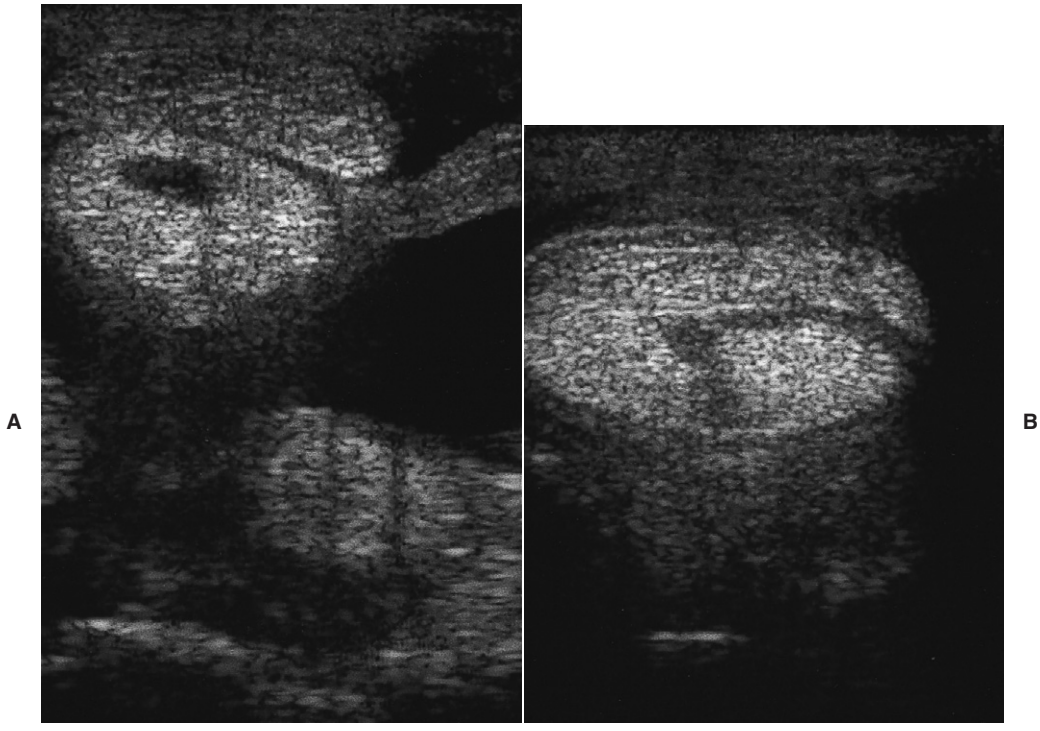

Fig. 71-2 Transverse ultrasonographic images of the distal metatarsal region of a horse with acute-onset right hindlimb lameness associated with distention of the digital flexor tendon sheath. Medial is to the left. An abnormal amount of fluid is within the digital flexor tendon sheath. **A,** There is a well-defined anechoic lesion within the deep digital flexor tendon, close to the plantar border. Note also the rather poorly defined dorsal border. **B,** Slightly farther distally the lesion can be seen to involve the dorsal and plantar borders of the tendon.

Enlargement or Change in Shape of the Deep Digital Flexor Tendon

In horses with low-grade injuries the only detectable ultrasonographic abnormality is a change in shape or size of the DDFT. The echogenicity and fiber pattern may appear normal; therefore these injuries are easily overlooked. The DDFT may look rounder in cross-section, rather than elliptical. Careful comparison with the contralateral limb at the same distance distal to the accessory carpal bone is important for accurate diagnosis. Comparison of the relative sizes of the SDFT and DDFT can also be helpful. Cross-sectional area measurements of the SDFT are prone to error at this level, and therefore measurements of the dorsopalmar thickness of the SDFT and DDFT are more accurate. If the horse fails to respond satisfactorily to conservative management, then consideration should be given to the presence of a marginal tear that may not be detectable with ultrasonography.[3]

Constriction of the DFTS and its contents by an enlarged palmar annular ligament may result in secondary compression of the DDFT.

Focal Hypoechogenic Lesions

The cross-sectional area of the DDFT may be enlarged. Focal hypoechoic defects vary in size and position within the cross-section of the tendon and in length. Some are small, occupying less than one tenth of the cross-sectional area of the tendon and extending less than 1 cm proximodistally, whereas others are considerably more extensive (Fig. 71-2).[5] Generally, larger lesions are associated with more severe lameness. These lesions generally occur immediately proximal to, or at the level of, the fetlock joint. An abnormal amount of synovial fluid is found within the DFTS, and sometimes adhesions are identified.

In some horses, inspection of the medial or lateral border of the DDFT reveals loss of definition of the margin of the tendon and an area of reduced echogenicity, indicating major fiber disruption. These lesions are easy to diagnose. The marginal tears described subsequently (see page 647) are more difficult to detect.

Small lesions have resolved with rest and horses have returned to full athletic function. However, large lesions tend to persist, and ultrasonographic examination may reveal no change, even if the horse is rested for more than 1 year. Large lesions have been associated with recurrent lameness.[5] Intrathecal medication with hyaluronan, triamcinolone, or methylprednisolone acetate has resulted in only temporary relief. Desmotomy of the palmar (plantar) annular ligament has resulted in only temporary remission of clinical signs. The prognosis for return to full athletic function is guarded.

Fibrosis and Mineralization Within the Deep Digital Flexor Tendon

Some horses develop widespread hyperechogenic foci within the DDFT in the fetlock region. Some of these create shadowing artifacts and therefore represent mineralization (Fig. 71-3). The foci generally but not invariably reflect a chronic injury.[7] If extensive, they make evaluation of the remaining tendon architecture difficult because of accoustic shadowing. The cross-sectional area of the tendon usually is enlarged. Ill-defined hypoechogenic regions often extend proximally or distally from hyperechogenic foci or are remote from them. Fibrous adhesions may extend from the DDFT to the DFTS wall.

The cause of these hyperechogenic lesions is unknown, although some affected horses have a history of previous injections of corticosteroids into the DFTS. Most of the affected horses are middle-aged Warmblood-type horses used

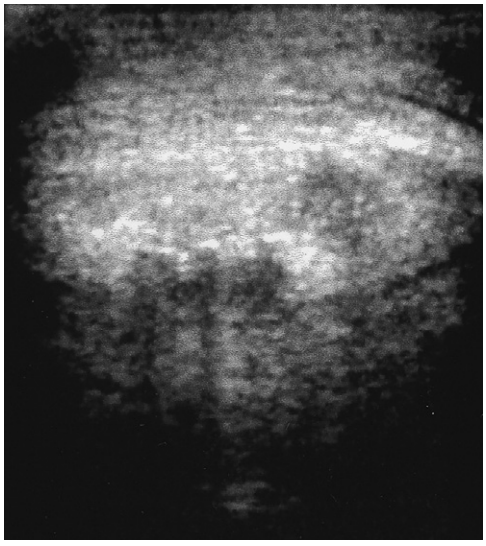

Fig. 71-3 Transverse ultrasonographic image of the distal metatarsal region of an 8-year-old event horse with chronic right hindlimb lameness associated with distention of the digital flexor tendon sheath. Medial is to the left. The deep digital flexor tendon is enlarged. Many hyperechogenic foci are within the deep digital flexor tendon, resulting in shadowing artifacts that make evaluating accurately the structure of the more dorsal aspects of the tendon impossible.

for show jumping or dressage. These lesions tend to result in persistent long-term lameness.

Marginal Tears of the Deep Digital Flexor Tendon

Marginal tears of the DDFT have been identified on the medial, lateral, and dorsal borders.[3,8] Lesions involving the lateral margin have been identified most commonly, varying in length (Fig. 71-4). Frequently the proximal extent of the tear is at the level of the manica flexoria. Some lesions extend as far distally as the proximal digital annular ligament. In some horses the lesion is a frontal plane split in the margin of the tendon; in other horses a sagittal tear of fibers occurs. Frontal plane splits in the DDFT may not be detectable by ultrasonography, although often a detectable enlargement of the cross-sectional area of the DDFT exists. The affected margin may be slightly less well defined compared with normal. Occasionally a torn echogenic strand is seen partially detached from the DDFT. Care must be taken not to confuse the synovial plicae on the medial and lateral borders of the tendon with a marginal tear.

Diagnosis is based on surgical exploration of the DFTS, which is indicated if a horse has pain associated with the DFTS along with abnormalities of the DDFT detected by ultrasonography, or no detectable changes, but a failure to respond to conservative management (see Chapter 75). Tenoscopic evaluation via a portal on the proximopalmar aspect of the pastern enables the most comprehensive view of the flexor tendons.[9] However, evaluating properly the DDFT underneath the manica flexoria may not be possible, unless the manica flexoria is transected. Treatment can be by debridement of the lesion, which can be done tenoscopically, or by debridement and suturing. The latter may be achieved most effectively by transection of the palmar (plantar) annular ligament (PAL) and opening the DFTS, followed by primary closure of the PAL. Four horses treated by tensocopic debridement became sound.[8] Five horses treated by debridement and suturing became sound, but five had persistent lameness.

Fig. 71-4 The lateral margin of the deep digital flexor tendon (DDFT) within the digital flexor tendon sheath in the distal metacarpal region, viewed tenoscopically. The deep digital flexor tendon has a marginal tear. Ultrasonographic examination revealed slight enlargement of the DDFT, but otherwise the tendon appeared structurally normal. (Courtesy I.M. Wright, Newmarket, England.)

However, some horses develop thickening of the PAL and or the proximal digital annular ligament post-operatively, together with subcutaneous fibrosis, which results in persistent lameness. Five of six horses used for dressage, show jumping, or horse trials treated by open surgery to repair defects in the margin of the DDFT had persistent lameness associated with this type of reaction.[10] Therefore tenoscopic debridement is the preferred method of management.

DEEP DIGITAL FLEXOR INJURIES IN THE PASTERN REGION

The DDFT within the pastern remains within the DFTS, over which lie the thin proximal and distal digital annular ligaments. The tendon is therefore relatively close to the skin surface and is therefore vulnerable to the effects of direct trauma and puncture wounds.

In the pastern region the DDFT is a bilobed structure, each lobe being similar in size and shape at any level. Care must be taken when evaluating the tendon by ultrasonography because off-incidence artifacts are created readily. These may be seen as central, round hypoechoic areas, which should not be confused as lesions.

Deep Digital Flexor Tendonitis

Deep digital flexor tendonitis in the pastern region is not a common cause of lameness and occurs less often than sprain of the oblique distal sesamoidean ligaments or strain of one of the branches of the SDFT (see Chapter 83). Tendonitis of the DDFT is seen most often in skeletally mature horses and occurs more often in forelimbs than in hindlimbs. Deep digital flexor tendonitis occurs in a variety of sports horses, but the incidence in racehorses is lower than in other performance horses.

Deep digital flexor tendonitis in the pastern usually results in acute-onset, unilateral, moderate to severe lameness that is

persistent. Less commonly lameness is only detectable after maximal exertion and has resolved with rest but has progressively deteriorated over 1 to 2 years.[3] Slight, firm soft tissue swelling may occur on the palmar midline of the pastern region. Often slight distention of the DFTS occurs in the pastern region, but an obvious windgall may not be apparent. Firm palpation on, or just to one side of, the palmar midline of the pastern region may cause pain. Lameness is often worse on a soft surface compared with a hard surface and generally is improved substantially by perineural analgesia of the palmar nerves at the level of the proximal sesamoid bones.

Diagnosis is based on ultrasonographic evaluation. Careful comparison of the size and shape of the contralateral DDFT is useful. The ease with which the tendon can be evaluated distally in the pastern depends on the conformation of the pastern and foot. Evaluation is more difficult in horses with a narrow heel and a deep cleft between each bulb. A lesion may involve just one lobe of the tendon or both and is usually characterized by enlargement and alteration in shape of the tendon, with or without hypoechoic regions within the tendon. The medial and lateral margins of the tendon should be carefully evaluated. In chronic injuries focal hyperechoic foci consistent with dystrophic mineralization may be seen. Occasionally a complex of injuries is identified involving not only the DDFT but also a distal sesamoidean ligament. All structures should be examined carefully and systematically. Lesions restricted to the DDFT, which have been recognized early, usually respond reasonably to prolonged rest (6 to 12 months), with progressive resolution of hypoechoic defects as assessed by ultrasonography. Some enlargement of the tendon may persist long term. Horses with more chronic injuries or complex injuries respond less favorably, with a high incidence of recurrent lameness.

Injury Caused by Blunt Trauma in the Pastern Region

Direct blunt trauma caused by, for example, a severe overreach can result in severe inflammation of the subcutaneous tissue, the digital annular ligaments, and sometimes also the DDFT. If the proximal or distal digital annular ligament becomes thickened and fibrosed, this can create undue pressure on the DDFT and chronic pain, without any structural abnormality of the DDFT. In the acute stage, generalized swelling occurs in the pastern region, and palpation elicits pain. Ultrasonographic examination is required to determine which structures have been damaged. This may need to be repeated as fibrotic reactions develop in the ensuing weeks. The prognosis is generally favorable unless the digital annular ligaments become substantially thickened or the palmar aspect of the DDFT is torn.

An overreach sometimes results in laceration of the skin and the palmar aspect of the DDFT. These lacerations may not coincide because of the mobile nature of the skin, and damage to the DDFT may be overlooked, unless the tendon is examined by ultrasonography. One or both branches of the SDFT may also be damaged, so all structures should be evaluated carefully and systematically. Such lesions often heal with extensive fibrotic reactions and adhesion formation to the DFTS, which may result in chronic lameness.

Puncture Wounds of the Deep Digital Flexor Tendon

Puncture wounds in the palmar (plantar) aspect of the pastern region, caused by sharp objects such as a flint, can cause sudden-onset, moderate to severe lameness and rapid development of effusion within the DFTS. Ultrasonographic examination can be used to determine whether the DDFT was penetrated. An anechoic defect may be seen in its palmar border. With prompt treatment by vigorous lavage of the DFTS combined with systemic broad-spectrum antimicrobial therapy, the outcome may be favorable. Ideally the DFTS and its contents should be inspected using an arthroscope to determine if any foreign material was embedded within the DDFT that might seriously compromise the outcome.

Rupture of the Deep Digital Flexor Tendon

Rupture of the DDFT in the pastern region or within the hoof capsule is usually a sequel to a previous neurectomy of the palmar digital nerves. Neurectomy is usually performed because of suspected navicular disease or to relieve chronic foot pain of unknown cause. Pre-existing lesions of the DDFT are likely to predispose to tendon rupture. I have never examined a horse with spontaneous rupture of the DDFT that did not have a history of neurectomy. Lameness may be insidious and progressive or sudden in onset, associated with extensive swelling in the pastern region. Thickening results from enlargement of the DDFT, peritendonous fibrosis, and in horses with long-term injuries, secondary superficial digital flexor tendonitis. Complete rupture results in the toe of the limb flipping up when the limb is bearing weight (Fig. 71-5). These clinical signs are pathognomonic. In such horses the proximal end of the DDFT may retract proximally, resulting in the SDFT becoming opposed to the fibrocartilaginous scutum on the palmar aspect of the pastern. Radiographically a variable degree of subluxation of the distal interphalangeal joint exists, depending on the degree of integrity of the DDFT. The prognosis is hopeless for athletic function. Extensive peritendonous fibrosis ultimately develops, providing adequate support to preserve life for breeding, assuming that the contralateral limb can withstand the strain in the interim.

Fig. 71-5 The distal part of the limb of a horse with rupture of the deep digital flexor tendon. The toe is flipped upward associated with subluxation of the distal interphalangeal joint. There is considerable thickening in the pastern region caused by peritendonous fibrosis.

LESIONS OF THE DEEP DIGITAL FLEXOR TENDON WITHIN THE HOOF CAPSULE

Lesions of the deep digital flexor tendon within the hoof capsule are discussed in Chapter 33.

LESIONS OF THE DEEP DIGITAL FLEXOR TENDON IN THE HOCK AND PROXIMAL METATARSAL REGIONS

Primary deep digital flexor tendonitis in the hock or proximal metatarsal region is an unusual cause of hindlimb lameness (see Chapter 77). Lesions in the proximal metatarsal region have been identified in young Thoroughbreds in race training, with lameness associated with mild swelling in the proximal plantar metatarsal region. Lameness was improved transiently by intra-articular analgesia of the tarsometatarsal joint in two horses, presumably because of local diffusion of local anesthetic solution.[11] Subtarsal analgesia of the plantar and plantar metatarsal nerves alleviated lameness in one horse. Ultrasonographic examination revealed enlargement of the DDFT in the proximal metatarsal region, poor definition of the margins, and diffuse hypoechoic areas within the tendon. Rest for 3 months has resulted in resolution of lameness, and the prognosis is favorable for return to racing.

Primary lesions of the DDFT in the hock region have been identified only in skeletally mature horses and are comparatively rare. Lameness is sudden in onset and moderate in degree. Mild distention of tarsal sheath may occur, but localizing signs may be absent. Lameness is improved by perineural analgesia of the tibial and fibular nerves, but it is unaffected by intra-articular analgesia of the hock joints. Diagnosis relies on ultrasonographic examination. The DDFT may be examined from the plantaromedial aspect of the hock within the tarsal sheath. The DDFT is a large oval-shaped structure with well-defined margins. The dorsolateral aspect of the tendon may appear slightly less echogenic than the remainder of the tendon, and care should be taken not to misinterpret this as a lesion. Careful comparison with the contralateral limb is essential. Abnormalities include enlargement of the tendon, poor demarcation of the borders, and hypoechoic areas (Fig. 71-6). Lesions may also be identified by tenoscopic examination of the tarsal sheath (see Chapters 24 and 77).

Lesions of the DDFT also have been identified in association with bony lesions of the sustentaculum tali of the fibular tarsal bone (calcaneus) and ectopic mineralization within the tarsal sheath.[12] These horses may have fibrillation of the DDFT and adhesion formation. These lesions generally are seen with obvious distention of the tarsal sheath and long-term lameness and probably occur secondary to primary pathological conditions of the bone. The sustentaculum tali should be evaluated radiographically using plantarolateral-dorsomedial oblique and flexed dorsoplantar views. The prognosis for athletic performance is poor with conservative or surgical management.

Dorsomedial luxation of the DDFT secondary to congenital malformation of the sustentaculum tali has been recognized in young Saddlebred horses and occasionally in Thoroughbreds.[3,13] Clinically the plantar aspect of the tarsal region appears broader than normal, with tarsus valgus. Lameness may not be obvious. Diagnosis is based on radiographic examination: the sustentaculum tali appears flattened in a dorsoplantar (flexed) view.[14] This may result in a mechanical lameness. Surgical treatment has been attempted, but the horse did not race.[15]

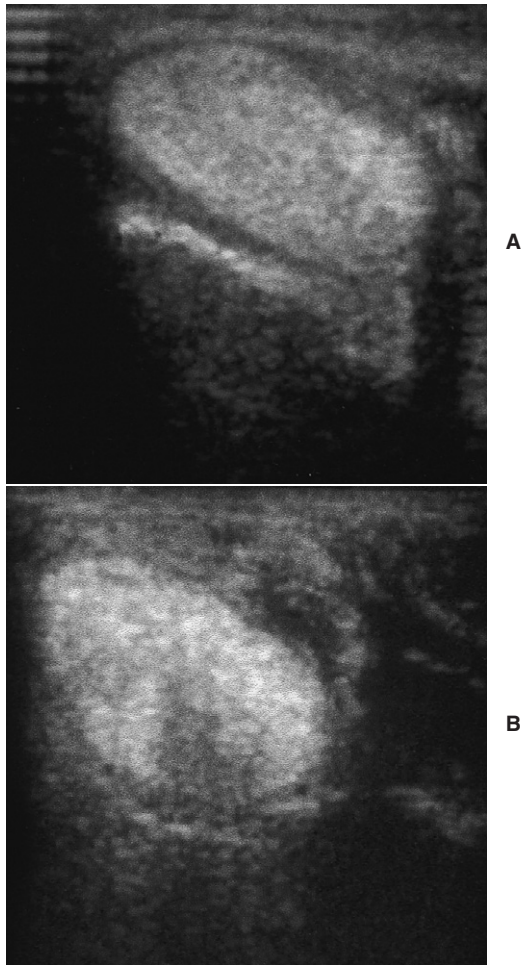

Fig. 71-6 **A,** Transverse ultrasonographic image of the plantaromedial aspect of the distal hock region of normal horse. Medial is to the left. **B,** Transverse ultrasonographic image of the plantaromedial aspect of the distal hock of a 7-year-old event horse with moderate lameness alleviated by tibial and fibular nerve blocks. No abnormalities were detected radiographically or scintigraphically. Medial is left. The deep digital flexor tendon has a large hypoechoic lesion dorsolaterally.

INFECTION OF THE DEEP DIGITAL FLEXOR TENDON

Infection of the deep digital flexor tendon is discussed in Chapter 38 (see page 373).

CHAPTER • 72

Desmitis of the Accessory Ligament of the Deep Digital Flexor Tendon

Sue J. Dyson

ANATOMY

In the forelimbs the accessory ligament of the deep digital flexor tendon (ALDDFT) is a substantial structure, similar in size to the deep digital flexor tendon (DDFT). The ALDDFT continues the common palmar ligament of the carpus.[1] Proximally the ALDDFT is broad and rectangular in cross-section; farther distally it becomes narrower and thicker and blends with the DDFT in the middle one third of the metacarpal region. Fibrous bundles run from the medial and lateral borders of the DDFT to the superficial digital flexor tendon (SDFT) in the proximal half of the metacarpal region, and these predispose the horse to develop adhesions between the ALDDFT in horses with severe superficial digital flexor tendonitis or severe desmitis of the ALDDFT. The ALDDFT forms the dorsal wall of the carpal canal, within which is the carpal synovial sheath, which is interspersed between the DDFT and its accessory ligament.

In the hindlimbs the size of the ALDDFT varies extremely, but it is generally smaller than in the forelimb and rarely more than half the thickness of the DDFT. The ligament is usually symmetrical in the left and right hindlimbs of an individual horse.

The ALDDFT has a low modulus of elasticity and a moderate strength to rupture, whereas the DDFT has a high modulus of elasticity and more than three times the strength to rupture. In the forelimb the ALDDFT is loaded during the late stance phase, during extension of the digital joints,[1] or when landing over a fence.[2] The ALDDFT prevents over-stretching of the DDFT by passively carrying the load during maximal extension of the distal interphalangeal and metacarpophalangeal joints. The ALDDFT also functions to facilitate carpal extension when the limb is loaded.[1] During flexion of the limb the ALDDFT is relaxed completely, and active muscle contraction results in the DDFT sliding proximally within the carpal sheath. The role of the ALDDFT in the hindlimb is less clear.

Desmitis of the ALDDFT usually occurs in forelimbs[3-6] but *occasionally* is recognized as a cause of hindlimb lameness.[3-7] Desmitis may occur alone[3,6] as an acute injury or develop secondarily to previous severe tendonitis of the SDFT. In the latter case the SDFT is enlarged substantially and wraps around the medial and lateral margins of the DDFT. Adhesions develop between adjacent structures. In horses with chronic, severe desmitis of the ALDDFT, additional injury may occur to the adjacent DDFT.[6,8] A flexural deformity of the metacarpophalangeal or metatarsophalangeal joint may develop after severe injury to the ALDDFT.[3,9] Occasionally a flexural deformity of the metatarsophalangeal joint develops in one or both hindlimbs without detectable lesions in the ALDDFT.[10] The cause of this condition is unknown, but the flexural deformity may be relieved by desmotomy of the ALDDFT, provided that contracture of peri-articular soft tissues has not already occurred.

PATHOGENESIS

Degenerative aging changes take place in the ALDDFT, and these may be a significant predisposing factor in the development of desmitis. The amount of fibrillar collagen and number of large collagen fibers in the ALDDFT decrease with increasing age.[11] In a study of mechanical properties of the ALDDFT in relationship to age, failure forces of the ALDDFT of older horses were significantly lower than those of the ALDDFT in younger horses.[12] Fibrillar ruptures developed in the ALDDFT of old horses at forces and strains that were approximately half

CHAPTER • 72

Desmitis of the Accessory Ligament of the Deep Digital Flexor Tendon

Sue J. Dyson

ANATOMY

In the forelimbs the accessory ligament of the deep digital flexor tendon (ALDDFT) is a substantial structure, similar in size to the deep digital flexor tendon (DDFT). The ALDDFT continues the common palmar ligament of the carpus.[1] Proximally the ALDDFT is broad and rectangular in cross-section; farther distally it becomes narrower and thicker and blends with the DDFT in the middle one third of the metacarpal region. Fibrous bundles run from the medial and lateral borders of the DDFT to the superficial digital flexor tendon (SDFT) in the proximal half of the metacarpal region, and these predispose the horse to develop adhesions between the ALDDFT in horses with severe superficial digital flexor tendonitis or severe desmitis of the ALDDFT. The ALDDFT forms the dorsal wall of the carpal canal, within which is the carpal synovial sheath, which is interspersed between the DDFT and its accessory ligament.

In the hindlimbs the size of the ALDDFT varies extremely, but it is generally smaller than in the forelimb and rarely more than half the thickness of the DDFT. The ligament is usually symmetrical in the left and right hindlimbs of an individual horse.

The ALDDFT has a low modulus of elasticity and a moderate strength to rupture, whereas the DDFT has a high modulus of elasticity and more than three times the strength to rupture. In the forelimb the ALDDFT is loaded during the late stance phase, during extension of the digital joints,[1] or when landing over a fence.[2] The ALDDFT prevents over-stretching of the DDFT by passively carrying the load during maximal extension of the distal interphalangeal and metacarpophalangeal joints. The ALDDFT also functions to facilitate carpal extension when the limb is loaded.[1] During flexion of the limb the ALDDFT is relaxed completely, and active muscle contraction results in the DDFT sliding proximally within the carpal sheath. The role of the ALDDFT in the hindlimb is less clear.

Desmitis of the ALDDFT usually occurs in forelimbs[3-6] but *occasionally* is recognized as a cause of hindlimb lameness.[3-7] Desmitis may occur alone[3,6] as an acute injury or develop secondarily to previous severe tendonitis of the SDFT. In the latter case the SDFT is enlarged substantially and wraps around the medial and lateral margins of the DDFT. Adhesions develop between adjacent structures. In horses with chronic, severe desmitis of the ALDDFT, additional injury may occur to the adjacent DDFT.[6,8] A flexural deformity of the metacarpophalangeal or metatarsophalangeal joint may develop after severe injury to the ALDDFT.[3,9] Occasionally a flexural deformity of the metatarsophalangeal joint develops in one or both hindlimbs without detectable lesions in the ALDDFT.[10] The cause of this condition is unknown, but the flexural deformity may be relieved by desmotomy of the ALDDFT, provided that contracture of peri-articular soft tissues has not already occurred.

PATHOGENESIS

Degenerative aging changes take place in the ALDDFT, and these may be a significant predisposing factor in the development of desmitis. The amount of fibrillar collagen and number of large collagen fibers in the ALDDFT decrease with increasing age.[11] In a study of mechanical properties of the ALDDFT in relationship to age, failure forces of the ALDDFT of older horses were significantly lower than those of the ALDDFT in younger horses.[12] Fibrillar ruptures developed in the ALDDFT of old horses at forces and strains that were approximately half

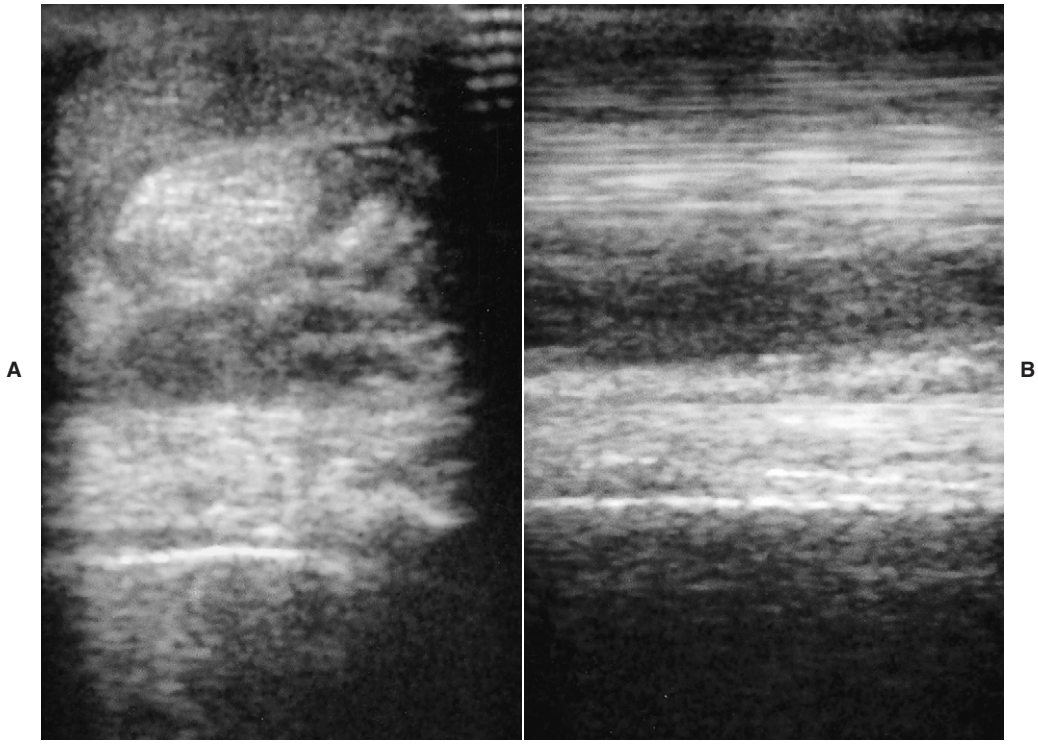

Fig. 72-1 **A,** Transverse ultrasonographic image of the palmar metacarpal soft tissue structures, 11 cm distal to the accessory carpal bone, of an 8-year-old Grand Prix show jumper. Medial is to the left. The accessory ligament of the deep digital flexor tendon is considerably enlarged and diffusely hypoechoic. **B,** Longitudinal ultrasonographic image of the palmar metacarpal sort tissues in zone 2A of the same horse as in **A.** Proximal is to the left. There is a diffuse reduction in echogenicity of the accessory ligament of the deep digital flexor tendon and poor fiber pattern.

those of the forces inducing total failure in young horses. It has been suggested that fibrillar rupture occurs at relatively low strains in older horses and that repetitive microtrauma may lead to clinical desmitis.[11]

The incidence of desmitis of the ALDDFT is rather different to other tendonous and ligamentous injuries. Injuries occur more often in horses older than 8 years of age.[3-5] The incidence in Thoroughbreds is comparatively low, and therefore this is an unusual injury in event horses or racehorses, except in older steeplechasers. Desmitis is a relatively common injury in ponies (see Chapter 127) and crossbred horses, including pleasure horses.[3,4] The incidence in Warmblood horses is also high.[5] Desmitis occurs in older show jumpers (see Chapter 116), especially Grand Prix level horses,[10] and also older dressage horses[10,13] and also sometimes occurs in young, extravagantly moving dressage horses (see Chapter 117). Desmitis is generally a unilateral forelimb injury (Fig. 72-1), although occasionally it occurs bilaterally, and is comparatively unusual in hindlimbs.

In hindlimbs, desmitis of the ALDDFT has been seen most frequently in cob-type breeds[10] and Quarter Horses or Quarter Horse crosses,[14] even in some horses or ponies of a comparatively young age, and does not appear to have been induced traumatically in all horses. In some of these horses the condition has been bilateral, developing simultaneously or sequentially in each hindlimb. Desmitis frequently has been associated with a tendency to stand with the fetlock of the affected limb partially flexed (Fig. 72-2), resulting in the development of a flexural deformity. The condition also has been recognized together with swelling on the plantar aspect of the pastern, associated with concurrent desmitis of the straight or oblique distal sesamoidean ligaments.[10]

HISTORY AND CLINICAL SIGNS

There is usually an acute-onset moderate to severe lameness during exercise.[3-5] A show jumper may pull up lame after jumping a large fence or after a water jump.[10] Swelling develops rapidly in the proximal one third of the metacarpal region, dorsal to the SDFT. Determining by palpation whether the DDFT or accessory ligament is enlarged can be difficult, but injuries of the DDFT in this area are unusual. Some horses develop desmitis secondary to previous superficial digital flexor tendonitis, and in these horses separating the margins of the SDFT from the ALDDFT often is difficult.

Clinical signs include swelling, heat, pain on palpation, and lameness. The horse may stand with slight elevation of the heel and flexion of the metacarpophalangeal joint. Some degree of swelling often persists, even after long-term convalescence. In horses with re-injury, new swelling may be only slight and careful palpation is required to identify a focus of pain.

Some horses with desmitis in the hindlimb may have similar clinical signs. However, some do not have an acute-onset lameness but show insidious enlargement and contracture of the ALDDFT, resulting in inability of the horse to place the heel of the affected limb(s) on the ground.

ULTRASONOGRAPHY

Diagnosis is confirmed by ultrasonography (see Fig. 72-1). The transducer should be focused initially at the depth of the ALDDFT, which should be examined in transverse and longitudinal planes. Comparative images of the contralateral limb

Fig. 72-2 **A,** A 6-year-old Fell pony with a flexural deformity of the left hind fetlock associated with chronic desmitis of the accessory ligament of the deep digital flexor tendon. The pony was unable to place the heel of the left hind foot on the ground. Even when the pony was heavily sedated, extending the left hind fetlock was not possible. Firm enlargement on the plantar aspect of the pastern associated with desmitis of the straight distal sesamoidean ligament was also apparent. Similar abnormalities had developed in the right hindlimb approximately 12 months previously. **B,** Transverse ultrasonographic image of the plantar metatarsal soft tissues approximately 10 cm distal to the tarsometatarsal joint. Medial is to the left. The accessory ligament of the deep digital flexor tendon is enlarged considerably, and there is a large anechoic lesion medially.

also should be obtained. If the transducer has a built-in standoff this may create artifacts at the level of the ALDDFT.

The ALDDFT is normally the most echogenic of the palmar metacarpal (plantar metatarsal) soft tissue structures, and its borders are well defined. In some ponies the ALDDFT is less echogenic than the DDFT and suspensory ligament.

With injury, the ALDDFT invariably is enlarged and tends to expand around the borders of the DDFT, especially laterally. With severe injuries, it may be necessary to move the transducer medially and laterally to evaluate properly the margins of the ligament. Often definition of the borders of the ligament is lost, with a diffuse reduction in echogenicity of the ligament, sometimes with anechoic areas. Occasionally a large proportion of the ligament is anechogenic. Central core lesions are comparatively rare. The dorsal border of the DDFT should be inspected carefully for evidence of concurrent injury, especially in horses with recurrent injury. In horses in which injury has been sustained secondary to previous superficial digital flexor tendonitis or in which desmitis of the ALDDFT is recurrent, the SDFT also should be evaluated for evidence of simultaneous recurrent injury or recent injury. The transducer should be focused on the SDFT, using a standoff. Adhesions between the ALDDFT and adjacent structures may be best identified in longitudinal images obtained with the limb not bearing weight. With passive flexion and extension of the fetlock it should be possible to see independent movement of the SDFT, DDFT, and ALDDFT, provided that no significant adhesion formation has occurred.

In horses with chronic desmitis, when substantial enlargement of the ALDDFT occurs, with or without enlargement of the SDFT, the cross-sectional area of the DDFT often is reduced significantly.[10]

In those horses that initially had an enlarged ALDDFT and inability to load the heel of the affected limb, the ALDDFT usually is enlarged massively, with poorly demarcated borders, and is diffusely hypoechogenic. Other structures in the metacarpal or metatarsal regions and pastern should be examined, because lesions have been identified simultaneously in the SDFT[14] and the distal sesamoidean ligaments.[10]

TREATMENT

In horses with acute, first-time primary injuries of the ALDDFT conservative treatment is usually satisfactory, but the prognosis is more guarded for longer-term injuries when the horse has continued to exercise. The horse should be restricted to box rest and controlled walking exercise for a minimum of 3 months and then should be re-evaluated ultrasonographically. Non-steroidal anti-inflammatory drugs should be given if the horse will not load the limb normally at rest to avoid development of a secondary flexural deformity of the metacarpophalangeal joint. Any foot imbalance should be corrected.

Improvement in echogenicity generally is seen more quickly than in comparable injuries of the SDFT. Box rest and

controlled walking exercise should continue until the ligament is of similar echogenicity to the DDFT in transverse and longitudinal images. Progress should be monitored monthly after the first re-evaluation 3 months after injury.

Horses that are allowed uncontrolled turnout in the initial 3-month period tend to have persistent clinical signs, and lesions persist ultrasonographically.

Treatment with β-aminoproprionitrile fumarate could be considered, especially in horses suffering a recurrent injury; however, no published reports of its efficacy in treating this condition are available, although successful results have been achieved.[15]

Differences in the reported success of conservative treatment have been significant.[3-5] A number of factors, including the chronicity of the injury when therapy was first instituted and the type of horse, probably account for this disparity in success. Dyson[3] reported complete functional recovery in 76% of 27 horses and ponies, whereas McDiarmid[4] reported only 43% success, and Van den Belt, Becker, and Dik[5] reported only 18%. Most of the horses in the series of Van den Belt, Becker, and Dik were large Warmbloods, whereas Dyson's series[3] included a large number of ponies. In my experience early recognition and aggressive treatment are key factors to a successful outcome.

In horses with chronic, recurrent desmitis, in horses with evidence of adhesions between the ALDDFT and the SDFT, or in those that tend to stand with the fetlock flexed, surgical treatment by desmotomy of the ALDDFT may be indicated.[3,6] The treated ligament heals by scar tissue that is inferior in strength to normal ligament, but the ligament will be longer, and this may reduce the strain on it[16] and thus reduce the risks of re-injury. Experimental removal of a full-thickness piece of the ALDDFT of 1 cm length resulted in long-term repair by scar tissue, in which orientation of the collagen was random. The healed ligaments were 1 cm longer than control ligaments and enlarged in cross-sectional area. The functional characteristics, force, and elongation at failure reached 80% of control values.[17]

The number of published long-term follow-up results for treatment of chronic desmitis of the ALDDFT by desmotomy is limited. In my experience desmotomy has been successful in horses with chronic desmitis of the ALDDFT alone, but in those with concurrent superficial digital flexor tendonitis, or a flexural deformity of the metacarpophalangeal joint that cannot be corrected passively, the results have been disappointing. Horses with concurrent superficial digital flexor tendonitis have been relieved of evidence of resting pain, but restoring these horses to full athletic function has not been possible.

The prognosis depends on the chronicity of the injury and evidence of any concurrent injury to the DDFT or SDFT. Horses with acute injuries have a better prognosis than those with chronic injuries. Horses with recurrent injuries have a more guarded prognosis, especially if lesions are identified in the DDFT. Horses with lesions of the ALDDFT that have developed secondary to superficial digital flexor tendonitis have the most guarded prognosis, especially if any evidence of flexural deformity exists.

CHAPTER • 73

The Suspensory Apparatus

Sue J. Dyson and Ronald L. Genovese

ANATOMY AND PATHOPHYSIOLOGY

The suspensory ligament (SL) is correctly called the third interosseous muscle, but it is referred to as the SL throughout this text. The anatomy in the forelimbs and hindlimbs is similar and separate mention of the hindlimb is only made when substantial differences exist.

The SL can be divided into three separate regions that are subject to injury: the proximal part, the body, and the branches. For clinical purposes, in the forelimb the proximal part extends from 4 to 12 cm distal to the accessory carpal bone, and in the hindlimb, from 2 to 10 cm distal to the tarsometatarsal joint. The distal sesamoidean ligaments are considered individually.

In the forelimb the SL originates from two heads that rapidly fuse. In the hindlimb this division is less obvious. The SL contains a variable amount of muscular tissue (2% to 11%), which tends to be bilaterally symmetrical.[1] In the forelimb the SL originates from the palmar carpal ligament and the proximal aspect of the third metacarpal bone (McIII), whereas in the hindlimb it originates principally from the proximoplantar aspect of the third metatarsal bone (MtIII). The SL in the forelimb is approximately rectangular in cross-section, but it is more rounded in the hindlimb.

The body of the SL descends between the second (McII, MtII) and fourth (McIV, MtIV) metacarpal (metatarsal) bones and divides into two branches at a variable site in the mid-metacarpal (metatarsal) region. The level of division is usually bilaterally symmetrical. Each branch inserts on the abaxial surface of the corresponding proximal sesamoid bone (PSB). Each branch detaches a thin extensor branch dorsodistally that courses obliquely across the pastern to join the dorsal digital extensor tendon just above the proximal interphalangeal joint. Each extensor branch also blends with the corresponding collateral sesamoidean ligament.

The distal sesamoidean ligaments are the functional continuation of the SL in the digit and comprise the straight sesamoidean ligament, oblique sesamoidean ligaments, cruciate sesamoidean ligaments, and short sesamoidean ligaments. All attach proximally to the base of the PSBs and the proximal scutum. The straight sesamoidean ligament is a flat trapezoid-shaped band that inserts via the scutum medium onto the proximal aspect of the middle phalanx. The oblique sesamoidean ligaments are triangular-shaped structures that converge to insert on the palmar aspect of the proximal phalanx. The cruciate sesamoidean ligaments form the palmar wall of the distal palmar synovial recess of the metacarpophalangeal joint. They consist of two thin layers of tissue that cross each other and insert on the proximal palmar tuberosities of the proximal phalanx. The short sesamoidean ligaments insert on the proximal palmar aspect of the proximal phalanx and are difficult to separate from the dorsal aspect of the oblique sesamoidean ligaments.

The palmar ligament of the fetlock, also referred to as the intersesamoidean ligament, is a thick collagen structure that completely covers the palmar and axial surfaces of the PSBs and is strongly attached to them. Together with the PSBs, the palmar ligament forms the proximal scutum. The concave palmar surface of the proximal scutum provides a smooth surface over which the digital flexor tendons glide.

In the forelimb the SL is innervated by the palmar metacarpal nerves, derived from the lateral palmar nerve, which receives fibers from the ulnar and median nerves.[2] The hindlimb SL is innervated by the plantar metatarsal nerves, branches from the deep branch of the lateral plantar nerve, which is derived from the tibial nerve. The proximal SL is closely related to the palmar outpouching of the carpometacarpal joint in the forelimb[3] and the plantar outpouching of the tarsometatarsal joint in the hindlimb.[4]

The principal function of the SL is to prevent excessive extension of the fetlock joint.[5] During weight bearing the relative tension in the SL and flexor tendons regulates the stresses applied to different aspects of the McIII bone. When a limb is fully load bearing, the distal part of the SL branches is apposed closely to the abaxial aspects of the metacarpal condyles and then moves to the palmar aspect as the fetlock drops. During hyperextension, the PSBs move distally and dorsally, so the branches of the SL act as articular surfaces to balance the position of the McIII bone. If the limb is loaded asymmetrically, so that torque is on the fetlock, the SL branches contribute to joint stability on the side opposite compression of the joint.

Some evidence exists that training increases the strength of the SL; the mean absolute load to failure in a single load-to-failure compression test was significantly higher in horses that had been in racehorse training compared with those that had been confined to box or paddock rest.[6] In the trained group failure was most likely to be by fracture of a PSB, whereas in the untrained group the SL failed. However, when six 2-year-old Thoroughbred (TB) fillies underwent an 18-month controlled exercise program including galloping and were compared with six fillies that were restricted to walking exercise, no differences in the collagen fibril mass-average diameter in the body of the SL were found.[7] Mass-average diameter is correlated with ligament strength.

PROXIMAL SUSPENSORY DESMITIS IN THE FORELIMB

Proximal suspensory desmitis (PSD) is a common injury in the forelimbs[8-12] of athletic horses and may occur unilaterally or bilaterally. Some confusion has occurred about what constitutes PSD, and many clinicians have used this term for lameness that is worse with the affected limb on the outside of a circle and that is alleviated by analgesia of the proximal palmar metacarpal region but in which radiographic and ultrasonographic findings have been negative. In our experience this case scenario is relatively unusual. Ultrasonographic abnormalities of the proximal SL are usually detectable, and the absence of detectable structural abnormality should alert the veterinarian to search for an alternative diagnosis.

PSD results in sudden onset lameness, which can be remarkably transient, resolving within 24 hours unless the horse is worked hard. In horses with more chronic desmitis, lameness may be persistent. Lameness varies from mild to moderate and is rarely severe, unless the lesion is extensive. Lameness in Standardbred (STB) racehorses may be apparent only at high speeds. Bilateral PSD may result in loss of action rather than overt lameness, which occurs more commonly in flat racehorses, probably because of failure to recognize earlier, subtle unilateral lameness. Lameness is usually worse on soft ground, especially with the affected limb on the outside of a circle, and when subtle may be more easily felt by a rider than seen by an observer. Lameness may not be apparent at the working trot but may be detectable at the medium or extended trot. Recognition of these features in the history may be important, because acute lameness often resolves rapidly, and working the horse hard to reproduce lameness, with the inherent risk of worsening the injury, may be undesirable. Lameness is often transiently accentuated by distal limb flexion.

In the acute phase slight edema in the proximal metacarpal region, localized heat, and distention of the medial palmar vein may occur, but these features may be transient or absent. Pressure applied to the SL against the palmar aspect of the McIII bone or forced extension and protraction of the limb may elicit pain.

The feet should be evaluated carefully, because frequently foot imbalance is a predisposing factor. Back-at-the-knee and tied-in below the knee conformation also may be predisposing factors.

PSD is a common compensatory injury; therefore the whole horse should be evaluated to ensure that other causes of lameness are not missed.

Diagnostic Analgesic Techniques

If PSD is suspected, perineural analgesia of the lateral palmar nerve[3] (2 ml mepivacaine) or the medial and lateral palmar metacarpal nerves (2 ml per site) is indicated (see Chapter 10). This should result in substantial improvement in. or alleviation of, lameness within 10 minutes, assuming PSD is the only cause of lameness. However, neither technique is necessarily specific. Blockade of the lateral palmar nerve also has the potential to alleviate pain associated with a lateral source of pain in the more distal limb (e.g., a splint). The risks of influencing middle carpal joint pain are less than using the subcarpal approach, but local anesthetic solution may diffuse and improve lameness associated with the middle carpal joint[13] or with the carpal canal. Perineural analgesia of the palmar metacarpal nerves may alleviate pain associated with the middle carpal or carpometacarpal joints because of local diffusion or inadvertent deposition of local anesthetic solution into the distopalmar outpouchings of the carpometacarpal joint capsule. A false-negative result may be achieved because of inadvertent injection into the carpal sheath or failure of the local anesthetic solution to diffuse proximally to the most proximal extent of a lesion. Although the SL receives innervation from fibers from the median and ulnar nerves, perineural analgesia of the ulnar nerve usually resolves or substantially improves lameness associated with PSD.

Intra-articular analgesia of the middle carpal joint may result in partial improvement or complete alleviation of pain associated with the proximal suspensory ligament in some horses (15 [65%] of 25 horses).[13] Using a dorsal approach to the middle carpal joint rather than a palmarolateral approach should theoretically reduce the risks of diffusion of local anesthetic solution to the proximal SL and palmar metacarpal nerves; however, in practice the difference seems minor. Comparison of the relative responses to middle carpal joint analgesia (6 ml mepivacaine; assessed 10 minutes after injection) and perineural analgesia of the lateral palmar nerve or the palmar metacarpal nerves is potentially useful but can be highly misleading. Generally a horse with lameness caused by PSD responds better to perineural analgesia than intra-articular analgesia, but this is not universal. Similarly primary middle carpal joint pain usually is improved best by intra-articular analgesia, but this is not always the case. Middle carpal joint pain and PSD may occur concurrently, especially in STB racehorses. The clinician should evaluate the response to these diagnostic analgesic techniques in the light of the following:

- The use of the horse and thus the likelihood of the site of injury, and other clinical signs
- Other clinical signs: for example, distention of the middle carpal joint capsule and pain on passive manipulation of the carpus
- The degree and character of the lameness

Perineural analgesia of the palmar nerves at the level of the base of the proximal sesamoid bones often results in lameness because of PSD appearing worse. Perineural analgesia of the palmar nerves (at mid-metacarpal level) and palmar metacarpal nerves (distal to the button of McII and McIV) (four-point or low palmar block) often results in some improvement in pain associated with PSD, presumably because of proximal diffusion of local anesthetic solution via lymphatic vessels or along fascial planes.

More than one source of pain may be contributing to lameness. PSD and concurrent foot pain occur commonly. Hindlimb lameness also may be concurrent, especially in the contralateral hindlimb, so it is important to assess and to re-evaluate the whole horse.

Differential Diagnosis

PSD should be differentiated from middle carpal joint pain, being aware that especially in young TB racehorses and STB racehorses lesions may occur in both locations simultaneously. Osteoarthritis of the carpometacarpal joint occasionally occurs (see page 368). Pain associated with palmar cortical fatigue fractures or stress reactions of McIII[11,14-16] responds similarly to diagnostic analgesic techniques; however, lameness tends to be more severe and worse on firm ground and often deteriorates the farther the horse trots (see page 364). Avulsion fractures of McIII at the origin of the SL (see page 367) occur less frequently and tend to be associated with more persistent and severe lameness.[1,17] Pain associated with the carpal sheath or carpal retinaculum also should be considered (see Chapter 76). Perineural analgesia of the deep branch of the lateral palmar nerve or the palmar metacarpal nerves alone should not alleviate pain associated with the deep digital flexor tendon (DDFT) or its accessory ligament (ALDDFT), the superficial digital flexor tendon (SDFT), or the fetlock region, without simultaneous blockade of the palmar nerves.

Diagnostic Ultrasonography

Diagnostic ultrasonography is essential for accurate diagnosis of PSD. The limb should be evaluated in transverse and longitudinal planes, and careful comparison should be made with the contralateral limb. High-quality images are required, because lesions can be subtle and easily missed if the gain controls are too high or if the transducer is not focused on the SL. Artifacts are readily created if the transducer is not in complete contact with the limb. The contours of the proximal palmar aspect of the metacarpal region can make obtaining longitudinal images difficult, especially because the proximal palmar aspect of the McIII bone slopes backward. Therefore creating hypoechoic artifacts at the enthesis of the SL on the McIII bone is easy. Cross-sectional area measurements may be extremely valuable, especially in horses with acute PSD, because enlargement of the ligament may be the only detectable ultrasonographic abnormality. Bear in mind that muscular tissue appears less echogenic than does ligamentous

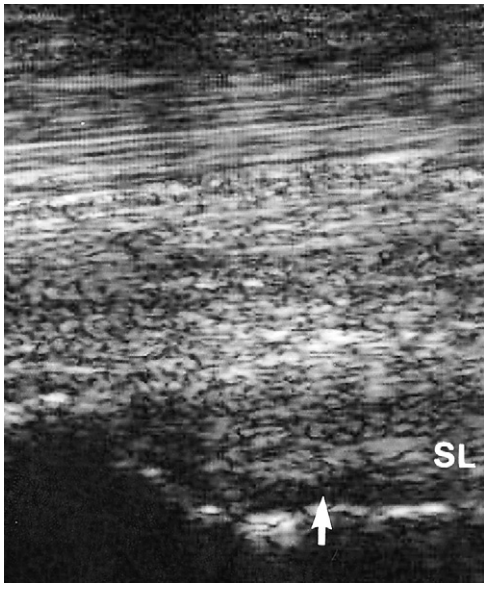

Fig. 73-1 Longitudinal (proximal is to the left) images of the proximal metacarpal region. The thin echogenic band from the suspensory ligament (*SL*) passes proximally from the enthesis of the suspensory ligament on the third metacarpal bone to blend with the palmar fascia. Dorsal to the suspensory ligament is anechoic fluid within the palmar recess of the carpometacarpal joint capsule (*arrow*).

tissue and that proximally the SL originates in two halves. Previous injuries to the SL may not resolve fully to restore normal, uniform echogenicity. Be aware that poor diagnostic analgesic technique may result in aspiration of air, which creates artifacts. A thin band of the SL passes proximally from the enthesis on the McIII bone to blend with the palmar carpal fascia. The anechoic space seen dorsal to the SL at this level is fluid in the palmar recess of the carpometacarpal joint and should not be confused as a lesion (Fig. 73-1).

Abnormalities associated with PSD include the following[18] (Figs. 73-2 and 73-3):

- Enlargement of the cross-sectional area. This may result in reduction of space between the SL and the palmar cortex of the McIII bone or reduced space between the SL and ALDDFT.
- Poor demarcation of the margins of the SL, especially the dorsal margin
- Focal or diffuse areas of reduced echogenicity. These may extend less than 1 cm proximodistally and occupy from less than 10% to up to the entire cross-sectional area of the ligament.
- Focal anechoic core lesions
- Reduced strength of fiber pattern
- Focal mineralization (rare in acute injuries)
- Mild increased echogenicity of the entire SL in long-term, chronic injuries

In a horse with bilateral PSD an obvious lesion may be detectable in the lamer limb, but abnormalities may be much more subtle and occasionally not apparent in the less lame limb. In a 3-year-old TB that sustains PSD at 2 years of age, mild lameness may be recurrent, and discerning any structural abnormality other than enlargement of the SL may not be possible.

The degree of ultrasonographic abnormality (cross-sectional area involved and proximodistal extent of the lesion) usually reflects the severity of the lameness. In horses with acute PSD the ultrasonographic abnormalities may be subtle, although if lameness is unilateral, slight enlargement of cross-sectional area may be detectable. Care should be taken to compare measurements in the contralateral limb at the same distance distal to the accessory carpal bone. Ultrasonographic abnormalities may deteriorate over the next 10 to 14 days, and re-evaluation may be useful to confirm the diagnosis.

In horses with an avulsion fracture of the McIII bone at the origin of the SL, the fracture fragment is usually readily identifiable and generally is associated with only a focal lesion in the SL itself, usually restricted to the dorsal aspect (see page 367).

Radiography

Usually no detectable radiographic abnormalities of the McIII bone occur in horses with acute PSD. With chronic PSD, increased opacity of the proximal aspect of the McIII bone may be seen in dorsopalmar views. This sclerosis should be differentiated from that associated with a palmar cortical fatigue fracture,[19] which is invariably medial. In a lateromedial projection subcortical sclerosis in the proximal palmar aspect of the McIII bone may be apparent. These secondary bony changes in a forelimb are associated with a more guarded prognosis.

Nuclear Scintigraphy

Reports in the literature about the usefulness of nuclear scintigraphy for diagnosing PSD are confusing because of failure to correlate scintigraphic findings with ultrasonographic and radiographic findings and because avulsion fractures of the McIII bone are not considered separately.[20,21] Nuclear scintigraphy is generally unnecessary for diagnosing PSD, provided that good-quality ultrasonographic images are obtained, but may give additional information about associated bone turnover at the insertion of the SL. Pool- and bone-phase images may be negative. Abnormal radiopharmaceutical uptake in the pool phase may actually reflect early bone uptake. Increased uptake of ^{99m}Tc–methylene diphosphonate was identified in the proximal palmar metacarpal region in 55% of pool-phase images and 44% of bone-phase images in 25 horses with ultrasonographic evidence of PSD.[22] Therefore negative scintigraphic images do not preclude the presence of PSD. Radiopharmaceutical uptake associated with either an avulsion fracture of the McIII bone at the insertion of the SL or a stress fracture is likely to be more intense. Abnormal radiopharmaceutical uptake in the bone phase, seen in the absence of ultrasonographic and radiographic abnormalities, is more likely to reflect a primary pathological condition of bone.

Treatment

Most horses with acute forelimb PSD respond well to box rest and controlled walking exercise for 3 months. Attention to correct foot balance is important. A premature resumption of work usually results in recurrent injury. Approximately 90% of horses resume full athletic function without recurrent injury.[1] Horses with chronic PSD may require more prolonged rehabilitation, and in a small proportion lameness is persistent. Some TB racehorses with chronic lesions have been able to be maintained in training with judicious use of phenylbutazone, without significant deterioration of the lesion. No fatalities associated with PSD occurred in 630 TB racehorses examined post mortem because of musculoskeletal injuries.[23] Some STB racehorses with acute lesions have been managed by slightly reducing the training schedule, local injections of corticosteroids and hyaluronan, symptomatic anti-inflammatory therapy (local icing, liniments such as dimethylsulfoxide [DMSO] and corticosteroid paints, and phenylbutazone as necessary), and shortening the toes and increasing hoof angle. Although a few treated horses were able to race successfully, prognosis after rest was better.[24]

Extracorporeal shock wave treatment (three treatments at 2-week intervals) has been successful in some horses with

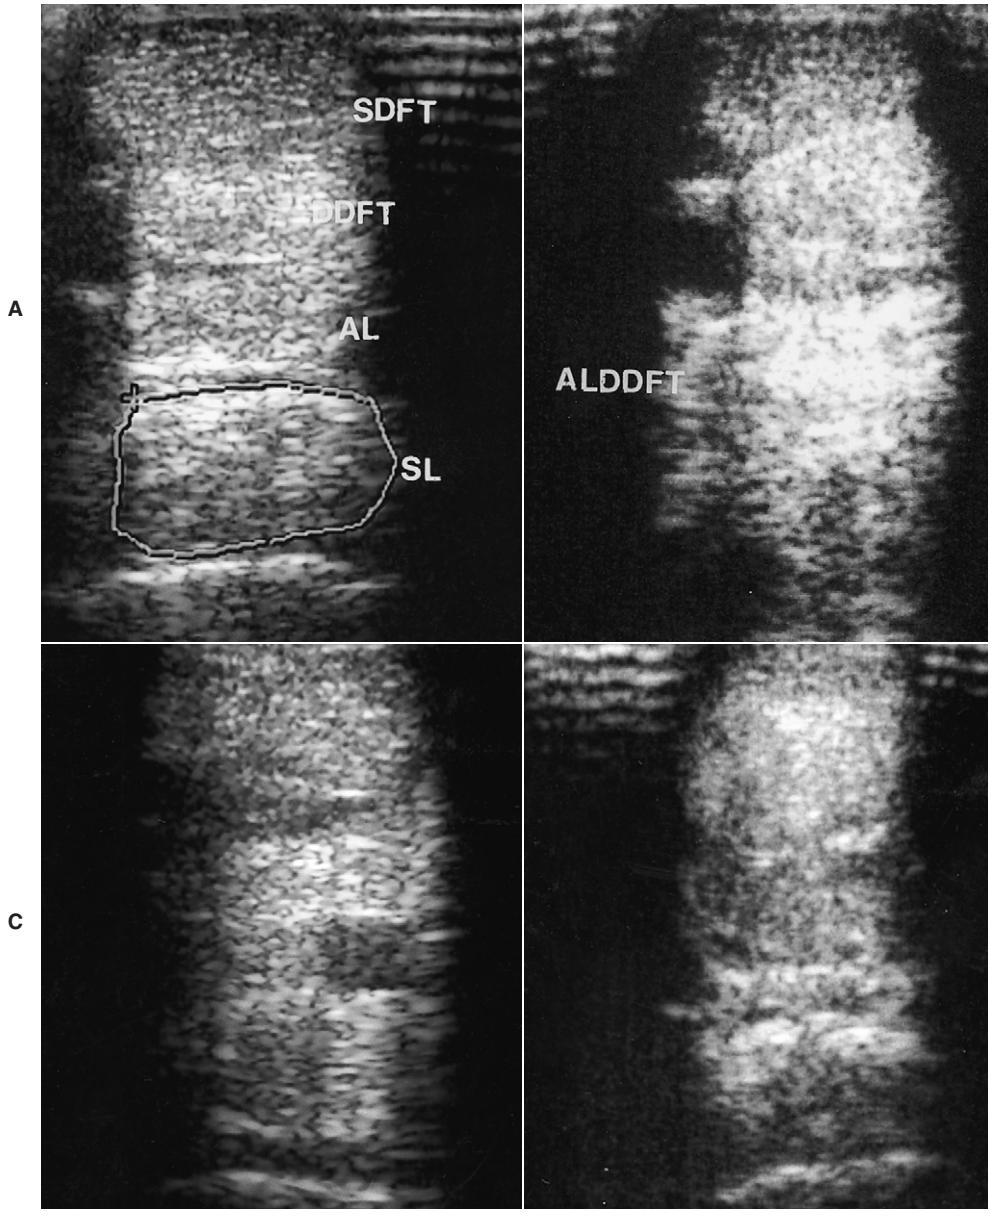

Fig. 73-2 **A,** Transverse ultrasonographic image of the metacarpal region of 3-year-old Thoroughbred, with mild forelimb lameness, at 9 cm distal to the accessory carpal bone. The suspensory ligament (*SL*) shows a slight overall reduction in echogenicity compatible with proximal suspensory desmitis. The ligament is enlarged (cross-sectional area 1.39 cm^2 compared with 1.25 cm^2 in the contralateral limb). The lesion extended less than 1 cm proximodistally. **B,** Transverse ultrasonographic image of the metacarpal region at 8 cm distal to the accessory carpal bone of the right forelimb of 7-year-old medium-level dressage horse. The entire cross-sectional area of the suspensory ligament is reduced in echogenicity. The lesion extended 1.5 cm proximodistally. Note also the hyperechoic appearance of the accessory ligament of the deep digital flexor tendon (*ALDDFT*). **C,** Transverse ultrasonographic image of the proximal metacarpal region of 6-year-old event horse with acute onset right forelimb lameness. There is a hypoechoic lesion in the medial aspect of the suspensory ligament that extends less than 1 cm proximodistally. Medial is left. **D,** Transverse ultrasonographic image of the right forelimb of 7-year-old dressage horse with bilateral forelimb lameness. The palmar aspect of the suspensory ligament is slightly increased in echogenicity, but the dorsal aspect is diffusely hypoechoic.

chronic lesions that had failed to respond to conservative management.[25] Ten (50%) of 20 horses with chronic forelimb PSD with lameness of greater than 3 weeks' duration were in full work 6 months after treatment.[26] Local infiltration with 4 to 6 ml of 2% iodine in almond oil also has been used successfully.[8]

In some horses the lesions disappear completely ultrasonographically. In others echogenicity may increase, but uniform echogenicity is never restored. Rest should be continued until the ultrasonographic appearance remains stable.

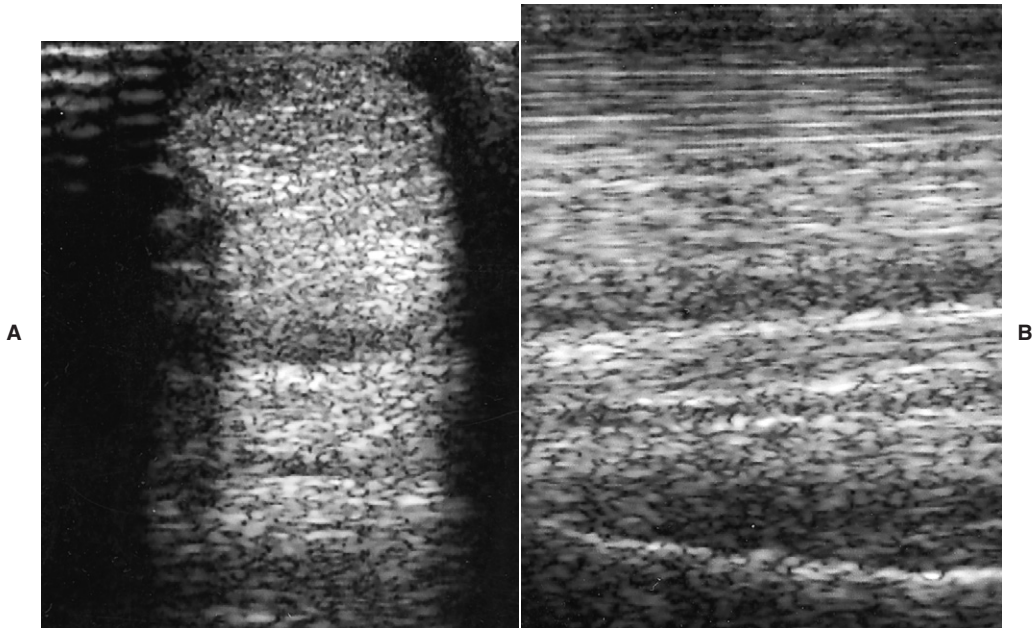

Fig. 73-3 **A,** Transverse ultrasonographic image of the proximal metacarpal region at 8 cm distal to the accessory carpal bone of the left forelimb of a Grand Prix show jumper. The horse had developed acute severe lameness immediately after completing a jumping round 2 weeks previously. The dorsal half of the suspensory ligament is diffusely hypoechoic. **B,** Longitudinal ultrasonographic image of the proximal metacarpal region of the same horse. Proximal is to the left. The dorsal aspect of the suspensory ligament is diffusely hypoechoic.

PROXIMAL SUSPENSORY DESMITIS IN THE HINDLIMB

PSD in the hindlimb results in either an insidious or a sudden onset lameness that may be mild or severe. Some horses show poor performance rather than a recognized lameness. In contrast to the forelimb, lameness may persist and remain severe, despite restriction to box rest. Such persistence probably is caused by a compartment-like syndrome and pressure on the adjacent plantar metatarsal nerves.[18] In view of the chronicity of some lesions when first identified and the finding of secondary radiological changes in sound horses, some lesions likely exist subclinically or are associated with a low-grade lameness that goes unrecognized. The incidence of bilateral lesions is higher than in forelimbs.

PSD in the hindlimb occurs in horses in all athletic disciplines and of all ages and is a particular problem in dressage horses working at advanced level. Horses with straight hock conformation or hyperextension of the metatarsophalangeal joint appear predisposed to injury (Fig. 73-4). Such conformational abnormalities were identified in 9 (21%) of 42 horses with hindlimb PSD but in only 4 (8%) of 50 horses examined consecutively with hindlimb lameness unrelated to the suspensory apparatus.[27] Hyperextension of the metatarsophalangeal joint may develop as a sequel to PSD. A long-toe and low-heel conformation also may be a predisposing factor, especially if associated with abnormal orientation of the distal phalanx, with the plantar aspect lower than the toe.[22]

PSD in the hindlimb in a STB racehorse is common and usually results in an abnormal gait at high speeds, which may or may not be apparent at the trot. Unilateral left hindlimb lameness may present as the horse drifting to the right shaft and being on the right line.

Horses with acute hindlimb PSD may have localized heat and swelling and pain on pressure applied to the SL, but frequently no localizing clinical features are apparent.

Lameness is often characterized by a reduced height of arc of foot flight, with or without intermittent catching of the toe. The cranial phase of the stride may be shortened. Lameness may be accentuated by proximal or distal limb flexion. Bilateral lesions may result in poor hindlimb action rather than obvious hindlimb lameness. Lameness may be more obvious on a circle on the lunge, but unlike forelimb PSD the lameness is not necessarily worse with the lamer limb on the outside. Like many horses with hindlimb lameness, lameness is often more obvious when the horse is ridden, especially when the rider sits on the diagonal of the lame or lamer limb.

Diagnostic Analgesic Techniques

Perineural analgesia of the plantar nerves (mid-metatarsal level) and plantar metatarsal nerves may result in slight improvement in lameness because of proximal diffusion of the local anesthetic solution. Lameness usually is improved substantially by perineural analgesia of the medial and lateral plantar metatarsal nerves (2 ml of mepivacaine 2% per site) or the deep branch of the lateral plantar nerve distal to the tarsus, but lameness may not be alleviated fully. Improvement is usually seen within 10 minutes of injection. Depositing the local anesthetic solution as proximal as ideal may be difficult because of the shape of the MtIV bone. This may result in only partial improvement in lameness. False-negative results also may be obtained because of inadvertent injection into the tarsal sheath or the tarsometatarsal joint capsule. Subtarsal analgesia can influence tarsometatarsal joint pain, and occasionally (2 [8%] of 24 horses[28]) intra-articular analgesia of the tarsometatarsal joint alleviates pain associated with PSD. Perineural analgesia of the tibial nerve alone alleviates pain associated with PSD without significantly influencing tarsal pain. However, the tibial nerve is large; therefore 20 minutes may pass before analgesia is achieved effectively. Occasionally PSD occurs together with pain associated with osteoarthritis of the tarsometatarsal joint.

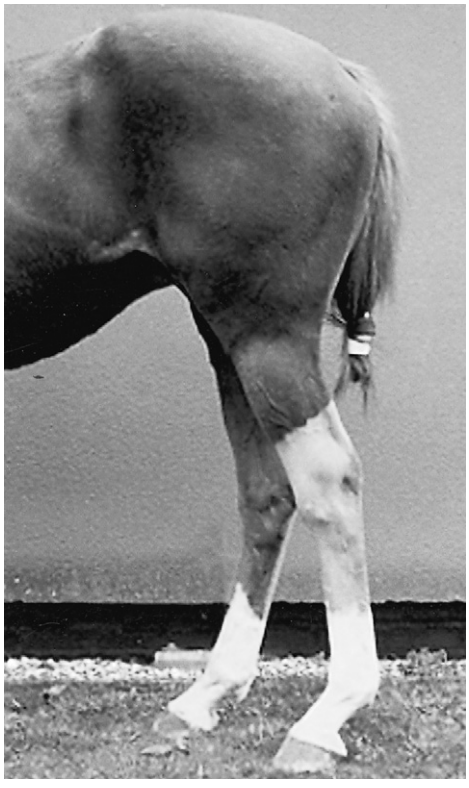

Fig. 73-4 The hindlimbs of 7-year-old show jumper with proximal suspensory desmitis of the left hindlimb. Note the relatively straight hock conformation and the sloping pasterns associated with hyperextension of the hind fetlocks. The horse also had a false thoroughpin on the left hindlimb that did not contribute to lameness.

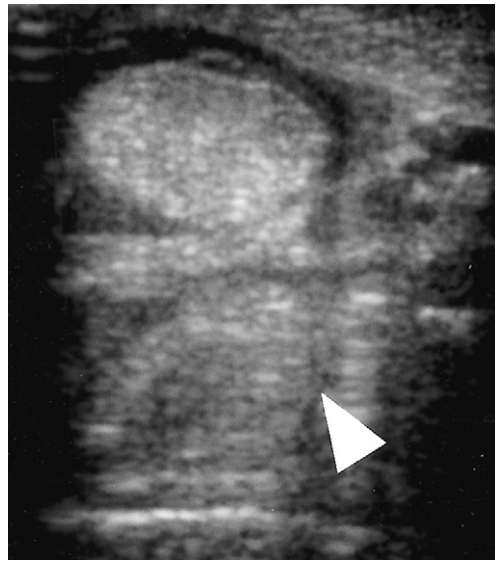

Fig. 73-5 Transverse ultrasonographic image of the proximal metatarsal region of a horse with proximal suspensory desmitis. Medial is to the left. The broad anechoic band through the suspensory ligament (*arrowhead*) is an artifact caused by the overlying plantar vessels. There is a hypoechoic region in the medial aspect of the suspensory ligament.

Diagnostic Ultrasonography

High-quality ultrasonographic images are essential for accurate diagnosis. Large vessels plantarolateral to the SL may result in broad linear anechoic artifacts within the SL (Fig. 73-5). In large Warmblood horses in particular the SL is situated deeply, and the ultrasound transducer must be focused accordingly. In transverse and longitudinal images the most proximal part of the SL in a normal horse may appear slightly less echogenic than the DDFT (Fig. 73-6). Detection of subtle abnormalities requires careful comparison with the contralateral limb and measurement of cross-sectional area. The SL should be imaged routinely in transverse and longitudinal planes.

In hindlimb PSD focal anechoic areas are relatively unusual, except in the STB racehorse. More commonly the SL is enlarged, with poor demarcation of its borders and a diffuse reduction in echogenicity of part or all of the cross-sectional area of the ligament (Figs. 73-5, 73-7, and 73-8). Ectopic mineralization occurs more often in hindlimbs compared with forelimbs. An irregular contour of the plantar aspect of the MtIII bone may reflect enthesophyte formation. In some horses, especially those with abnormal conformation, the lesions may progress despite box rest.

Radiography

Diagnosis should never be based on radiography alone, because some sound horse have some sclerosis of the proximal aspect of the MtIII bone. In horses with chronic active PSD this tends to be more extensive. In the dorsoplantar view opacity of the proximal aspect of the MtIII bone is increased, often more obvious laterally. In a lateromedial projection subcortical sclerosis and alteration of the trabecular pattern of the proximoplantar aspect of the MtIII bone may be caused by endosteal new bone, extending up to 4 cm proximodistally (Fig. 73-9). The plantar cortex may itself be thickened, and in addition enthesophyte formation may be visible on the plantar aspect. However, in some acute horses with injury no radiological abnormality is detectable.

Nuclear Scintigraphy

Nuclear scintigraphy is not a sensitive means of detecting PSD in hindlimbs. Pool-phase images were positive in only 25% of 20 horses with ultrasonographic evidence of PSD.[22] In bone-phase images increased radiopharmaceutical uptake in the proximoplantar aspect of the MtIII bone was found in 42% (Fig. 73-10). Increased radiopharmaceutical uptake in the proximoplantar aspect of the MtIII bone, with no detectable ultrasonographic abnormality of the SL and no radiographic change associated with enthesopathy, should be associated with a primary pathological condition of bone.

Differential Diagnosis

PSD should be differentiated from pain associated with the tarsometatarsal joint, an avulsion fracture of the MtIII bone at the origin of the SL, and primary stress reactions in the MtIII bone.

Treatment

The prognosis for horses with PSD in the hindlimb generally has been poor. Only 6 (14%) of 42 horses seen in a referral practice were able to resume full work without detectable lameness for at least 1 year, all of which had been lame for less than 5 weeks.[27] All these horses showed substantial improvement in clinical signs within 3 months of the onset of lameness. Two additional horses resumed full work but suffered lameness in another limb. Seven horses improved greatly and were able to work, despite persistent mild lameness. Twenty-four horses (57%) had persistent or recurrent lameness. Results from a first opinion practice also were disappointing, with only 10 (58%) of 17 horses resuming work.[1]

Horses with acute (less than 4 to 6 weeks' duration) hindlimb PSD respond reasonably well to local infiltration with

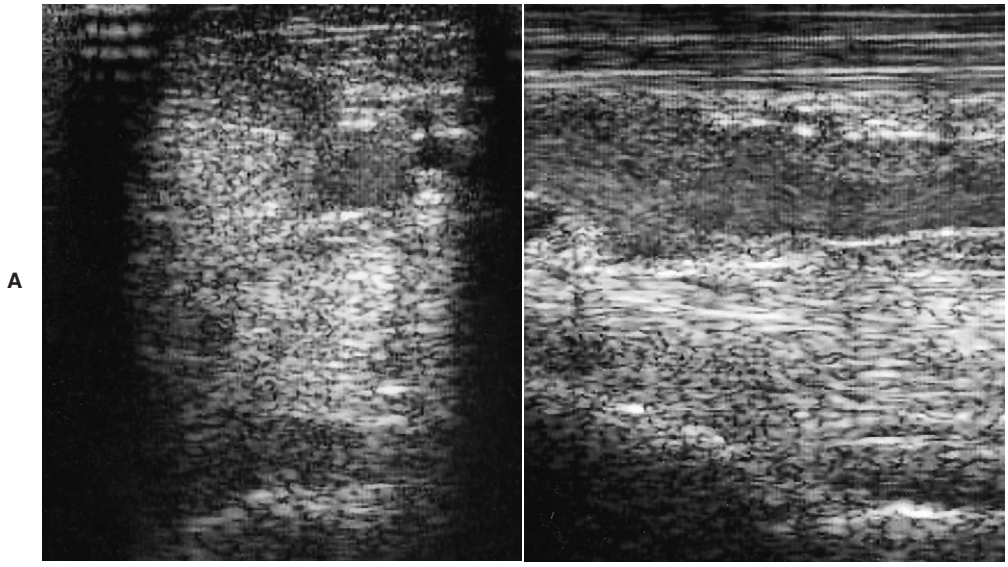

Fig. 73-6 **A,** Transverse ultrasonographic image of the proximal metatarsal region of a normal horse, 4 cm distal to the tarsometatarsal joint. Medial is to the left. The suspensory ligament is similar in echogenicity to the deep digital flexor tendon. **B,** Longitudinal ultrasonographic image of the proximal metatarsal region of a normal horse. Proximal is to the left.

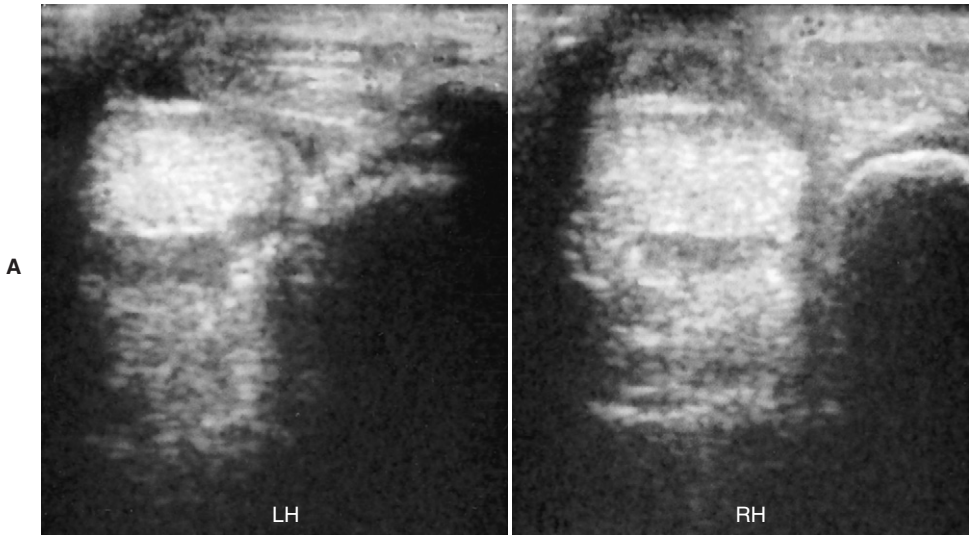

Fig. 73-7 Transverse ultrasonographic images of left (*LH*) and right (*RH*) hindlimbs, at 4 cm distal to the tarsometatarsal joint, of an 11-year-old show jumper with left hindlimb lameness caused by proximal suspensory desmitis. The damaged suspensory ligament is diffusely hypoechoic and enlarged.

corticosteroids, aimed at reducing inflammation and therefore swelling, and thus minimizing the risk of developing a compartment syndrome (see the following discussion). Foot imbalance is corrected and egg bar shoes are used to reduce extension of the fetlock. Horses with chronic PSD have a guarded prognosis regardless of the treatment. Lameness often tends to persist unchanged, even after prolonged box rest, which is unusual for a primary soft tissue lesion. In some horses lesions are progressive. Local infiltration with corticosteroids, glycosaminoglycan polysulfate, hyaluronan, or homeopathic drugs such as actovegin and traumil has given disappointing results.

In some horses an initial improvement in lameness is seen after box rest and controlled walking exercise for 2 to 3 months, and then no further improvement is seen. Increasing the exercise despite the lameness sometimes results in further improvement. Some horses have worked satisfactorily while being treated with phenylbutazone, without apparent deterioration of clinical signs.

Extracorporeal shock wave therapy appears to be helpful in some horses.[27] Eighteen of 30 horses with PSD in forelimbs or hindlimbs were in work 6 months after treatment. Eighteen (40%) of 45 horses with unilateral or bilateral hindlimb PSD were in full work 6 months after treatment[26]; however, a small proportion of these horses have experienced recurrent lameness subsequently. Injection of 2% iodine in almond oil resulted in 12 (54%) of 22 horses returning to work.[29]

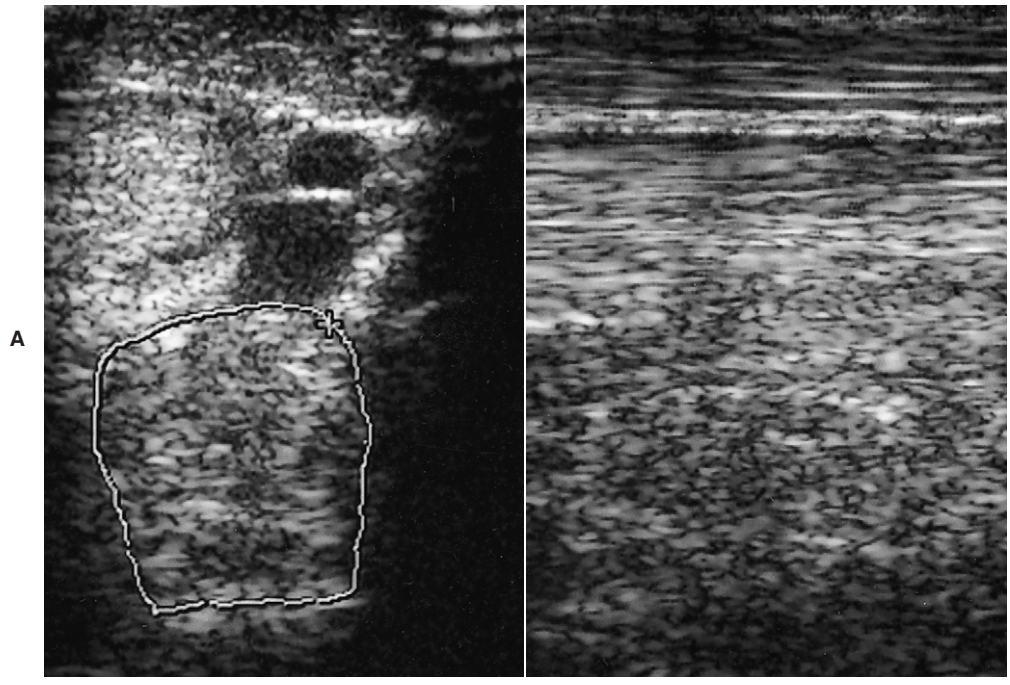

Fig. 73-8 **A,** Transverse ultrasonographic image of the left hindlimb at 3 cm distal to the tarsometatarsal joint of 12-year-old pleasure riding horse that had a lack of hindlimb impulsion. The horse had bilateral proximal suspensory desmitis. The suspensory ligament is enlarged (cross-sectional area 2.4 cm^2) and diffusely hypoechoic. **B,** Longitudinal ultrasonographic image of the proximal metatarsal region of the left hindlimb of the same horse. The suspensory ligament has poor fiber pattern.

Fig. 73-9 Lateromedial radiographic view of the right hindlimb of 7-year-old dressage horse with chronic proximal suspensory desmitis. The proximoplantar aspect of the third metatarsal bone (*arrows*) has sub-cortical sclerosis.

Fig. 73-10 Lateral scintigraphic image of the left hindlimb of 9-year-old Warmblood show jumper with proximal suspensory desmitis. There is marked focal increased radiopharmaceutical uptake in the proximoplantar aspect of the third metatarsal bone.

Tibial neurectomy performed in eight horses enabled six to return to full athletic function (show jumping and horse trials) for at least 2 years after surgery, with no post-operative complications.[22] Neurectomy of the deep branch of the lateral plantar nerve has been combined with incising the thin fascial covering of the plantar aspect of the SL and was successful in five of six horses.[29] A further six of eight horses treated by one author (S.J.D.) have returned to full athletic function after neurectomy of the deep branch of the lateral planter nerve, but two horses experienced deterioration because of progressive lesions in the SL.[22] Both of these horses had pre-existing excessively straight hock conformation and hyperextension of the fetlock of the lame limb. Fasciotomy of the deep plantar metatarsal fascia has been successful in some horses.[30] Injection of about 30 ml of bone marrow also is claimed to be successful, especially if combined with fasciotomy, allowing 85% of horses to return to the former level of function[31] (see Chapter 74).

Gross Pathological and Histopathological Findings

Post-mortem examinations have been performed on both hindlimbs of eight horses, six with unilateral lameness and two with bilateral lameness.[17,22,28] Abnormalities of the SLs were confined to the lame limbs. The SLs were grossly enlarged, with thickening of surrounding fascia and periligamentous tissues, especially on the plantar aspect. Histological changes in the SL included hypercellularity and acellular areas; hemosiderin deposition; fibrosis; hyalinization of collagen; an increased number of fibrous septae, some with blood vessels; neovascularization; and chondroid metaplasia. Although chondroid metaplasia was seen at the ligament bone interface in lame and sound limbs, intraligamentous chondroid metaplasia was only seem in the lame limbs.

Evidence of compression of adjacent peripheral nerves was found in the lame limb of five horses. Abnormalities of the plantar metatarsal nerves included thickening of the perineurium, perineural fibrosis, reduction or absence of nerve fibers, and Renaut bodies.

These changes support the theory that PSD in the hindlimb results is a compartment syndrome.

AVULSION FRACTURES OF THE THIRD METACARPAL OR METATARSAL BONE AT THE ORIGIN OF THE SUSPENSORY LIGAMENT

Avulsion fractures of the third metacarpal or metatarsal bone at the region of the SL are discussed on page 367.

SUSPENSORY DESMITIS: BODY LESIONS

Desmitis of the body of the SL is principally an injury of horses that race, STBs and TBs (flat racehorses and jumpers). In TBs in Europe the incidence is much higher in horses that race over fences (National Hunt Racing and point to pointing; see Chapter 113) compared with flat racehorses. Although PSD and desmitis of the medial and or lateral branches of the SL are relatively common injuries in event horses, show jumpers, dressage horses, and endurance horses, body lesions are recognized less frequently, except as associated with an exostosis of the McII or MtIV (splint) bones or as a sequel to a branch injury. Injuries occur in forelimbs and hindlimbs, and in STBs several limbs may be affected concurrently, whereas in TBs lesions generally are restricted to the forelimb.[23,33] There is frequently a poor correlation between the extent of the lesions and the degree of lameness. Performance, however, can be compromised despite no evidence of overt lameness. In STB racehorses lameness may be observed or tolerated while athletic function continues. This continued exercise may result in progressive injury or injury to other tendonous or ligamentous structures.

Soreness on palpation of the SL is not synonymous with structural damage. Event horses frequently have sore SLs for several days after fast work or competition, but rarely does this appear to be associated with a significant problem. Soreness does not appear to be a warning sign of impending desmitis.

Clinical Signs

The clinical signs associated with suspensory body desmitis vary in presence and degree and include the following:

- Localized heat
- Periligamentous edema. Severe periligamentous soft tissue swelling may make accurate palpation of the SL difficult.
- Rounding of the margins of the SL
- Enlargement of the body of the SL
- Pain on palpation of the margins of the SL
- Abnormal stiffness of the SL
- Pain on palpation of the distal third of the McII or MtIV bones, if there is a concurrent fracture
- Lameness. The absence of lameness does not preclude significant desmitis.

Diagnosis

Diagnosis is based on clinical signs and ultrasonographic assessment. Diagnostic analgesic techniques rarely are required unless another contributory cause of lameness or recurrence of previous desmitis is suspected. In a horse with previous desmitis a previously enlarged SL may have no detectable change in size, shape, or reaction to palpation. Perineural analgesia of the palmar metacarpal nerves proximal to the site of the suspect lesion should remove associated lameness.

The body of the SL of a normal horse is not always uniform in echogenicity because of variable amounts of muscle tissue in the ligament and variations in the level of bifurcation of the SL between horses. This can make detection of subtle lesions difficult. The maximum injury zone is frequently at the region of the bifurcation of the SL, which may appear hypoechoic in normal horses (Fig. 73-11). Careful comparison with the contralateral limb may help if clinical signs are unilateral. Ultrasonographic abnormalities associated with active desmitis include the following:

- Enlargement of the body of the ligament in transverse and median planes
- Loss of definition of one or more of the margins of the ligament
- Focal hypoechoic areas, peripheral or central, extending a variable distance proximodistally
- A diffuse reduction in echogenicity of some or all of the cross-sectional area of the ligament
- In horses with chronic desmitis, focal hyperechoic areas

Enlargement may be the only detectable abnormality. Careful comparison with the contralateral limb can be helpful. Reference can be made to studies of sizes in normal horses of similar breed, but caution is urged because notable differences do exist between American and European TBs. The extent of ultrasonographic abnormality is not always correlated with the severity of clinical signs. A reasonable correlation exists with the severity of the ultrasonographic grade of the injury and the prognosis; however, a diffuse reduction in echogenicity of the cross-sectional area has a similarly poor prognosis to a large anechoic lesion. Lesions may extend into the branches, which should also be examined by ultrasonography.

Many lesions persist long term, although focal lesions in STBs may fill in. In TBs a readily detectable defect often persists, despite some increase in echogenicity and slight reduction in size. This can limit the value of serial ultrasonographic

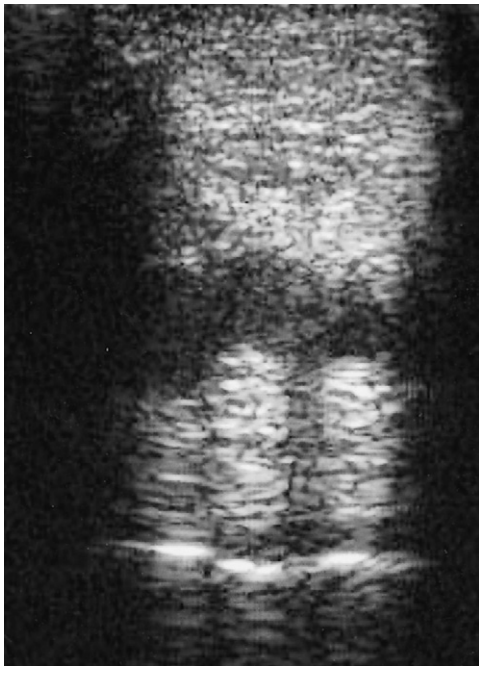

Fig. 73-11 Transverse ultrasonographic image of a normal forelimb suspensory ligament at the level of the beginning of the bifurcation, 18 cm distal to the accessory carpal bone. The central, less echogenic region should not be confused with a lesion.

evaluations to determine when a horse might be able to withstand work. Determining objectively to what extent healing has taken place and the strength of the repair tissue often is not possible. This may explain the high rate of recurrence of body lesions in STBs and TBs. Racing careers of STBs can usually be extended, whereas managing TBs is much more difficult, because lameness in TBs rarely stabilizes.[23] Horses with slight lesions may be responsive to symptomatic treatment, and a horse may train and race well; however, the lesion is likely to be progressive. The risk of catastrophic breakdown of the suspensory apparatus must always be considered in a TB racehorse. In STB racehorses rest for about 3 months may confer no extra advantage to symptomatic treatment and continued training[24] with respect to racing performance. Lesions are usually progressive, and periodic ultrasonographic monitoring is recommended.

There is a high rate of re-injury to the body of the SL of the same or contralateral limb or to a branch of the same or contralateral limb subsequent to desmitis of the body of the SL.[32]

Radiographic examination of the McII and McIV bones is indicated if clinical examination suggests abnormal modeling or a fracture, because surgical amputation may be indicated[23] (see page 371).

Management

Treatment is aimed at reducing inflammation by the administration of systemic NSAIDs, local or systemic corticosteroids, hydrotherapy, and controlled exercise. Cryotherapy is used by some clinicians to provide pain relief, but a real risk of progressive deterioration of the lesion exists (see Chapter 90).

Progress is monitored clinically and by serial ultrasonographic examinations. Ideally there should be progressive reduction in cross-sectional area, improvement in echogenicity and fiber alignment, no restrictive periligamentous fibrosis, and reasonable stability in all of these feature as exercise is increased. In STBs hand walking exercise is advocated for the first 4 weeks.[23] Provided that some improvement in the ultrasonographic appearance of the ligament occurs and the horse is sound when jogged in hand, the horse is harnessed and walked in the jog cart for another 4 weeks. Flat shoes are preferred. The horse is re-assessed by ultrasonography after 8 weeks, and if further filling in of the defect occurs, short slow jogging is reintroduced and gradually increased. A third ultrasonographic examination is performed after 8 weeks of jogging, and provided that the lesion is uniformly echogenic to the remainder of the SL and has a linear arrangement of fibers, normal jogging and speed work are resumed. Although this method is successful in some STBs, in others a longer period of convalescence is required.

Continued medical therapy includes daily hydrotherapy; for example, whirlpool boots, stable and exercise bandages, massage with emollient oils, leg sweats, and leg tighteners with or without DMSO. The aim is to stimulate circulation, reduce inflammation, and provide pain relief. The work program should be adapted so that days of light work are interspersed with hard work. Swimming is a useful method of maintaining cardiovascular fitness but should not be used alone, because the musculoskeletal system requires regular stimulus to avoid other injuries.

Intralesional treatment with β-aminoproprionitrile fumarate has been used in STB and TB racehorses with moderate to severe injuries of the SL body.[24] Eleven of 18 horses successfully returned to racing, although some dropped in class.

Surgical splitting of the body of the SL usually is not advocated in STBs or TBs.[23] However, occasionally, large chronic lesions with associated McII or McIV bone fractures are split, combined with surgical removal of the fracture piece in STB and, less commonly, TB racehorses. Pin firing combined with rest may be of benefit in some horses with chronic desmitis[23] (see Chapter 89).

SUSPENSORY DESMITIS ASSOCIATED WITH AN EXOSTOSIS ON THE SECOND OR FOURTH METACARPAL OR METATARSAL BONE (SPLINT)

Suspensory desmitis associated with exostosis of the second or fourth metacarpal (metatarsal) bone is discussed on page 370 (Fig. 73-12).

SUSPENSORY DESMITIS ASSOCIATED WITH FRACTURE OF THE DISTAL THIRD OF THE SECOND OR FOURTH METACARPAL OR METATARSAL BONE

Suspensory desmitis associated fracture of the distal third of the second or fourth metacarpal or metatarsal bone is discussed on page 371.

SUSPENSORY DESMITIS: BRANCH LESIONS

Desmitis of the medial and or lateral branches of the SL in forelimbs and hindlimbs is a relatively common injury in all types of sports horses. Usually only a single branch is affected in a single limb, although both branches may be affected, especially in hindlimbs. Foot imbalance often is recognized in affected horses and may be a predisposing factor. Some horses, particularly event horses, have acute onset distention of the metacarpophalangeal joint capsule concurrent with SL branch desmitis. Detection of radiographic abnormalities (modeling or fracture of the distal aspect of the McII or McIV bone or a PSB) in some horses at the time of recognition of an acute, first time injury, suggests a sub-clinical pre-existing problem.

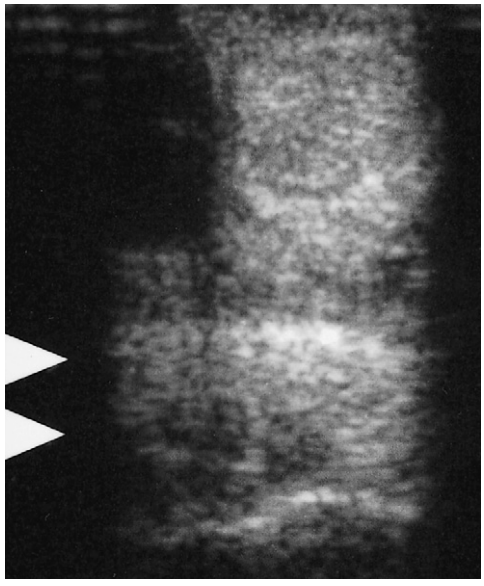

Fig. 73-12 Transverse ultrasonographic image of the mid-metacarpal region of 7-year-old show jumper with intermittent left forelimb lameness associated with localized enlargement of the axial aspect of the second metacarpal bone (a splint). Slight pain could be elicited by pressure. Separating the axial border of the bone from the suspensory ligament by palpation was not possible. Lameness was alleviated by local infiltration of local anesthetic solution. Echogenic material (*arrowheads*) extends from the medial aspect of the suspensory ligament, which was slightly hypoechoic dorsomedially. Surgical exploration revealed a loose spicule of bone adjacent to the splint and a granulomatous reaction between it and the suspensory ligament. A focal defect was found in the medial border of the suspensory ligament.

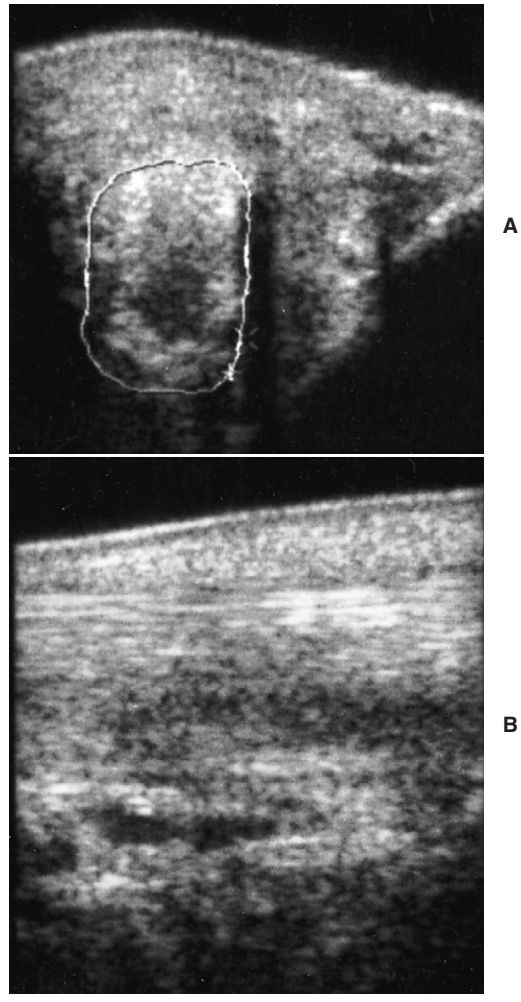

Fig. 73-13 **A,** Transverse ultrasonographic image of the medial branch of the suspensory ligament of the right forelimb of 14-year-old Grand Prix dressage horse. The suspensory ligament branch is enlarged (cross-sectional area 2.02 cm^2) and has a large, almost anechoic lesion. The echogenic material subcutaneously also contributed to the soft tissue swelling. **B,** Longitudinal ultrasonographic image of the medial branch of the suspensory ligament of the right forelimb of the same horse. Proximal is to the left. There is a marked loss of fiber pattern within the suspensory ligament. Note also the subcutaneous echogenic material.

Clinical Signs

The clinical signs depend on the degree of damage and chronicity of the lesion(s) and include localized heat and swelling. Swelling often is caused by enlargement of the branch, together with periligamentous edema or fibrosis. Associated distention of the metacarpophalangeal joint capsule may occur. In hindlimbs sometimes considerable distention of the digital flexor tendon sheath (DFTS) occurs, making assessing the SL branches by palpation difficult. Pain usually is elicited by direct pressure applied to the injured branch or by passive flexion of the fetlock. Lameness varies, may be absent, usually is proportional to the degree of damage, and is related inversely to the duration of injury. A notable exception is in the hindlimbs of older dressage horses, in which occasionally both branches sustain damage, and strong adhesions develop between them. These horses experience persistent, severe lameness. Occasionally younger horses from any discipline develop acute-onset, severe, and persistent hindlimb lameness associated with progressive stretching of a single branch and the development of periligamentous fibrosis. There is associated hyperextension of the fetlock.

Diagnosis

Diagnosis is based on clinical signs and ultrasonographic examination. Diagnostic analgesic techniques usually are required only if more than one lesion is suspected as the cause of lameness. In horses with acute branch injury, with concurrent distention of the metacarpophalangeal joint capsule, we suggest that the horse be re-evaluated after 2 to 3 weeks. If joint capsule distention and pain on manipulation persist, then the joint should be blocked intra-articularly.

The entire SL should be examined by ultrasonography, because lesions may extend beyond areas that are palpably abnormal. Ultrasonographic abnormalities include the following (Figs. 73-13 to 73-15):

- Abnormalities of the body of the SL (see page 662)
- Enlargement of the branch
- Change in shape of the branch
- Loss of definition of one or more margins of the branch
- Well-defined or poorly defined hypoechoic areas, central or peripheral
- A diffuse reduction of echogenicity involving some or all of the cross-sectional area of the branch
- Echogenic material subcutaneously
- Echogenic material between the medial and lateral branches
- Hyperechoic foci or larger masses within the branch
- An irregular contour or fracture of the ipsilateral PSB
- An abnormal amount of fluid within the DFTS

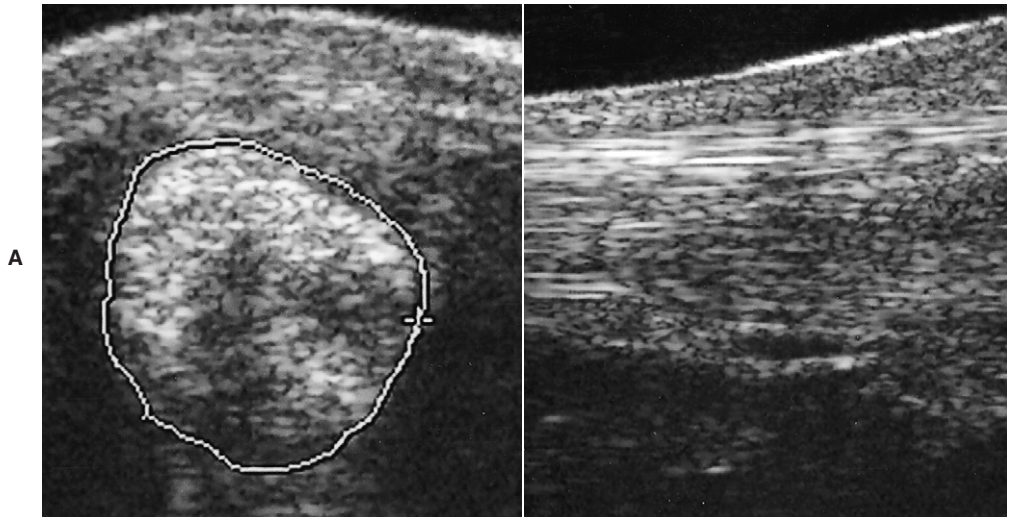

Fig. 73-14 **A,** Transverse ultrasonographic image of the lateral branch of the suspensory ligament of the left hindlimb of 7-year-old intermediate-level event horse with lameness of 2 weeks' duration. The suspensory branch is considerably enlarged (cross-sectional area 2.0 cm^2). Its margins are poorly defined and there is marked loss of echogenicity. **B,** Longitudinal ultrasonographic image of the lateral branch of the suspensory ligament of the same horse. Proximal is to the left. The ligament is hypoechoic, with loss of fiber pattern.

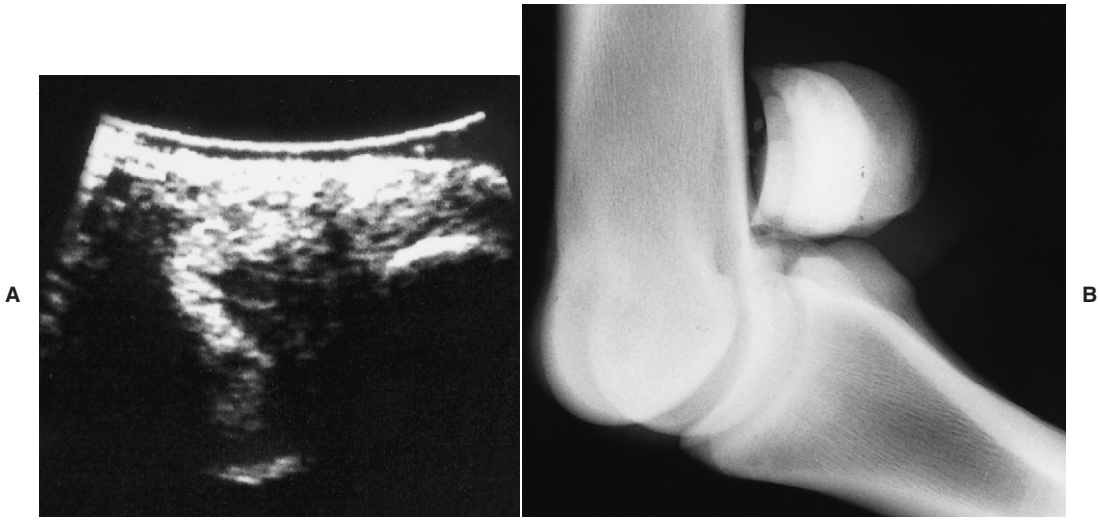

Fig. 73-15 **A,** Transverse ultrasonographic image of the lateral branch of the suspensory ligament, close to its insertion on the lateral proximal sesamoid bone, of the right hindlimb of 9-year-old advanced event horse with acute onset lameness. The ligament has a large, almost anechoic defect. **B,** Flexed, slightly oblique lateromedial radiographic view of the right hind fetlock of the same horse. The lateral proximal sesamoid bone is positioned slightly more dorsally. Several small osseous opacities are seen dorsal to it. These were removed arthroscopically, and torn fibers at the suspensory ligament branch insertion were debrided.

The branches should be examined in transverse and longitudinal planes. Lesions restricted to the insertion are sometimes only detectable in longitudinal images. Sometimes horses show slight localized swelling and heat in the region of a SL branch, with a subtle alteration in gait, in which no ultrasonographic abnormality of the SL can be identified. The swelling appears to be principally periligamentous. Some of these horses can be maintained safely in work, whereas in others clinical signs deteriorate with the development of a branch lesion.

Radiographic examination of the ipsilateral splint bone and PSB should be performed. Abnormalities may include the following:

- Dystrophic mineralization in the SL
- Distortion in shape of the ipsilateral splint bone
- Fracture of the distal aspect of the ipsilateral splint bone
- Fracture(s) of the ipsilateral PSB (see Fig. 73-15)
- Radiating lucent lines within the ipsilateral PSB
- Modeling of the palmar aspect of the PSB

Fractures influence the treatment and prognosis. However, radiographic evidence of sesamoiditis is not well correlated with the outcome, although primary sesamoiditis unassociated with SL desmitis can cause recurrent lameness (see Chapter 37).

Management

Treatment depends on the occupation of the horse, the breed, and the severity of the clinical signs and ultrasonographic abnormalities. Horses with acute central core lesions may be treated by splitting, with horses returning to work within 9 months. Horses with more peripheral lesions or those poorly demarcated are not suitable for splitting, but their injuries can be managed conservatively by appropriate trimming and shoeing, box rest, and a controlled increasing exercise program. Intra-lesional injection of β-aminoproprionitrile fumarate (five 7-mg injections on alternate days) combined with a controlled increasing work program over 6 to 9 months has been successful.[22]

Dressage horses and show jumpers with minor lesions and only subtle ultrasonographic abnormalities have been managed successfully by appropriate trimming and shoeing with egg bar shoes, combined with modification of the training program for 6 to 8 weeks. Some horses can be managed successfully and maintained in work by aggressive local therapy (e.g., use of whirlpool boots, laser or ultrasound therapy, leg sweats, and cold therapy). Continued work in an event horse usually results in significant progression of the lesion. In a TB racehorse, continued training in the face of SL branch injury runs the risk of an acute breakdown injury of the suspensory apparatus. In STB racehorses symptomatic treatment is common, with NSAIDs as required, daily icing, topical application of a DMSO-cortisone liniment, and modification of the training schedule to light jogging or swimming between races. Lesions may remain stable or progress slowly and usually ultimately compromise performance significantly. Management is more difficult in horses that race at a high level, so training cannot be reduced enough, or the speed of the race results in overload of the compromised structure. Horses seem to do less well on a slower track surface, with a deep cushion, compared with a fast track surface.

Ultrasonographic lesions are often slow to resolve and some persist long term (longer than 18 months). Some horses are able to resume full work after a convalescent period of at least 9 months, despite the persistence of a lesion, although the incidence of recurrent injury is high. If a lesion persists as viewed by ultrasonography, knowing when to recommend resumption of work is difficult. Generally the horse should have been rested at least 6 months and no appreciable change should be found in the ultrasonographic appearance of the SL branch between two examinations 3 months apart. With increased exercise the ligament should remain stable in size and echogenicity.

Horses with hindlimb suspensory branch lesions with periligamentous fibrosis and shortening of a SL branch or echogenic material extending between the two branches have a poor prognosis. This echogenic material represents firm fibrous adhesions between the branches.

PROXIMAL SESAMOID BONE FRACTURE ASSOCIATED WITH A BRANCH INJURY

Sesamoid fractures associated with SL branch injury are discussed on page 354.

AVULSION FRACTURE OF THE PROXIMAL SESAMOID BONE AT THE INSERTION OF THE PALMAR ANNULAR LIGAMENT

Avulsion injuries of the palmar annular ligament (PAL) at its insertion on a PSB are not common[22,34] and must be differentiated carefully from abaxial proximal sesamoid bone fractures (see Chapter 37, page 354). Injuries occur in forelimbs and hindlimbs. Horses with acute injury show lameness associated with diffuse soft tissue swelling palmar to a proximal sesamoid bone.[22] Swelling does not involve the ipsilateral SL branch unless that branch has been damaged concurrently. There may also be mild distention of the fetlock joint capsule and the digital flexor tendon sheath. It may be possible to elicit pain by firm pressure applied to the abaxial aspect of the sesamoid bone. In horses with more chronic injury no localizing clinical signs may be apparent. Radiographic examination may reveal a punched-out lesion of the PSB (Fig. 73-16) or a small detached fragment of bone (Fig. 73-17), the origin of which cannot be determined. Ultrasonographic examination helps to determine the origin of the fragment. The PAL should be examined from the palmar aspect of the limb and then followed around to its insertion. An osseous echogenic body may be seen attached to the PAL close to the PSB. Treatment by surgical removal of the fragment or conservative management has resulted in return to full athletic function.[22,34]

Fig. 73-16 Dorsolateral-palmaromedial oblique radiographic view of the right front fetlock of 7-year-old advanced event horse. A punched-out opacity is visible on the palmar aspect of the bone (*arrow*). This is an avulsion injury at the insertion of the palmar annular ligament. Note also the new bone on the palmar distal aspect of the bone.

DAMAGE OF THE PALMAR (PLANTAR) LIGAMENT OF THE FETLOCK (INTERSESAMOIDEAN LIGAMENT)

Focal Tears in the Body of the Intersesamoidean Ligament

Focal tears in the body of the intersesamoidean ligament are an unusual cause of lameness and can only be diagnosed definitively by arthroscopic evaluation of the palmar (plantar) pouch of the metacarpophalangeal (metatarsophalangeal) joint.[22] Lameness is usually acute in onset and moderate to severe. Lameness improves with rest but often persists. There may be effusion in the metacarpophalangeal joint. Lameness is improved by intra-articular analgesia. Usually no identifiable radiographic abnormalities occur. Small focal tears are extremely difficult to identify using ultrasonography. Nuclear

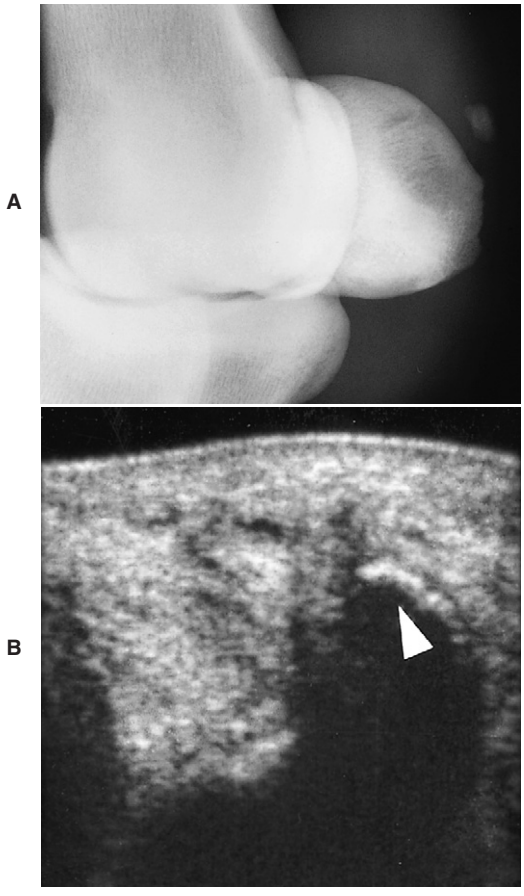

Fig. 73-17 **A,** Dorsomedial-palmarolateral oblique radiographic view of the right front fetlock of 9-year-old Grand Prix show jumper with acute-onset lameness associated with soft tissue swelling on the medial aspect of the fetlock, palmar to the medial branch of the suspensory ligament. There was also slight edematous swelling around the distal aspect of the medial branch of the suspensory ligament. There is an osseous fragment palmar to the proximal sesamoid bones, but its origin could not be determined radiographically. **B,** Transverse ultrasonographic image of the palmaromedial aspect of the fetlock. A thick hyperechoic line represents the osseous fragment (*arrow*) that was an avulsion of the insertion of the palmar annular ligament.

scintigraphic examination of a small number of horses with small focal tears not involving the insertion of the ligament has revealed slight generalized increased radiopharmaceutical uptake in the fetlock region but not localized to the PSBs. Horses with focal ligament tears have a poor response to surgical debridement and prolonged rest, with or without intra-articular medication, and the prognosis for return to athletic function is guarded.

Degeneration or Partial Rupture of the Intersesamoidean Ligament

Degenerative lesions and partial rupture of the intersesamoidean ligament have been seen only in older, mature athletic horses and are relatively rare.[35] The condition has been recognized in forelimbs and hindlimbs and may occur as a single injury or with other soft tissue or bony lesions.

Lameness is acute in onset and moderate to severe. Mild distention of the metacarpophalangeal (metatarsophalangeal) joint capsule or the DFTS may occur. Lameness may be improved by intra-articular analgesia, but the response to perineural analgesia of the palmar and palmar metacarpal nerves is often better.

Diagnosis is based on ultrasonography, and a number of abnormalities have been identified:

- An increase in the space between the PSBs
- An increased thickness of the palmar ligament
- Reduced echogenicity of the palmar ligament
- Focal hyperechoic regions in the palmar ligament
- Dorsal displacement of the flexor tendons
- Thinning of the palmar ligament and reduction in the space between the ligament and the dorsal aspect of the DDFT
- Irregularity of the facies flexoria of a PSB (This may correlate with radiolucent areas in the axial aspect of the bone.)

Careful examination of the flexor tendons, the PAL, and the distal sesamoidean ligaments should be performed to identify any concurrent injuries.

Radiographic examination occasionally may reveal osteolytic lesions on the axial aspect of the PSBs (see the following discussion).

The prognosis for return to athletic function is extremely guarded.[22]

Insertional Injury of the Intersesamoidean Ligament

Aseptic necrosis of the axial aspect of the PSBs has been described as a cause of lameness in forelimbs and hindlimbs.[35,36] The condition has been characterized by the development of radiolucent zones in the axial aspect of one or both PSBs (Fig. 73-18), lesions which have also been seen with infection (see the following discussion). Histological examination of two horses indicated that these lesions reflect trauma of the insertion of the intersesamoidean ligament.[22] Insertional lesions of the palmar ligament of the fetlock also may occur without radiographic change and have been identified arthroscopically (Fig. 73-19).

In contrast to horses with associated infection, usually no substantial soft tissue swelling occurs in the fetlock region, although distention of the metacarpophalangeal (metatarsophalangeal) joint capsule, the DFTS, or both may occur. In some horses eliciting pain by palpation may be difficult. Lameness may vary from moderate to severe and is often worse with the horse walking in a circle compared with walking in a straight line.

Regional analgesia by a four-point block usually results in much better improvement in lameness than intra-articular analgesia. In the acute stage radiographic examination may be negative. Ultrasonographic evaluation may be unrewarding, but in some horses an irregular outline of one of the PSBs may be seen, with reduced echogenicity of the intersesamoidean ligament (see Fig. 73-18).

Nuclear scintigraphic examination usually reveals increased radiopharmaceutical uptake in one or both PSBs in contrast to the pattern of uptake that has been seen with focal lesions in the body of the intersesamoidean ligament (see the previous discussion). Increased radiopharmaceutical uptake localized to a PSB also may be caused by an incomplete fracture or subchondral trauma. Sequential radiographic examination may reveal the development of lucent zones on the axial aspect of the sesamoid bones.

These lesions may be associated with long-term lameness, although surgical debridement has resulted in return to former athletic function in some horses.[36,37] Arthroscopic evaluation usually reveals a defect in the palmar ligament, through which a probe can be inserted into the bony defect. Defects usually are more pronounced in one PSB, but they can involve both PSBs. Damaged palmar ligament and bone are debrided. Occasionally, to approach lesions not involving the articular surface, it may be necessary to create a small apical fracture to gain access to the bony defect.

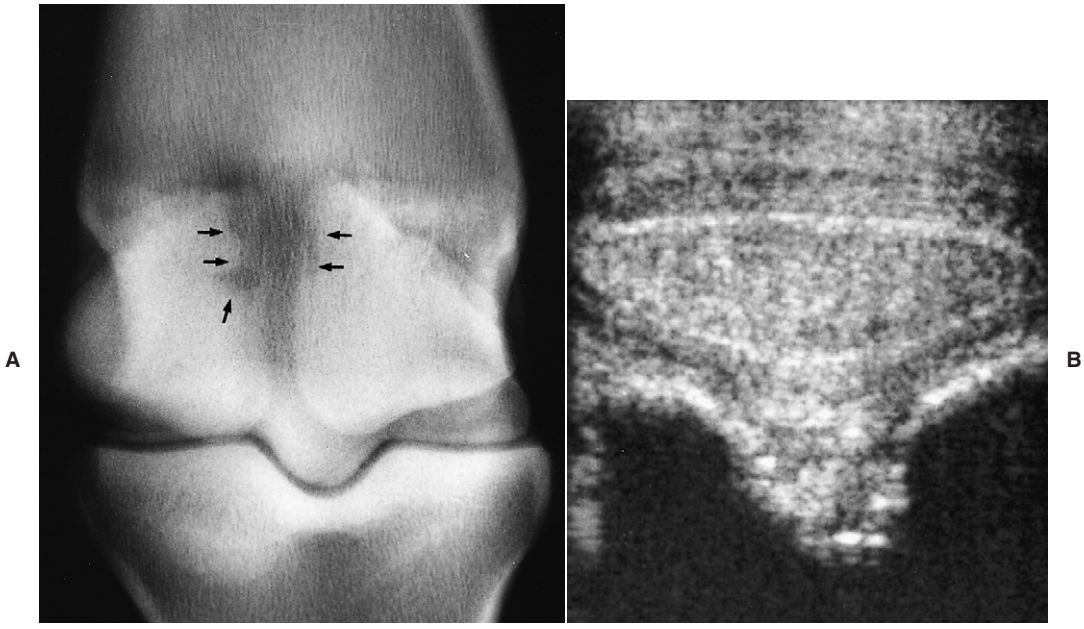

Fig. 73-18 A, Dorsoplantar radiographic image of the right hind fetlock of 6-year-old Thoroughbred with severe lameness associated with moderate distention of the metatarsophalangeal joint capsule and mild distention of the digital flexor tendon sheath. Medial is to the left. The axial borders of the proximal sesamoid bones are poorly defined proximally, with lucent areas in the bone (*arrows*). Histological examination confirmed traumatic insertional injuries of the palmar ligament of the fetlock. **B,** Transverse ultrasonographic image of the plantar aspect of the fetlock of the same horse. Medial is to the left. Note the irregularity of the outline of the proximal sesamoid bones and the rather heterogeneous echogenicity of the intersesamoidean ligament.

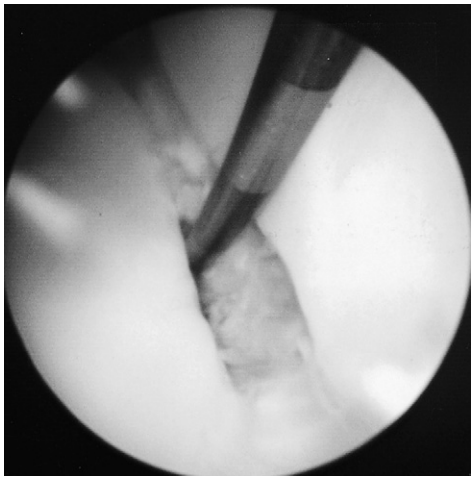

Fig. 73-19 Arthroscopic picture of focal tear in the palmar ligament of the fetlock at its insertion on the medial proximal sesamoid bone. (Courtesy I.M. Wright, Newmarket, Suffolk, England.)

INFECTION OF THE AXIAL ASPECT OF THE PROXIMAL SESAMOID BONES

Aseptic necrosis[36,37] and osteomyelitis[38] of the PSBs have been described, but in one author's experience (S.J.D.) aseptic necrosis occurs more commonly. Aseptic necrosis is probably an inappropriate term because the Editors believe that lesions develop secondary to trauma of the insertion of the intersesamoidean ligament (see the previous discussion). Infection is not necessarily associated with a known route of infection, but several horses with infection have been seen after puncture wounds in the pastern region or cellulitis[22] (see Fig. 73-19).

Infection of the PSBs may occur in forelimbs and hindlimbs and is characterized by radiolucent zones involving the axial margin of the medial or lateral PSB, or both. Pain may be elicited by pressure over the PSBs. Fetlock flexion usually is resented. Distention of the fetlock joint capsule and the DFTS and surrounding soft tissue swelling are variable features. Synoviocentesis may reveal evidence of infection in adjacent structures. In some horses a penetrating wound can be identified in the palmar aspect of the fetlock or pastern. Lameness varies from moderate to severe.

High-resolution dorsal 15° to 20° proximal-palmaro (plantaro) distal oblique radiographic views, with adequate penetration, are essential for diagnosis. If the radiographs are underexposed, lesions will be missed. Ultrasonography is useful for confirming the diagnosis and for identifying other concurrent lesions (Fig. 73-20), such as extensive tenosynovitis of the DFTS, deposition of echogenic material around the affected PSB, reduced echogenicity of the intersesamoidean ligament, and lesions of the flexor tendons or adhesions between them.[1]

The prognosis with conservative or surgical management is extremely guarded.

STRAIGHT DISTAL SESAMOIDEAN DESMITIS

Desmitis of the straight distal sesamoidean ligament is an unusual cause of lameness that usually occurs in a forelimb, but it has been recognized in hindlimbs.[39] One of us (S.J.D.) has recognized it most commonly in event horses. The condition may occur alone or together with injury to an oblique distal sesamoidean ligament. Lameness is sudden in onset, usually with no detectable swelling in the acute phase. Some

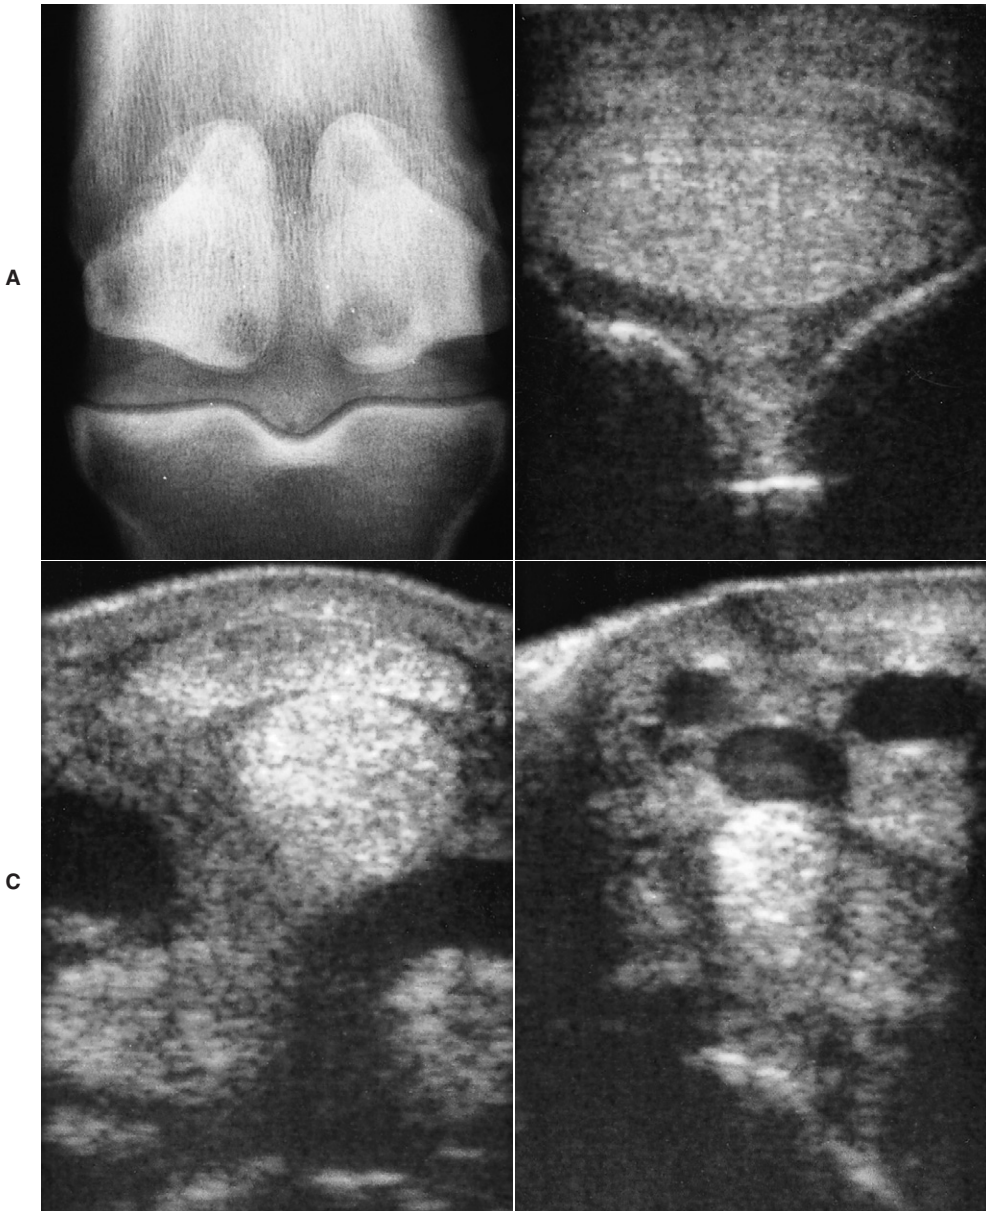

Fig. 73-20 **A,** Dorsopalmar radiographic view of the right metacarpophalangeal joint of 8-year-old Thoroughbred with massive swelling of the metacarpal region, restricted flexibility of the fetlock and distention of the digital flexor tendon sheath. There are large radiolucent zones involving the distal axial borders of the proximal sesamoid bones. **B,** Transverse ultrasonographic image of the distal aspect of the metacarpal region of the same horse. Note the asymmetrical appearance of the proximal sesamoid bones and the difference in distance between them and the dorsal border of the deep digital flexor tendon. **C,** Transverse ultrasonographic image of the distal metacarpal region of the same horse. Note the abnormal amount of fluid within the digital flexor tendon sheath and the echogenic material around the deep digital flexor tendon. **D,** Palmar oblique ultrasonographic view. Note the subcutaneous echogenic material and the distended vessels.

swelling may develop subsequently, but this can be difficult to detect if the lesion is far proximal. Concurrent effusion may occur in the DFTS, and palpation on the palmar midline of the pastern region may elicit pain, but not invariably so. Lameness may be severe acutely and then rapidly improving but persisting. Lameness is alleviated by palmar nerve blocks at the level of the base of the PSBs. Diagnosis is based on ultrasonography and abnormalities include the following (Fig. 73-21):

- Enlargement of the straight sesamoidean ligament and therefore reduction in the space between it and the DDFT
- Focal or diffuse reduction in echogenicity
- Increased fluid within the DFTS in some horses

Care should be taken not to misinterpret the normal hypoechoic area in the most distal part of the ligament as a lesion. This represents the cartilaginous scutum at the insertion.

Lesions may occur localized to the insertion, either unilaterally or bilaterally, and alone or in conjunction with other causes of palmar foot pain, such as navicular disease. There is usually no palpable abnormality. Lameness is removed by perineural analgesia of the palmar nerves at the base of the proximal sesamoid bones. However, improvement may be seen after

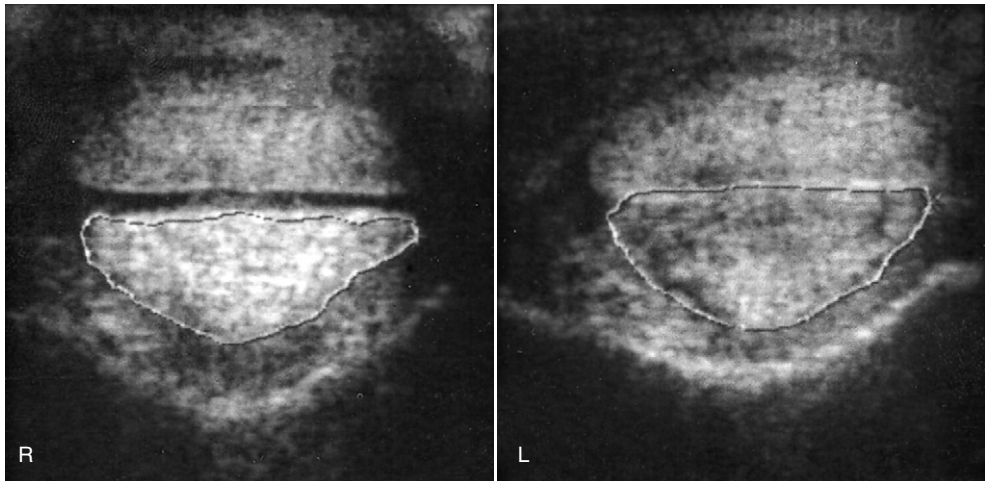

Fig. 73-21 Transverse ultrasonographic images of the left (on the left) and right proximal pastern regions of an advanced event horse with acute onset, severe right forelimb lameness after completing a cross-country course. The lameness improved greatly within 24 hours. Flexion of the right front fetlock elicited pain, but no swelling or pain on direct palpation could be detected. Lameness was alleviated by perineural analgesia of the palmar nerves at the level of the fetlock joint. The right straight sesamoidean ligament is enlarged (cross-sectional area 1.46 cm^2) compared with the left (1.35 cm^2), resulting in loss of space between it and the deep digital flexor tendon. The ligament is also hypoechoic.

palmar digital nerve blocks if these are performed in the midpastern region or because of proximal diffusion from a more distal injection site. Although some lesions can be identified ultrasonographically, the shape of the pastern influences the ease with which these structures can be imaged accurately. Recent experience with magnetic resonance imaging (MRI) suggests that these injuries may occur more frequently than previously recognized. MRI seems more sensitive for the detection of insertional injuries compared with ultrasonography.

Occasionally concurrent lesions of the straight and oblique sesamoidean ligaments occur and have a more guarded prognosis.

Treatment has consisted of box rest, corrective trimming and shoeing, and controlled walking exercise, with periodic reevaluation with ultrasonography. Usually progressive resolution of lameness occurs over 6 to 8 weeks, with gradual improvement in the ultrasonographic appearance of the ligament over 6 months. However, the prognosis for return to full athletic function at a high level of competition is guarded, because the incidence of recurrent injury is high.

Loss of tension (relaxation) of the straight sesamoidean ligament may occur if the SL is ruptured, resulting in instability or luxation of the proximal interphalangeal joint (palmar/plantar subluxation). Ultrasonographic abnormalities include the following:

- Apparent enlargement of the ligament cross-sectional area
- Loss of fiber alignment
- Focal hypoechoic areas caused by lack of tension

OBLIQUE (MIDDLE) DISTAL SESAMOIDEAN DESMITIS

Desmitis of one or both oblique sesamoidean ligament occurs in forelimbs and hindlimbs, but it is a more common source of forelimb lameness. Lameness is usually acute in onset and moderate to severe. In the acute stage often no localizing clinical signs are apparent, but in the following 7 to 10 days swelling may develop in the pastern region, and pain may be elicited by firm palpation. However, lesions may occur without detectable palpable abnormalities, alone or with another cause of lameness. Lameness, which is often worst on a soft surface, is alleviated by palmar (abaxial sesamoid) nerve blocks. One should note that tendonitis of the medial or lateral branch of the SDFT is a more common injury in the pastern, has a similar clinical presentation, and is more likely to be associated with detectable soft tissue swelling.

One also must recognize that enthesophyte formation on the palmar aspect of the proximal phalanx at the site of insertion of the oblique sesamoidean ligaments is a common incidental radiographic abnormality frequently unassociated with clinical signs and often not associated with any detectable ultrasonographic structural abnormality of the ligament. Well-circumscribed, smoothly marginated osseous bodies, possibly old avulsion fractures from the base of a PSB, are common radiographic and ultrasonographic observations in mature horses in which the oblique sesamoidean ligament appears to be structurally normal (see Fig. 115-7).

Ultrasonographic abnormalities of the oblique sesamoidean ligament are often identified concurrently with some other cause of lameness; for example, osteoarthritis of the proximal interphalangeal joint or desmitis of a branch of the SL.

Ultrasonographic abnormalities include one or more of the following (Figs. 73-22 and 73-23):

- Enlargement
- Diffuse reduction of echogenicity
- Focal hypoechoic areas
- Poor demarcation of the margins of the ligament
- Reduction in space between the ligament and the SDFT
- Entheseophyte formation on the palmar (plantar) aspect of the proximal phalanx or the base of the ipsilateral PSB
- An avulsion fracture of the base of the ipsilateral PSB or at the insertion on the palmar aspect of the proximal phalanx

Each ligament should be evaluated carefully in transverse and longitudinal planes. Occasionally lesions occur together with injuries to other soft tissues of the pastern, so all structures should be evaluated systematically.

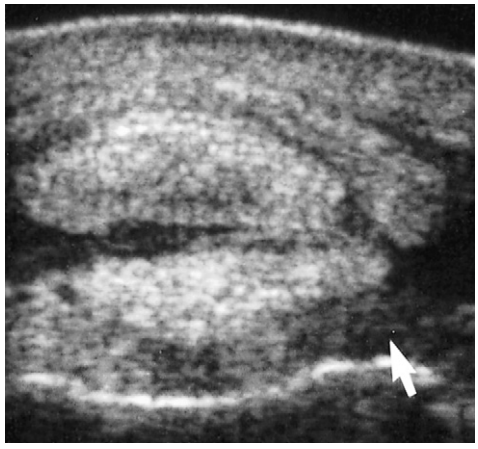

Fig. 73-22 Transverse ultrasonographic image of 7-year-old Thoroughbred with left forelimb lameness of 10 days' duration. Medial is to the left. The lateral oblique sesamoidean ligament is diffusely hypoechoic (*arrow*).

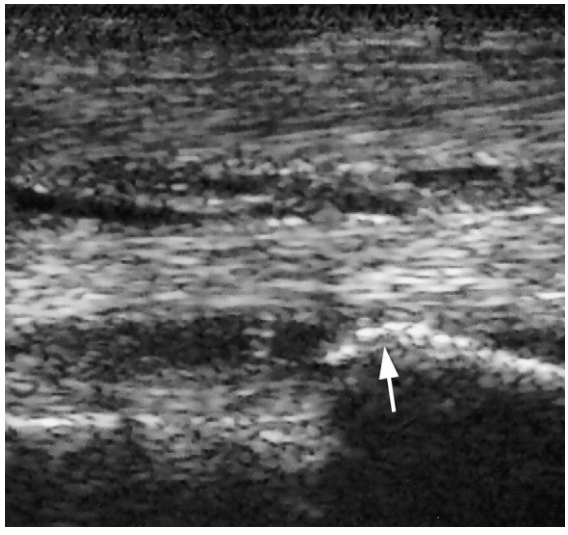

Fig. 73-23 Longitudinal ultrasonographic image of the right front pastern of 7-year-old pleasure riding horse with moderate lameness. Proximal is to the left. A large enthesophyte (*arrow*) is visible on the palmar aspect of the proximal phalanx. The region of insertion of the oblique sesamoidean ligament is reduced markedly in echogenicity. The horse also had osteoarthritis of the proximal interphalangeal joint.

Horses with a primary injury of the distal sesamoidean ligaments have a high incidence of recurrent injury if returned to full athletic function after conservative management. However, horses with primary lameness of another cause may be seen with an enlarged oblique sesamoidean ligament of normal echogenicity, apparently unassociated with clinical signs.

PROGRESSIVE ATRAUMATIC BREAKDOWN OF THE HINDLIMB SUSPENSORY LIGAMENTS

Progressive degenerative changes in hindlimb SLs have been seen in a small number of horses that originally showed PSD and had straight hock conformation. These horses developed hyperextension of the hind fetlock joints (Fig. 73-24). The condition has been characterized by a diffuse decrease in echogenicity of the proximal suspensory ligaments, which

Fig. 73-24 **A,** The hindlimbs of 14-year-old Thoroughbred gelding with hyperextension of the hind fetlocks and soft tissue enlargement around the distal aspect of the branches of the suspensory ligaments. The superficial digital flexor tendon of the right hindlimb was subluxated laterally. **B,** The distal aspect of the suspensory ligament branches of the same horse. Considerable fibrous tissue surrounds the branches. The ligaments were discolored substantially, with no normal-appearing ligamentous tissue.

becomes progressively more extensive distally. A similar clinical condition has been recognized in older horses, especially broodmares, with progressive hyperextension (dorsiflexion) of the hind fetlock joints, which may result in abrasion of the plantar aspect of the fetlocks. Progressive hyperextension of the hind fetlock joints also has been seen in middle-aged performance horses with apparent lengthening of branches of the SL and periligamentous fibrous reaction. Some breeds, including the Peruvian paso and Andalusian horses, seem particularly at risk. The condition is generally bilateral and is associated with a deterioration in hindlimb gait rather than an overt lameness. Secondary lateral luxation of the SDFT from the point of hock occurs occasionally, probably associated with the straight angle of the hock.

The cause of these conditions is not known. They are generally progressive. Flat shoes with plantar extensions help to lift the fetlock and may prevent secondary trauma, but the prognosis for proper athletic function is guarded.

TRAUMATIC DISRUPTION OF THE SUSPENSORY APPARATUS

Traumatic disruption of the suspensory apparatus is discussed on page 359.

CHAPTER • 74

Clinical Use of Stem Cells and Marrow Components to Stimulate Suspensory Ligament Regeneration

Doug Herthel

As a result of 22 years of diagnosing and treating suspensory ligament (SL) injuries and experiencing few advances in returning horses to full soundness, a novel, minimally invasive method of obtaining bone marrow aspirates from an anesthetized patient's sternum and injecting it into damaged ligament was initiated 6 years ago at Alamo Pintado Equine Medical Center. As a result of using fresh autologous stem cells and bone marrow components intralesionally, we were able to accelerate and improve the ultrasonographic quality of ligament healing and return horses to soundness sooner and with much less incidence of recurrence than previously experienced. The technique is a useful alternative and adjunct to other non-invasive and invasive therapies and is safe, economical, and effective. The procedure has been used in more than 500 horses with ligament or tendon damage at the medical center and in hundreds of horses with suspensory desmitis at many private and university equine hospitals in the United States and in Europe.

SCIENTIFIC RATIONALE FOR USING BONE MARROW

Autologous bone marrow contains many of the elements required for ligament regeneration, such as growth and differentiation factors, cell transplants, pluripotential cells (mesenchymal stem cells), and fibrin matrices. Stem cells are primitive undifferentiated cells that exist in bone marrow. These cells have the capacity to reproduce themselves and to form the entirety of bone marrow. In people, bone marrow transplants are used to achieve permanent marrow engraftment. Bone marrow aspirate contains about 2 stem cells per 100,000 cells. Stem cells have potential for limitless replication and differentiation into multiple cell lineages in response to the local environment (e.g., local cytokines and growth factors). One hundred stem cells have the ability completely to repopulate the entire immune system of a laboratory mouse, and 1×10^6 stem cells are enough to repopulate a person's immune system.

Bone marrow aspirates also contain numerous growth factor peptides, macrophages, neutrophils, platelets, fibrinonectin, fibrinogen, and endothelial cells, all of which have potential to facilitate ligament regeneration. Certain growth factors such as platelet-derived growth factor are chemoattractant agents for fibroblasts and can cause migration of these cells to the recipient site. Growth factors can induce mitogenesis of existing cells and up-regulation of extracellular matrix and collagen production. Similar results were seen in dog wound healing studies using transforming growth factor β (TGF-β). Platelet-derived growth factors have the additional ability to stimulate angiogenesis, inducing mitosis and formation of new functioning capillary blood vessels. In our unpublished studies new capillary formation has been prominent after bone marrow injection. Bone marrow contains about 0.06 ng of platelet-derived growth factor per 1 million platelets, or about 1,200 molecules of platelet-derived growth factor per individual platelet. Bone marrow aspirate contains about 6×10^9 platelets per 30 ml. Experimental studies using as little as 2 ng of platelet-derived growth factor applied to laboratory animal wound models increased fibroblast migration, collagen synthesis, and wound strength by 70%. Percutaneous injection of bone marrow for ligament healing was first reported in 1987; platelet-derived growth factor and TGF-β in aspirates enhanced wound healing in rats by stimulating collagen synthesis.[1] Seeding cultured stem cells into a tendon gap resulted in significantly improved repair biomechanics.[2] With the stimulation and signaling of cytokines and growth factors we hypothesized that equine stem cells may have the ability to morph into collagen-producing fibroblasts that may be deficient in damaged equine SLs and that fibroblasts already present in the damaged SL may be stimulated to produce collagen.

SUSPENSORY DESMITIS

Suspensory desmitis is a common musculoskeletal injury in sport horses and is discussed in detail in Chapter 73. Most injuries are mild and heal uneventfully, but some horses develop severe, acute suspensory desmitis or chronic suspensory desmitis that causes protracted clinical signs and horses are prone to re-injury. Many different therapeutic approaches, including ligament splitting, hyaluronan and iodine injections, blistering, pin firing, acupuncture, cold laser, and rest and rehabilitation have been used to promote ligament healing, but success rate is poorly documented.

TECHNIQUE

All horses are placed under general anesthesia and positioned in dorsal recumbency. Aseptic preparation of the affected suspensory ligament and the sternum is performed. A 60-ml syringe attached to a Jamshidi 10-gauge bone marrow needle is used to aspirate 20 to 30 ml of liquid bone marrow from the sternebrae (12 to 15 cm cranial to the xyphoid). Bone marrow is transferred immediately to 6-ml syringes using a sterile three-way stopcock, and lesions are injected through preplaced 18-gauge needles using ultrasound guidance. A total volume of 20 to 30 ml is used for each suspensory lesion, but additional bone marrow can be harvested from other sites in the sternum. No antibiotics or anticoagulants are added to bone marrow to prevent injury or to depress cells and proteins. Multiple lesions are treated with bone marrow aspirated from different locations to prevent dilution of the marrow with blood.

In horses with proximal suspensory desmitis in which dramatic clinical and ultrasonographic evidence of ligament

enlargement existed, concurrent forelimb or hindlimb fasciotomy was performed. Using a medial approach the fascia superficial to the proximal SL was transected to allow direct open injection of bone marrow. In most horses the original 2-cm incision was extended in both proximal and distal directions using a straight Mayo scissors.

RESULTS OF INTRALESIONAL BONE MARROW INJECTIONS

Between October 1995 and December 1998, 100 horses were treated for suspensory desmitis using bone marrow injection. Fifteen horses had concurrent fasciotomy. Horses satisfied one of the following criteria: clinical and ultrasonographic evidence of a severe, acute suspensory desmitis or moderate to severe lameness from chronic suspensory desmitis. Ultrasonographic changes included circumscribed peripheral or central hypoechoic lesions, significant increase in cross-sectional area, loss of ligament margins, and associated third metatarsal or metacarpal bone avulsion fractures, or combinations of these. Some horses were included that lacked substantial evidence of suspensory desmitis, but they had lameness abolished by diagnostic analgesia in the proximal palmar metatarsal or metacarpal regions and a substantial increase in radiopharmaceutical uptake in scintigraphic images.

Nine breeds of horses were represented, including in descending order, Warmbloods, Thoroughbreds, Quarter Horses, Andalusians, Peruvian pasos, Arabians, Standardbreds, Saddlebreds, and Morgans. Horses ranged from 2 to 24 years of age. Eighty-one horses had forelimb suspensory desmitis, and 19 horses had hindlimb suspensory desmitis. The most common sporting activities were dressage, jumping, and racing. Follow-up clinical and ultrasonographic examinations were performed at 60, 90, 120, and 180 days. Two horses had second injections.

After 6 months, 84 horses were sound and had returned to full work. Eight horses improved and went back to work but had mild but manageable lameness. Five horses remained too lame to return to normal work. Three horses died from unrelated causes and could not be followed past 6 months.

In one horse a hematoma developed at the injection site, likely from inadvertent puncture of a nearby artery. In two horses mild lameness was seen for 2 days after surgery, but in all others lameness did not increase at any evaluation period.

DISCUSSION

Although this study lacked controls, results were impressive. Theoretical benefits of bone marrow injection in returning damaged SL to near its previous biochemical, morphological, and biomechanical properties could be expected. Bone marrow injection, compared with natural healing, may improve blood supply and establish cell numbers to produce high-quality collagen and matrix. The clinical results of these 100 horses are promising, and many have competed in upper levels of sporting events. Bone marrow injection can be used for horses with tendonitis of the superficial or deep digital flexor tendons, desmitis of the accessory ligament of the deep digital flexor tendon, and desmitis of the straight distal sesamoidean and sacroiliac ligaments. Based on my clinical and ultrasonographic findings this procedure has proved to be a dramatic advance over conventional therapies and normal healing of these structures.

CHAPTER • 75

Diseases of the Digital Synovial Sheath, Palmar Annular Ligament, and Digital Annular Ligaments

Michael C. Schramme and Roger K.W. Smith

Synovial effusion of the digital synovial sheath is common in all types of working horses. Frequently, effusion is idiopathic in origin and affects the digital sheath of both hindlimbs without causing lameness. Occasionally synovial effusion is seen in a single limb along with lameness. Before the advent of ultrasonography and tenoscopy, injury to the soft tissue structures of the digital synovial sheath often remained unrecognized. The cause of chronic synovial effusion and lameness remained elusive, and a diagnosis of idiopathic tenosynovitis was made readily. Because modern diagnostic techniques have become commonplace in equine lameness practice, specific injuries of the structures of the digital sheath have been identified.

ANATOMICAL CONSIDERATIONS

The detailed anatomy of the digital flexor tendon sheath (DFTS) and its contents has been well described[1] and is similar in forelimbs and hindlimbs. Reference is made to palmar and metacarpal region throughout, but the terms *plantar region* and *metatarsal region* strictly apply to the hindlimb. The DFTS is a thin-walled structure that encompasses the superficial digital flexor tendon (SDFT) and the deep digital flexor tendon (DDFT) from the level of the distal third of the metacarpal region to the T ligament, just proximal to the navicular bursa and the palmar pouch of the distal interphalangeal joint. The DFTS is mesenchymal in cell origin

CHAPTER • 75

Diseases of the Digital Synovial Sheath, Palmar Annular Ligament, and Digital Annular Ligaments

Michael C. Schramme and Roger K.W. Smith

Synovial effusion of the digital synovial sheath is common in all types of working horses. Frequently, effusion is idiopathic in origin and affects the digital sheath of both hindlimbs without causing lameness. Occasionally synovial effusion is seen in a single limb along with lameness. Before the advent of ultrasonography and tenoscopy, injury to the soft tissue structures of the digital synovial sheath often remained unrecognized. The cause of chronic synovial effusion and lameness remained elusive, and a diagnosis of idiopathic tenosynovitis was made readily. Because modern diagnostic techniques have become commonplace in equine lameness practice, specific injuries of the structures of the digital sheath have been identified.

ANATOMICAL CONSIDERATIONS

The detailed anatomy of the digital flexor tendon sheath (DFTS) and its contents has been well described[1] and is similar in forelimbs and hindlimbs. Reference is made to palmar and metacarpal region throughout, but the terms *plantar region* and *metatarsal region* strictly apply to the hindlimb. The DFTS is a thin-walled structure that encompasses the superficial digital flexor tendon (SDFT) and the deep digital flexor tendon (DDFT) from the level of the distal third of the metacarpal region to the T ligament, just proximal to the navicular bursa and the palmar pouch of the distal interphalangeal joint. The DFTS is mesenchymal in cell origin

and is composed of two layers, an outer fibrous layer and an inner synovial layer. The fibrous layer provides strength and vascularity to the sheath. The synovial layer provides a smooth, frictionless surface and produces constituents of the synovial fluid. The palmar wall of the sheath incorporates three annular ligaments: the palmar annular ligament (PAL) and the proximal and the distal digital annular ligaments. These annular ligaments bind the flexor tendons to the palmar aspect of the digit, are effectively thickenings of the fibrous layer of the sheath wall with a transverse fiber orientation, and measure 2 mm or less in thickness.

The PAL or annular ligament of the fetlock joint inserts on the palmar border of the proximal sesamoid bones (PSBs), is continuous with the palmar (intersesamoidean) ligament of the fetlock joint, and thus converts the proximal scutum into an inelastic canal. The strong, transversely arranged fibers of the PAL bind down the flexor tendons into the proximal scutum. Distal to the PAL and immediately under the skin, the deep fascia forms a second, quadrilateral ligament, the proximal digital annular ligament. This ligament is a fibrous sheet that covers and adheres to the palmar surface of the SDFT and attaches laterally and medially by two bands to the proximal phalanx: one to the proximopalmar tuberosity and one that joins the insertion of the distal branch of the SDFT to the distal part of the proximal phalanx. This arrangement firmly binds the SDFT and DDFT, enveloped by the DFTS, in the palmar pastern region. The distal digital annular ligament adheres to the palmar surface of the distal part of the DDFT and binds down the terminal part of this tendon. The ligament is a crescent-shaped fibrous sheet attached by a strong band on either side of the middle of the proximal phalanx, covering the distal branches of the SDFT.

The dorsal wall of the DFTS is formed by the proximal scutum, middle scutum, and distal sesamoidean ligaments. The proximal scutum and the middle scutum are strong fibrocartilaginous pads that allow sliding of the flexor tendons along the palmar aspect of the fetlock and pastern regions, respectively. The proximal scutum is composed of the two PSBs and the thick intersesamoidean ligament. The latter is a thick sagittal structure made of transversely aligned collagen fibers. The intersesamoidean ligament covers and is attached strongly to the whole palmar and axial aspect of the PSBs and creates a solid union between these bones. The concave palmar face of the proximal scutum allows sliding of the flexor tendons in the palmar fetlock region. The proximal scutum extends proximally to the apex of each PSB between the two distal branches of the suspensory ligament (SL). Distally the proximal scutum gives insertion to the distal sesamoidean ligaments, which represent the functional continuation of the SL and consist of the straight, oblique, cruciate, and short distal sesamoidean ligaments. The straight distal sesamoidean ligament inserts distally on the middle scutum, together with the distal branches of the SDFT and the palmar ligaments of the proximal interphalangeal joint. The middle scutum is a thick, fibrocartilaginous structure attached to the proximopalmar aspect of the middle phalanx. The middle scutum contacts the palmar aspect of the distal condyles of the proximal phalanx dorsally and the DDFT palmarly.

Within the DFTS, the SDFT and DDFT are intimately related. A fibrous ring (the manica flexoria) emanates from the lateral and medial borders of the SDFT and encircles the DDFT completely, from the proximal limit of the DFTS to the proximal aspect of the PSBs. The synovial lining of the DFTS adheres to the palmar surface of the SDFT in the sagittal midline proximal to the PAL, along the dorsal surface of the PAL and along the dorsal surface of the proximal digital annular ligament. The synovial lining of the DFTS also adheres to the palmar surface of the DDFT between the proximal digital annular ligament and the distal digital annular ligament, and along the dorsal surface of the distal digital annular ligament. The sagittal adhesion-like mesotenon between the SDFT and PAL is referred to as the vinculum of the SDFT. The DDFT also has a mesotenon that attaches to its palmar surface at the level of the proximal interphalangeal joint (see Fig. 71-1, *B*). These mesotenon attachments contain vascular branches that contribute to the arterial supply of the intra-synovial part of the tendon.

The DFTS facilitates displacement of the flexor tendons during flexion and extension of the fetlock and interphalangeal joints. During metacarpophalangeal (metatarsophalangeal) joint movements, the two flexor tendons displace together, but during interphalangeal joint movements, displacement of the DDFT is greater than that of the SDFT.

DIAGNOSTIC TECHNIQUES

Diagnostic techniques that localize disease to the DFTS include synoviocentesis and synovial fluid analysis and intrathecal or perineural injection of local anesthetic solutions. Synoviocentesis of the DFTS can be performed in one of the several recesses of the sheath. Access to the proximal pouch is possible when the sheath is distended with synovial fluid but difficult when it is not. Synoviocentesis can be achieved by introducing a 2.5-cm needle along the dorsal aspect of the DDFT, between the DDFT and the lateral branch of the SL, a few centimeters proximal to the lateral PSB. Easier access can be gained via the distal palmar pouch of the sheath, which extends between the two distal branches of the SDFT and between the two digital annular ligaments, along the palmar surface of the DDFT. One should remember that this pouch is divided sagittally by the mesotenon of the DDFT in its distal part. The needle therefore should be aimed to access this pouch between the lateral or medial border of the DDFT and the ipsilateral distal branch of the SDFT to minimize the risk of inadvertent needle penetration of the DDFT. The DFTS also can be accessed through its proximal or distal collateral recesses. The proximal collateral recess is situated in the triangular space palmaromedially or palmarolaterally, between the base of a PSB, the proximal insertion of the proximal digital annular ligament, and the dorsal border of the DDFT. The space can be entered 1 cm distal to the base of a PSB and 1 cm palmar or plantar to the neurovascular bundle. The distal collateral recess is located on the lateral (or medial) aspect of the pastern, between the flexor tendons and the distal sesamoidean ligament and between the proximal and distal insertions of the proximal digital annular ligament. A cadaver study has shown that synoviocentesis of the DFTS is most consistently successful when performed at the level of the proximal lateral recess on a non–weight-bearing limb.[2] Ten milliliters of local anesthetic solution is injected for adequate desensitization of the DFTS (see Chapter 10).

Characteristics of synovial fluid of the DFTS do not vary from those of the distal limb synovial joints. Normal synovial fluid is clear yellow and has a nucleated cell count of 770 cells/μl or less and a total protein concentration of 1.0 g/dl or less.[3]

IMAGING OF THE DIGITAL SYNOVIAL SHEATH

Diagnostic ultrasonography is by far the most commonly used technique for evaluating the DFTS. The DFTS is first encountered at level 3A and continues distally to level P1C and beyond (see Chapter 16).[4] The PAL can be demonstrated in normal horses as a thin (1 to 2 mm) echogenic band immediately adjacent to the palmar surface of the SDFT at level 3C. The proximal digital annular ligament and distal digital annular ligament usually cannot be recognized in the palmar

midline, unless they are abnormally thickened. The vinculum of the SDFT at the level of the PSB is easily identifiable by ultrasonography, but the distal mesotenon of the DDFT in the phalangeal region is only occasionally visible, usually when distention of the DFTS provides negative contrast (see Fig. 71-1, *B*). A normal synovial reflection or mesotenon joins the lateral and medial borders of the DDFT in the proximal recess of the DFTS, which should not be mistaken for an adhesion (see Fig. 71-1, *A*). The thickness of the DFTS can be assessed at levels 3A and 3B, where the capsule is identifiable as an echogenic band dorsal to the DDFT and the manica flexoria.

Before the widespread use of ultrasonography for examining the soft tissues of the DFTS, negative contrast radiography was described for the assessment of tenosynovitis and annular desmitis.[5] To perform this technique, a tourniquet is applied distal to the carpus in the standing or anesthetized horse, 50 to 100 ml of air is injected into the DFTS, and another 200 to 300 ml of air is injected subcutaneously. Sometimes extra air is injected between the SDFT and DDFT at mid-metacarpal level. One post-inflation lateromedial radiograph taken at half the milliampere second (mAs) value of standard skeletal exposure for this region is normally sufficient to make an accurate diagnosis. Although this technique effectively demonstrates the thickness of the PAL, its use has become superseded by the widespread availability of diagnostic ultrasound.

Survey radiography of the DFTS is performed to demonstrate evidence of intrathecal air or gas caused by a penetrating wound, the presence of metaplastic mineralization of injured soft tissue structures, or concurrent pathological conditions of the bone. Positive contrast radiography may provide the most conclusive evidence of wound communication with the synovial space. Although fistulography and filling of the intra-thecal space with sterile iodine-based contrast medium is diagnostic of communication between the wound and the DFTS, we prefer to access the DFTS by placing a needle at a site remote from the wound. This minimizes the risk of forcing bacteria or foreign material present in the deeper layers of the wound into the synovial space. Using a remote site further avoids the risk of inadvertently introducing bacteria while passing the needle through an area of cellulitis into the synovial cavity. Infiltration of 10 to 20 ml of sterile contrast medium followed by manipulation of the digit should result in flow of contrast medium from the wound and can be demonstrated radiographically (Fig. 75-1).

Tenoscopy is the ultimate imaging modality for evaluating the internal structures of the DFTS.[6] The endooscope is introduced routinely in the proximal collateral recess of the sheath, 1 cm distal to the base of PSB and 1 cm palmar or plantar to the neurovascular bundle, but access to other synovial recesses is also possible (see Chapter 24). This approach allows for a complete examination of the DFTS and its contents, except for the palmar surface of the SDFT, unless significant thickening of any of the annular ligaments or extensive subcutaneous fibrosis has occurred. The approach also facilitates therapeutic maneuvers within the DFTS, such as PAL desmotomy, adhesiotomy, synovial mass removal, and debridement of fibrillated or torn areas of the flexor tendons, manica flexoria, or intersesamoidean ligament.

The superior soft tissue contrast of magnetic resonance imaging is likely to improve diagnostic imaging of the DFTS in the near future.

Fig. 75-1 Lateromedial radiographic view of the fetlock region. A positive-contrast tenogram of the digital synovial sheath, followed by manipulation of the digit, resulted in flow of radiopaque contrast medium from the wound (*arrow*).

DISEASES OF THE DIGITAL SYNOVIAL SHEATH

Non-Infectious Tenosynovitis

Etiopathogenesis

Acute non-infectious tenosynovitis is a traumatic synovitis/capsulitis of the sheath lining. As for joints, a traumatic synovitis/capsulitis can be caused by accumulative low-grade trauma associated with normal exercise, acute trauma associated with direct impact force (e.g., overreach), or an abnormal force outside the normal range of movement of the fetlock region (e.g., hyperextension). Synovitis/capsulitis can be complicated by damage to the internal or supporting structures of the DFTS, such as disruption of the visceral or parietal synovial layers, tearing of the vincula, tearing of the fibrous capsule with herniation, central or marginal damage to the flexor tendons, tearing of the manica flexoria, and spraining of the PAL or proximal digital annular ligament. Each of these complicating conditions is likely to result in continuous irritation of the sheath and cause chronic tenosynovitis. Chronic tenosynovitis may be associated with villonodular thickening of the sheath lining, especially in the proximal recess; adhesion formation between the visceral and parietal synovial lining; and fibrosis with reduced elasticity of the DFTS capsule. When these conditions are present, a self-perpetuating cycle occurs of improvement with rest, followed by repeat tearing of fibrous tissue (in adhesions and the fibrosed sheath capsule) with exercise. This results in increased inflammation and lameness, further fibrosis, and eventually thickening of the annular ligament and stenosis of the fetlock canal (see the following discussion of annular ligament syndrome). *Complex tenosynovitis* has been defined as tenosynovitis with thickening of the PAL, synovial distention, and adhesions or synovial masses, or both.[7] Windgalls, especially those occurring in the hindlimbs, are another form of low-grade chronic tenosynovitis. Although lameness is not usually a feature of windgalls, the synovial effusion is still likely to reflect the presence of low-grade chronic synovitis of the DFTS, caused by the continuous stress of use-induced overloading.

Diagnosis

Acute tenosynovitis is characterized by a sudden onset of mild to severe lameness, accompanied by DFTS distention that can

Fig. 75-2 Stage 3 tenosynovitis of the digital synovial sheath with adhesions and synovial mass formation (*arrow*).

be palpated in the proximolateral and proximomedial pouches of the sheath and in the palmarodistal recess between both branches of the SDFT. The palmar or plantar region of the fetlock has increased skin temperature, and forced flexion of the fetlock is painful and exacerbates lameness. Chronic tenosynovitis produces similar signs, except for the signs of acute inflammation, although repeat injury may cause these signs to be superimposed on an established tenosynovitis.

Ultrasonographic examination is essential for identifying adhesions and complicating injuries of the flexor tendons (see Figs. 70-7, *B* and 70-8, *A*), the intersesamoidean ligament, or annular ligaments and to document the staging of the condition.[8] DFTS effusion may accompany injury to the intrathecal part of the SDFT associated with a classic bowed tendon (see Chapter 70). However, intrathecal tendon injuries occur more commonly as focal core lesions in the DDFT (see Chapter 71) or as longitudinal tears of the SDFT, DDFT, or manica flexoria.

Tenosynovitis has been described in three ultrasonographic stages of progression.[8] Symmetrical distention of the DFTS, without evidence of synovial proliferation represents stage 1, or the effusive stage of synovitis. More pronounced, often asymmetrical distention of the proximal pouch, which feels firm on palpation and is accompanied by synovial proliferation, is stage 2. In stage 3 synovitis, extensive synovial proliferation occurs with adhesion formation and synovial masses in the sheath. Unless obviously abnormal synovial masses occur within the sheath, the presence of adhesions easily can be overestimated with ultrasonography (Fig. 75-2).

Treatment

Treatment of horses with acute tenosynovitis consists of rest with bandage immobilization, cold therapy, and systemic anti-inflammatory medication. The latter can be commenced with a single systemic dose of a short-acting corticosteroid (dexamethasone phosphate 0.06 mg/kg IV, or betamethasone phosphate 0.04 mg/kg IV), followed by a 5-day systemic course of flunixin meglumine (1.1 mg/kg sid) or phenylbutazone (4.4 mg/kg sid). After the initial 7 to 14 days, in-hand walking can be resumed for a period of 2 weeks, before returning the horse to riding. If the clinical signs have not resolved after 7 to 14 days, intrathecal injection of hyaluronan and a corticosteroid (40 to 80 mg methylprednisolone or 10 mg triamcinolone acetonide) can be considered. However, an intrathecal injection of a corticosteroid may enable a horse with a complicating flexor tendon injury to return to soundness temporarily, thereby potentially allowing it to exacerbate the underlying cause for continued irritation of the digital sheath. The clinician therefore should ensure with the aid of ultrasonographic evaluation that no injuries to the flexor tendons in the DFTS exist before intrathecal corticosteroids are administered. However, one should remember that many marginal tears of the SDFT or the DDFT within the DFTS may not be identifiable with ultrasonography, especially if they are located at the level of the ultrasonographic blind spot beneath the ergot. Measuring the cross-sectional area of each flexor tendon (see Chapter 16) and comparing the same measurements in the contralateral limb may help veterinarians recognize subtle flexor tendon injuries, without obvious changes in echogenicity.

Treatment of horses with chronic tenosynovitis usually involves the aspiration of excess synovial fluid, followed by intrathecal injection of hyaluronan and corticosteroids. In horses that are unresponsive to this treatment, or in horses with complex tenosynovitis (those characterized by thickening and fibrosis of the PAL, adhesions, synovial masses, or focal and accessible tendon lesions), tenoscopic exploration of the DFTS and intrathecal soft tissue debridement are indicated.

Prognosis

The prognosis for horses with acute, uncomplicated noninfectious tenosynovitis is favorable if treatment starts immediately. The prognosis for those with complex tenosynovitis with synovial masses and adhesions is favorable after tenoscopic debridement and PAL desmotomy. In one report, 18 of 25 horses returned to athletic soundness.[7] Tendon injuries have an unfavorable effect on the prognosis for return to athletic soundness. Only 11 of 20 horses with longitudinal tears of the flexor tendons within the DFTS[9] and 7 of 24 horses with DDFT tendonitis within the digital sheath[10] made a full recovery (see Chapters 70 and 71).

Infectious Tenosynovitis

Infectious tenosynovitis is a critical condition in the horse because of the severity of lameness, the difficulty in eliminating infection from the DFTS, and the high risk of long-term sequelae such as adhesions and fibrosis, which contribute to permanent lameness even if infection is eliminated.

Etiopathogenesis

The most common cause of DFTS infection is a penetrating wound. Occasionally, small puncture wounds that readily seal over may not be recognized as the cause of acute, severe lameness associated with DFTS infection. Penetrating injuries to the DDFT in the pastern region are frequently undiagnosed at the outset.[11] Most penetrations in this region lead to infectious tenosynovitis and rarely infectious tendonitis of the DDFT. However, occasionally a traumatic penetration may enter the DDFT through its distal mesotenon and form a localized abscess that remains separate from the intrathecal space, thereby preventing infectious tenosynovitis. Infection may also occur after intrathecal injection or surgery of the PAL. Rarely hematogenous spread of infection to the digital sheath may result from bacteremia.

Diagnosis

Heat and effusion of the DFTS and severe lameness are classic signs of DFTS infection. Typically horses are reluctant to put the heel of the affected limb to the ground. Exception to this may be seen in horses with an open wound to the DFTS that allows free drainage of infected synovial fluid. The reduction in intrathecal pressure and bacterial numbers provided by continuous flow of synovial fluid may reduce inflammation and lameness considerably. With a closed wound, however, the affected sheath is grossly distended. Generalized and painful

lower limb edema caused by cellulitis associated with the entry wound may hinder specific palpation that would aid in identifying DFTS distention. Horses with penetrating injuries to the DDFT in the pastern region are characterized by moderate to severe lameness, localized swelling in the pastern, and a pronounced pain response to focal pressure on the palmar surface of the DDFT in the pastern region.

Radiography and ultrasonography are useful to recognize complicating factors such as osteomyelitis, concurrent tendon injury, foreign bodies, and infectious tendonitis. Contrast radiography may help confirm a penetrating tract. In the absence of a penetrating tract, confirmation of the diagnosis relies on synovial fluid analysis. This should be performed as early as possible when DFTS infection is suspected. A total nucleated cell count greater than or equal to 30,000/μl, with more than 90% neutrophils, and a total protein concentration greater than or equal to 4.0 g/dl is considered pathognomonic for infection. Attempts should be made to identify bacteria by Gram stain and culture. Using broth culture bottles enhances the likelihood of obtaining a positive culture. Bacteria cultured from wounds or draining tracts are not representative of intrathecal bacterial populations. Positive cultures have been reported from 67% to 81% of infectious tendon sheaths.[12] Of the positive cultures in one study, 46% were mixed cultures. *Streptococcus* and *Klebsiella* species were the most common isolates from adult horses with infectious tenosynovitis.[13] In another study, iatrogenic synovial infection was more likely to result in a pure culture of *Staphylococcus aureus*, where as Enterobacteriaceae were most frequently cultured from synovial sepsis caused by a penetrating wound.[14]

Treatment

As for joint infections (see Chapter 66), the principles of antimicrobial therapy, synovial debridement, and drainage apply to infections of the DFTS. Treatment of infectious tenosynovitis must consist of aggressive intrasynovial and systemic broad-spectrum antimicrobial therapy with lavage of the sheath. Regional intravenous perfusion of antibiotics,[15] slow-release antibiotic-depot systems in collagen or polymethylmetacrylate,[16,17] and antibiotic infusion pumps (MILA Joint Infusion System; MILA International, Inc., Florence, KY)[18] all have been used to maximize the intra-thecal concentration of antibiotics over a protracted period of time.

Although primary closure of an open DFTS shortly after injury usually is indicated, closure may be contraindicated in some horses with extensive contamination, because closure may trap bacteria in the sheath. In such horses, cleaning the wound thoroughly and maintaining it under sterile wraps to allow for healing by second intention to occur may be preferable, or consideration may be given to delayed closure when the wound is sufficiently clean and lameness has resolved.[12]

The ideal surgical treatment for DFTS infection consists of tenoscopic debridement of fibrin, adhesions, and synovial masses along with simultaneous lavage. Transection of the PAL often relieves pain that results from excessive fluid accumulation and fibrosis and thickening of the sheath wall. This is best performed through a tenoscopic approach to minimize the risk of wound dehiscence that accompanies a transcutaneous approach. After tenoscopy, portals usually are closed or can be left open for continued drainage. Indwelling fenestrated drains may be placed at surgery for continued through-and-through lavage. Fenestrated polyvinylchloride or silicone drains are preferable to Penrose drains, because they allow for lavage and drainage. The drain is covered with a sterile dressing under a bulky pressure bandage, and lavage is continued twice daily for 3 to 5 days. Because adhesion formation and fibrosis are the most common causes for surviving horses' failure to return to the intended use, specific recommendations have been made to reduce the incidence of these crippling complications. After removal of the drain and healing of the skin portals, hyaluronan is injected into the sheath at 14-day intervals to reduce adhesion formation. These injections are best started between 7 and 14 days after injury during the time of fibrosis and adhesion formation. Early passive motion and hand-walking exercise have been advocated to prevent restriction of range of motion.[12,13]

Elevation of the heel often causes improved weight bearing and ambulation during this period. Cast immobilization of the distal limb is contraindicated during treatment for DFTS infection if the flexor tendons are intact. Although immobilization limits recurrent inflammation associated with continuous movement of the damaged tissues, it limits drainage and promotes the restrictive nature of any scar tissue and adhesions. However, immobilization effects more rapid soft tissue healing and is therefore indicated to decrease wound motion once infection has been resolved. A commercial or homemade splint is adequate for immobilization.

Prognosis

Horses with wounds of the DFTS have a good prognosis for return to soundness if the wound is diagnosed and treated before infectious tenosynovitis develops. If infection occurs, the prognosis is guarded. Although the prognosis for elimination of infection and survival is good in most studies (as high as 100% in one study[14]), another study reported a 45% failure of return to soundness and intended use for horses with infectious DFTS tenosynovitis. Even if infection can be resolved successfully, digital sheath fibrosis, adhesions, and occasionally tendon rupture or osteomyelitis of the PSB may cause permanent lameness. Most authors believe that the chance of resolution is related directly to the duration of infection.[12]

ANNULAR LIGAMENT SYNDROME

Etiopathogenesis

The PAL counteracts a tendency of the PSBs to move in a dorsal and abaxial direction during weight bearing. The distal branches and the extensor branches of the suspensory ligament effect strong traction in a dorsal direction at the respective insertion sites on the abaxial surface of the PSBs during extension of the fetlock joint. This traction is balanced by the intersesamoidean ligament and the PAL.[1] The role of disease of the PAL as a cause of lameness is a subject of debate. Thickening of the PAL has been associated with lameness in a number of different diseases of the DFTS and associated structures. All of these diseases have characteristic clinical manifestation of distention of the DFTS and thickening of the PAL in common and have therefore as a group been referred to as *annular ligament syndrome.* Other terms that have been used to describe this clinical presentation include *stenosis of the fetlock canal, annular ligament constriction, fetlock canal dysfunction,* and *stenosing palmar ligament desmitis.* The role of desmitis in this syndrome is supported by histopathological evidence of chronic inflammation and repair tissue in PAL biopsies from horses with clinical disease.[19,20] Undoubtedly, however, the cause of PAL desmitis is multifactorial. Direct external trauma to the PAL may be caused by laceration or by direct impact (e.g., overreach). Overextension of the fetlock at high speed is likely to be associated with high tensile forces in the PAL and may lead to injury and failure of the PAL under tension. Excessive tendon swelling within the DFTS, although uncommon, may result in sustained pressure on and inflammation of the PAL (see Chapter 70). Finally, chronic inflammation of the DFTS (non-infectious or infectious tenosynovitis) leads to fibrosis and thickening of the fibrous part of the DFTS capsule, which includes the PAL. In some horses the subcutaneous connective tissue in the area of the PAL becomes greatly thickened and fibrotic. Once an inflammatory response is initiated, the PAL becomes thick-

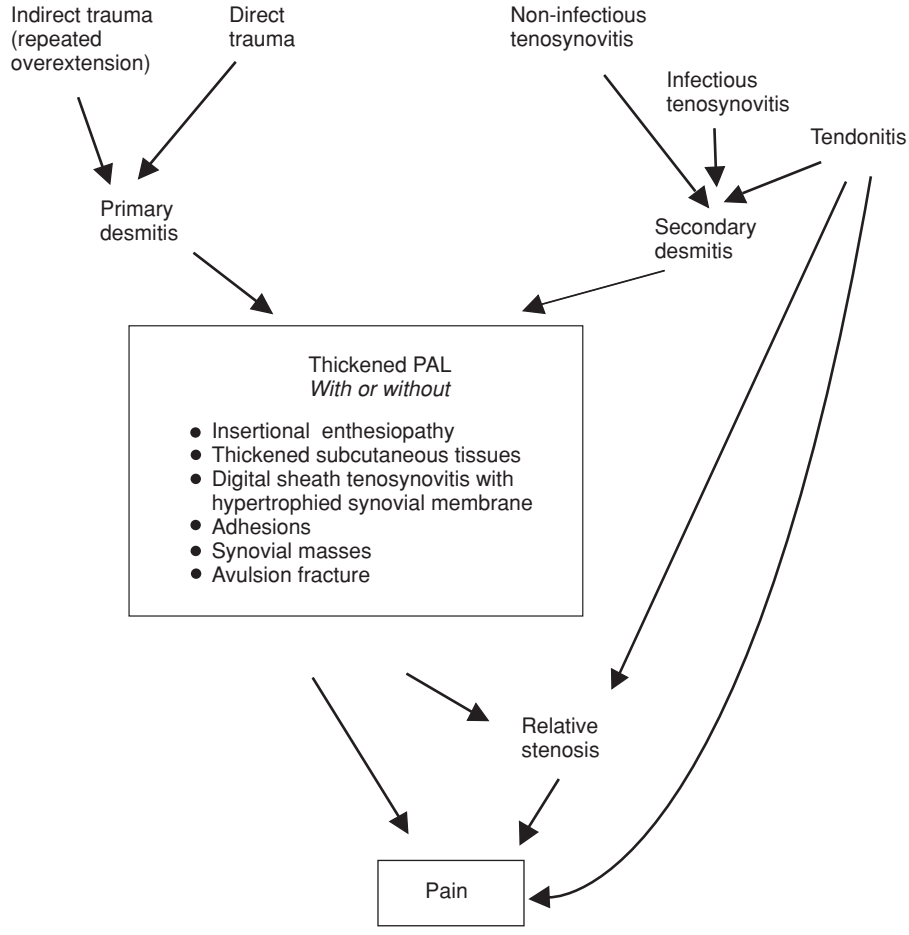

Fig. 75-3 Etiopathogenesis of palmar annular ligament (*PAL*) syndrome.

ened, whatever the cause. Thickening of the PAL reduces the space within the fetlock canal and results in a relative stenosis. The continuous pressure from the tendons associated with this relative stenosis is a source of trauma and perpetuates this sequence of events, leading to further inflammation, fibrosis, and thickening of the PAL and persistent pain (Fig. 75-3).

A positive relationship exists between incidence of desmitis and increasing age of the patient, a predisposition in some breeds (Paso Fino and Warmbloods), and location (especially hindlimbs in the mentioned breeds).[19] Rarely, small avulsion fractures may occur at the site of insertion of the PAL to the palmar border of the PSB after overextension injury or local trauma (see page 666 and Fig. 73-17).[21]

Diagnosis

Occasionally, acute lameness may be caused by acute PAL desmitis without tenosynovitis. Clinical signs include localized heat, swelling, and pain on palpation of the palmar aspect of the fetlock. The clinical signs of the more common chronic PAL syndrome are characteristic. Horses have long-term, persistent, mild to moderate lameness that improves little with rest and worsens with return to exercise. A fetlock flexion test exacerbates lameness. DFTS distention with a notch in the palmar outline of the fetlock is virtually pathognomonic for the syndrome (Fig. 75-4). This notch is caused by the inability of the DFTS to distend at the site of intimate attachment between the SDFT and the dorsal surface of the thickened, inelastic PAL. Sometimes enlargement of the PAL or the overlying subcutaneous tissues results in a localized bulge rather than a notch over the palmar aspect of the fetlock region. Extension of the affected fetlock often is decreased during weight bearing at walk or trot, and occasionally affected horses are reluctant to put the heel of the affected foot to the ground. This splinted fetlock posture is assumed by the affected horse to decrease pressure of the flexor tendons on the inflamed PAL.

Lameness often is improved, but not always completely eliminated by, intrathecal analgesia. The response to a low four- or six-point nerve block is often better. Sometimes an abaxial sesamoid nerve block improves lameness. Fibrosis of the PAL and DFTS may result in mechanical gait restriction, which cannot be abolished totally by regional analgesia.

Various imaging techniques can be used to support the clinical diagnosis of PAL desmitis. In horses with chronic lameness, entheseous new bone may be present at the PAL insertions on the palmar border of one or both PSBs. Air tenography or ultrasonography must be used to demonstrate thickening of the PAL or the overlying subcutis. The ultrasonographic appearance of the diseased PAL differs between affected horses and may be helpful in differentiating the etiopathogenic mechanisms behind each injury. The unaffected PAL can be difficult to identify because it is only 1 to 2 mm thick, and imaging the ligament in the sagittal mid-line is complicated by the vinculum between the PAL and the SDFT, which makes resolution of the ligament difficult. The PAL is identified most easily at its attachment to the PSB by tilting the transversely positioned transducer laterally or medially from the palmar midline. The ligament then can be followed toward the midline. Several measurements of the thickness of the PAL should be made on transverse and longitudinal images to obtain reliable data. Because of the difficulties in consistently

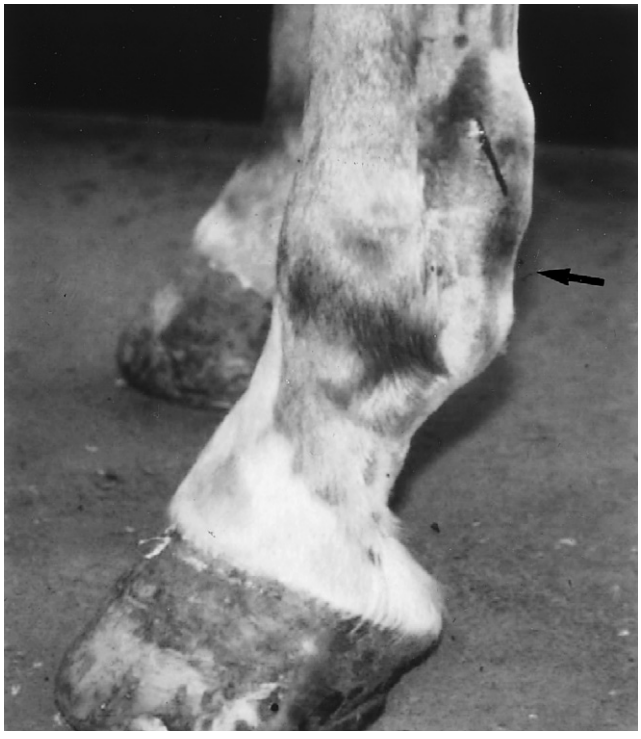

Fig. 75-4 Digital sheath distention with characteristic notch in the plantar outline of the fetlock region (*arrow*) in a horse with plantar annular ligament syndrome.

identifying the PAL, some clinicians have proposed measuring the distance between the palmar surface of the SDFT and the skin surface.[22] Any increase in thickness over 5 mm is considered to be abnormal. However, three different structures are in this region, each of which can be thickened to varying degrees: the subcutaneous tissues, the PAL, and the parietal and visceral layers of the synovial membrane of the DFTS.

Primary Palmar Annular Ligament Thickening

Primary PAL thickening is characterized by ultrasonographic evidence of thickening of the PAL, without evidence of pathological conditions of the structures within the DFTS (Fig. 75-5). Although tenosynovitis is present, the synovial lining of the sheath is not substantially thickened. With acute desmitis the ligament is enlarged and contains focal hypoechoic areas, or it is diffusely hypoechoic.

Primary Tenosynovitis with Secondary Palmar Annular Ligament Thickening

Ultrasonographic differentiation between secondary PAL thickening and primary desmitis is sometimes difficult, but the synovial lining of the DFTS usually is considerably thickened, including the lining at the level of the PAL (Fig. 75-6). Horses with chronic, complex tenosynovitis may have adhesions and synovial masses.

Subcutaneous Fibrosis with a Normal or Minimally Enlarged Palmar Annular Ligament

Subcutaneous fibrosis in the region of the PAL can produce clinical signs similar to those of PAL thickening and often can be distinguished only by careful ultrasonographic imaging (Fig. 75-7). These injuries frequently are caused by focal trauma to the PAL area and can involve portions of the PAL and the surface of the underlying SDFT.

Tendon Injuries with Secondary Palmar Annular Ligament Thickening

Injuries of the SDFT, manica flexoria, or DDFT within the fetlock canal may result in inflammatory tenosynovitis, which also can lead to PAL thickening. Although tendonitis usually

can be diagnosed by ultrasonography, many focal longitudinal tears of the SDFT and DDFT remain undetected, especially if they are located at the level of the ultrasonographic blind spot beneath the ergot.

Treatment and Prognosis

Treatment of horses with acute desmitis with rest and topical anti-inflammatory medication often results in rapid resolution of lameness and swelling. In many horses, however, PAL desmitis becomes a chronic condition, treatment of which requires surgical release (desmotomy) of the inflamed and thickened PAL. Desmotomy resolves pain from traction on the ligament during weight bearing and eliminates pressure from structures within the stenotic fetlock canal on the PAL. This can be per-

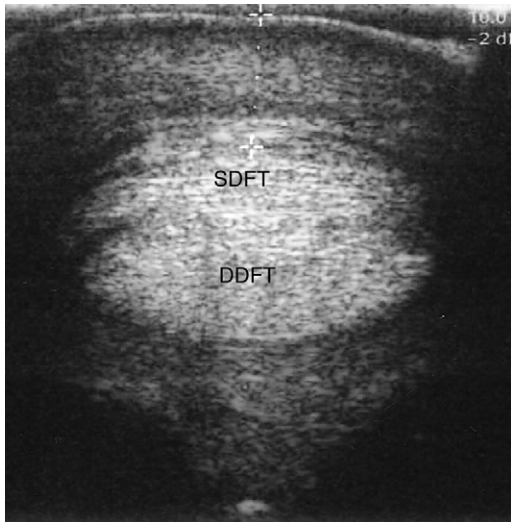

Fig. 75-7 Transverse ultrasonographic image of the distal metacarpal region. There is subcutaneous fibrosis, with minimal thickening of the palmar annular ligament, associated with clinical signs of palmar annular ligament syndrome. Although the distance from the skin to the plantar surface of the superficial digital flexor tendon amounts to 9.19 mm (+ to +), the palmar annular ligament is only 1.59 mm thick. *SDFT,* Superficial digital flexor tendon; *DDFT,* deep digital flexor tendon.

formed via a traditional surgical approach, using an open or a closed technique. A minimally invasive approach through a small skin incision in the proximal recess of the digital sheath is simple and quick, but subcutaneous transection of the PAL is performed blind (see Chapter 70). An alternative tenoscopic technique has been described.[6] Tenoscopically guided PAL desmotomy can be performed with a slotted canula used for carpal tunnel release in people (Smith & Nephew Dyonics Inc, Andover, MA; AM Surgical, Smithtown, NY), or by direct tenoscopic evaluation and use of a freehand, angle-tip knife or Metzenbaum scissors. Tenoscopy offers the advantage of enabling the surgeon to evaluate the entire DFTS and treat any concurrent pathological conditions, such as adhesions, synovial masses, and longitudinal tendon tears, simultaneously. However, passing a 5-mm arthroscope from distal to proximal through a severely constricted fetlock canal can be difficult, especially in smaller breeds. A minimally invasive approach (incisional or tenoscopic) decreases the risk of wound dehiscence and fistulation and allows for earlier, safe return to exercise. If a traditional open approach is used, particular attention should be paid to careful closure of the subcutaneous tissues in two layers, and of the skin, to minimize the risks of synovial fistulation and wound dehiscence. Contrary to previous reports, our opinion is that horses that have undergone an open surgical approach to the DFTS should not be returned to exercise before healing of the incisional wound is complete. Instead the horse should be confined to a stable and the limb enclosed in a firm, padded bandage until the time of suture removal at 2 weeks. After this, a gradually increasing exercise regimen can be initiated (2 weeks walking in hand, 4 weeks lunging) before return to ridden work. Some authors report the need for 4 to 6 months of rest and controlled exercise before soundness can be expected.[22]

Specific recommendations for treating PAL syndrome can be made according to the specific ultrasonographic characteristics. Unresponsive primary desmitis requires PAL desmotomy. In horses with primary tenosynovitis with secondary PAL desmitis, therapeutic planning should be aimed at discovering and treating the primary cause of the synovitis (e.g., infection, traumatic tendon injuries, and hypertrophic synovitis), with or without PAL desmotomy. Tenoscopy is indicated in these horses.

If the stenotic effect is caused by extensive subcutaneous fibrosis over the PAL, conservative management with rest and anti-inflammatory medication is occasionally successful in resolving lameness. However, if this approach fails to bring resolution, surgical release of the PAL and subcutaneous ring of fibrosis may resolve lameness. Lameness associated with small avulsion fractures of the palmar border of the PSB may be relieved by PAL desmotomy near its insertion site. In one study, however, three horses regained soundness without surgery after a prolonged period of 3 to 6 months of controlled exercise.[21] Finally the resolution of tendonitis of the SDFT or DDFT within the DFTS may be assisted by PAL desmotomy, although the benefit of surgical treatment has proved less obvious in these horses.[10,22] In spite of these reports, PAL desmotomy has proved useful in managing SDF tendonitis in Standardbreds (see Chapter 70).[23] The prognosis after surgical desmotomy is generally favorable for soundness in horses with desmitis of the PAL without tendonitis and has ranged from 64% to 87%.[7,22] Factors with a negative influence on outcome are the presence of tendonitis, infection, or adhesions. Although in one study, adhesions reduced the return to soundness to 44% after PAL desmotomy,[22] a recent study showed that 72% of horses with complex tenosynovitis made a full recovery after tenoscopic debridement and PAL desmotomy.[7]

DISEASES OF THE INTERSESAMOIDEAN (PALMAR) LIGAMENT OF THE FETLOCK

Etiopathogenesis

When the fetlock overextends, the proximal scutum slides distally to the metacarpal condyle and its palmar surface undergoes pressure from the flexor tendons. Moreover, in this position the distal and extensor branches of the SL induce high tension on the abaxial surface of the PSBs, thus creating high tension on the intersesamoidean ligament.[24] The effect of these forces could provide a biomechanical explanation for injuries to the intersesamoidean ligament. Post-mortem examination of 305 pairs of PSBs revealed radiological changes in 25.8% and gross abnormalities of the intersesamoidean ligament in 25.9%,[25] although pre-mortem recognition of intersesamoidean ligament pathological conditions causing lameness has been considerably less common.[24] Diseases of the intersesamoidean ligament have been classified by the ultrasonographic and radiographic appearance as rupture of the intersesamoidean ligament, avulsion fracture of the intersesamoidean ligament from the PSBs, desmitis of the intersesamoidean ligament (non-infectious and infectious), and enthesopathy of the intersesamoidean ligament.[24,26-28] Infectious desmitis and axial osteomyelitis of the PSBs usually are associated with infectious arthritis of the fetlock joint or infectious tenosynovitis of the DFTS. Which condition precedes the other is not always obvious. If infectious desmitis or osteomyelitis is the primary condition, a hematogenous route for the infection is likely.

Diagnosis

Injuries of the intersesamoidean ligament usually cause acute-onset, moderate to severe lameness. Enthesopathy with thinning of the intersesamoidean ligament and erosion of the flexor surface of the corresponding PSB may have a more insidious course. Avulsion fractures of the axial border of the PSBs often are accompanied by fetlock effusion. Lameness accompanying these conditions is improved, but not always abolished, by intra-synovial analgesia of the fetlock joint or the DFTS and is eliminated by a low four-point block. Scintigraphy may be required to find the exact site of the

pathological condition. In horses with suspected infectious desmitis or osteomyelitis, cytological examination of synovial fluid of the fetlock joint or DFTS often, but not always, indicates synovial infection.

Diagnosis of injury to the intersesamoidean ligament and associated structures mainly is based on abnormal imaging features. Evidence of osseous fragmentation or lysis along the axial border of the PSB, predominantly centered at the proximal half of the intersesamoidean space, indicates desmitis, enthesopathy with osteitis, avulsion fracture, or osteomyelitis. Evidence of osteolysis also may be observed along the flexor surface of the PSB in association with enthesopathy of the intersesamoidean ligament. Ultrasonographic abnormalities include enlargement of the distance between both PSBs with intersesamoidean ligament rupture (>6 mm), enlargement of the intersesamoidean ligament, and alteration of the echogenicity within the intersesamoidean ligament in case of desmitis, and asymmetrical reduction in the thickness of the intersesamoidean ligament and irregular bony outline to the flexor surface of a PSB in association with enthesopathy.

Treatment and Prognosis

No effective treatment exists for rupture of the intersesamoidean ligament with abaxial displacement of the PSB or for enthesopathy with thinning and degeneration of the intersesamoidean ligament within the DFTS, and the prognosis for soundness in either situation is grave. We have observed complete recovery in a general purpose riding and jumping horse with intersesamoidean desmitis and a small avulsion fracture of the axial border after a prolonged period of confinement (6 months). Some reports also have documented favorable outcome for horses with non-infectious desmitis with or without avulsion fracture, after arthroscopic removal of fracture fragments and debridement of the osteochondral defect and the associated discolored area of the intersesamoidean ligament.[27,28] Histological evaluation of the damaged intersesamoidean ligament in these horses revealed chronic inflammation and granulation tissue, with thrombosis of the microvasculature. All horses with non-infectious desmitis treated surgically in one study returned to previous level of performance, although the horses' intended uses were not mentioned.[27] Recovery time was 7 to 12 months. In the same study, similar treatment was generally unsuccessful for horses with infectious desmitis and osteomyelitis.[27]

DISEASES OF THE DIGITAL ANNULAR LIGAMENTS

Desmitis and avulsion fractures of the proximal insertion sites of the proximal digital annular ligament may occur.

Etiopathogenesis

Hyperextension of the fetlock causes differential movement between the SDFT and the proximal phalanx. The proximal digital annular ligament is adhered intimately to the palmar surface of the SDFT in this region, and the proximal digital annular ligament inserts to the proximal phalanx at two levels, thus this differential movement may result in injury of the proximal digital annular ligament or its insertions. Additionally, external trauma to the palmar aspect of the pastern may result in desmitis of the proximal digital annular ligament. Desmitis of the proximal digital annular ligament also has been described in association with injury of the SDFT or infectious tenosynovitis with thickening of the DFTS in horses with infectious desmitis and osteomyelitis.[29] It has been suggested that thickening of the proximal digital annular ligament or fibrosis of the subcutaneous tissues on the palmar aspect of the pastern may result in functional constriction of the DFTS and the flexor tendons, causing lameness, as is the case with the palmar annular ligament syndrome.[30]

Diagnosis

Characteristic clinical findings in horses with desmitis of the proximal digital annular ligament are soft tissue thickening in the palmar pastern region, prominent palmar protrusion of the DFTS distal to the proximal digital annular ligament, and abolishment of lameness by an abaxial sesamoid nerve block or intra-thecal analgesia of the DFTS. Ultrasonography provides a definitive diagnosis. The normal proximal digital annular ligament is not visible on ultrasonographic examination, but the palmarodorsal thickness of the combined skin–proximal digital annular ligament layer should not exceed 2 mm. In horses with proximal digital annular desmitis, this distance increased to 4 to 5 mm (Fig. 75-8).[30] It is important to rule out pathological conditions of the flexor tendons or distal sesamoidean ligaments as causes of soft tissue swelling in the palmar pastern region (see Chapter 83).

Avulsion fractures of the proximal insertion of the proximal digital annular ligament were seen as a cause of lameness in three horses.[31] There were few localizing signs, and diagnosis relied on response to nerve blocks and radiography. Radiographs showed an avulsion fracture fragment at the insertion site of the proximal digital annular ligament on the palmarolateral or palmaromedial border of the proximal phalanx (Fig. 75-9).

Treatment

Desmitis of the proximal digital annular ligament with constriction of the DFTS was treated successfully in two horses by desmotomy of the proximal digital annular ligament.[30] Two horses with avulsion fractures of the proximal digital annular ligament were treated with 2 months of rest alone and one with 6 weeks of immobilization, followed by 6 weeks of rest. All three horses returned to the previous level of performance.[31]

SYNOVIAL GANGLION OR HERNIA OF THE DIGITAL SYNOVIAL SHEATH

A synovial hernia or ganglion is a thin-walled cyst originating from a tendon sheath or joint capsule.[32] Hernias of the DFTS result from a traumatic defect in the fibrous layer of the

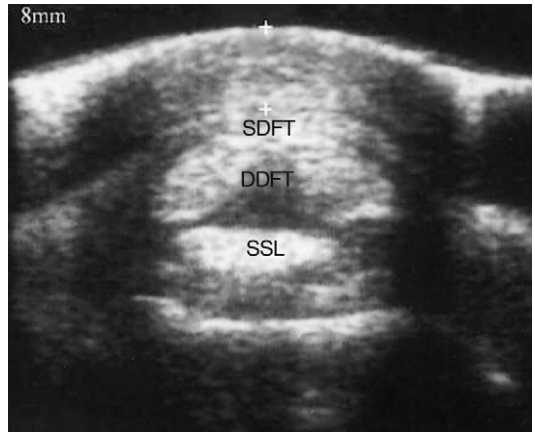

Fig. 75-8 Transverse ultrasonographic image of the proximal pastern region of a hindlimb. The distance from the skin surface to the plantar surface of the SDFT (*+* to *+*) is enlarged to 8 mm in this horse with chronic desmitis of the proximal digital annular ligament. *SDFT,* Superficial digital flexor tendon; *DDFT,* deep digital flexor tendon; *SSL*, straight sesamoidean ligament.

tendon sheath wall, allowing the synovial lining to herniate through it. Subsequent irritation to the hernial sac causes secretion of synovium and filling of the sac. The opening in some hernial sacs or ganglions can act as a one-way valve that prevents movement of synovial fluid back to the digital sheath. Injection of a radiopaque dye into the DFTS has resulted in flow of the dye from the parent synovial cavity into the ganglion (Fig. 75-10), but not vice versa. We have encountered such a ganglion at the level of the proximolateral recess of the DFTS in a hindlimb in two Warmbloods, associated with mild lameness, which was increased by lower limb flexion. Intrathecal analgesia of the DFTS abolished the lameness. Surgical exploration revealed a cystic structure, connected to a small slit-like opening in the DFTS wall. Resection and closure of the DFTS wall defect resulted in complete resolution of lameness.

CHAPTER • 76

The Carpal Canal and Carpal Synovial Sheath

Sue J. Dyson

ANATOMY

The carpal canal encloses the carpal synovial sheath, which contains the superficial (SDFT) and deep (DDFT) digital flexor tendons. The dorsal wall of the carpal canal is formed by the common palmar ligament of the carpus, which is a thickened part of the fibrous joint capsule that extends distally as the accessory ligament of the DDFT (ALDDFT). Proximally the accessory ligament of the SDFT (ALSDFT) forms the medial wall of the canal. Laterally the carpal canal is formed by the accessory carpal bone and the accessorioquartale and accessoriometacarpeum ligaments extending distally. The caudal antebrachial fascia, flexor retinaculum, and palmar metacarpal fascia form the palmar aspect of the canal.

The carpal synovial sheath extends from 7 to 10 cm proximal to the antebrachiocarpal joint to the mid-metacarpal region. The proximal recess is wide and extends between the ulnaris lateralis and lateral digital extensor muscles laterally, but it is firmly supported on the medial aspect by the antebrachial fascia. The distal recess extends between the DDFT and its accessory ligament. If the carpal sheath is distended, swelling can be seen on the lateral aspect of the distal antebrachium and between the DDFT and its accessory ligament, medially or laterally in the metacarpal region.

The ALSDFT arises from the caudomedial aspect of the radius about 10 cm proximal to the antebrachiocarpal joint. The ALSDFT is a fibrous fan-shaped band that merges with the SDFT at the level of the antebrachiocarpal joint and prevents overload of the SDFT muscle during overextension of the metacarpophalangeal joint. After desmotomy of the ALSDFT, load on the SDFT is increased.[1] At the level of the distal radius is an extension from the lateral aspect of the sheath wall between the SDFT and DDFT. At the level of the accessory carpal bone is a mesotendon extending from the lateral aspect of the DDFT to the sheath wall. In clinically normal horses the amount of fluid within the carpal sheath varies, but it is usually the same bilaterally in each horse.

Fluid within the sheath may be seen readily by ultrasonography between the DDFT and its accessory ligament in normal horses, with no palpable distention of the sheath wall.[2] Within the proximal part of the carpal sheath the SDFT and DDFT contain muscular tissue and therefore on ultrasonographic examination have hypoechoic regions within them.[3] However, the ALSDFT is uniform in its echogenicity.[4] The position of the accessory carpal bone prohibits ultrasonographic examination from the caudal aspect of the carpus. The carpal sheath and its contents are evaluated most easily from the caudomedial aspect of the distal antebrachium and carpus and the palmar aspect of the proximal metacarpal region. The

CHAPTER • 76

The Carpal Canal and Carpal Synovial Sheath

Sue J. Dyson

ANATOMY

The carpal canal encloses the carpal synovial sheath, which contains the superficial (SDFT) and deep (DDFT) digital flexor tendons. The dorsal wall of the carpal canal is formed by the common palmar ligament of the carpus, which is a thickened part of the fibrous joint capsule that extends distally as the accessory ligament of the DDFT (ALDDFT). Proximally the accessory ligament of the SDFT (ALSDFT) forms the medial wall of the canal. Laterally the carpal canal is formed by the accessory carpal bone and the accessorioquartale and accessoriometacarpeum ligaments extending distally. The caudal antebrachial fascia, flexor retinaculum, and palmar metacarpal fascia form the palmar aspect of the canal.

The carpal synovial sheath extends from 7 to 10 cm proximal to the antebrachiocarpal joint to the mid-metacarpal region. The proximal recess is wide and extends between the ulnaris lateralis and lateral digital extensor muscles laterally, but it is firmly supported on the medial aspect by the antebrachial fascia. The distal recess extends between the DDFT and its accessory ligament. If the carpal sheath is distended, swelling can be seen on the lateral aspect of the distal antebrachium and between the DDFT and its accessory ligament, medially or laterally in the metacarpal region.

The ALSDFT arises from the caudomedial aspect of the radius about 10 cm proximal to the antebrachiocarpal joint. The ALSDFT is a fibrous fan-shaped band that merges with the SDFT at the level of the antebrachiocarpal joint and prevents overload of the SDFT muscle during overextension of the metacarpophalangeal joint. After desmotomy of the ALSDFT, load on the SDFT is increased.[1] At the level of the distal radius is an extension from the lateral aspect of the sheath wall between the SDFT and DDFT. At the level of the accessory carpal bone is a mesotendon extending from the lateral aspect of the DDFT to the sheath wall. In clinically normal horses the amount of fluid within the carpal sheath varies, but it is usually the same bilaterally in each horse.

Fluid within the sheath may be seen readily by ultrasonography between the DDFT and its accessory ligament in normal horses, with no palpable distention of the sheath wall.[2] Within the proximal part of the carpal sheath the SDFT and DDFT contain muscular tissue and therefore on ultrasonographic examination have hypoechoic regions within them.[3] However, the ALSDFT is uniform in its echogenicity.[4] The position of the accessory carpal bone prohibits ultrasonographic examination from the caudal aspect of the carpus. The carpal sheath and its contents are evaluated most easily from the caudomedial aspect of the distal antebrachium and carpus and the palmar aspect of the proximal metacarpal region. The

heterogeneous echogenicity of the flexor tendons proximally can make definitive diagnosis of a tendon lesion difficult. Endoscopic evaluation may yield further information and permit surgical debridement of torn fibers (see Chapter 24).

The transverse ridge of the distal radius is at about the same level as the distal physis. Irregular roughening of this ridge may be seen radiographically in normal horses and should not be confused with entheseous new bone associated with tearing of the attachment of the ALSDFT further proximally.

CLINICAL SIGNS

Lameness associated with the carpal synovial sheath almost invariably is associated with some distention of the sheath. The horse may have restricted flexibility of the carpus, with pain on passive flexion. Rarely, increased pressure within the carpal sheath may result in compromised blood flow within the median artery and reduction in arterial pulse amplitudes in the more distal part of the limb.[5] Palpation of the structures within the proximal part of the carpal sheath is not possible, but in the metacarpal region the SDFT, DDFT, and ALDDFT should be assessed carefully. Lameness varies from mild to severe and usually is improved by intrathecal analgesia. Clinical investigation should include radiographic and ultrasonographic examination. Carpal sheath effusion also may occur secondary to cellulitis in the antebrachial or metacarpal regions (see Chapters 14 and 38).

IDIOPATHIC SYNOVITIS

Synovitis of the carpal sheath usually results in acute-onset, moderate to severe unilateral lameness associated with distention of the carpal sheath. No palpable abnormalities of the flexor tendons are apparent. Ultrasonographic examination reveals an abnormal amount of fluid within the sheath but no other structural abnormality. Horses usually respond well to box rest and controlled walking exercise for 4 to 6 weeks, combined with intrathecal administration of corticosteroids and hyaluronan.

INTRATHECAL HEMORRHAGE

Hemorrhage within the carpal sheath may be idiopathic, result from trauma (e.g., a fall), or occur secondary to a fracture of the accessory carpal bone (see pages 391 and 686). The horse may be very lame. Diagnosis is confirmed by synoviocentesis. The fluid within the sheath may appear more echogenic than synovial fluid. Careful ultrasonographic examination of the flexor tendons and the retinaculum should be performed to identify any primary lesion. In the absence of a primary tendon lesion and fracture, some relief of pain may be gained by draining blood from the sheath. This should be followed by administration of hyaluronan to reduce the risks of subsequent adhesion formation.

TRAUMA RESULTING IN CHRONIC ENLARGEMENT OF THE CARPAL SHEATH

A horse may have acute distention of the carpal sheath and moderate to severe lameness after a fall. In the acute stage ultrasonographic examination may reveal only an abnormal amount of fluid within the sheath, but over the next several weeks thickening of the sheath wall and the palmar retinaculum may become apparent, with echogenic fibrous material within the sheath (Fig. 76-1). The margin of the SDFT or DDFT may be poorly demarcated, and either structure may be enlarged. Some horses respond satisfactorily to rest and controlled exercise combined with repeated medication of the sheath with hyaluronan. Early aggressive treatment seems to yield the best results. Passive flexion of the carpus also may be beneficial. If lameness persists for more than 6 weeks, endoscopic evaluation of the sheath and its contents should be considered (see Chapter 24).

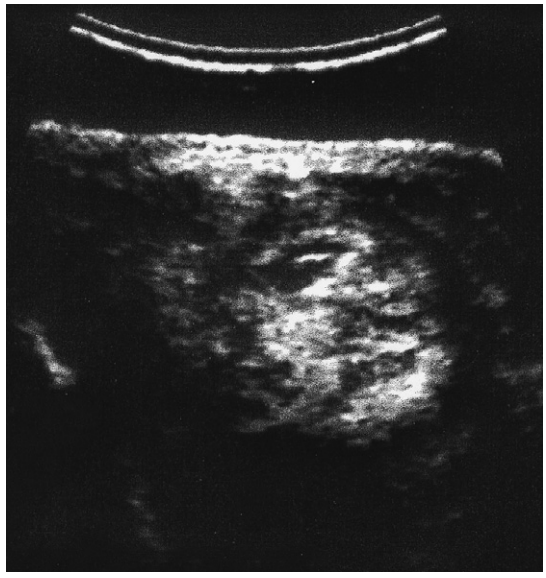

Fig. 76-1 Transverse ultrasonographic image of the carpal sheath of 9-year-old dressage horse with chronic left forelimb lameness of 3 months' duration. Medial is to the left. There is thickening of the sheath wall and enlargement of the superficial digital flexor tendon, but no internal structural abnormality could be defined because of the normal heterogeneous echogencity of the tendon at this level from muscle tissue. The horse failed to respond to intrathecal medication or endoscopic debridement of the proliferative synovial membrane (also see Fig. 21-9.)

DESMITIS OF THE ACCESSORY LIGAMENT OF THE SUPERFICIAL DIGITAL FLEXOR TENDON

Desmitis of the ALSDFT is an unusual injury in show jumpers, event horses, dressage horses, and Thoroughbred racehorses, but it seems to occur more commonly in European Standardbred trotters.[6] The condition is rarely recognized in North American trotters.[7] Lameness is usually sudden in onset and associated with localized swelling.

Diagnosis is based on ultrasonographic examination. Abnormalities of the ALSDFT include enlargement, abnormal fiber pattern, and reduced echogenicity. Enlargement of the ALSDFT results in increased distance between the caudal radius and the median artery. Injuries to the ALSDFT are often seen with other injuries, either in the carpal canal including superficial digital flexor tendonitis or thickening of the flexor retinaculum, or elsewhere.[8,9] These injuries include tenosynovitis of the flexor carpi radialis tendon sheath and suspensory desmitis.

Treatment consists of box rest and controlled exercise for up to 6 months, combined with intrathecal administration of hyaluronan and corticosteroids. The prognosis for horses with simple injuries is fair. Six of eight horses with uncomplicated desmitis of the ALSDFT returned to the former athletic function.[8] However, horses with concurrent injuries were more likely to suffer recurrent lameness.

SUPERFICIAL DIGITAL FLEXOR TENDONITIS

Older horses (>15 years of age) may show acute superficial digital flexor tendonitis within the carpal canal (see Chapter 70).[2] In the acute stage the carpal sheath is distended, but the horse may show no palpable abnormality of the SDFT in the metacarpal region or only slight peritendonous edema proximally. Diagnosis is based on ultrasonographic identification of lesions of the SDFT. In some horses lesions may not be detectable acutely but may become apparent over the next several weeks. Some older horses initially show superficial digital flexor tendonitis, which progresses proximally to involve the SDFT within the carpal sheath. These horses have a poor prognosis regardless of the method of management.

Younger horses may develop superficial digital flexor tendonitis in the proximal metacarpal region. Such lesions may extend proximally into the carpal region, with only slight distention of the carpal sheath. A high proportion of these lesions result in recurrent lameness if treated conservatively. In horses with chronic tendonitis, surgical treatment by desmotomy of the ALSDFT combined with carpal fasciotomy should be considered (see Chapter 70). Moderate results have been achieved in a small number of racehorses and ponies.[7]

DEEP DIGITAL FLEXOR TENDONITIS

Primary deep digital flexor tendonitis within the carpal sheath is unusual, but marginal tears have been identified endoscopically in a small number of horses with persistent lameness associated with carpal sheath distention (Fig. 76-2). Surgical debridement has resulted in clinical improvement. Secondary tears on the cranial aspect of the DDFT may occur with a solitary osteochondroma (see the following section). Carpal sheath distention with incomplete rupture of the cranial head of the DDFT has been reported.[10] Hemorrhagic fluid was aspirated from the sheath, and disruption of the deep digital flexor muscle was identified by ultrasonography.

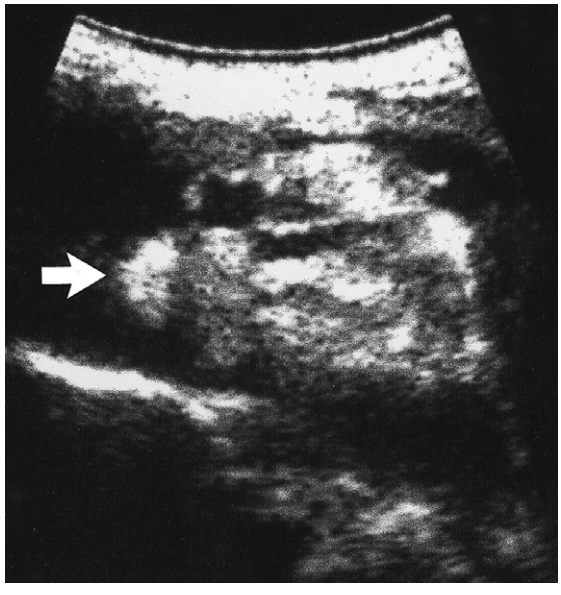

Fig. 76-2 Transverse ultrasonographic image of the carpal sheath of 8-year-old dressage horse with moderate lameness associated with distention of the carpal sheath of 4 months' duration. Medial is to the left. The horse had not responded to intrathecal medication and rest. An echogenic mass appears on the medial aspect of the deep digital flexor tendon. Endoscopic evaluation revealed a large granulomatous structure, which was surgically debrided. Histological examination revealed evidence of a marginal tear of the deep digital flexor tendon, with surrounding fibrous material. The lameness resolved satisfactorily.

SOLITARY OSTEOCHONDROMA

An osteochondroma is an exostosis continuous with the cortex of the bone and is covered by cartilage. The distal caudal radius is a common site, immediately proximal to the distal radial physis. An osteochondroma is readily identifiable by radiography and ultrasonography. Almost invariably an impingement lesion is found on the cranial aspect of the DDFT. Treatment is by surgical removal of the osteochondroma and debridement of any torn fibers of the DDFT. Treatment usually produces an excellent functional and cosmetic result.[2]

FRACTURE OF THE ACCESSORY CARPAL BONE

Fractures of the accessory carpal bone are often the result of a fall and result in acute-onset, moderate to severe lameness (see Chapter 39). The majority have a vertical configuration.[11,12] Reports are conflicting about the incidence of carpal canal syndrome secondary to a fibrous or non-union of the accessory carpal bone.[11-13] Seven of 11 horses returned to full athletic function without complications after a vertical (frontal) fracture of the accessory carpal bone, despite healing by fibrous union in the six horses re-examined radiographically.[12] The four remaining horses were sound: two were retired for breeding, and two were used for pleasure riding. I have had similar experience. However, if lameness associated with thickening of the carpal sheath wall persists, resection of a piece of the carpal retinaculum may be successful.[13] Radiographs should be inspected carefully, because occasionally chip fractures of the articular margin of the accessory carpal bone occur alone or concurrently with a more typical vertical fracture. Horses with such fractures warrant a more guarded prognosis.

CHAPTER • 77

Tarsal Sheath

Eddy Cauvin

The tarsal sheath corresponds to the synovial sheath of the lateral digital flexor tendon at the level of the hock. Tenosynovitis of this sheath is a well recognized condition[1-6] and can be caused by a wide range of lesions. Nonpainful, chronic distention in the absence of obvious pathological lesions, often called *idiopathic thoroughpin*, is common and should be distinguished from other debilitating causes of tenosynovitis, many of which can cause persistent, severe lameness.[7,8] Specific lesions within the sheath can be difficult to confirm clinically.[8,9]

FUNCTIONAL ANATOMY

The deep digital flexor tendon (DDFT) in horses is formed by the fusion in the proximal metatarsal region of the thin medial digital flexor tendon and the larger lateral digital flexor tendon.[10-13] The two tendons pass within separate sheaths. The lateral digital flexor muscle covers the caudal aspect of the tibia and is joined by the tibialis caudalis muscle in the distal crus. The tendon starts 2 to 4 cm proximal to the tarsocrural joint and passes medial to the tuber calcanei over a fibrocartilage-covered groove on the plantar aspect of the sustentaculum tali of the calcaneus. The lateral digital flexor tendon passes over the thick distal plantar ligament in the distal tarsus, medial to the superficial digital flexor tendon (SDFT), before being joined by the medial digital flexor tendon 1 to 3 cm distal to the tarsometatarsal joint.

The tarsal sheath is 16 to 20 cm long and starts near the musculotendonous junction of the lateral digital flexor tendon in the distal caudal crus. At this level the tarsal sheath forms a large pouch between the lateral digital flexor muscle and the common calcanean tendon. The distended pouch is largest over the lateral aspect of the crus. At the level of the tarsocrural joint the sheath extends laterally to surround the lateral digital flexor tendon. Cranially a rigid groove is formed by fibrocartilaginous thickening of the tarsocrural joint capsule. The sheath terminates as a recess dorsomedial to the DDFT in the proximal third of the metatarsal region.

The tarsal sheath is enclosed at the level of the sustentaculum tali by a thick, transversely oriented ligament, the plantar retinaculum (Fig. 77-1) and in the distal tarsus by a superficial fascia. The plantar nerves and vessels run within the retinaculum, in the plantar two thirds of its width, that is, plantar and plantaromedial to the lateral digital flexor tendon. The sheath is lined by a parietal synovial membrane with few villi, except distally. This membrane reflects plantarly to wrap around the tendon, leaving a thin but continuous membrane, or mesotenon, along the plantaromedial aspect of the lateral digital flexor tendon. This membrane carries vessels to the tendon and therefore should be preserved during surgery.

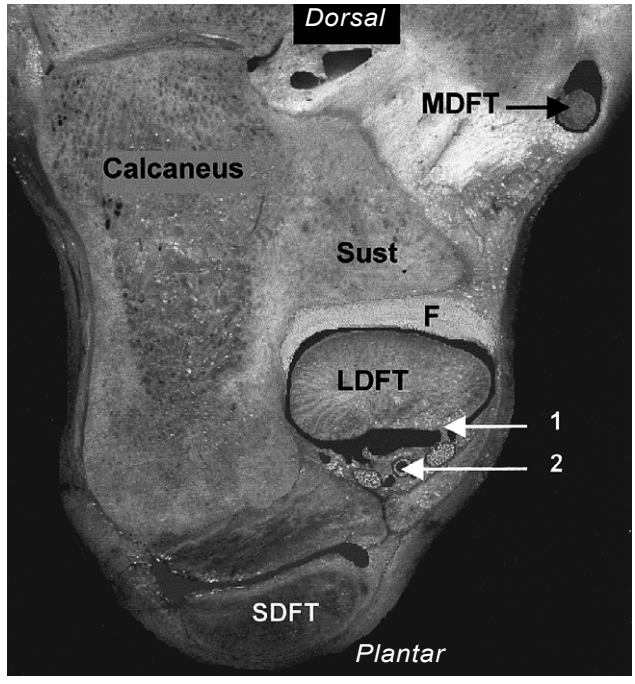

Fig. 77-1 Transverse section of the proximal tarsus, showing the lateral digital flexor tendon (*LDFT*) in the fibrocartilaginous groove (*F*) on the plantar aspect of the sustentaculum tali (*Sust*). Lateral is to the left. Vessels and nerves course within the retinaculum (*2*), lateral to the attachment of the mesotenon (*1*). *MDFT,* Medial digital flexor tendon; *SDFT,* superficial digital flexor tendon.

CAUSES OF TARSAL TENOSYNOVITIS

Distention of the tarsal sheath (Fig. 77-2) is commonly termed *thoroughpin*, or *true thoroughpin*,[14] but the condition may have distinct causes.

CHAPTER • 77

Tarsal Sheath

Eddy Cauvin

The tarsal sheath corresponds to the synovial sheath of the lateral digital flexor tendon at the level of the hock. Tenosynovitis of this sheath is a well recognized condition[1-6] and can be caused by a wide range of lesions. Nonpainful, chronic distention in the absence of obvious pathological lesions, often called *idiopathic thoroughpin*, is common and should be distinguished from other debilitating causes of tenosynovitis, many of which can cause persistent, severe lameness.[7,8] Specific lesions within the sheath can be difficult to confirm clinically.[8,9]

FUNCTIONAL ANATOMY

The deep digital flexor tendon (DDFT) in horses is formed by the fusion in the proximal metatarsal region of the thin medial digital flexor tendon and the larger lateral digital flexor tendon.[10-13] The two tendons pass within separate sheaths. The lateral digital flexor muscle covers the caudal aspect of the tibia and is joined by the tibialis caudalis muscle in the distal crus. The tendon starts 2 to 4 cm proximal to the tarsocrural joint and passes medial to the tuber calcanei over a fibrocartilage-covered groove on the plantar aspect of the sustentaculum tali of the calcaneus. The lateral digital flexor tendon passes over the thick distal plantar ligament in the distal tarsus, medial to the superficial digital flexor tendon (SDFT), before being joined by the medial digital flexor tendon 1 to 3 cm distal to the tarsometatarsal joint.

The tarsal sheath is 16 to 20 cm long and starts near the musculotendonous junction of the lateral digital flexor tendon in the distal caudal crus. At this level the tarsal sheath forms a large pouch between the lateral digital flexor muscle and the common calcanean tendon. The distended pouch is largest over the lateral aspect of the crus. At the level of the tarsocrural joint the sheath extends laterally to surround the lateral digital flexor tendon. Cranially a rigid groove is formed by fibrocartilaginous thickening of the tarsocrural joint capsule. The sheath terminates as a recess dorsomedial to the DDFT in the proximal third of the metatarsal region.

The tarsal sheath is enclosed at the level of the sustentaculum tali by a thick, transversely oriented ligament, the plantar retinaculum (Fig. 77-1) and in the distal tarsus by a superficial fascia. The plantar nerves and vessels run within the retinaculum, in the plantar two thirds of its width, that is, plantar and plantaromedial to the lateral digital flexor tendon. The sheath is lined by a parietal synovial membrane with few villi, except distally. This membrane reflects plantarly to wrap around the tendon, leaving a thin but continuous membrane, or mesotenon, along the plantaromedial aspect of the lateral digital flexor tendon. This membrane carries vessels to the tendon and therefore should be preserved during surgery.

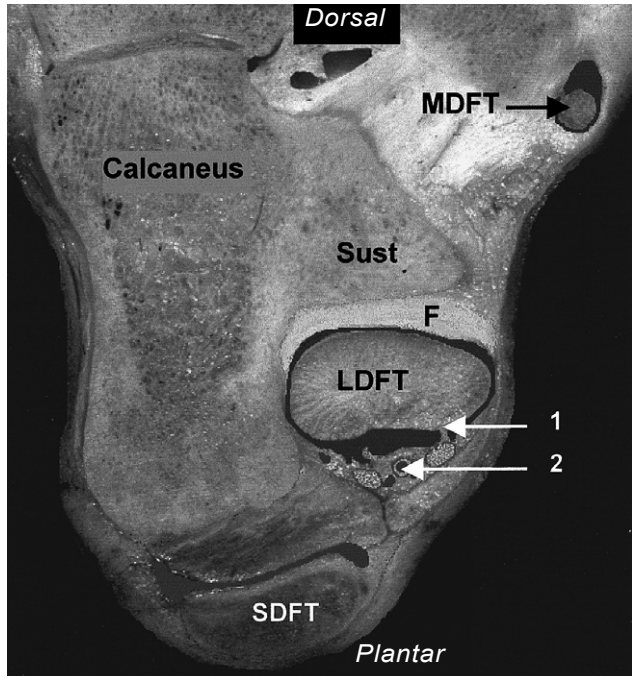

Fig. 77-1 Transverse section of the proximal tarsus, showing the lateral digital flexor tendon (*LDFT*) in the fibrocartilaginous groove (*F*) on the plantar aspect of the sustentaculum tali (*Sust*). Lateral is to the left. Vessels and nerves course within the retinaculum (*2*), lateral to the attachment of the mesotenon (*1*). *MDFT,* Medial digital flexor tendon; *SDFT,* superficial digital flexor tendon.

CAUSES OF TARSAL TENOSYNOVITIS

Distention of the tarsal sheath (Fig. 77-2) is commonly termed *thoroughpin*, or *true thoroughpin*,[14] but the condition may have distinct causes.

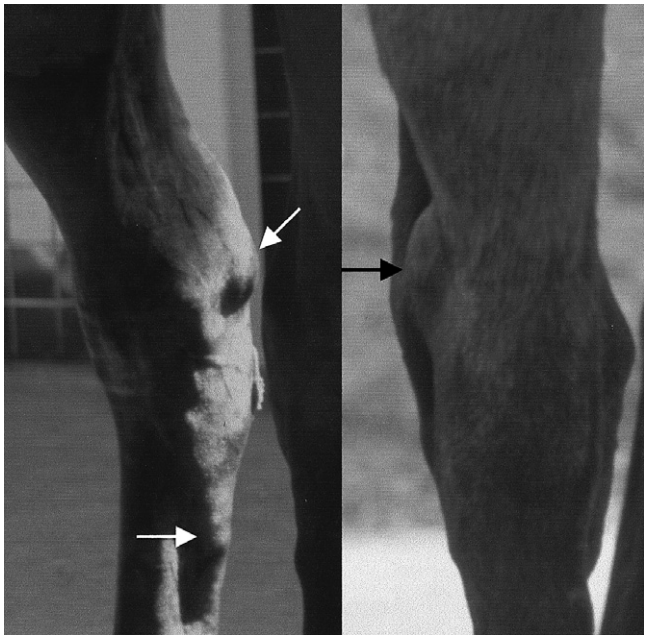

Fig. 77-2 Distention of the tarsal sheath, giving the typical thoroughpin swelling, medially in the distal caudal crus and proximal metatarsal region (*white arrows*) and laterally, caudal to the tibia (*black arrow*).

Idiopathic Thoroughpin

Slight to moderate distention of the tarsal sheath is often seen in young horses.[8,9] It also occurs in adults, particularly in Warmbloods and Western performance horses and horses with a straight hock conformation, after extended box rest or transport. Effusion also may result from acute inflammation in nearby tissues, congestion, and edema in the distal limb (sympathetic effusion). The distention usually is not associated with signs of inflammation or lameness and tends to resolve spontaneously.[8] However, in some horses the distention can become recurrent or persistent.

Traumatic Thoroughpin

Tenosynovitis may be induced by trauma, leading to acute inflammation and hemorrhage in the sheath. In my experience, direct trauma to the medial plantar aspect of the sheath is common and most often results from a kick by another horse. Tenosynovitis also may result from hitting hard objects during jumping or occasionally interference from the contralateral hindfoot. These traumatic injuries may be associated with a chip fracture or fragmentation of the medial edge of the sustentaculum tali at the insertion of the plantar retinaculum.[3,13] Transverse fracture of the calcaneus involving the sustentaculum tali also has been described.[3] In most horses no signs of direct trauma are apparent, and overstretching, or sprain, which may or may not involve the lateral digital flexor tendon, are suspected of causing acute tenosynovitis.[8,9] Intrathecal hemorrhage always causes substantial inflammation and pain and can induce the formation of fibrinous adhesions. The inflammation often leads to chronic distention, with synovial thickening, fibrosis, and fibrous adhesion formation between the lateral digital flexor tendon and parietal sheath lining, which occasionally can cause persistent pain and mechanical lameness. Acute tenosynovitis without overt lameness also has been described.[9]

Primary Lateral Digital Flexor Tendon Injuries

Sprain injuries to the lateral digital flexor tendon do occur in the tarsal sheath region, and they are characterized with ultrasonography by longitudinal fraying and irregular hypoechoic lesions at the level of the sustentaculum tali. These lesions may be caused by overstretching and compression of the tendon over the bone.

Infectious Tenosynovitis

Direct trauma to the medial aspect of the hock can result in breach and contamination of the tarsal sheath.[3,9,13,15] The medial edge of the sustentaculum tali is the most prominent relief on the medial aspect of the tarsus, and a wound at this level often disrupts the retinaculum, thus opening the sheath.[6,13] Puncture wounds are rare in my experience, but they may occur especially in the distal caudal crus. Iatrogenic contamination induced by intrathecal injection is also common and should be suspected in horses with worsening of the lameness and signs of inflammation after such injections.[9] If untreated, suppurative tenosynovitis may lead to infectious tendonitis, destruction of the fibrocartilage, and eventually osteitis or osteomyelitis of the calcaneus.[3,4,6,13] Infection also may result from extension of abscesses in adjacent tissues.

Other Causes

One horse with hemangiosarcoma involving the tarsal sheath has been described.[7] Chondrosarcomata, extending from the tarsocrural joint, and systemic lupus-like synovitis have been reported as rare causes of thoroughpin.[9]

DIAGNOSIS OF TARSAL SHEATH INJURIES

Clinical Signs

Distention of the tarsal sheath is visible in the distal crus, particularly laterally between the common calcanean tendon and the tibia, and to a lesser extent, on the medial aspect of the caudal crus (Fig. 77-2). Such distention should not be confused with swellings associated with the plantar pouch of the tarsocrural joint (see Chapter 45), situated farther distally between the tuber calcanei and distal tibia (bog spavin) or with distention of other bursae; for example, the deep calcanean bursa and calcanean bursa of the SDFT (see Chapter 80).[8,10] False thoroughpin may result from soft tissue masses such as hematomata, tarsal sheath herniation, granulation tissue,[8,9] or abscesses (see Chapter 80). Distention of the tarsal sheath also may be detected in the proximal metatarsal region on the medial aspect of the DDFT.

In horses with idiopathic tenosynovitis the swelling is soft and non-painful and unassociated with lameness.[9,16] In inflammatory conditions swelling is soft, warm, and painful in the acute stage and hard and rarely painful in chronic injuries. The degree of lameness varies.[3,7] The level of pain is not always correlated with the severity of the condition. Usually prominent pain is induced by hock flexion in acute and chronic injuries, and the degree of hock flexion may be greatly decreased. Confirming that the lameness is associated with the sheath may be necessary by using intrathecal injection of 5 to 10 ml of local anesthetic solution and by elimination of other sources of pain. Synoviocentesis may be difficult in horses with acute injuries because of edematous, hypertrophic, and congested synovial membrane.

Confirming infection is not always easy in all horses in the absence of a wound. Wounds over the sustentaculum tali always should be considered suspicious and warrant a contrast tendovaginogram or tendovaginocentesis.

Radiography

Radiographic examination is paramount in all horses with severe tarsal tenosynovitis to rule out fractures or osteitis of the sustentaculum tali and tuber calcanei (see Chapter 45).[2-4,13] Lesions are most visible on dorsoplantar and dorsomedio-

Fig. 77-3 Dorsomedial-plantarolateral oblique radiographic view of the calcaneus, showing erosion (*plain arrow*) and fragmentation (*dotted arrow*) of the edge of the sustentaculum tali.

Fig. 77-4 Skyline radiographic view of the calcaneus, highlighting fragmentation of the edge of the sustentaculum tali (*arrow*), medial to the groove.

plantarolateral oblique projections to highlight the medial and plantaromedial aspects of the calcaneus (Fig. 77-3). A flexed skyline projection of the plantar aspect of the sustentaculum tali (flexed proximocaudal-distoplantar projection) is essential to demonstrate some lesions[17] (Fig. 77-4). Contrast radiography is also useful to highlight the surface of the fibrocartilages and the outline of the lateral digital flexor tendon[18] but has been replaced largely by ultrasonography.[12] However, contrast radiography remains a useful technique to confirm puncture wounds into the sheath. After collecting synovial fluid, 5 ml of an iodinated contrast medium mixed with 5 ml of Hartman's solution is injected in the proximal pouch of the sheath, and lateromedial, dorsomedial-plantarolateral oblique, and dorsoplantar radiographs are obtained to highlight a communication with the skin.

Ultrasonography

Ultrasonographic examination of the sheath is best performed with a linear 7.5-MHz or higher-frequency transducer. The lateral digital flexor tendon is best imaged from the medial aspect of the limb.[12,13,19] Accurate imaging requires high-definition equipment and experience. The chestnut can be trimmed and soaked with warm water to improve imaging. In idiopathic distention, the sheath is filled with anechoic fluid, and no evidence of synovial membrane hyperplasia is apparent. In acute tenosynovitis the sheath is distended, and significant thickening of the synovial membrane occurs. Hemorrhage is seen frequently as a hypoechogenic, whorl-like structure in the proximal pouch. Lesions may be seen in the lateral digital flexor tendon, but they are relatively rare. Longitudinal tears and superficial fraying are the most common types of lesions, but they should not be confused with hyperplasia of the visceral synovial membrane covering the tendon. Early fibrinous adhesions may be visible. The integrity of the fibrocartilage groove and retinaculum can be assessed and fragmentation of the edge of the sustentaculum tali may be detected.[8,13] In chronic injuries, significant fibrosis may be seen around the sheath, and often large adhesions are between the lateral digital flexor tendon and parietal sheath, especially in the proximal pouch (Fig. 77-5). The visceral lining is usually thick (several millimeters) and has an increased echogenicity. Horses with chronic lameness and those that have received multiple injections of corticosteroids may have large, nodular fibrocartilaginous or partially mineralized masses, termed *ossicles.*[2,9] Differentiating these from chip fractures or mineralization of the tendon or sheath lining without the use of tenoscopy may be difficult. Ultrasonography can help to differentiate true from

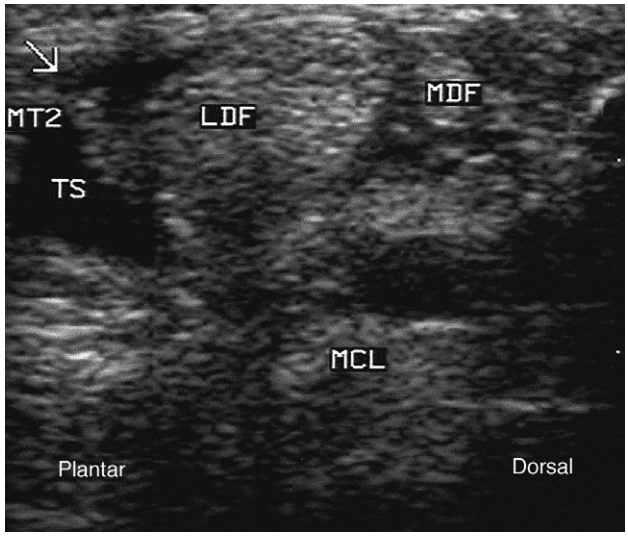

Fig. 77-5 Transverse ultrasonographic image of the tarsal sheath at the level of the tarsometatarsal joint obtained from the plantaromedial aspect. Plantar is to the left. There is hyperplasia of the synovial membrane around the lateral digital flexor tendon (*LDF*) and a well-organized adhesion between the tendon and parietal sheath wall (*arrow*). The tarsal sheath (*TS*) is distended. *MCL*, Medial collateral ligament; *MT2*, plantar border of the second metatarsal bone; *MDF*, medial digital flexor tendon.

false thoroughpin (see Chapter 80). Infection is characterized by severe inflammation of the synovial lining, and the fluid is often echogenic and heterogeneous because of the fibrin clots and debris.[6,13] This may not be obvious early in the condition.

Tenovaginocentesis

Tenovaginocentesis (collecting fluid from the tendon sheath) is useful to rule out infection and confirm inflammation.[9,15] The fluid may be normal in appearance, but it is usually contaminated by blood. A moderate increase of cellularity (less than 8000/µl) may be evident, except in acute traumatic injuries where the nucleated cell count can exceed 10,000/µl. Generally infection is associated with a thin, cloudy to purulent fluid and cell counts well in excess of 10,000/µl. Note that centesis should be carried out after ultrasonography to avoid bleeding and gas artifacts.

Tenoscopy

Tenoscopy (see Chapter 24) is rarely necessary as a purely diagnostic method, because the sheath is evaluated adequately with ultrasonography in most horses. A major exception is in infectious conditions, where it may be useful to assess potential damage to the fibrocartilages, which may not be visible with other diagnostic imaging methods.[13]

MANAGEMENT OF TARSAL TENOSYNOVITIS

Idiopathic and Traumatic Tenosynovitis

Treatment is of little value in horses with idiopathic tenosynovitis, which generally resolves spontaneously.[8,9,16] Reduced (but not interrupted) exercise, sweats, and systemic anti-inflammatory therapy can be helpful.[9] It is not advisable to place a needle in the sheath, because this may cause bleeding and subsequent inflammation.

Treatment of acute tenosynovitis is controversial. In the absence of tendon or bony lesions, rest, systemic or local non-steroidal anti-inflammatory drugs (NSAIDs), local dimethylsulfoxide creams, and cryotherapy (ice packs or cold hosing) are often effective.[9] The horse should be rested in a box for 24 to 48 hours and then walked out in hand to reduce sheath fibrosis. Hyaluronan may be useful for horses with more severe tenosynovitis or in horses in which tendon lesions are present. Intrathecal corticosteroids may be useful in horses with acute tenosynovitis, but they certainly are contraindicated if tendon lesions exist. The latter carry a poor prognosis, except for superficial fraying.[8,9] Bone fragments should be removed by means of tenoscopy, because they can cause chronic inflammation and interference with the tendon.

In horses with more chronic tenosynovitis with associated lameness, corticosteroids such as methylprednisolone acetate (40 mg), triamcinolone acetonide (10 mg), or betamethasone have been used with varying success.[8,9] Fluid retrieval to decrease the volume of the sheath, followed by rest and the application of pressure bandages may produce temporary relief of the distention,[9] but recurrence is common, probably because of chronic proliferative synovitis. Repeated injections have been associated with mineralization of the tendon and synovial lining, and rupture of the lateral digital flexor tendon has been reported,[9] and therefore are not recommended. If possible, the cause of the chronic inflammation should be ascertained. With bony fragments, ossicles, or adhesions, conservative treatment and medical therapy are often disappointing, and surgical debridement appears to be the most effective treatment.[9,13] Debridement is best achieved by tenoscopy (see Chapter 24) (Fig. 77-6). NSAIDs are administered for 1 to 2 weeks post-operatively, and the horse is restricted to box rest for 10 days, after which hand walking starts several times daily. The horse may be turned out in a small paddock or ridden gently after 2 to 3 weeks. Hyaluronan may be injected intra-thecally at least 10 days after surgery.

Infectious Tenosynovitis

Acute infectious tenosynovitis may be treated by thorough lavage of the sheath, with 5 L of sterile, polyionic isotonic fluids, through large-bore catheters or needles placed in the proximal pouch and distal recess of the sheath.[9,15] Lavage may be carried out in the standing horse, but it is best performed with the horse under general anesthesia for accurate needle placement and use of a high-velocity, high-pressure lavage system. This technique is less useful if purulent material, adhesions, or bony lesions are present. These horses are best treated by tenoscopic lavage and debridement.[13] All debris and hypertrophic synovium, frayed areas on the tendon, and lesions on the sustentaculum tali (Fig. 77-7) are debrided, preferably using motorized equipment, and bone fragments are removed. Drains are rarely necessary, except with recurrent infectious tenosynovitis, but in horses with chronic lameness, leaving a 2- to 4-cm incision (the arthroscope portal) open for drainage is advisable. If a wound is present at the level of the sustentaculum tali, this may be used as an endoscopic portal and then enlarged and left to heal by second intention. Drainage can be prolonged, and primary closure and use of a closed suction drain may be preferable. Fragmentation and osteitis of the sustentaculum tali outside the sheath is best approached through a separate incision. Curettage down to healthy bone is performed. Damage to the long medial collateral ligament of the tarsus should be assessed. Aminoglycoside antimicrobial drugs may be inserted into the sheath at the end of surgery. The horse is treated with systemic broad-spectrum antibiotics (see Chapter 66) for at least 2 weeks postoperatively. NSAIDs are used for at least 5 days and may be continued as necessary. A pressure bandage is applied from foot to mid-crus and changed every 1 to 3 days, depending on the amount of exudate produced. The horse should be rested in a box until the wound has healed and then walked out in hand for 2 to 3 weeks before being turned out in a small paddock.

Fig. 77-6 Tenoscopic view of the tarsal sheath at the level of the sustentaculum tali. A large ossicle is seen lateral to the lateral digital flexor tendon.

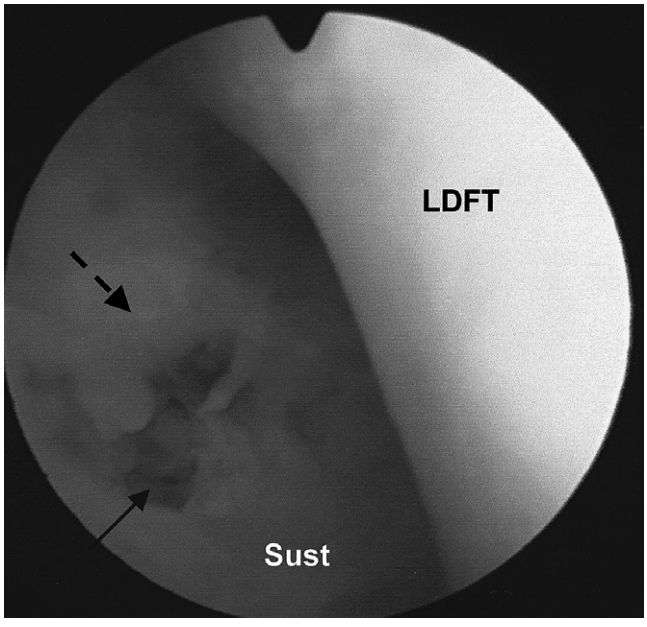

Fig. 77-7 Tenoscopic view of the tarsal sheath at the level of the sustentaculum tali (*Sust*). A small erosion in the fibrocartilage (*plain arrow*), surrounded by fibrinous pannus (*dotted arrow*), is secondary to subacute infectious tenosynovitis. *LDFT,* Lateral digital flexor tendon.

In more chronically infected horses with significant damage to the fibrocartilaginous groove on the sustentaculum tali, or to the lateral digital flexor tendon, open surgery has been advocated.[6,8] The sheath is approached through a desmotomy (longitudinal transection) of the flexor retinaculum to debride all the lesions, followed by the application of a fenestrated drain and repeated lavages for several days. The retinaculum is left unsutured to relieve pressure, and the skin is closed over it.[6] A tenectomy of the damaged tendon within the sheath was performed in one horse unresponsive to this approach. This, however, was associated with significant complications from poor healing of the wound. In another horse, mid-metatarsal tenotomy of the DDFT was carried out, with a heel extension shoe applied to prevent digital hyperextension. This decreased the lameness, presumably by decreasing shearing of the lateral digital flexor tendon on the roughened sustentaculum tali. In my opinion, most horses respond to tenoscopic treatment. More aggressive techniques should be reserved for horses that are unresponsive or those with severe damage to the tendon.

Prognosis

The prognosis is good in horses with idiopathic thoroughpin,[8,9,16] although some horses may have persistent, nonpainful distention of the sheath. In these horses surgery to imbricate the stretched synovial sheath has been advocated,[9] but recurrence is common. The prognosis is fair in horses with acute tenosynovitis treated medically[8,9] and in horses with chip fractures of the sustentaculum tali treated by tenoscopy.[13] In chronic traumatic tenosynovitis, some horses may respond to a single injection of corticosteroids,[3] but most have recurrent distention and lameness caused by adhesion formation and peritendovaginal fibrosis. These may respond well to tenoscopic treatment,[13] but a guarded prognosis should be given if lameness is a prominent feature. In horses with infection the prognosis is fair with prompt drainage and curettage, but poor in horses with severe tendon lesions or extensive damage to the sustentaculum tali.[2,4,9]

CHAPTER • 78

Extensor Tendon Injury

Jane C. Boswell and Michael C. Schramme

The extensor tendons of the carpus and digit and the respective synovial sheaths are vulnerable to injury because they lie relatively unprotected in the subcutaneous fascia on the dorsal surface of the limb. This section discusses lameness caused by injuries and disorders of the extensor tendons of the carpus and digit. Injuries of the extensor tendons of the hock (gastrocnemius and calcaneal tendons) are discussed elsewhere (see Chapter 81).

ANATOMY

The *extensor carpi radialis* muscle is the largest extensor muscle of the forelimb and has a prominent muscle belly on the cranial aspect of the antebrachium. The extensor carpi radialis muscle extends the carpus, smooths carpal joint movement by dampening oscillations as the hoof strikes the ground, and flexes the elbow.[1,2] The extensor carpi radialis tendon extends through most of the muscle belly and appears on the surface of the muscle in the middle of the antebrachium. The tendon passes through the middle groove at the distal end of the radius, over the dorsal aspect of the carpus, and inserts on the metacarpal tuberosity on the dorsal surface of the proximal end of the third metacarpal bone.[1] As the tendon passes over the carpus, it is bound by the extensor retinaculum and enveloped by a synovial sheath, which extends from 8 to 10 cm proximal to the carpus, to the level of the middle carpal joint. Distal to the sheath the tendon is attached to the carpometacarpal joint capsule. Usually a small bursa is beneath the tendon at the level of the third carpal bone.[1,3]

The *common digital extensor* muscle is a compound muscle with three heads (humeral, radial, and ulnar). It lies lateral to the extensor carpi radialis muscle on the craniolateral aspect of the radius and acts to extend the digit and carpal joints and to flex the elbow. The main common digital extensor tendon appears on the surface of the muscle in the middle of the antebrachium and passes distally through the lateral groove on the cranial aspect of the distal end of the radius and over the capsule of the carpal joints. As the tendon passes distally over the dorsal aspect of the metacarpal region, it courses medially and reaches the dorsal midline just proximal to the fetlock. At the level of the distal end of the proximal phalanx the tendon becomes wider as it is joined by branches of the interosseous tendon (suspensory ligament). The common digital extensor tendon inserts on the extensor process of the distal phalanx and the dorsal surface of the proximal extremities of the proximal and middle phalanges.

The common digital extensor tendon is enveloped by a synovial sheath as it passes over the carpus. The sheath extends from about 8 cm proximal to the carpus to the proximal end of the metacarpal region.[1,3] At the level of the fetlock a bursa occurs between the tendon and the dorsal pouch of the fetlock joint capsule.[1,3,4]

A small tendon also arises from the smaller head (the radial head) of the common digital extensor muscle. This tendon runs through the synovial sheath of the principal tendon and then passes laterally to fuse with the tendon of the lateral digital extensor, or it may continue separately between the common and lateral digital extensor tendons to the fetlock. A small tendon also may arise from the ulnar head of the common digital extensor muscle, which may fuse with the principal tendon, or insert on the joint capsule dorsal to the fetlock joint.

The *lateral digital extensor* muscle is smaller than the other extensor muscles and is situated caudal to the common digital extensor muscle. The action of the lateral digital extensor muscle is to extend the digit and carpus. The lateral digital extensor tendon arises at the level of the distal third of the antebrachium and passes distally through the groove on the lateral styloid process of the radius and over the lateral aspect of the carpus. The tendon becomes flatter and larger distal to the carpus, as it joins the tendon of the radial head of the common digital extensor muscle and a strong band from the accessory carpal bone. The lateral digital extensor tendon runs lateral to the common digital extensor tendon and gradually inclines toward the dorsal aspect of the metacarpal region and inserts on the eminence on the dorsal proximal aspect of the proximal phalanx.[1]

A synovial sheath envelops the lateral digital extensor tendon as it passes over the carpus. It begins 6 to 8 cm proximal to the carpus and extends to the proximal end of the metacarpal region.[1,3] At the fetlock a small bursa lies between the tendon and the joint capsule.[1]

The *extensor carpi obliquus,* or *abductor digitus longus,* is a small muscle that extends the carpus. The tendon of the extensor carpi obliquus arises at the distal end of the radius and courses distally, cranially, and medially over the extensor carpi radialis tendon and then passes through the oblique groove at the distal end of the radius to insert on the head of

Extensor Tendon Injury

Jane C. Boswell and Michael C. Schramme

The extensor tendons of the carpus and digit and the respective synovial sheaths are vulnerable to injury because they lie relatively unprotected in the subcutaneous fascia on the dorsal surface of the limb. This section discusses lameness caused by injuries and disorders of the extensor tendons of the carpus and digit. Injuries of the extensor tendons of the hock (gastrocnemius and calcaneal tendons) are discussed elsewhere (see Chapter 81).

ANATOMY

The *extensor carpi radialis* muscle is the largest extensor muscle of the forelimb and has a prominent muscle belly on the cranial aspect of the antebrachium. The extensor carpi radialis muscle extends the carpus, smooths carpal joint movement by dampening oscillations as the hoof strikes the ground, and flexes the elbow.[1,2] The extensor carpi radialis tendon extends through most of the muscle belly and appears on the surface of the muscle in the middle of the antebrachium. The tendon passes through the middle groove at the distal end of the radius, over the dorsal aspect of the carpus, and inserts on the metacarpal tuberosity on the dorsal surface of the proximal end of the third metacarpal bone.[1] As the tendon passes over the carpus, it is bound by the extensor retinaculum and enveloped by a synovial sheath, which extends from 8 to 10 cm proximal to the carpus, to the level of the middle carpal joint. Distal to the sheath the tendon is attached to the carpometacarpal joint capsule. Usually a small bursa is beneath the tendon at the level of the third carpal bone.[1,3]

The *common digital extensor* muscle is a compound muscle with three heads (humeral, radial, and ulnar). It lies lateral to the extensor carpi radialis muscle on the craniolateral aspect of the radius and acts to extend the digit and carpal joints and to flex the elbow. The main common digital extensor tendon appears on the surface of the muscle in the middle of the antebrachium and passes distally through the lateral groove on the cranial aspect of the distal end of the radius and over the capsule of the carpal joints. As the tendon passes distally over the dorsal aspect of the metacarpal region, it courses medially and reaches the dorsal midline just proximal to the fetlock. At the level of the distal end of the proximal phalanx the tendon becomes wider as it is joined by branches of the interosseous tendon (suspensory ligament). The common digital extensor tendon inserts on the extensor process of the distal phalanx and the dorsal surface of the proximal extremities of the proximal and middle phalanges.

The common digital extensor tendon is enveloped by a synovial sheath as it passes over the carpus. The sheath extends from about 8 cm proximal to the carpus to the proximal end of the metacarpal region.[1,3] At the level of the fetlock a bursa occurs between the tendon and the dorsal pouch of the fetlock joint capsule.[1,3,4]

A small tendon also arises from the smaller head (the radial head) of the common digital extensor muscle. This tendon runs through the synovial sheath of the principal tendon and then passes laterally to fuse with the tendon of the lateral digital extensor, or it may continue separately between the common and lateral digital extensor tendons to the fetlock. A small tendon also may arise from the ulnar head of the common digital extensor muscle, which may fuse with the principal tendon, or insert on the joint capsule dorsal to the fetlock joint.

The *lateral digital extensor* muscle is smaller than the other extensor muscles and is situated caudal to the common digital extensor muscle. The action of the lateral digital extensor muscle is to extend the digit and carpus. The lateral digital extensor tendon arises at the level of the distal third of the antebrachium and passes distally through the groove on the lateral styloid process of the radius and over the lateral aspect of the carpus. The tendon becomes flatter and larger distal to the carpus, as it joins the tendon of the radial head of the common digital extensor muscle and a strong band from the accessory carpal bone. The lateral digital extensor tendon runs lateral to the common digital extensor tendon and gradually inclines toward the dorsal aspect of the metacarpal region and inserts on the eminence on the dorsal proximal aspect of the proximal phalanx.[1]

A synovial sheath envelops the lateral digital extensor tendon as it passes over the carpus. It begins 6 to 8 cm proximal to the carpus and extends to the proximal end of the metacarpal region.[1,3] At the fetlock a small bursa lies between the tendon and the joint capsule.[1]

The *extensor carpi obliquus,* or *abductor digitus longus,* is a small muscle that extends the carpus. The tendon of the extensor carpi obliquus arises at the distal end of the radius and courses distally, cranially, and medially over the extensor carpi radialis tendon and then passes through the oblique groove at the distal end of the radius to insert on the head of

the second metacarpal bone. The tendon is enveloped by a synovial sheath.[1]

In the hindlimb, the *long digital extensor* muscle is situated superficially on the craniolateral aspect of the leg and acts to extend the digit and flex the hock. The tendon of the muscle begins in the middle of the muscle belly and passes distally over the dorsal aspect of the hock, where the tendon is bound by the extensor retinacula and enveloped by a synovial sheath. The sheath begins slightly proximal to the level of the lateral malleolus of the tibia and extends to the proximal third of the metatarsal region. The long digital extensor tendon is joined by the lateral digital extensor tendon about 10 cm distal to the tarsus. In the angle of this union the *extensor digitorium brevis* also joins the principal tendon of the long digital extensor.[1] Distal to this point the arrangement of tendons is the same as in the forelimb.

The lateral digital extensor lies on the lateral surface of the limb caudal to the long digital extensor. The lateral digital extensor tendon runs through the entire length of the muscle belly and emerges at the level of the distal third of the tibia. The tendon descends through the groove on the lateral malleolus of the tibia, where it is bound by the extensor retinacula, and usually blends with the tendon of the long digital extensor. Occasionally the tendon does not insert on the long digital extensor tendon but passes separately lateral to the long digital extensor tendon and inserts on the eminence on the dorsal proximal aspect of the proximal phalanx, like the corresponding tendon in the forelimb.[1] The tendon is surrounded by a synovial sheath that extends from 4 to 6 cm above the lateral malleolus of the tibia to the proximal third of the metatarsal region.[1,3]

DIAGNOSTIC TECHNIQUES

Many disorders of the extensor tendons, particularly acute injuries, maybe diagnosed by careful clinical examination, gait analysis, and palpation. Diagnostic perineural or intrathecal analgesia may be useful in horses with chronic injuries to the extensor tendons to determine the importance of clinical findings. Synoviocentesis of distended tendon sheaths or bursae also may be helpful to distinguish between tenosynovitis caused by injury or sepsis.

Plain radiography is of little value in identifying soft tissue injuries of the extensor tendons. However, radiography may be useful to evaluate mineralization within the tendons or the synovial sheaths, enthesopathy, and associated osseous abnormalities. Contrast radiography may demonstrate a penetrating tract, intrathecal adhesions, or synovial fistulae between the extensor tendon sheaths and carpal joints.[5,6]

Ultrasonography is a safe, non-invasive method of evaluating the extensor tendons, the synovial sheaths, and bursae. Because of a superficial position, a 7.5-MHz or 10-MHz transducer and standoff pad are used to image the extensor tendons and their respective tendon sheaths. Careful evaluation of transverse and longitudinal images allows the clinician to determine the extent of tendon damage, the presence of foreign bodies within the tendon or tendon sheaths, synovial membrane hyperplasia, and intrathecal adhesions.[7]

CONDITIONS AFFECTING THE EXTENSOR TENDONS

Laceration of the Digital Extensor Tendon

Lacerations of the extensor tendons commonly occur in the metacarpal or metatarsal regions of the limbs because of the superficial location at these sites (see Chapter 82). Extensor tendon lacerations are more common in the hindlimb[8-10] and are frequently associated with considerable soft tissue damage and opening of the extensor tendon sheaths.

Transection of an extensor tendon below the carpus or tarsus leads to reduced ability to extend the digit, which results in an exaggerated, rapid flip of the hoof at the end of the swing phase of the stride, intermittent knuckling over at the fetlock, or tripping at the walk. The horse, however, will bear weight in a normal posture if the foot is placed flat on the ground. This gait abnormality is more obvious in horses with hindlimb injuries and when the laceration is near the fetlock, because remaining peritendonous fascial attachments provide some support to the distal part of the tendon in more proximal injuries.

Transection of the extensor tendons proximal to the carpus, and at or just proximal to the tarsus, is also common. Transection of the common digital extensor and extensor carpi radialis tendons commonly occurs proximal to the carpus and often results in pain on flexion of the carpus. Transection of the long digital extensor tendon proximal to or at the tarsus results in greater tarsal flexion during the swing phase of the stride and intermittent knuckling of the digit. Within a few days of transection of an extensor tendon the horse learns to adapt its gait, and tripping and knuckling of the fetlock become less frequent.

The diagnosis of extensor tendon laceration is often apparent from the gait deficit. If necessary, the diagnosis may be confirmed by exploration of the wound with a sterile, gloved finger after aseptic preparation and wound lavage. Plain and contrast radiography should be used to evaluate concomitant joint or bone damage and to help to identify foreign bodies.

After aseptic preparation, wounds over the extensor tendons should be debrided and lavaged. It is important to debride any exposed or obviously devitalized bone and, where possible, to cover bone with skin to reduce the risk of sequestrum formation. Primary apposition of the lacerated tendon is unnecessary, even if a large gap has formed between the distracted tendon ends. Progressive ultrasonographic evaluations show that fibrous tissue develops between the transected tendon ends, and gradually becomes more organized, and regains the linear arrangement of collagen along the line of the original tendon. This fibrous tissue provides an adequate mechanical link between the tendon ends, allowing extensor function of the digit to return.[11]

Although lacerations of extensor tendons may heal without external coaptation, wound healing is facilitated and exuberant granulation tissue formation controlled if limb immobilization is used during the first 3 to 6 weeks after injury. Immobilization may be achieved using a polyvinyl chloride (PVC) splint or cast. Full-limb PVC splints may be applied to the dorsal or palmar aspect of the forelimb to prevent knuckling of the fetlock and carpal flexion. In the hindlimb a distal limb splint applied to the dorsal or plantar aspect of the limb can be used. Application of a shoe with a toe extension also may be applied to help with flat foot placement and to prevent tripping or knuckling over of the fetlock in the early postoperative period. Casts provide an inexpensive and efficient means of immobilizing the limb and tendon ends, and are especially useful when extensor tendon lacerations occur with extensive, contaminated wounds, in which primary wound closure cannot be achieved.

After removal of the cast or splint, the horse should remain confined to a box stall for another 4 to 6 weeks. After cast removal, the toe should be trimmed short so that the toe does not catch to cause knuckling at the fetlock and disruption of the organizing fibrous tissue. A controlled exercise program of in-hand walking exercise may be initiated at this time to strengthen the tendon and improve gliding function. Passive range of movement exercises also may be beneficial. If no signs of knuckling are present after 10 to 12 weeks of controlled exercise, a gradual return to athletic use may begin.

The prognosis for return to athletic function after extensor laceration is good.[8-10] In a retrospective study of 50 horses with extensor tendon lacerations, 73% returned to athletic function, 18% were pasture sound, and 3% remained lame.[10] Complications in that study included wound infection and dehiscence, exuberant granulation tissue, and sequestrum formation. Stringhalt also may occur as a complication of lacerations or injury to the extensor tendons in the dorsoproximal aspect of the metatarsal region. It is speculated that stringhalt may either result from adhesion formation, which decreases the ability of the long or lateral digital extensor tendons to stretch during tarsocrural flexion, or from abnormalities in the myotactic reflex that governs extensor muscle tone and relaxation.[12]

Rupture of Common Digital Extensor Tendon
