Diagnosis and Management of Lameness in the Horse ISBN 0-7216-8342-8

NOTICE

Veterinary medicine is an ever-changing field. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the licensed prescriber, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the publisher nor the author assumes any liability for any injury and/or damage to persons or property arising from this publication.

Abbreviations

AAEP	American Association of Equine Practitioners
ALARA	As low as reasonably achievable
ALDDFT	Accessory ligament of the deep digital flexor tendon
ANA	Antinuclear antibodies
AST	Aspartate aminotransferase
AVA	Arteriovenous anastomosis
BAP	Bone-specific alkaline phosphatase
BID	Twice daily
BSP	Bone sialoprotein
CdCr	Caudocranial
CdL-CrMO	Caudolateral-craniomedial oblique
Ci	Curie
CK	Creatine kinase
CNS	Central nervous system
COMP	Cartilage oligomeric matrix protein
COX	Cyclooxygenase
CrCd	Craniocaudal
CRGP	Calcitonin gene related peptide
CS	Chondroitin sulfate
CSA	Cross-sectional area
CSF	Cerebrospinal fluid
CT	Computed tomography
CTX	Collagen C telopeptides
CVM	Cervical vertebral malformation
DDFT	Deep digital flexor tendon
DFTS	Digital flexor tendon sheath
DIP joint	Distal interphalangeal joint
DL-PaMO	Dorsolateral-palmaromedial oblique
DL-PlMO	Dorsolateral-plantaromedial oblique
DM-PaLO	Dorsomedial-palmarolateral oblique
DM-PlLO	Dorsomedial-plantarolateral oblique
DMSO	Dimethylsulfoxide
DPa	Dorsopalmar
DPl	Dorsoplantar
DPr-PaDiO	Dorsoproximal-palmarodistal oblique
EDM	Equine degenerative myeloencephalopathy
EHVI	Equine herpes virus I
EIPH	Exercise-induced pulmonary hemorrhage
EL	Exercise level
EM	Electron microscopy
EMG	Electromyography
EPM	Equine protozoal myelitis
ER	Exertional rhabdomyolysis
EVA	Equine viral arteritis
FAS	Fiber alignment score
FEI	Federation Equestre Internationale
FFD	Focus film distance
GAG	Glycosaminoglycan
GBE	Glycogen binding enzyme
GBq	Giga becquerel
GRF	Ground reaction force
GSH	Glutathione peroxidase
HDP	Hydroxymethane diphosphonate
H & E	Hematoxylin and eosin
HU	Hounsfield unit
HyPP	Hyperkalemic periodic paralysis
ICR	Instant center of rotation
IM	Intramuscularly
IRU	Increased radiopharmaceutical uptake
IV	Intravenously
KS	Keratin sulfate
LDH	Lactate dehydrogenase
LF	Left forelimb
LH	Left hindlimb
LH	Luteinizing hormone
LM	Lateromedial
MAC	Minimum alveolar concentration
MBq	Mega becquerel
mCi	Millicurie
McII	Second metacarpal bone
McIII	Third metacarpal bone
McIV	Fourth metacarpal bone
MCP joint	Metacarpophalangeal joint
MDP	Methylene diphosphonate
MIC	Minimum inhibitory concentration
MMP	Metalloproteinase
MRI	Magnetic resonance imaging
MSD	Minimum sagittal diameter
MtII	Second metatarsal bone
MtIII	Third metatarsal bone
MtIV	Fourth metatarsal bone
MTP joint	Metatarsophalangeal joint
NKA	Neurokinin A
NPY	Neuropeptide Y
NSAID	Non-steroidal anti-inflammatory drug
OAAM	Occipitoatlantoaxial malformation
OC	Osteocalcin
PaPr-PaDiO	Palmaroproximal-palmarodistal oblique
PAS	Periodic acid—Schiff
PASM	Periodic acid—silver methanamine
PCR	Polymerase chain reaction
PET	Photon emission tomography
PHI	Peptide histidine isoleucine
PIP joint	Proximal interphalangeal joint
PMMA	Polymethylmethacrylate
PSB	Proximal sesamoid bone
PSGAG	Polysulfated glycosaminoglycans
PSSM	Polysaccharide storage myopathy
QH	Quarter Horse
RER	Recurrent exertional rhabdomyolysis
RF	Right forelimb
RH	Right hindlimb
RVI	Rubeola virus immunomodulator
SDFT	Superficial digital flexor tendon
SID	Once daily
SL	Suspensory ligament
SLE	Systemic lupus erythematosus
SP	Substance P
SPECT	Single photon emission computed tomography
STB	Standardbred
T1-T18	First to eighteenth thoracic vertebrae
TB	Thoroughbred
TENS	Transcutaneous electrical stimulation
TGF-β	Transforming growth factor β
TNF	Tumor necrosis factor
TS	Type or echo score
VIP	Vasoactive intestinal peptide
WBL	Warmblood

FOREWORD

It has been said that "no one drinks from the same water when dipping from a fast river." Nothing is more true or better describes the fast flow of information that has come from veterinary medicine and surgery. I remember when I was a senior veterinary student watching a highly recognized equine specialist fire a horse with a large chip fracture of the distal, lateral radius. The horse was rested for sure and returned to training and did win. Yes, the old fracture became a large spur.

Any swelling of the fetlock joint was considered an osselet and the horse was treated either by blister or firing and blister. This was done until Dr. Ed Churchill found it best to remove the apex fracture from the top of the proximal sesamoid bone. Dr. Churchill's contribution inspired others such as Dr. Jacques Jenny and Dr. Charles Raker to perform surgery on horses with other fractures of the fetlock joint. Drs. Jenny and Raker were the first to remove a base fracture from the proximal sesamoid bone, to remove chip fractures from the carpus, and to reattach a slab fracture of the third carpal bone. These three men added a large clear stream to the veterinary river that many of us have used from the late '50s to the present. Although Dr. Jenny was the first to use a lag screw to repair a stress fracture of the third metacarpal bone and many advocate this form of management, I still find that deep firing well above and below the fracture site is more satisfactory. In horses that are fired, there is no pain from the screw and the screw does not have to be removed. Dr. M.B. Teigland used this method, deep firing, to treat many good racehorses with stress fractures with excellent success. It is important to remember that methods that have worked well for many years are not necessarily worthless or antiquated. Many times a great river comes from many small but important tributaries.

Other tributaries that helped swell the river were from the work of Dr. John Wheat on the subject of treating horses with tendonitis. He pointed out the necessity of preventing edema, which can lead to fibrosis of the injured tendon. Dr. James Rooney helped us better understand how lameness occurred, and Dr. Norman Rantanen and Dr. Ron Genovese were first to give us information on how to use ultrasound to better diagnose tendon and ligament injuries. Dr. Virginia Reef enlarged this tributary and made the use of the ultrasound more sophisticated in lameness diagnosis. Excellent radiologists such as Dr. Charles Reid at New Bolton Center and others have provided us with better knowledge when using our x-ray machines. The stream continued with better quality radiographs, xeroradiographs, scintigraphy, and recently, magnetic resonance imaging. These modalities have made us all better diagnosticians.

When it comes to treating lame horses, we have to remember the flow that came from Dr. Larry Bramlage and Dr. David Nunamaker. When arthroscopic surgery was first done by Dr. Steve Selway in Florida and by Dr. Wayne McIlwraith in Colorado, many thought that it should never be used on the horse. Both men forged a very wide tributary, one that has helped us all become more effective surgeons. After arthroscopic surgery, horses suffer less and many return faster to competition. Fear of something new is only normal and being skeptical is expected, since most of us have tried something new that just did not work. With any fast-moving river there will always be something picked up that is superfluous, but it will soon settle out.

The better one gets as a lameness diagnostician, the better he or she will be in selecting the best treatment. The many authors who have contributed to this book, *Diagnosis and Management of Lameness in the Horse,* have helped to clean false debris from the ever-increasing flow of veterinary knowledge and should be congratulated and thanked for sharing their knowledge and experiences with us. We will all be indebted to them after procuring and reading this book.

Both Dr. Mike Ross and Dr. Sue Dyson were well acquainted with me early in their careers during internship (Sue) and surgical residency (Mike) programs at New Bolton Center, University of Pennsylvania, at which I taught for 32 years. They both know very well that one does not become skilled in lameness diagnosis and management overnight. They both became quickly aware that lameness diagnosis in the gaited American Saddler or the Dressage horse was considerably different than in the racing Standardbred or Thoroughbred. For these reasons I am especially pleased that they have added a new dimension by providing actual videos on the CD showing the abnormal gaits of lame horses. This will be great for everyone.

I am confident that many will drink and benefit from the text, *Diagnosis and Management of Lameness in the Horse,* which should both widen and deepen the veterinary river.

FOREWORD

The history of veterinary lameness diagnosis and treatment has gone through three stages.

The first stage could be termed the personal stage; there was principally anecdotal observation occasionally supported by post-mortem evidence. Much of this was limited to first- or second-hand accounts. The focus was on workhorses, with some information about cavalry mounts. Occasionally a gifted veterinarian was prescient and insightful. People like Horace Hayes and Dollar come to mind. They were very experienced horsemen and careful observers, with an intuitive insight into lameness. Unfortunately, intuition is not easily taught or passed on. The European veterinary literature was frequently dominated by pathologists, and the clinical findings were underemphasized.

The second stage, beginning in the 1960s, was characterized by the organization of lameness and a more scientific approach to diagnosis. Included was the use of diagnostic nerve blocks, radiography, and later, ultrasonography and scintigraphy. By this time the focus had shifted from the workhorse to the light horse for pleasure and competition. This was typified by the work of J. Hickman in the United Kingdom and O.R. Adams in the United States. There was also good work and valuable observations by individuals or groups. This was reported in the veterinary literature and in various proceedings, some even as letters to the editor. Unfortunately, some of these are not easily discovered through literature searches. There was also the stimulating writing of J. Rooney to explain lameness from a biomechanical perspective. This has been followed by the work of Clayton, Denoix, Barrey, and others. Much of the work pertaining to conformation and its effect on performance has never found its way into the veterinary literature and remains in hippological sources.

As so often happens in science, just when it appears that we are almost confident of our basic understanding, new observations question our assumptions. The past decade has seen a burst of new documented clinical investigation and anatomical knowledge. Some of the accepted and codified lameness beliefs are now in question. This includes nerve blocks. Unfortunately, rather than simplifying the subject, these careful observations have introduced complexities and uncertainties into what was previously regarded as a straightforward diagnostic procedure. As Dr. Sue Dyson was largely responsible for this, it is only apposite that she should make amends by way of contributing to this book. The same goes for Dr. Bowker.

The third phase is one of synthesis. It combines the latest technology and science with an understanding that the lame horse must be viewed from an athletic perspective. This often depends on the demands of specific sports. This book, *Diagnosis and Management of Lameness in the Horse* by Ross and Dyson, is the prototype treatise for this phase. An important premise of this book considers "lameness" in its most sophisticated form, to subsume all of the musculoskeletal and neurological dysfunctions that have an impact on maximal athletic performance. This is much more than is obvious by just trotting the horse to evince gait asymmetry. There is an understanding that it is frequent to have two or more "lamenesses" in an individual and that their etiology, effects on specific movements, and prognosis are interrelated and require an understanding of the competitive implications to best manage the horse. Thus the chapters by veterinarians experienced with different types of horses are an integral part of this book. The adjunctive approaches of acupuncture, manipulative procedures, physical, and herbal medicine are covered. It is hoped that the inclusion of these in a book with an impeccable scientific background will encourage practitioners to seek education in these modalities rather than be contemptuous prior to investigation. The Editors do not make the easy error of neglecting the clinical examination to focus principally on glamorous technology. All this culminates in maximum benefit to the veterinarian who must try to solve real-world problems. Hopefully the horse will also benefit.

The incorporation of a CD-ROM with moving pictures is so obvious it is surprising it has not been done before. Verbal description of a visual (and to a much lesser extent, auditory) phenomenon is a poor substitute. This is especially so since there is not yet even a general agreement of how to describe the alterations of movement associated with lameness. Another vital but often perplexing area is communication with the horse's connections. For example, many high-level dressage riders are acutely perceptive and analytical. Understanding is greatly facilitated by the veterinarian having a background in the field. One of the difficult problems is to decide whether a complaint about the horse's performance results from a "lameness"; is a training or riding problem, a shoeing problem, or a tack (saddle, bitting, hobbles, boots) problem; results from the horse's character and physiology; is an inherent biomechanical limitation for this individual; or even exists at all. There is a human tendency to discount what we cannot directly perceive. If the veterinarian cannot see any lameness or deficit in movement, then there is an inclination to assign the problem to being in the rider's head," or "the horse is just not good enough." Now, the latter are real possibilities. How does one decide? There are many strategies: a course of non-steroidal anti-inflammatory analgesic drugs, treating suspected locations, blocking suspicious areas, incorporating acupuncture and chiropractic evaluation and treatment, or changing the training, the rider, the going, the shoeing, the tack, and so on. However, if the veterinarian is also an educated and a sensitive rider, who can get on the horse and interpret the feelings in biomechanical and diagnostic criteria, then you have someone like Sue Dyson. She is the rare combination of a high-level rider and horsewoman *and* a talented veterinarian. I can speak of Sue's abilities because we have been friends and colleagues for over 20 years. I admire her for her veterinary and equestrian abilities, which include a rigorously honest intellectual approach with a tough dedication. Dr. Mike Ross I know through his many publications and lectures and the high standard of his academic work at a leading university and his pursuit of being in the forefront. His particular interest in Standardbred racehorses and methodical approach have provided a new perspective to lameness in these horses. This complementary combination of talent and experience make Mike and Sue ideal co-Editors.

Notwithstanding Churchill's comment about being divided by a common language, here is a successful collaboration between Editors on both sides of the pond. The incorporation of leading American, Australian, and European veterinarians as co-authors adds additional perspective. The nature of this book promises regular updates to include forthcoming knowledge. One hopes that the Editors' schedules will permit this.

Daniel Marks, VMD
August 2002
Santa Fe, New Mexico

PREFACE

We come from different equine, veterinary, and cultural backgrounds, but we share a passion for lameness diagnosis and have individually developed very similar diagnostic approaches, believing that there is both art and science to lameness diagnosis. In the past 20 years we have seen huge advances in our knowledge of conditions that cause lameness through careful clinical observation combined with the more stringent use of diagnostic analgesia. It was with consideration of a strong belief in the values of clinical examination and diagnostic analgesia that our list of contributors was formulated. We have experienced advances in diagnostic imaging with the development of ultrasonography, scintigraphy, diagnostic arthroscopy, and more recently, computed tomography and magnetic resonance imaging (MRI). Doubtless, while we continue to look, we will continue to find new causes of lameness and this text will rapidly become outdated. There have even been significant developments from the time of manuscript submission to completion of production of the book, especially in the field of MRI. It is nonetheless our aim to provide information as up to date as possible, based on our own experiences and those of other experienced veterinarians worldwide.

When we embarked on this project, we felt strongly that the emphasis on different lameness conditions in other texts did not reflect our own personal experiences and it did not reflect the differences seen in horses used for a variety of sports disciplines. We set out to provide a comprehensive, thought-provoking text, viewed from a global perspective, sometimes challenging long-held dogma. We wanted to provide a balanced approach, reflecting as much as possible our own personal experiences based on careful observation while also including the opinions of other respected lameness diagnosticians in areas where we believed we did not have sufficient experience or expertise.

We selected the term *management of lameness* carefully, recognizing that our treatment abilities are limited and currently fall behind our diagnostic capabilities. We have tried to be as broad minded as possible, including many aspects of alternative therapy. We recognize that many of these treatment modalities have not undergone scientific scrutiny, and they do not necessarily form part of our own therapeutic armamentarium. Although we are not implying endorsement, we felt that the experiences of others should be chronicled.

We were fortunate to enlist a broad cross-section of coauthors, with widely ranging experiences, but regret that several notable veterinarians were unable to accept because of other commitments. We challenged all authors to provide practical information, reflecting not only the current literature but also their own experiences. However, when our experiences were strongly at variance with an author, we have added editorial comments accordingly.

The book is divided into five major sections, first presenting an in-depth diagnostic approach, then dealing with lameness conditions based on anatomical location. Different disease entities are then considered in depth, followed by a broad review of different treatment modalities. The final section addresses different types of horses and the injuries to which they are particularly prone, providing a unique insight into different diagnostic and therapeutic approaches. It also provides a background to each sport, which is so important in understanding why particular problems occur and how they may be manifested. Inevitably, this approach creates some duplication of information, but often there are subtle and fascinating differences among authors based on the type of horse with which they deal and where in the world they practice. To encompass all this, of necessity we sacrificed didactic chapters on anatomy, and we have not included a comprehensive review of all standard radiographic views and surgical procedures. We believe that other dedicated texts are better suited to provide this information.

We tried to be as generous as possible with page allocation to authors but found that we had hugely outstripped the total page allocation for the book. To try to reduce the text, we introduced many abbreviations, which some readers will find difficult. Therefore we have included a list of these abbreviations for easy reference. Space limitations made it necessary to limit the number of figures, which we regret. Ideally, we would have liked to provide examples of all conditions, but this was impractical. Good and useful examples have been chosen.

Although the title of the book is *Diagnosis and Management of Lameness in the Horse,* we have tried to address all potential musculoskeletal and neurological causes of gait abnormalities or changes in performance of sport horses. We have addressed the common problem of what to do when a diagnosis cannot be made.

We believe strongly that accurate diagnosis of lameness relies heavily on clinical experience and the development of an eye for the horse, both stationary and in movement. Lameness diagnosis cannot be taught in the classroom but must be learned from many hours of observation of normal and lame horses and tutelage. We have therefore included a CD-ROM, showing short video clips of a variety of lameness conditions, which we hope are representative examples and will assist an inexperienced clinician in developing an eye for lameness.

When we embarked on this project, we were both keen to learn from other peoples' experiences and to broaden our own horizons, and we have not been disappointed. We have learned a huge amount, both from each other and from contributing authors. We remain constantly excited by the challenges of lameness diagnosis and management, since many horses do not entirely fit the textbook picture. Nonetheless, we are also sometimes frustrated that a diagnosis eludes us. We hope that by continued careful observation and a logical, comprehensive diagnostic approach, in the future our knowledge will further expand to understand causes of lameness and altered performance better and to provide further information for the next edition of *Diagnosis and Management of Lameness in the Horse.*

ACKNOWLEDGMENTS

We owe a huge debt of gratitude to our co-authors, since the scope of this book far exceeds our combined knowledge and experience. Writing a book chapter brings no financial rewards and the time involved always far exceeds expectations. While it is invidious to single out specific authors, we are particularly grateful to Ron Genovese, who contributed large sections on ultrasonographic examination and soft tissue injuries and also gave constant encouragement through the long gestation period of the book. We were tremendously excited when our colleague, co-author, and friend Fabio Torre agreed to help with our cover. His original paintings reflect the unique approach we have taken to review our beloved subject. Fabio's illustrations, based on one of the earliest analytical assessments of gait ever to be made by Muybridge, encourage us to both look and see.

We have received tremendous support from Karena Bean and Sally Whitefield, secretaries at the Animal Health Trust, who deciphered many editorial hieroglyphics and were responsible for cheerfully and tirelessly re-typing the majority of manuscripts. We thank Joyce Underwood, Vivian Stacy, and Karyn Van Norman from New Bolton Center for their help and support. We especially thank Jan Butler and John Wilkinson, who have produced a large number of the photographic illustrations, and Alex Baker for her excellent artwork.

The book would not have been possible without key people from WB Saunders Company: Stephanie Donley, Ray Kersey, Arlene Chappelle, Denise LeMelledo, Judy Ahlers, Julia Dummitt, David Saracco, and Bruce Robison.

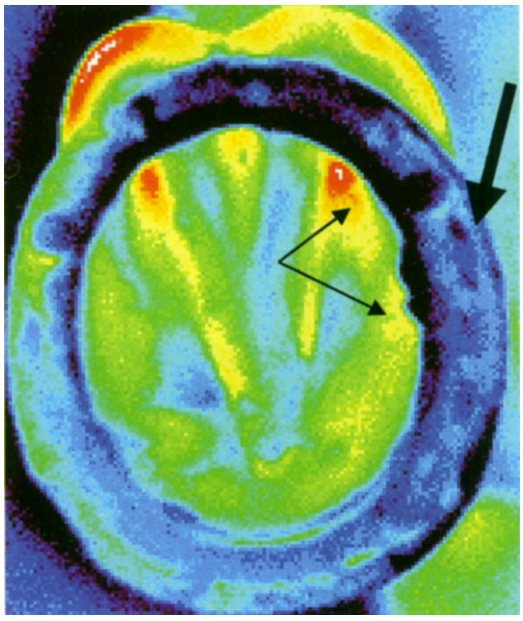
We have both been influenced and tutored by notable people in our careers. Sue's early teaching in equine orthopaedics came from John Hickman at the University of Cambridge, who was later a consultant at the Animal Health Trust. John Ayliffe, an equine practitioner and lameness enthusiast, encouraged Sue to go to the United States, where she spent a year at New Bolton Center and a year in practice. This was initially made possible through a Thouron Scholarship, one of the principal aims of which is to foster Anglo-American relationships. This book, with Sue and Mike as co-Editors, is a true fulfillment of that goal. Charlie Reid at the University of Pennsylvania stimulated an interest in diagnostic imaging, while Bill Moyer, Dan Marks, and Midge Leitch were all hugely influential in the development of an approach to lameness diagnosis. A little later Ron Genovese shared his knowledge, experience, and enthusiasm for ultrasonography. Colleagues, past and present at the Animal Health Trust, notably Svend Kold, Ian Wright, Chris Whitton, and Michael Schramme, have provided stimulus and support. The interns, by testing the hypothesis that by teaching you learn, have been a constant inspiration to improve diagnostic capabilities, to advance knowledge, and to distill clarity of thought. McGinty, Kinvarra, and Otterburn were internationally famous horses in their own right. As horses produced by Sue, they were great teachers in the art and science of equestrianism and in the diagnosis and management of lameness.

For Mike, John "Jack" Lowe of Cornell University, whose support and encouragement were unequalled, instilled an early interest and passion for lameness. Jack allowed him the freedom of thought and provided a solid foundation of clinical investigation and experience on which to build. He had excellent instructors, colleagues, and friends at the New York State College of Veterinary Medicine, Cornell University as a student and intern, and from New Bolton Center, University of Pennsylvania as a surgery resident, lecturer, and faculty member, but special thanks go to Norm Ducharme, Dean Richardson, and David Freeman. Loren Evans, mentor, lameness diagnostician, horseman, surgeon, and friend, had a unique influence, instilling confidence and imparting knowledge but most importantly in showing him the value of careful clinical examination and observation. Mike owes tremendous gratitude to Howard "Gene" Gill, Ben Martin, Jim Palmer, Paul Nolan, and Ron Gurfein for their loyalty and guidance, and the Standardbred racehorse, which allowed him to "cut his teeth" and taught him so much. Mike has been motivated by the many dedicated interns and residents and referring veterinarians, whose ideas, energy, and enthusiasm for his work throughout the years have truly been inspirational.

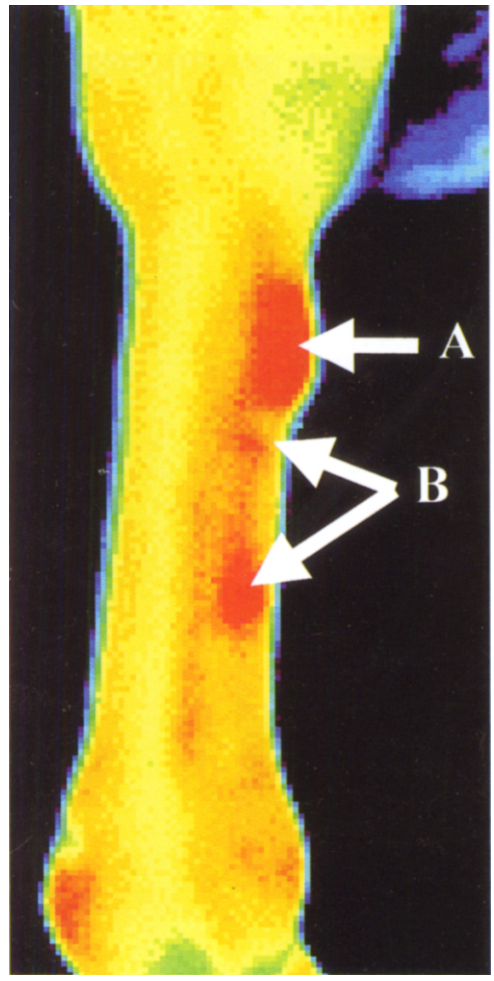
We must not forget the horse. Watching, palpating, listening to, and trying to understand the horse has taught us so much.

Finally we owe an enormous thank you for the love, friendship and support of our partners, John and Debbie, themselves veterinarians. They have been extraordinarily patient and understanding throughout this huge project, have provided constructive criticism, have listened to our frustrations, and have shared our enthusiasm and passion for the book. Mike gives special thanks to Stone for his patience and love, and the inspiration only a son can endow, his daughter Kennedy, and his parents.

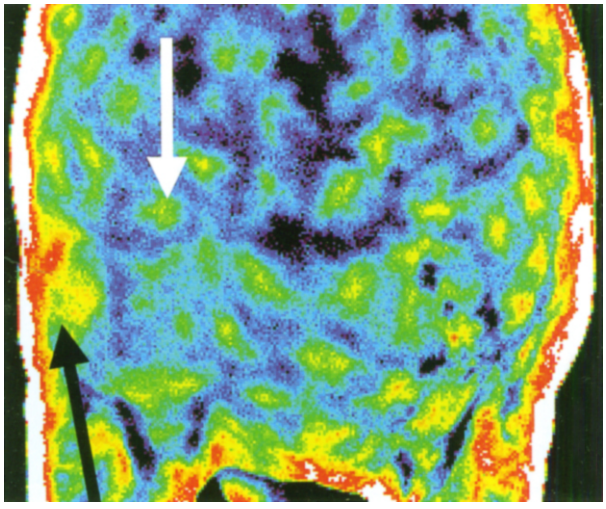
Sue Dyson and Mike Ross



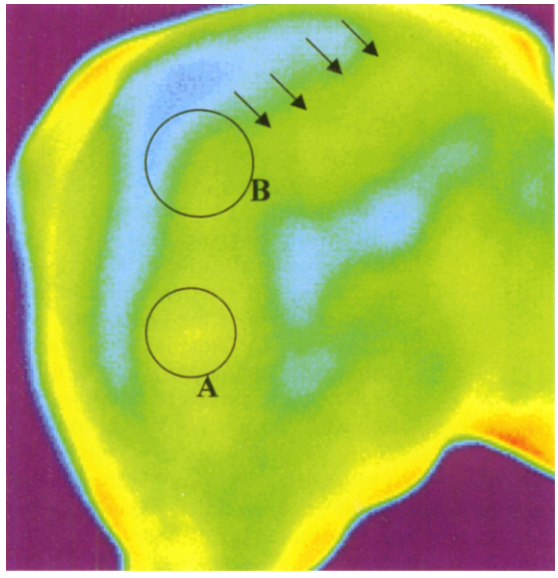
Color Plate 1 Thermal image of the sole of a horse's foot showing asymmetrical heat in the sole of the hoof (*small arrows*). The shoe on that side (*bold arrow*) is colder, indicating less friction on the shoe, probably as a result of avoiding the injured sole.



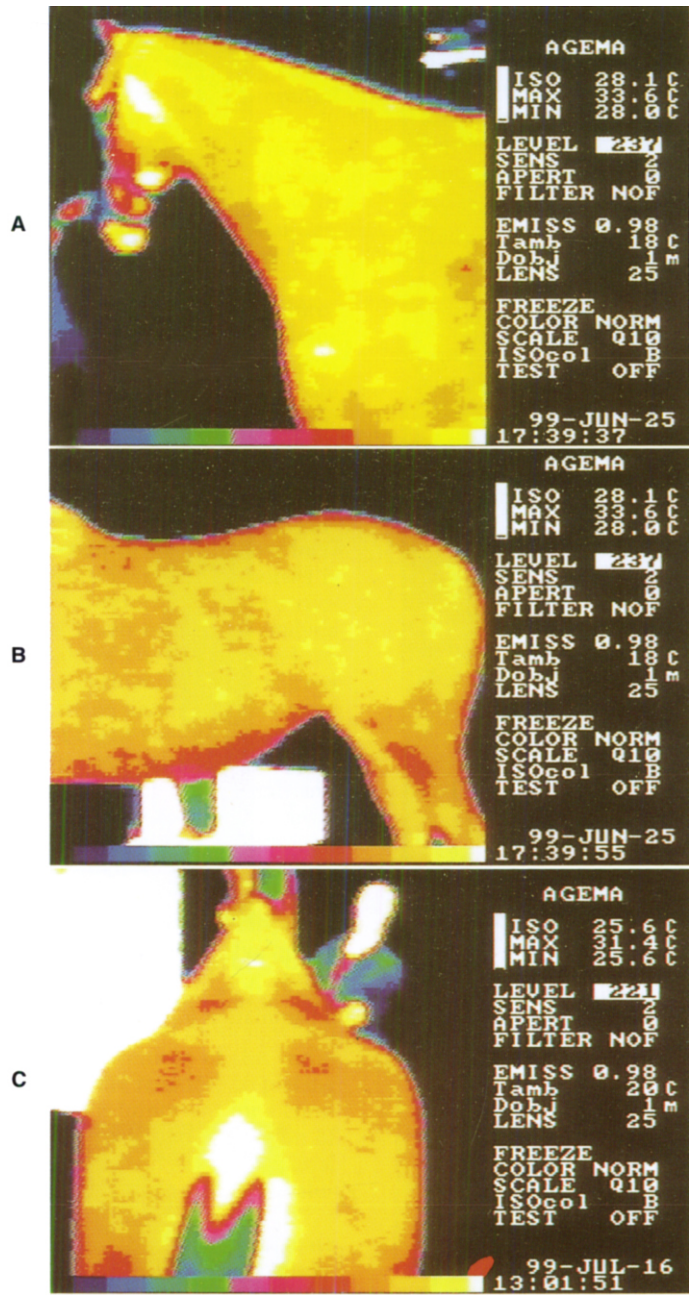
Color Plate 2 Thermal image of the left medial metacarpal region showing an active splint (*A*) that is causing secondary inflammation in the suspensory ligament distal to the injury (*B*).



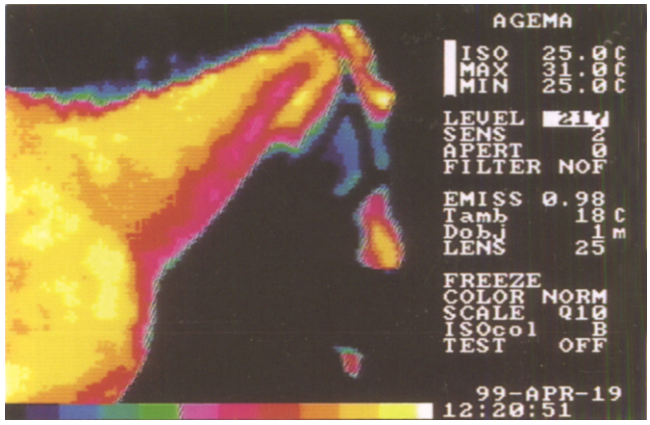
Color Plate 3 Thermal image, front view, of a horse's chest showing increased heat over the lateral aspect of the right shoulder (*black arrow*) and decreased heat over the right bicipital tendon (*white arrow*). Ultrasonography showed increased fluid in the intertubercular (bicipital) bursa. The decreased heat over the muscle was presumed to be due to lack of use because of pain.



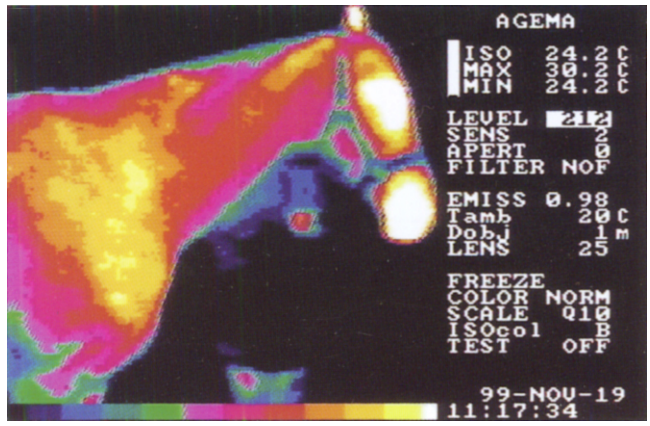
Color Plate 4 Thermal image of the lateral view of the right hip region showing increased heat over the third trochanter (*A*) and greater trochanter (*B*). In addition, the body of the gluteal muscle has increased heat (*small arrows*). This condition was diagnosed as a gluteal muscle strain.



Color Plate 5 Thermographs show the appearance of normal horses. The color scale represents 5.6° C, using 10 colors; that is, each color represents about a 0.5° C change in temperature. The color bar under the image shows the colors used; those to the right-hand side are the hottest and those to the left are the coldest. White is above the top of the scale and black below the scale. **A,** Lateral view of the head, neck, and shoulder. **B,** Lateral view of the thorax, abdomen, and hindquarters. **C,** Oblique dorsal view from behind the horse looking toward its head and neck. Temperature variation is 1° C over the neck, trunk, and hindquarters. A warm midline dorsal stripe along the back extends from the withers to the base of the tail, with symmetrical muscle temperature on either side.

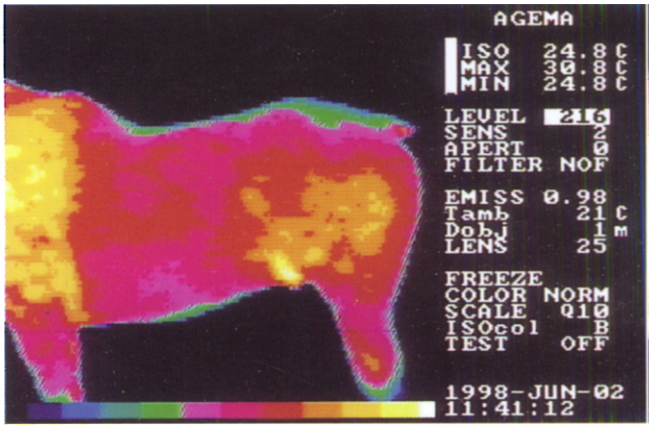


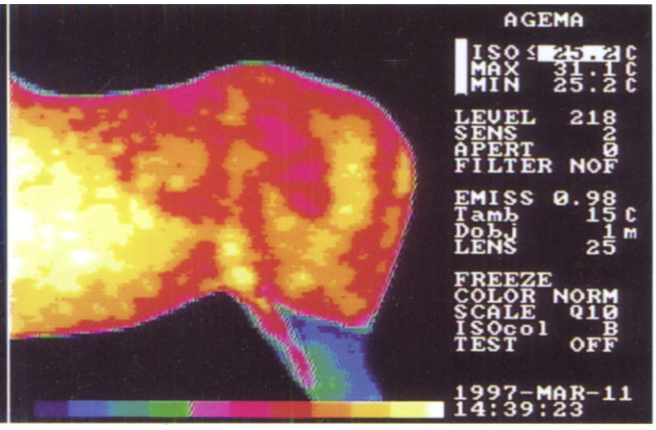
Color Plate 6 Lateral view of the neck of horse with reduced mobility in the occipito-atlantal and atlanto-axial joints. A cool line runs obliquely from the region of the atlanto-axial joint caudally to the base of the neck and is 1.5° C cooler than the surrounding muscle, indicating an area of sympathetic dystonia.



Color Plate 7 Lateral view of the neck of horse with reduced mobility in the neck. Note the significant cooling from the occiput back to the level of the sixth and seventh cervical vertebrae, indicating a problem involving all joints in the neck.

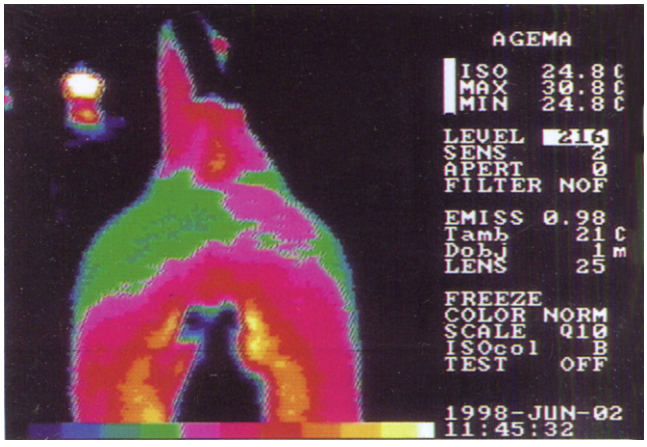
A



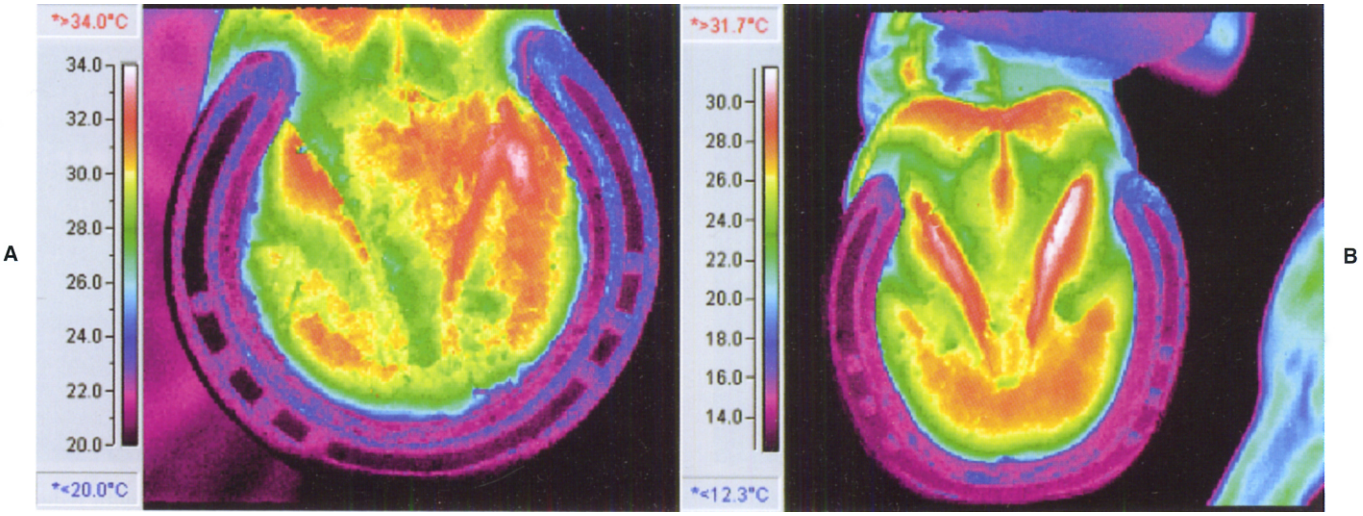


B

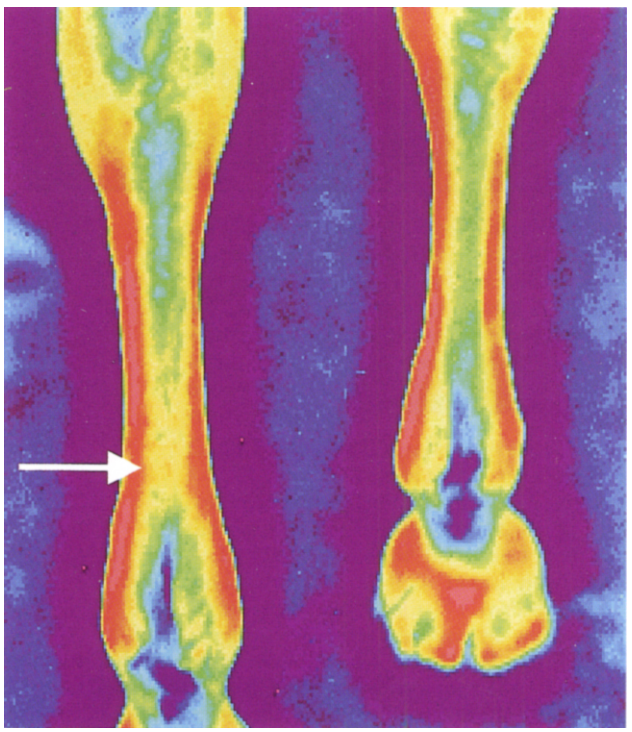
Color Plate 8 Lateral views of the thoracolumbar area of two horses, both showing significant cooling in the musculature of the dorsal spine from the saddle region caudally. **A,** The vertical cranial boundary to the zone of cooling indicates that the injured area is in the region of the cervicothoracic junction, but the shoulder muscles overlying this area receive innervation from the lower neck, partly masking the muscles supplied by the upper thoracic area. **B,** The typical appearance of cooling in the muscle resulting from an injury to the region of the twelfth thoracic vertebra, with the cranial border of the region running obliquely down and back. This horse has been clipped, but long hair left on the hind limb shows as an area 5° C cooler than the surface temperature of the thorax of the horse.



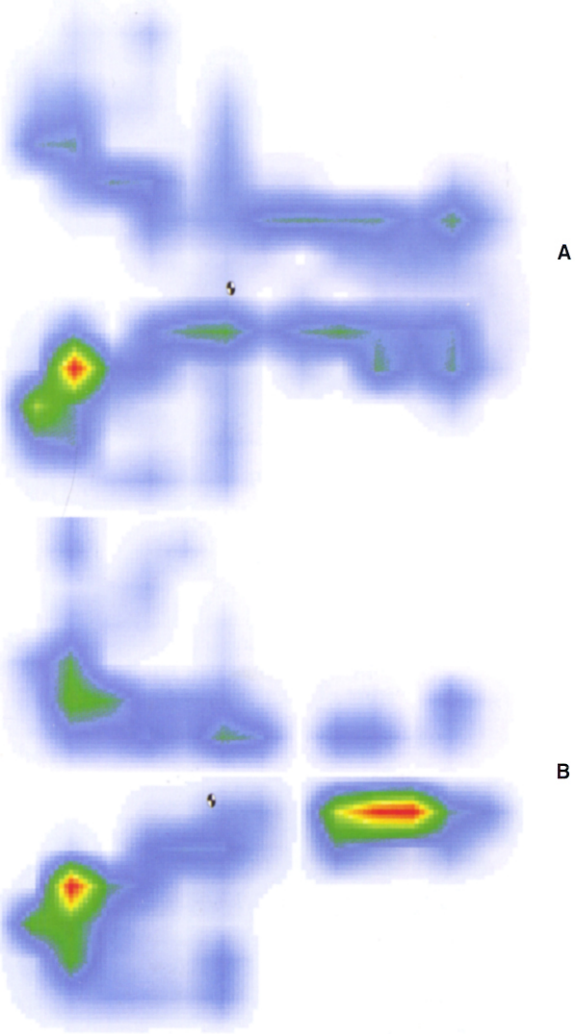
Color Plate 9 Dorsal view of horse showing abnormal heat patterns of the thoracolumbar spine. Note the complete loss of the normal central stripe, with significant cooling indicating the presence of reduced mobility of the entire thoracolumbar spine and pelvis. The asymmetrical nature of the heat pattern indicates the horse is likely to move with an asymmetrical gait, resulting from increased muscle tone on the left-hand side of the body.



Color Plate 10 Examples of different thermographic foot patterns (solar views). **A,** This hoof has a medial corn, manifested as a focal hot spot (*white*) within an area of increased temperature. **B,** This hoof has subacute laminitis, with a pattern of increased heat in the region of the tip of the distal phalanx.



Color Plate 11 Palmar thermographic image and subsequent transverse (on the left) and longitudinal ultrasonographic images of an advanced event horse 10 days after successfully completing a Three Day Event. The horse was having a routine examination, and no clinical localizing signs were evident in the tendon. The thermogram demonstrates a focal hot spot over the left distal superficial digital flexor tendon (*arrow*), and the ultrasonographic images reveal a hypoechoic core lesion in the same region.



Color Plate 12 Computerized saddle pressure analysis images. Cranial is to the left, and left is to the bottom. **A,** This image shows a poorly fitting saddle, with a focal pressure point in the left wither region. **B,** This image demonstrates failure of a gel pad to alleviate the pressure point and the development of an additional pressure point caudally.

SECTION • 1
The Lameness Examination

CHAPTER • 1

Lameness Examination: Historical Perspective

Mike W. Ross

If your horse is lame in his shoulder, take off his shoes…Young and inexperienced practitioners are quite too apt to commit the error of overlooking the examination of the foot, looking upon it as a matter of secondary importance, and attending to it as a routine and formal affair only.

A. Liautard, 1888[1]

As the twenty-first century begins, the extent of change in the diagnosis of lameness in the horse depends on the individual's clinical and ideological perspective. A veritable explosion of new imaging capabilities has advanced the current understanding of many musculoskeletal abnormalities. Yet, to accurately assess clinical relevance, the clinician must possess a feel for the horse, developed only by careful clinical examination, a procedure that has changed little in hundreds of years. Successful detection of equine lameness does not so much require knowledge of science as it does art. Inasmuch as *art* is defined as "skilled workmanship, craft, or studied action,"[2] the lameness examination demands artistic experience acquired by years of clinical practice and working and learning from experienced practitioners. From Liautard's advice more than 100 years ago to that of modern lameness diagnosticians, the change in the basic skills of lameness diagnosis may be small.

Development of the artistic skills needed to become a true lameness diagnostician requires a thorough, somewhat methodical approach, much like that of a crime scene detective. I often refer to the lameness diagnostician as a lameness detective, and although this statement may lack sophistication, in reality, how boring the task would be if the horse could talk. To make a horse talk to you through careful palpation and observation is the essence of the lameness examination yet the most difficult to teach. Great lameness diagnosticians likely possess this ability to read or feel the horse and skilled, workmanship-like qualities to appreciate the art in lameness diagnosis. Some, with the added ability to share this knowledge effectively, have influenced clinicians more than others simply by writing about those experiences. In the mid- to late 1900s, Adams had the most profound influence by his teachings and writings. His former students and friends acknowledge his artistic talent, gained primarily from a ground-up approach to the lame horse, and his profound interest in corrective shoeing. More important, Adams' original lameness notes became his classic textbook.[3] For most clinicians, *Lameness in Horses* represented the "lameness Bible," an excellent resource of information on equine lameness. Adams himself revised the textbook several times; most recently, his respected colleague, Ted S. Stashak, has continued in Adams' footsteps. This important work served as the foundation for the fundamentals of equine lameness.

Adams was influenced greatly by the work of Dollar and Lacroix. Adams' original notes contain many drawings similar to those originally published in Dollar's *A Handbook of Horseshoeing*,[4] a wonderful collection of drawings and excellent descriptions of shoeing, conformation, and lameness of the equine foot. Adams references the work of Lacroix[5] in the late 1800s. In fact, until Adams' treatise on lameness, scant information existed about equine lameness. The information available in the American literature during most of the 1900s consisted of only sporadic case reports or case series in the *Journal of the American Veterinary Medical Association*. A potential explanation may lie in the importance of the World Wars or other important social events in the early to mid-1900s. Experience in the cavalry also may have influenced later writings in the 1900s.

Peters'[6] work detailing lameness in the Thoroughbred racehorse emphasized the importance of lameness in the racetrack practice and the most common cause of poor performance. Many problems he observed in 1939 still exist, although treatment options have expanded considerably. Early important writings included manuscripts by Churchill[7] and Wheat and Rhode[8] on surgical removal of proximal sesamoid bone fractures (the Churchill approach), Forsell[9] on surgical management of navicular bursitis and tendonitis, and Lundvall[10] and later Delahanty[11] debating the subject of the existence or nonexistence of fibular fractures. An early reference of note was the surgical textbook by Frank.[12] Originally written in 1939, with several subsequent editions, this influential and often quoted textbook contained information about numerous musculoskeletal problems and often sensational examples of common and rare abnormalities.

In the late 1800s, several informative, interesting, and entertaining textbooks about equine lameness were written, primarily by European authors. Most publications contained wonderful descriptions of lame horses, and many emphasized shoeing techniques, a mainstay in management of the lame horse both then and now. The writings of Percivall[13] and Gamgee[14] are particularly informative. Although a definitive reason was not provided, Gamgee observed that 42% of horses in the United Kingdom were lame, whereas only 9% of horses in Paris were lame. Disorders of the foot, many of which increased in frequency with age, were most common, and marked remodeling of the distal phalanx was seen in horses undergoing postmortem examination.[14] In addition to the time-honored management technique of shoeing the lame horse, conformation and its relationship to lameness also were emphasized. In *How to Judge a Horse,* Bach[15] emphasized balance, body part length and angulation, and distal extremity conformational faults. In a chapter entitled "Horse-Docturing in the Nineteenth Century," Dunlop and Williams[16] emphasized the contribution of Mayhew, described as artist, activist, and veterinary surgeon. Mayhew described and illustrated many common abnormalities of the locomotor system recognized at that time, including splints, spavin, curb, tendon sprains, and thoroughpin, most of which are still recognized today.[16] Of interest, Mayhew was credited for trying "experimental" injections into inflamed areas, an obviously important

treatment modality practiced today.[16] Detailed descriptions of laminitis, navicular disease, and other common conditions of the equine foot were provided.[16] Dunlop and Williams,[17] in their treatise on the history of veterinary medicine, also detailed the transition from farriery to veterinary medicine that occurred in the 1700s, although the close association and harmonious working relationships between blacksmiths and equine diagnosticians remain integral parts of a successful lameness management team today. In fact, "the term veterinarian came into use when colleges were established in different parts of Europe for improving, or rather for creating the art of treating disease in the lower animals."[17] The first veterinary school was founded in France in 1761, and soon veterinary schools were formed in the United Kingdom.[17]

Although an exhaustive historical review might be interesting, this brief review highlights critical issues central to modern lameness diagnosis. First, the basics have not changed for hundreds of years and will likely not change in the foreseeable future. Second, with the exception of Adams' work, few comprehensive reports on lameness diagnosis were written in the 1900s. The modern lameness detective likely has learned most from experience working with accomplished lameness diagnosticians and by word of mouth. Third, many of the most knowledgeable colleagues have not published writings but have made their contributions in day-to-day teachings in academic settings, private practice, and small gatherings at national meetings.

Since 1955 the annual convention of the American Association of Equine Practitioners has played a special role in the dissemination of information and ideas about lameness. Early meetings included a handful of practitioners, gathering and discussing equine medicine and surgery, sometimes late into the night. Much current lameness experience can be traced to these early meetings and practitioners such as Adams, Peters, Frank, Farquharson, Churchill, Goddall, Gabel, and Delahanty. Loren Evans and Howard "Gene" Gill influenced the molding of many modern lameness detectives, including me. Emphasizing the value of acquiring horse sense and spending time palpating and "learning" the horse, Gill often quotes Will Rogers, "…the outside of a horse is good for the inside of a man."

In the United Kingdom the British Equine Veterinary Association was established in 1961, providing a similar formula for dissemination of information through its annual congress and regular day meetings. The establishment of the *Equine Veterinary Journal* in 1968 provided a high-quality, refereed journal. The standard for the journal was set by the first editor, John Hickman, an astute observer of lame horses and an influence on many practitioners.

No substitute exists for careful clinical examination and observation, experience gained over many years of treating and developing a feel for the lame horse. This textbook on lameness is a collection of the best and most knowledgeable lameness diagnosticians worldwide. Some are "household lameness names," whereas others are less renowned. All have one thing in common: they practice the art of lameness diagnosis in the horse.

CHAPTER • 2

Lameness in Horses: Basic Facts before Starting

Mike W. Ross

DEFINITION

Lameness is therefore not so much an original evil, a disease per se, as it is a symptom and manifestation of some antecedent vital physical lesion, either isolated or complicated, affecting one or several parts of the locomotive apparatus.—A. Liautard, 1888[1]

The clinical manifestations of lameness in the horse are well known, but an exact definition is difficult. The word *lame* is an adjective, meaning "crippled or physically disabled, as a person or animal,…in the foot or leg so as to limp or walk with difficulty."[2] A medical dictionary defines *lameness* as "incapable of normal locomotion, deviation from the normal

treatment modality practiced today.[16] Detailed descriptions of laminitis, navicular disease, and other common conditions of the equine foot were provided.[16] Dunlop and Williams,[17] in their treatise on the history of veterinary medicine, also detailed the transition from farriery to veterinary medicine that occurred in the 1700s, although the close association and harmonious working relationships between blacksmiths and equine diagnosticians remain integral parts of a successful lameness management team today. In fact, "the term veterinarian came into use when colleges were established in different parts of Europe for improving, or rather for creating the art of treating disease in the lower animals."[17] The first veterinary school was founded in France in 1761, and soon veterinary schools were formed in the United Kingdom.[17]

Although an exhaustive historical review might be interesting, this brief review highlights critical issues central to modern lameness diagnosis. First, the basics have not changed for hundreds of years and will likely not change in the foreseeable future. Second, with the exception of Adams' work, few comprehensive reports on lameness diagnosis were written in the 1900s. The modern lameness detective likely has learned most from experience working with accomplished lameness diagnosticians and by word of mouth. Third, many of the most knowledgeable colleagues have not published writings but have made their contributions in day-to-day teachings in academic settings, private practice, and small gatherings at national meetings.

CHAPTER • 2

Lameness in Horses: Basic Facts before Starting

Mike W. Ross

DEFINITION

Lameness is therefore not so much an original evil, a disease per se, as it is a symptom and manifestation of some antecedent vital physical lesion, either isolated or complicated, affecting one or several parts of the locomotive apparatus.—A. Liautard, 1888[1]

The clinical manifestations of lameness in the horse are well known, but an exact definition is difficult. The word *lame* is an adjective, meaning "crippled or physically disabled, as a person or animal,…in the foot or leg so as to limp or walk with difficulty."[2] A medical dictionary defines *lameness* as "incapable of normal locomotion, deviation from the normal

gait."[3] The noun *lameness* can be but infrequently is used interchangeably with *claudication*, described as "limping or lameness."[3]

Lameness is simply a clinical sign, a manifestation of the signs of inflammation, including pain, or a mechanical defect, that results in a gait abnormality characterized by limping. The definition is simple, but recognition, localization, characterization, and management are complex.

LOCALIZATION OF PAIN

In certain conditions, characteristic gait abnormalities allow immediate and straightforward recognition and localization of the problem. Sweeny, fibrotic myopathy, upward fixation of the patella, stringhalt, shivers, and radial nerve paresis are examples. However, similar gait deficits exist for a variety of lameness problems, complicating recognition and localization. A fundamental concept in lameness diagnosis is the application of diagnostic analgesic techniques to localize the source of pain causing lameness. The sequence of properly determining the lame leg (recognition) and then abolishing the clinical sign of lameness by use of diagnostic analgesia (localization), only to have lameness return when the local anesthetic effects abate, is essential for accurate diagnosis. With experience and under certain circumstances, this step in lameness diagnosis can be omitted. The degree of lameness, certain gait characteristics, and palpation findings allow the clinician to strongly suspect a certain diagnosis. The next step may be diagnostic imaging. Trial and error also occasionally work and in some instances may be the preferred approach. However, because pathognomonic signs are rare, proficiency in diagnostic analgesic techniques is mandatory for the lameness diagnostician.

BASELINE AND INDUCED LAMENESS

Baseline, or primary, lameness is the gait abnormality recognized when the animal is examined at a walk or trot in hand, before flexion or manipulative tests are used. The clinician usually recognizes this abnormality by watching the horse on a firm or hard surface, while it is being trotted in a straight line. Diagnostic analgesia is used to abolish this lameness. Changing the surface or nature of the exercise by lunging, or circling the horse at a trot in hand, potentially changes the baseline lameness. The surface and exercise (gait and speed) must be consistent. In some horses, no observable lameness is present at a walk or trot in hand. Lameness may be evident when the horse is ridden, and this lameness becomes the baseline lameness.

Flexion tests and other forms of manipulation are used to exacerbate baseline lameness or to induce lameness. An induced lameness is one that is observed after flexion or manipulative tests, but induced lameness may not be the same as the baseline lameness. Manipulative tests are expected to, and often do, exacerbate the primary lameness. However, flexion and manipulative tests can cause development of additional lameness, unrelated to the primary or baseline lameness, and test results must be interpreted carefully.

COEXISTENT LAMENESS

Horses often have several sites of pain, although one usually is most obvious and the cause of baseline lameness. In many horses, secondary or compensatory (sometimes referred to as *complimentary*) lameness develops in predictable sites or limbs. Concomitant bilateral forelimb or hindlimb lameness is common, but horses often demonstrate more prominent clinical signs in one limb or the other. In horses with palmar heel pain, initially pronounced single forelimb lameness that is abolished by palmar digital analgesia may be present, with subsequent recognition of contralateral forelimb lameness. In racehorses, bilateral lameness, such as in the carpi or metacarpophalangeal or metatarsophalangeal joints, is common. The clinician should carefully examine the contralateral limb. Predictable compensatory or secondary lameness often exists in the ipsilateral or contralateral forelimb, when primary lameness is present in the hindlimb, or vice versa. In a Thoroughbred (TB) racehorse with left forelimb lameness, compensatory problems in the right forelimb and left hindlimb are not uncommon, because these limbs presumably are succumbing to excessive loads, while protecting the primary source of pain. In a trotter, diagonal lameness often occurs (primary lameness in the left hindlimb and compensatory lameness in the right forelimb), whereas in pacers, ipsilateral lameness is most common (primary right forelimb and compensatory right hindlimb). When several limbs are involved, identification of the primary or major source of pain is important. If forelimb and hindlimb lameness exist simultaneously, diagnostic analgesic techniques should begin in the hindlimb (see Chapter 10). A common secondary lameness abnormality, proximal suspensory desmitis, can develop in the compensating forelimb or hindlimb.

LAMENESS DISTRIBUTION

Among all types of horses, forelimb lameness is more common than hindlimb lameness. A horse's center of gravity or balance, while dictated to a certain extent by conformation (see Chapter 4), is not located in the center of the horse but is closer to the forelimbs than the hindlimbs. Thus the forelimb/hindlimb (F/H) weight (load) distribution ratio is approximately 60%:40% (Fig. 2-1). Higher loads are expected on the individual forelimbs (30% each), predisposing the horse to greater injury.

At certain times during the stride cycle of gaits such as the canter (three-beat gait) and gallop (four-beat gait), a single forelimb is weight bearing, which predisposes the limb to injury. The weight of a rider may shift F/H load distribution to 70%:30% (Fig. 2-2). Two-beat gaits, such as the pace and trot, allow more equal load sharing between forelimbs and hindlimbs because a forelimb and hindlimb (ideally, if the gait is balanced perfectly) hit the ground simultaneously. In pacers and trotters the proportion of forelimb lameness is less. The added load of pulling a sulky, cart, or any heavy load increases the likelihood of hindlimb lameness in Standardbreds (STBs), other harness breeds, and draft horses (Fig. 2-3). The F/H distribution of lameness in STB racehorses is 55%:45%. Sporting activities such as dressage and jumping also may shift lameness distribution to the hindlimbs because collection (working off the hindlimbs) and propulsion needed by horses to perform these activities may predispose to hindlimb lameness.

In the forelimb, up to 95% of lameness problems occur at the level of or distal to the carpus.[4] The distal parts of the limb always should be excluded as a potential source of lameness before the upper limb is addressed, although many owners believe otherwise, and may try to mislead an inexperienced practitioner. The foot should be suspected first. Pain in the foot is one of the most common causes of forelimb lameness in all types of horses, except draft breed horses, in which the foot is the most common site of pain in the hindlimb.

Hindlimb Lameness

Hindlimb lameness should not be underplayed, although its recognition is more difficult. In the forelimb lameness–prone TB racehorse, many hindlimb lameness problems are overlooked. However, a rider or jockey often may suspect a hindlimb problem when the lameness actually exists in the forelimb.

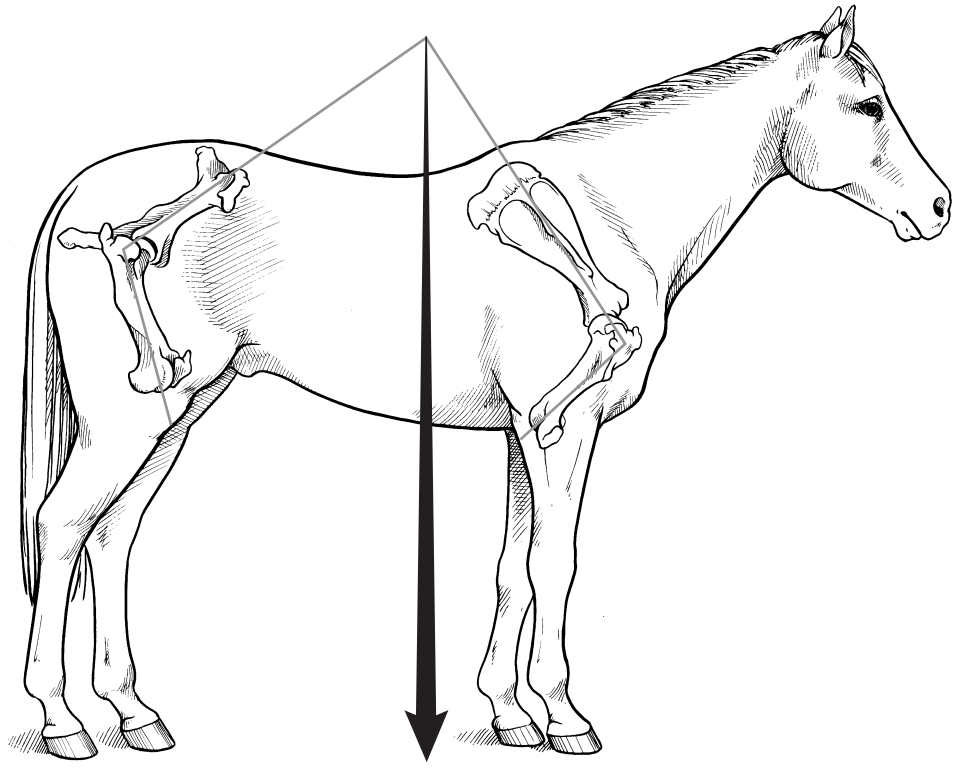

Fig. 2-1 The center of balance (gravity) of the horse is located closer to the forelimbs, which accounts for the load distribution difference between the forelimbs and hindlimbs. Conformation, namely the angles of the shoulder and rump, and weight of the head and neck and gait can change this load distribution.

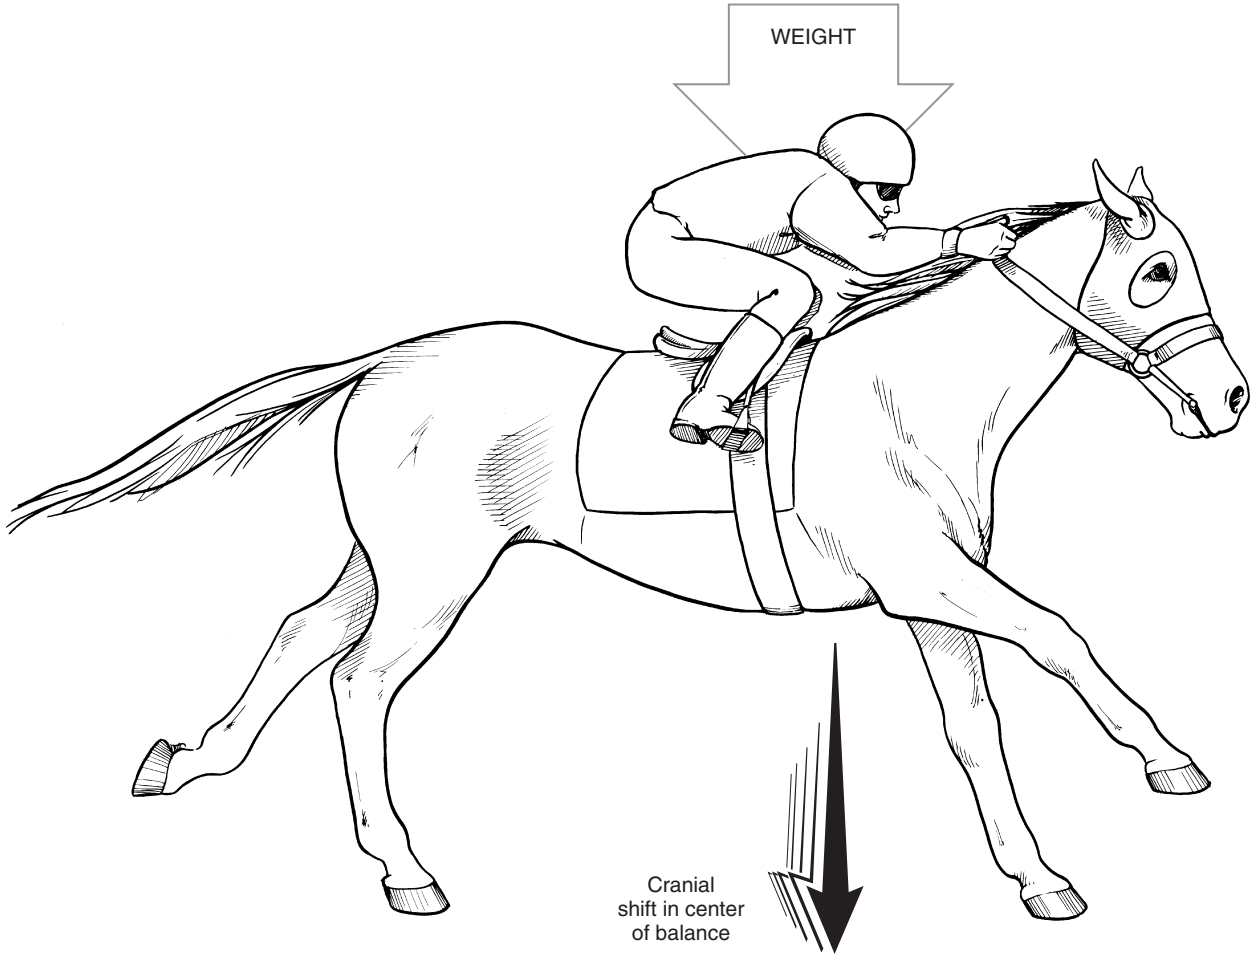

Fig. 2-2 Gaits such as the canter and gallop (depicted) and the added weight of a rider, as shown here in a Thoroughbred racehorse, increase load on the forelimbs by shifting the center of balance, thus increasing the likelihood of forelimb lameness.

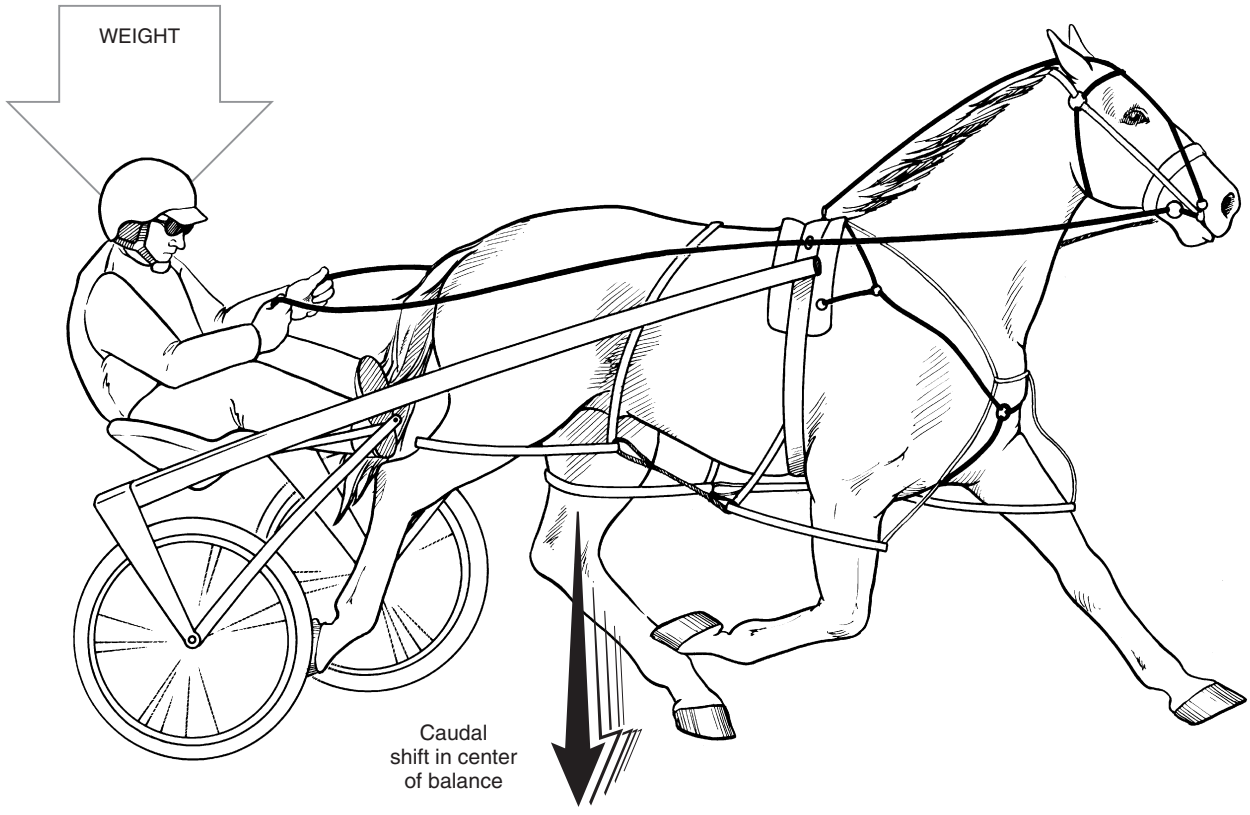

Fig. 2-3 In a Standardbred racehorse (pacer depicted), the hindlimbs share added load compared with a Thoroughbred racehorse because of a caudal shift in the center of balance. The type of harness with the overcheck bit, the added weight of the sulky and driver, and the necessity of pulling a load increase the likelihood of hindlimb lameness in this breed.

A practitioner should consider carefully the distribution of sites of hindlimb lameness. Historically, the hock has been regarded as the major source of problems, and although it is an important source of hindlimb lameness, other sites also are important. For instance, in the STB racehorse the metatarsophalangeal joint is a major source of lameness that historically has been overlooked.[5,6] Stress or nonadaptive bone remodeling of the distal third metatarsal bone (MtIII) cannot be seen radiographically in early stages and requires careful diagnostic analgesic techniques to achieve localization. Scintigraphic examination is mandatory for definitive diagnosis.[7] Lameness of the metatarsophalangeal joint in STBs is almost as common as that of the hock, but without careful examination and the use of diagnostic analgesia, hock lameness is suspected in many such horses and they are treated for it. The combined use of diagnostic analgesia, ultrasonography, and scintigraphy has increased clinical knowledge of the broad spectrum of lameness conditions in the hindlimbs.

In the draft horse, lameness in the hindlimb most commonly develops in the foot. Lameness in this area reflects the work performed by these horses, and innate characteristics of the draft horse foot, which predispose the foot to conditions such as laminitis. In jumping and dressage horses, problems in the fetlock region such as osteoarthritis and tenosynovitis are common and reflect the stress imposed by these disciplines. Although owners, trainers, and veterinarians often suspect an upper hindlimb lameness, gait characteristics of lower limb lameness problems often are similar. Only use of diagnostic analgesia allows an accurate diagnosis.

RELATIONSHIP OF LAMENESS AND CONFORMATION

Conformation of the distal extremities, and to a lesser extent the overall body, plays a major role in the development of forelimb and hindlimb lameness (see Chapter 4). When a practitioner examines a weanling or yearling with poor conformation, predicting the time and the exact way the lameness will occur may be difficult, but many well-recognized conformational faults can lead directly to lameness problems. Conformation faults of the carpus, such as carpus varus or valgus, back-at-the-knee, and offset knees, can be important factors in carpal and lower forelimb lameness. In the hindlimbs, excessively straight hindlimbs ("straight behind"), sickle hocked, and in-at-the-hock conformation can lead directly to predictable lameness conditions. Although exceptions do exist, in the case of poor conformation, predictable lameness conditions consistently develop in poorly conformed horses. Evaluation of conformation is therefore an essential part of a lameness examination.

POOR PERFORMANCE

Convincing trainers and owners may be difficult, but the leading cause of poor performance in racehorses is lameness, and lameness is the most prevalent health problem among all horses.[8-11] In a recent study, 50% of U.S. operations with three or more horses had one or more lame horses, and 5% of the

horses could be expected to be lame.[10] In another study, 74% of racehorses evaluated for poor racing performance had substantial musculoskeletal abnormalities contributing to poor performance. Lameness examination was emphasized as a most important aspect of comprehensive performance evaluation.[12,13] Others have emphasized the importance of lameness in epidemiological studies evaluating wastage in TB racehorses.[14,15] The same is likely true among all sport horses, particularly those competing at upper levels, although comprehensive studies have not been performed. Obvious lameness need not be demonstrated for performance to be compromised in horses, especially those competing at high speeds or upper levels. The possibility of achieving maximal performance in horses with substantial lameness is a common misconception. Notwithstanding the ignorance of many in the horse industry, the ability of many horses with obvious lameness to compete is a tribute to the mental and physical toughness. For example, bilateral forelimb or hindlimb lameness is common in STBs, but in some instances goes unrecognized if the condition is of similar severity. Unilateral lameness of this magnitude would be recognized easily, but because the lameness is bilateral, horses still race, albeit at a lower level. Bilateral third carpal slab fractures and sagittal fractures of the proximal phalanx have been diagnosed in horses examined for poor racing performance but, if seen unilaterally, would have caused pronounced lameness.

GAIT DEFICITS NOT CAUSED BY LAMENESS

Gait abnormalities can exist with or without the presence of clinically apparent lameness. Deficits such as stringhalt, mild intermittent upward fixation of the patella, and shivers (see Chapter 49) can be present without obvious lameness and may complicate diagnosis of a completely different primary source of lameness. Horses with neurological disease may have gait deficits that are considered the result of painful lameness conditions (see Chapter 11). Horses with lower motor neuron diseases, such as equine protozoal myelitis, may have lameness associated with muscle atrophy or unexplained low-grade lameness associated with the disease. Concomitant lameness conditions can and do occur in these horses. Recurrent exertional rhabdomyolysis can cause stiffness and in some instances lameness, or it can cause poor racing performance, all of which can be misinterpreted as lameness (see Chapter 84).

UNEXPLAINED LAMENESS

A diagnosis is made for most, but not, all lame horses through careful clinical examination and ancillary imaging modalities. Even with advanced imaging techniques a solution is not always found (see Chapter 12), but hopefully future innovations in clinical examination and imaging will result in the continued expansion of the science of lameness diagnosis.

COMPONENTS OF THE LAMENESS EXAMINATION AND LAMENESS STRATEGY

Lameness Examination

Lameness examinations should be performed in an orderly, step-by-step way, but many factors may change or abbreviate the examination (Box 2-1). Owner financial constraints may not allow performance of certain diagnostic tests and may curtail the time necessary to complete the entire examination. Drug testing of competing racehorses or show horses may limit a practitioner's ability to perform diagnostic analgesic techniques and restrict management options. Clients do not always understand the need for diagnostic analgesia. Education about the value of this technique, and the difficulties of interpretation of the results of diagnostic imaging without it, is vital.

Box • 2-1

Components of the Lameness Examination

History—anamnesis
Examination from a distance—conformation, symmetry, posture
Palpation
  Hoof tester examination
Physical examination—other ancillary testing
Movement
  Baseline
  Additional movement
Selected examinations—manipulation, flexion, direct pressure, wedge
Diagnostic analgesia
Imaging
Diagnosis
  Certain, presumptive, open
Management
Follow-up examination

Abbreviated lameness examinations often are performed in horses that exhibit severe lameness compatible with a fracture. Typical or obvious clinical signs may accompany severe lameness, and in many instances, prolonged or extensive lameness examination is contraindicated. If incomplete fractures are suspected, diagnostic analgesic techniques may be dangerous and should be performed only in certain situations. A clinician may proceed directly to conventional or advanced imaging techniques before completing the initial steps of the conventional lameness examination.

Many other factors affect the ability to complete a comprehensive evaluation. Time constraints (usually of the veterinarian) often are cited, although shortcuts, if taken, usually create future problems. Omission of a diagnostic block or failure to perform detailed palpation often leads to misdiagnosis. Omission of a brief physical examination, including assessment of the horse's temperature, can lead to embarrassing situations.

The footing available on which to complete the lameness examination can be problematic. A dry, flat, hard surface or space for lunging or riding may be unavailable. The horse's temperament may preclude adequate movement and often limits the practitioner's ability to perform diagnostic analgesia. Many ill-tempered horses are referred for advanced imaging techniques, such as scintigraphic examination, because diagnostic analgesic techniques are dangerous to the veterinarian and handler.

Lameness Etiquette

Owners frequently request an opinion from more than one veterinarian. Therefore professional, ethical conduct is important, with practitioner acknowledgment that horses can appear very different every day and response to diagnostic analgesia is not always consistent. For example, differences of opinion concerning radiographic interpretation can exist. A good working relationship with the client or agent is essential but should extend also to the farrier and any paraprofessionals involved in the management of the horse, even when opinions differ.

Prognosis Assessment

Assessment of prognosis for performance is important, but because few published data relating to many sports disciplines are available, clinicians often must rely on personal experience based on an understanding of the sport. Owners and trainers should consider prognosis carefully when making decisions to pursue therapeutic options, particularly when a long layoff period is required. I prefer to define prognosis as the "chance the horse will return to its previous level of competition." However, this may not be a fair or reasonable definition.

Retrospective studies can be used to evaluate prognosis after surgical or conservative management for various conditions in racehorses. Objective data such as numbers of race starts, race times, earnings per start, and time from treatment to first race start can be assessed. The criterion, earnings per start, is important because it establishes racing class or level of competition. However, in most retrospective studies, earnings per start decrease after treatment. The question is whether practitioners can accurately state that the horse will drop in class after treatment and whether this drop in class is the result of the injury, treatment, or aging of the horse an additional year before returning to racing. Use of this information is not easy.

Most owners and trainers have a different view of prognosis than the veterinarian. In considering the prognosis for a horse undergoing arthroscopic surgical removal of a small osteochondral fracture of the carpus, most owners emphasize the surgery rather than the original injury. Clinicians must explain thoroughly the magnitude of the injury and related damage and discuss prognosis, using terminology that clearly indicates that the extent of injury is the factor that determines prognosis.

Expecting a racehorse to return to its previous racing class may be an unrealistic expectation or at least a very strict definition for success. In a recent retrospective study of postoperative racing performance of STBs treated for carpal chip fractures, 74% of horses made at least one race start after surgery.[16] Median earnings per start significantly decreased, but the median race mark (best winning time) also significantly decreased, indicating horses made less money but ran faster after surgery.[16] These results must be compared with a normal population of STBs as the horses age, without considering injury, because STB racing performance is not standard over time.[17] Average earnings per start is highest in 2-year-old horses and decreases exponentially until retirement.[17] A population of horses undergoing any long-term layoff that requires recommencement of racing the following year can be expected naturally (unrelated to the original injury) to have lower earnings per start, regardless of whether the injury occurred or treatment was given. Therefore retrospective studies may underestimate prognosis associated with injuries and management choices.

Success criteria and outcome assessment must be standardized to compare treatment results and define prognosis. The current standard for racehorses is comparison of performance for five starts before and after injury and treatment. This criterion is strict; a practitioner first may prefer to predict the chance of the horse returning to racing and then assess the chance that the horse will perform at or near its previous level.

Other statistical methods have been used to evaluate racing performance in TBs using a regression model accounting for variables such as track surface, race distance, and age.[18-20] To date, this performance analysis has been restricted to evaluation of horses after upper respiratory tract surgery but probably will be applied to horses with musculoskeletal injuries.

CHAPTER • 3

Anamnesis (History)

Mike W. Ross

The importance of a detailed clinical history, the anamnesis, cannot be overemphasized. Information is divided into two categories, basic facts necessary for every patient and additional information from questions tailored to the specific patient. The veterinarian must understand the breed, use, and level of competition of each horse, because prognosis varies greatly among different types of sport horses. Firsthand experience of the particular type of sport horse being examined is useful but is not essential. Clinicians must understand the language associated with the particular sporting event, and this may be a challenge. For some sporting events, understanding the clinical history and the ability to ask the right questions is like speaking a different language. A veterinarian unfamiliar with the sporting activity should briefly review the type of activities performed and the array of potential lameness problems encountered with them. In some instances the veterinarian may lose credibility when talking to trainers or riders, particularly those involved in upper-level competition, if they perceive unfamiliarity.

The veterinarian must understand the difference between subjective and objective information in the clinical history. Objective information is gained from the horse, and subjective information is perceived by the rider or owner. Information about a horse's performance such as "the horse is bearing out," "the horse is on the right line," "the horse is lugging in," "the horse has just started to refuse fences," or "the horse no longer takes the right lead" is valuable objective information. Common examples of information perceived by the owner or rider include "the horse feels off behind," "the horse is stiff behind," or "the horse is lame behind" and it "feels up high." Such information generally is useful and indicates a change in the horse's gait, but only an experienced rider or trainer can discriminate accurately between forelimb and hindlimb lameness at any gait. Erroneous information obtained from the rider can complicate communication during lameness examination, particularly if the individual is strong willed and seemingly authoritative; this situation occurs if riders or trainers insist they are correct and the veterinarian disagrees. In my experience, many horses considered to have hindlimb lameness by a rider actually are lame in front, but convincing a disbelieving trainer is difficult. Similarly, lameness perceived as "up high" in most horses originates from the lower part of the limb. The veterinarian must understand that everyone is trying resolve the problem, but sometimes diplomacy is needed for successful communication. The veterinarian must be forthright and objective to determine the current source of lameness, even if the determination contradicts well-intentioned but strong-willed trainers.

Clinical history is important but should not override clinical findings. In racehorses that perform at high speed, physical examination generally supports the finding that a horse bears away from the source of pain. During counterclockwise racing or training and with left forelimb lameness, a Thoroughbred (TB) will lug out (away from the inside of the track) and a Standardbred (STB) will be on the "left line" (bearing out; the driver must pull harder on the left line). Some horses, however, especially STBs with medial right forelimb pain, bear out particularly in the turns, presumably because the source of pain is medial or on the compression side of the limb.

The veterinarian must seek out as much information as possible, particularly if the problem is complex or not readily apparent. Videotapes are useful, particularly if the gait deficit, behavioral problem, or any other circumstances necessary to elicit the suspected lameness cannot be duplicated during the examination. Paraprofessionals working with the horse provide useful information, but not everyone may agree about the source of the problem, and in some instances diplomacy is key to negotiating among concerned individuals.

CLINICAL HISTORY: BASIC INFORMATION

Signalment

Age

The age, sex, breed, and use of the horse are basic vital facts (Box 3-1). Flexural deformities, physitis, other manifestations of osteochondrosis, and angular limb deformities are age-related problems. Infectious arthritis (hematological origin), lateral luxation of the patella, and rupture of the common digital extensor tendon are conditions usually unique to foals. Emphasis on training skeletally immature, 2- and 3-year-old racehorses causes predictable soft tissue and bone changes, often resulting in stress-related injury. Liautard observed more than 100 years ago: "When an undeveloped colt, whose stamina is not yet established and constitution not yet confirmed, with tendons and ligaments relatively tender and weak, and bones scarcely out of the gristle, is unwisely condemned to hard labor, it is irrational to expect any other results than lesions of one or another portion of the abused apparatus of locomotion. They will be fortunate if they escape a fate still worse, and become sufferers from nothing worse than mere lameness."[1] This statement aptly summarizes the situation then and now. The high value of races for 2- and 3-year-olds results in high-intensity training as an early 2-year-old, which may result in injury such as nonadaptive remodeling of the third carpal bone (C3), precluding racing at a young age.

Some problems are unique to older horses (Box 3-2). Overall, osteoarthritis and other degenerative conditions such as navicular disease are most common but certainly not unique to the geriatric patient. These problems worsen with advancing age, particularly if several limbs are involved. In former racehorses, progressive osteoarthritis is of particular concern; this condition most commonly affects the carpal and metacarpophalangeal joints (Fig. 3-1). Occasionally in older horses, severe, progressive osteoarthritis of the carpometacarpal joint occurs without any history of carpal lameness (Fig. 3-2). In some horses, angular deformities develop at the carpometacarpal joint. Primary osteoarthritis of this joint is rare in young horses, even in racehorses with middle carpal joint abnormalities, unless C3 slab fracture or infectious arthritis occurs. Osteoarthritis of the coxofemoral joint is rare

Box • 3-1

Anamnesis: Basic and Specific Information

Basic Information

Signalment: age, sex, breed, use
Current lameness: what is the problem?
- History of trauma
- Duration of lameness
- Deterioration or improvement of lameness
  - Circumstances when lameness worsens or improves
- Effects of exercise: worsening or improvement in lameness
- Management changes
  - Changes in shoeing and related issues
  - Changes in training or performance intensity
  - Changes in surface
  - Changes in diet and health
  - Changes in housing
- Current medication and response; response to rest

Past lameness problems

Specific Information

Type of sporting activity
- Level of competition: current and future

Box • 3-2

Summary of Lameness Conditions of the Geriatric Horse

Chronic, progressive osteoarthritis
- Proximal, distal interphalangeal joints
- Metacarpophalangeal joint
- Carpometacarpal joint*
- Coxofemoral joint*
- Femorotibial joints
- Tarsus
- Progressive osteoarthritis—previous injury (usually retired racehorses)

Navicular disease
Unexplained, severe soft tissue injuries*
- Superficial digital flexor tendonitis
- Flexural deformity
- Suspensory desmitis

Fractures during anesthetic recovery

*Some of these conditions are unique to the older horse and often are unexplainable.

in horses with the exception of young horses with osteochondrosis, but it does occur in older horses.

An unusual group of soft tissue injuries of unknown origin occurs in older horses. Superficial digital flexor tendonitis and suspensory desmitis generally are considered

Fig. 3-1 An aged Thoroughbred broodmare with severe forelimb deformity caused by primary severe osteoarthritis of the right metacarpophalangeal joint and secondary or compensatory (chronic overload) carpus varus in the left forelimb.

overuse injuries and usually occur in upper-level performance horses or racehorses. However, severe tendonitis and desmitis do occur, often suddenly and without provocation, in older (teenage) horses. Horses usually are turned out at pasture when initial lameness is observed. In some patients, superficial digital flexor tendonitis is severe and progressive, leading to later flexural deformity because of adhesions. Suspensory desmitis may be unilateral or bilateral, may involve the forelimbs or hindlimbs, and is most common in the older broodmares.

Older horses, particularly older broodmares, are at greater risk than younger horses to fracture long bones during recovery from general anesthesia.[2] Between 1988 and 1994, 9 of 14 horses with catastrophic fractures or dislocations that developed during recovery from general anesthesia were older than 10 years of age.

Age prominently affects prognosis. A common premise in considering lameness in foals is that young horses have time to outgrow the problem. Maturation will aid in angular limb deformities, some forms of osteochondrosis, and distal phalanx and diaphyseal fractures. However, fractures of important physes such as the proximal tibia may result in progressive angular deformities or disparity in limb length, limiting future prognosis. Early surgical management of flexural deformity of the distal interphalangeal (DIP) joint before 6 to 8 months of age optimizes future soundness and the possibil-

Fig. 3-2 Dorsolateral-palmaromedial oblique radiograph of the carpus of an aged horse showing unusual, severe osteoarthritis of the carpometacarpal joint.

ities for normal hoof conformation. In one study the reported success rate was 80%.[3] If surgical management is done later in life or when deformity is severe, the prognosis decreases substantially. The prognosis for survival of foals treated for infectious arthritis is reasonable, but only 31% of TB foals and 36% of STB foals started one or more races, indicating the prognosis for future racing performance is poor, because articular healing even in young foals is not possible.[4]

In middle-aged (12 to 18 years of age), upper-level performance horses, prognosis is difficult to assess, particularly in horses with several problems. Level of competition, rather than age, may be the most important factor, and often performance level declines.

Sex

Most lameness conditions affect stallions, geldings, and mares with similar frequency. Sex-specific conditions are unusual but do exist. The most important consideration, however, regarding the sex of the patient is future breeding potential or lack thereof in the case of geldings. In many types of horses, and specifically in racehorses, decisions about future performance or racing potential often are important when considering management options and financial aspects. This factor is particularly important when life-or-death decisions must be made after catastrophic injury (see Chapter 13). Frank discussions about the prognosis for return to the current sporting activity or level of performance often are necessary, and the clinician should consider reproductive capability of the horse. Owners are more likely to refrain from racing females and elect treatment for geldings and, in some instances, stallions. Future stallion prospects usually must prove race or performance success, thereby putting pressure on trainers to continue horses in training or racing.

Behavioral abnormalities associated with the estrous cycle in fillies or mares are well recognized and may cause performance problems confused or misinterpreted as lameness (refusing fences, going off stride, striking) (see Chapter 50). An ill-defined behavioral problem in middle-aged nonracehorse mares could explain sudden performance problems often associated with or misinterpreted as lameness.[5] Recurrent exertional rhabdomyolysis (RER) is more common in female TB racehorses[6] and event horses.[7] An association between sex and RER in STBs may exist and be more common in fillies administered anabolic steroids.

Obscure or unexplained hindlimb lameness has been attributed, rightly or wrongly, to retained testicles. The origin of lameness in these horses is difficult to prove without removing the retained testicle, and anecdotal reports suggest that hindlimb lameness has resolved after castration in some horses. The origin of pain in an abdominal cryptorchid is difficult to explain and questionable. The source of pain may be easier to understand in a horse with a testicle located within the inguinal canal. Activity of the external and internal abdominal oblique muscles and tension on the spermatic cord are possible explanations.

Breed and Use

Most lameness conditions affect all breeds of horses. Although breed has considerable influence on sporting activity, sporting activity or use primarily has the greatest impact on lameness distribution (see Chapters 116 through 130).

Current Lameness

Determination of the Problem

Accurate information is necessary to determine precisely the horse's current problem. Obtaining reliable information may be difficult if the horse has been purchased recently. Additional objective information may be necessary to assess the effect of lameness on the horse's performance. Evaluation of the horse's race record may indicate when the problem began and if it is ongoing or new. The groom, rider (if not the owner), assistant trainer, blacksmith, and other paraprofessionals may have other pertinent information. Horses with poor performance usually are lame, although respiratory problems, rhabdomyolysis, shoeing, tack or equipment, and other medical problems can contribute.

The horse's past history is important in determining the cause of the current problem, particularly in racehorses training or racing with existing low-grade osteoarthritis that develop new overload injury to supporting limbs (secondary or compensatory lameness). Existing problems such as osteoarthritis worsen insidiously but may reach critical levels, causing sudden, severe unexpected lameness. Osteoarthritis of the metacarpophalangeal joint may exist for months in racehorses without causing obvious lameness, although in many horses joint effusion ultimately leads to treatment ("maintenance injections"). The horse suddenly may be much lamer after racing or training, and the trainer may assume the cause is different. Because intra-articular analgesia may only partially relieve lameness, persuading the trainer that the problem is still the fetlock may be difficult. Horses can endure extensive cartilage damage in any joint for many months, but at some point they reach a threshold level beyond which they cannot tolerate the pain.

History of Trauma

Many lameness problems develop during or shortly after a traumatic incident, but unfortunately many owners presume trauma played a role, even though no one witnessed the

alleged incident. A common but often erroneous assumption when examining a lame foal is that the dam stepped on it, but usually infection is the cause. Conditions such as osteochondrosis dissecans of the shoulder or stifle often are expressed after a traumatic incident, and yet most lame weanlings or yearlings are assumed to be lame because of trauma, not a developmental problem.

Duration

The veterinarian must understand the duration of the current lameness problem and determine whether a preexisting chronic, low-grade lameness exists and if now sudden exacerbation of this problem has occurred, or a completely unrelated new problem has developed.

Worsening of Condition

The veterinarian must establish if the horse's current problem is worsening or improving, under which conditions or circumstances the lameness deteriorates or improves, and if the horse responds to treatment such as shoeing or management changes. Most lameness problems worsen with time, particularly if training or performance continues despite owner or trainer recognition. Racehorses with stress-related bone injury often are noticeably lame after work but become sound relatively quickly, within 1 to 3 days. A minimal number of other clinical signs are present, particularly because the most common bones (tibia, humerus) are difficult to palpate and buried by soft tissue. This cycle of lame-sound-work-lame is an important part of the history.

Improvement of lameness with rest is important from historical and therapeutic perspectives. Lameness in most horses with severe articular damage, usually from severe osteoarthritis, does not improve substantially with rest. Severe osteoarthritis most commonly appears in the fetlock, femorotibial, and tarsocrural joints. Horses with fractures or mild to moderate soft tissue injuries generally improve with rest.

Warming into Lameness

Warming into lameness means the horse's lameness worsens during the exercise period. *Warming out of lameness* means the lameness improves. This concept is important. Lameness associated with stress or incomplete fractures, soft tissue injuries (tendonitis and suspensory desmitis), splints, curb, and foot soreness worsens with exercise. In racehorses a worsening lameness appears as progressive bearing in or out during training or racing. In riding horses, this may be progressive stumbling, problems taking leads, progressive asymmetry in diagonals, or refusing to jump later fences. Horses with osteoarthritis may be stiff and obviously lame at a walk, but lameness may improve with work. In western performance horses, osteoarthritis of the proximal and distal interphalangeal joints, and in some horses navicular syndrome, cause lameness with this characteristic. The most dramatic example is distal hock joint pain, particularly in racehorses. Horses may be noticeably lame at a walk and trot, warm out of the lameness to the point of racing successfully, and then show pronounced lameness after the race.

One frequent statement at the racetrack is that the horse throws the lameness away at speed. This decrease occurs with some lameness conditions, such as distal hock joint pain, but two other factors are important. A horse may be able to race with lameness but not be able to perform at peak, particularly if lameness is bilateral. Horses often can race with bilateral conditions and show minimal signs of lameness, but performance is reduced. Lameness at the gallop may be impossible to perceive, and even at the fast trot or pace, most persons have difficulty seeing lameness. The same limitation occurs in observing a dressage or jumping horse at the canter. The veterinarian may gain some information by observing that a horse is reluctant to take either the left or right lead, but lameness is difficult if not impossible to detect at the canter. Unless slow-motion video analysis is available, the horse appears to be able to "throw lameness away," but lameness *is* present but difficult to see. In this situation, horses do not warm out of lameness but simply cope with the pain while racing. Horses in this situation are at risk of developing compensatory problems.

Older horses with osteoarthritis may have difficulty in getting up and later may warm out of the lameness. Horses of any age with pelvic fractures or severe lameness may have difficulty in rising.

Recent Management Changes

Many lameness conditions start after a change in management. Changes in shoeing, training or performance intensity, surface, housing, and diet or other medical issues can have a profound effect on the musculoskeletal system. Changes in ownership often dictate changes in exercise intensity and certainly in owner expectations. The veterinarian must be careful in questioning and responding to questions if a horse has been purchased recently, especially if a colleague performed a prepurchase examination. Clinicians should avoid implying that a condition may have been preexisting or missed.

Shoeing. The veterinarian should determine when the horse was last shod and whether the shoeing strategy was changed. Nail bind often causes acute progressive lameness related temporally to shoe application. Abscesses that result from a "close nail" may take several days to cause lameness.

Foot balance is critical and, in some horses, changing foot angles results in lameness. A substantial increase or decrease in heel angle in a horse with chronic laminitis may exacerbate lameness. In horses with palmar heel pain, raising the heel angle may produce an obvious improvement in clinical signs briefly, whereas in horses with subchondral pain of the distal phalanx, raising the heel may worsen clinical signs. In racehorses with "sore feet" resulting from soft tissue and bone pain, changing shoes may result in improvement, related in part to temporary reduction in weight bearing in the painful area of the foot.

Temporary lameness often occurs in horses with recently trimmed but unshod hooves, particularly if the horses' hooves are trimmed aggressively or the ground is unusually hard for that time of year. The veterinarian must remember that a horse with recently trimmed hooves often shows bilateral forelimb lameness when trotted on flat or uneven hard surfaces, regardless of the primary cause of the current lameness. The horse should be reassessed on a soft surface.

Attempts to make both front feet symmetrical may create substantial lameness immediately after trimming. Horses may cope well with different size and shaped front feet, but when radical trimming is performed, they may develop severe lameness.

The veterinarian must determine whether any recent or past changes in shoeing either improved or worsened lameness. Lameness in a STB trotter with foot pain may improve by changing from conventional shoes, such as half-round or flat steel shoes in the front, to the "flip-flop" shoe.

The farrier often first notices the common problem that a horse is reluctance to pick up the hindlimbs. In some horses, this problem is purely behavioral, whereas in others it is a real sign of pain. This history most often is associated with conditions such as osteoarthritis of one or more joints but also may be a sign of pelvic or sacroiliac pain. In Warmbloods, draft breeds, and draft-cross horses, reluctance to pick up a hindlimb may be an early sign of shivers.

Training or performance intensity. Lameness that worsens in response to recent increase in training intensity may be related to stress-related subchondral or cortical bone injury. Stress fractures, bucked shins, or nonadaptive stress-related injuries of subchondral bone occur typically during defined periods of training and often after brief periods of rest. When horses in active race training are given time off, even

brief periods such as 7 to 21 days, bone undergoes detraining, leaving it subject to stress-related injury. If training resumes at the pre-rest level or is accelerated, stress fractures or bucked shins often develop. In 3-year-old TBs, stress fractures of the humerus often occur within 4 to 8 weeks after returning to training. Bucked shins often develop in 2-year-old horses after a brief rest period for an unrelated medical condition.

Surface. Most lameness conditions worsen if the horse performs on a harder surface. In show horses such as the Arabian or half-Arabian breeds, foot lameness often results when horses are warmed up or shown on harder surfaces. An association exists between fracture development and hard racing surfaces. A dramatic change in any racing surface may lead to unexpected episodic lameness in racehorses. On breeding farms, anecdotal evidence suggests drought conditions causing harder than normal pastures lead to a higher prevalence of osteochondrosis or distal phalanx fractures.

Lameness that is most pronounced on hard surfaces is often seen with conditions of the foot. Lameness that worsens on softer surfaces, however, may be associated with soft tissue injuries such as proximal suspensory desmitis. Uneven surfaces may exacerbate lameness and other gait abnormalities. Horses prone to stumbling on uneven surfaces may have palmar heel pain, proximal suspensory desmitis, or neurological disease. Horses with bilateral lameness may be lame in one leg going in a particular direction on a banked surface (such as a racetrack) and lame in the opposite leg going the other way. Bilateral lameness may be confused with other causes of poor performance because of inconsistencies in gait. Lameness may worsen or improve when a horse goes uphill or downhill.

Diet and health. Changes in diet or dietary factors may lead to or exacerbate existing lameness conditions. Dietary factors, especially dietary excesses or deficiencies, are important in the many manifestations of developmental orthopedic disease (see Chapter 57). Sudden changes in diet, such as those associated with turning horses out on lush pastures or consumption of large quantities of grain (grain overload), may cause laminitis or exacerbate existing chronic laminitis. Overweight horses normally consuming a high-grain diet may be prone to laminitis or gastrointestinal tract disturbances that lead to laminitis.

Lameness may be associated with, or result from, other medical conditions. Obvious associations exist in foals between conditions such as infectious arthritis and physitis with umbilical, gastrointestinal, or respiratory tract infections. Immune-mediated synovitis also occurs in older foals with chronic infections (see Chapter 67). In adult horses, infectious arthritis generally develops after intra-articular injections or penetrating wounds but may result from hematological spread of bacteria. Occasionally, horses develop distal extremity edema and lameness after vaccination, presumably caused by vasculitis or other immune-related mechanisms. Similar signs appear in horses with purpura hemorrhagica or viral illnesses such as equine viral arteritis.

Housing. Many lameness conditions develop while a horse is turned out, or as the result of turnout, often as the result of trauma such as kick wounds or fence-related injuries. Sudden changes in weather may excite horses, particularly those turned out at pasture. During thunderstorms horses may run into fences or buildings and suffer unexpected injuries. One such problem is suprascapular nerve injury. Minimizing problems with turnout requires the use of well-groomed and well-maintained pastures or paddocks with individual paddocks to reduce horse to horse interactions.

Dramatic housing changes have a substantial impact on the development of lameness. Shipping to and from sales, foaling, and weaning are associated with soft tissue injuries, puncture or kick wounds, and other injuries.

Current Medication Changes and Response

The veterinarian must establish if the horse currently is receiving medication or was administered medication recently and the response to treatment. Response to medication or a management change is important information in formulating a treatment plan. For example, recent improvement with rest and the administration of nonsteroidal anti-inflammatory drugs indicates more of the same treatment may be reasonable. The veterinarian must establish dosages of medication because a horse may not respond to phenylbutazone because of under-dosage.

Many owners and trainers do not understand that although intra-articular analgesia relieves lameness, intra-articular medication may not, thus causing doubt about the diagnosis. This characteristic commonly appears in horses with subchondral bone pain and is useful in diagnosis. Horses with early osteoarthritis and negative or equivocal radiographic signs, or those with short, incomplete fractures, often do not respond to intra-articular medication. Negative radiographic findings are a good sign because dramatic radiographic evidence of subchondral lucency or fracture reduces the prognosis considerably. However, convincing the trainer of the validity of the diagnosis may be difficult.

The amount and quality of rest are important. Many acquired conditions, such as osteoarthritis, or degenerative conditions, such as navicular syndrome, take many months and usually years to develop. Therefore expectation that a horse will show marked improvement with a brief rest period is unreasonable. Lameness in many horses with severe osteoarthritis may not improve substantially, even with prolonged rest. In horses with early osteoarthritis in which pain occurs primarily in subchondral bone and for which radiographic findings are negative or equivocal, rest or controlled exercise for 3 to 6 months may be necessary. The same regimen applies for horses with navicular syndrome, fractures, and many soft tissue injuries.

Quality of rest is equally important. Did the horse receive absolute box stall rest with handwalking, or was it lunged or turned out in a paddock or field with other horses? Was a brief rest period followed by an attempt to ride or train the horse? Those associated with the horse often consider this type of intermittent rest *complete* rest, but many conditions remain chronically active. Without adequate rest, re-injury follows temporary improvement and early healing.

Past Lameness History

Obtaining the horse's entire lameness history may not be necessary or possible, but the veterinarian should gather as much information as is practically available. Prognosis for many injuries is affected adversely by recurrence, and often management options differ in these situations. Recurrence may prompt more aggressive therapy, considerations for referral, or perhaps surgical evaluation if the problem involves a joint. If a reliable diagnosis was made previously, retreatment for the past problem may be a reasonable or preferred management approach, particularly between races or competitions. If a horse has responded previously to intra-articular medication, re-injection may be reasonable. However, in many horses with progressive osteoarthritis, results of additional therapy often are diminished. The veterinarian should not assume that the failed response to intra-articular medication means the problem lies elsewhere because medication does not affect subchondral bone pain in early or late osteoarthritis.

Recent history is important. Small, innocuous-looking wounds over the third metacarpal bone or third metatarsal bone, radius, tibia may be associated with bone trauma with delayed-onset severe lameness. Incomplete or spiral fractures may develop from small cortical defects (Fig. 3-3).

Fig. 3-3 Dorsopalmar radiographs of left third metacarpal bone in an 18-year-old Thoroughbred gelding showing initial (**A**) and 2-week follow-up (**B**) views. The initial view was taken after the horse was found to have a small skin wound in the region but was sound. Acute, severe lameness developed 9 days after initial injury, and the follow-up radiograph shows a long oblique fracture of the third metacarpal bone.

Fig. 3-4 Craniocaudal radiograph of the left antebrachium of a 5-year-old Thoroughbred mare showing a displaced, long oblique fracture of the radius. This filly had sustained a small puncture wound to the lateral aspect of the antebrachium 5 days earlier but was sound. The mare was turned out and developed acute, severe lameness and was later euthanized.

Catastrophic failure of long bones occurs even when initial radiographs show no or minimal cortical trauma. The radius appears to be at greatest risk (Fig. 3-4).

New problems may and often do arise despite a long history of recurrent lameness. Comprehensive reevaluation is the best and safest approach to avoid delays in proper diagnosis and treatment.

FURTHER INFORMATION

Full understanding of the horse's use, type and level of sporting activity, and value, all of which help the veterinarian assess prognosis, requires specific information. If the horse previously was under the veterinary care of another individual in the same or different practice, it is important to obtain accurate case records and view previous radiographs and other images.

CHAPTER • 4

Conformation and Lameness

Mike W. Ross

The idea of a good horse with poor legs is a misnomer, the legs are the essence of the horse, and every other part of the equine machine is of only subservient and tributary importance.
A. Liautard[1]

That the way a horse is conformed determines the way it moves is well accepted. The relationship of conformation, especially of the distal extremities, and lameness also is well recognized. "Conformation determines the shape, wear, flight of the foot, and distribution of weight."[2] Veterinarians often are asked to comment on conformation during lameness and prepurchase examinations, especially with regard to the suitability of the horse to perform the intended task. In some instances, as in the case of presale yearling evaluations, the veterinarian's opinion is paramount, and purchase is contingent on judgment of the yearling's potential to perform as a racehorse, given its conformation, or in some instances its conformational faults (see Chapter 102). "It is by a study of conformation that we assign to a horse the particular place and purpose to which he is best adapted as a living machine and estimate his capacity for work, and the highest success in this connection will be best attained by the judicious blending of practice with science."[3] Evaluation of conformation and its influence on lameness is based largely on observation, experience, and pattern recognition. Recognizing desirable conformational traits in horses suited for a particular sporting activity and learning when to overlook a minor fault that has little clinical relevance is important.

RELEVANCE OF CONFORMATION EVALUATION

Conformation is one piece of the complex puzzle of a lame horse, although poor conformation does not necessarily condemn a horse to lameness: "faulty conformation is not an unsoundness…it is a warning sign."[2] All lameness diagnosticians should evaluate conformation briefly at the beginning of each examination. The association of lameness and faulty conformation will be obvious. The clinician must evaluate the horse from afar, assessing the whole horse for balance, angles and lengths, and posture and symmetry. The clinician must remember that horses come in all shapes, sizes, and types, and therefore conformation varies accordingly, but certain conformational faults produce predictable lameness conditions and are undesirable. However, good conformation is not synonymous with success, and although horses of certain body types tend to have longer strides and are more athletic than others, intelligence, aggression, "will to win," and other intangible factors are important. I am convinced that a well-bred horse from a successful family can endure faulty conformation much better than a poor- or mediocre-bred horse.

HEREDITARY ASPECTS OF CONFORMATION

Certain conformational faults appear to be highly heritable traits. Evaluation of broodmares and foals often reveals that the early conformational defects seen in a foal are present in the dam. The dam seems to contribute more to faulty conformation than does the sire, although the stallion also is important. This difference may be explained in part by the fact that fillies with faulty conformation may develop problems or be retired early and subsequently bred, whereas most stallions usually are proven performers with exceptional conformation. Conformational faults such as toeing in and toeing out commonly are passed down from generation to generation. Back-at-the-knee (calf-knee), offset (bench) knee, tied-in below the knee, sickle-hock, and straight behind conditions are also highly heritable.

Certain lameness conditions are common in horses with faulty conformation, but similar lameness conditions develop inexplicably in some breeding lines year after year in offspring with apparently acceptable conformation. Lameness of the carpus or tarsus appears to be most important. For example, in Standardbreds (STBs), siblings commonly develop similar lameness conditions, such as proximal suspensory avulsion injury, carpal osteochondral fragments, distal hock joint pain, or curb.

OBJECTIVE EVALUATION OF CONFORMATION: IS IT POSSIBLE?

A recent attempt to quantify conformation used a linear assessment trait evaluation system that allows the observer to assess where, given a particular trait, a single animal falls within a population of animals.[4] A population of 101 Irish Thoroughbred (TB) flat racehorses and 19 top stallions was used and 27 common conformational traits were evaluated, including various heights, lengths, angles, and distal extremity conformation (Figs. 4-1 to 4-3). Of the 27 traits, 6 were significantly linked to age, and 5 were linked to sex (head and neck shape; neck size at poll and larynx and at withers, and manubrium of the sternum; and forelimb hoof pastern axis). Most traits exhibited large phenotypic variation within the population, but 21 of 27 non–age-linked traits were judged suitable for possible inclusion in a linear assessment protocol.[4] Researchers judged a high percentage of horses to be toed out, suggesting this trait may even be desirable.

More recent studies have used video-image analysis, but direct physical measurements may be more accurate than those obtained by analyzing videotapes or photographs.[5] Potential errors in image analysis occur because of movement of skin markers over selected bony protuberances, a phenomenon more common in the upper limb and in motion studies.[5,6] Skin marker location is critical for evaluation of joint angulation and movement during locomotion or conformation analysis. Instant center or axis of rotation (ICR) is defined as the point with zero velocity during movement of that joint; accurate measurements of joint angulation require positioning markers at the ICR.[7] Conventional positions of skin markers and ICR in most joints agree well, but use of traditional marker sites on the scapulohumeral and femorotibial

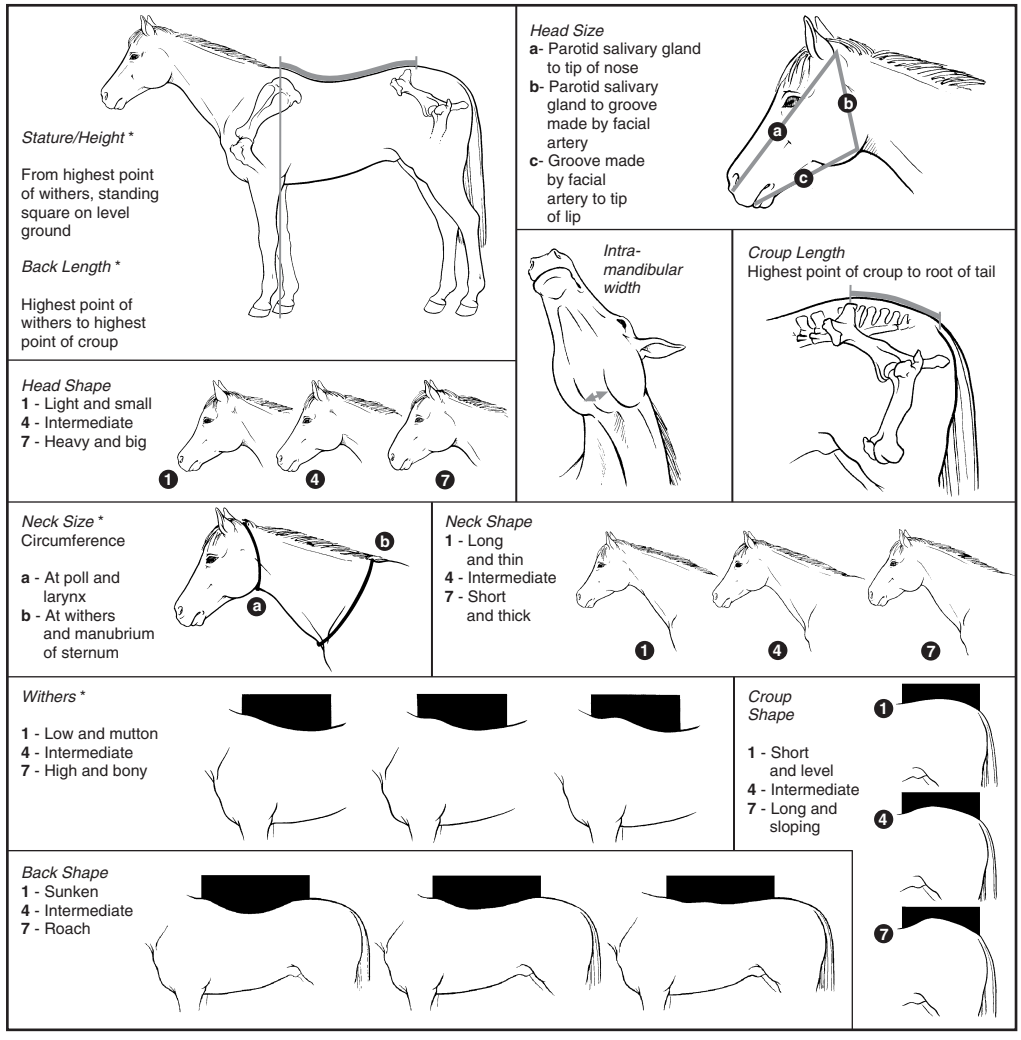

Fig. 4-1 Conformation traits used for linear assessment of conformation in a population of Irish Thoroughbreds. Asterisks indicate traits significantly linked to age. (Modified from Mawdsley A, Kelly AP, Smith FH, et al: Linear assessment of the Thoroughbred horse: an approach to conformation evaluation, *Equine Vet J* 28:461, 1996.)

joints results in overestimation and underestimation, respectively, of caudal joint angles.[8] Although video-image analysis may be fraught with potential or in some instances real error, objectivity is a major advantage. Other advantages include the ability to replay images, reduction of observer fatigue, elimination of observations and measurements in real time, and permanent recording of the observation. Ideally, objective measurements would withstand statistical evaluation, distinguish between desirable and undesirable traits, and account for differences among different types of horses.[5]

A combination of direct measurement and photography has been used to to evaluate conformation of Swedish Warmblood and elite sport horses.[9,10] Whereas most of the conformational defects were mild or moderate, 80% of Warmblood (WBL) horses were toed out behind, suggesting this may be a normal finding in this breed as in the STB trotter. More than 50% of horses had bench knees and 5% were toed out in front, contrary to findings in STB trotters.[9,11] Many of the elite horses were bucked kneed, whereas the riding school horses tended to have calf knees. It was speculated that this occurred because elite horses were evaluated after competition and muscle fatigue may have contributed to the tendency to be over at the knee. Sex had significant influence on conformation; females were smaller and had longer bodies and smaller forearms and metacarpi. There were interesting findings regarding hock angle. A sickle hock is defined as a hock angle of 53° or less; a large hock angle is referred to as straight behind. Sickle-hocked conformation was nearly absent in elite horses, and it was hypothesized that sickle-hocked conformation either predisposed a horse to lameness or impaired a horse's ability to achieve upper levels of competition.[9] A positive relationship between larger hock angles and soundness in STB trotters also exists.[12] In forelimbs of WBL show jumpers and the forelimbs and hindlimbs of STB trotters, smaller fetlock joint angles (less upright) were desirable.[9,12]

Radiography was used to assess the degree of hyperextension of the carpus to study the potential effect of back-at-the-knee (calf-knee) conformation on the subsequent development of carpal chip fractures.[13] Lateromedial radiographic views of 21 horses with carpal chip fractures and of 10 normal horses were obtained, with and without the contralateral limb raised. No relationship between measured carpal angle and carpal chip fracture formation existed, suggesting that this group of TB racehorses did not develop carpal chip fractures as a result of calf-knee conformation. The sample size was small, however, and a larger study may produce different results. Horses with severe calf-kneed conformation may develop other problems and not advance enough in training to develop carpal chip fractures. They may be judged poor surgical candidates, are not referred, or are slow.

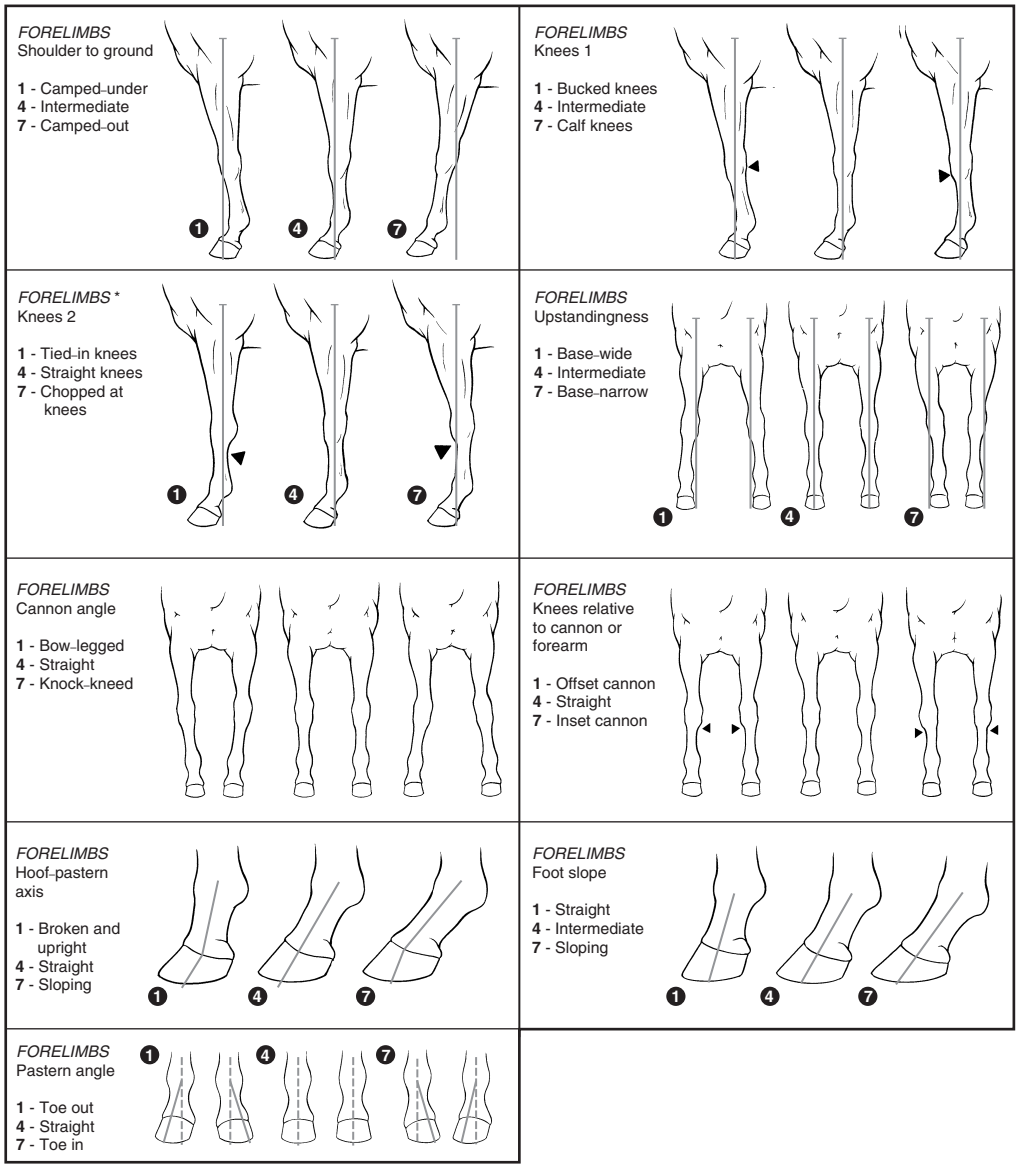

Fig. 4-2 Conformation traits used for linear assessment of conformation in a population of Irish Thoroughbreds. Asterisk indicates traits significantly linked to age. (From Mawdsley A, Kelly AP, Smith FH, et al: Linear assessment of the Thoroughbred horse: an approach to conformation evaluation, *Equine Vet J* 28:461, 1996.)

Two recent studies evaluated TBs and Quarter Horses (QHs) using skin markers, photography (three views: front, side, back), and computer-image analysis. The TB study evaluated the change in conformation with age; as expected, most body parts increased in length from birth to 2 years. Horses became more bench kneed from birth to 3 years, and the dorsal hoof angle decreased as horses grew (hoof wall became less upright). A strong relationship existed between long bone length and withers height, including the radius (taller horses have longer bones).[14] In the TBs, clinical observations (lameness) associated with conformational variables included effusion of the fetlock and carpal joints, carpal fractures, and other traumatic conditions of the fetlock joint. Risk of effusion of the fetlock joint increased with increased dorsal hoof angle, and the odds of carpal fracture decreased with scapular length. Carpus valgus decreased risk for carpal fracture, but fetlock lameness increased in horses with offset knees.[14]

In the second study, odds ratios were created for increase in bone length of 2.54 cm (1 inch) or joint angle of 1° and development of lameness. For every 1-inch increase in humeral length, odds for fracture of the proximal phalanx or carpal synovitis or capsulitis increased. Increased length from elbow to ground and increased toe length increased chances for carpal fracture, and in horses with offset knees greater than 10% the potential for carpal or fetlock synovitis or capsulitis increased. The potential for fracture of the proximal phalanx increased with an increase in shoulder angle.[14]

The relationship of many lower limb lameness conditions with limb length is interesting and somewhat unexpected because longer limb length generally is considered desirable. Although a relationship between longer toes and carpal fracture is not unexpected, the increased chance for fetlock lameness with more upright hooves is surprising. The relationship between offset knees and lower limb lameness was expected, but unexpected were fewer carpal fractures in TBs with this conformational fault. Because development of lameness, termed clinical outcomes in these studies, is complex, confounding variables such as track conditions, training regimen, breeding, individual horse ability, and experimental error could have contributed to outcome.

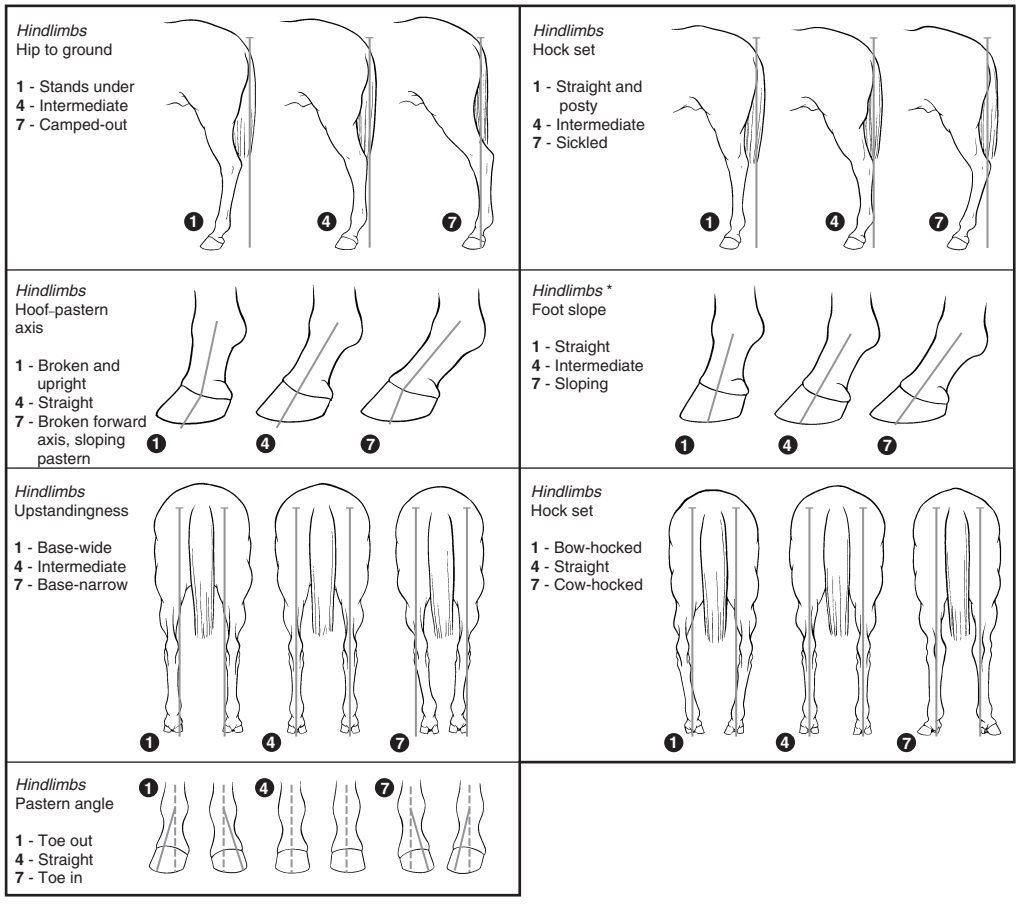

Fig. 4-3 Conformation traits used for linear assessment of conformation in a population of Irish Thoroughbreds. Asterisk indicates traits significantly linked to age. (From Mawdsley A, Kelly AP, Smith FH, et al: Linear assessment of the Thoroughbred horse: an approach to conformation evaluation, *Equine Vet J* 28:461, 1996.)

Little doubt exists that acquiring objective information is useful, not only to determine what is abnormal but also to define what is normal in a population. In both WBLs and STB trotters in Europe, toed-out conformation in the hindlimbs should likely be considered normal because a majority of both breeds have this conformational trait.[9,11] These populations differed, however, in forelimb conformation. Few STB trotters had bench-kneed conformation, a finding supported by my clinical observations that this conformational fault is highly undesirable in this breed (see Chapter 109).

EVALUATION OF CONFORMATION

Conformation determines the way a horse moves, and I am convinced that a relationship exists between faulty conformation and the development of lameness. Therefore assessment of conformation should be an integral part of lameness examination. Conformation evaluation has four basic components: (1) balance, (2) assessment of lengths, angles and heights, (3) muscling, and (4) conformation of the limbs. All are intertwined but should be evaluated separately, considering the whole horse not just the limbs, and then consolidated. The clinician should evaluate the horse on firm, level ground, preferably a smooth, nonslip surface that does not obscure the view of the feet. The horse should stand squarely with equal weight on all four limbs. Dynamic assessment of limb conformation while the horse is walking also is essential.

Balance

Balance is the way all parts of the horse fit together and is linked directly with assessment of lengths, angles, and heights. The horse should be proportional and thus well balanced. A horse may be visualized in thirds—the forehand, the midbody, and the hindquarters—by drawing three circles incorporating these areas (Fig. 4-4). The circles should overlap but not excessively. Horses in good balance are likely to be superior athletes. Horses with a short, thick (throatlatch and shoulder regions) neck are often heavy and straight in the shoulders (Fig. 4-5). A horse with a short back has naturally closer dorsal spinous processes and may be predisposed to impingement or over-riding, whereas a horse with a long back (Fig. 4-6) may have difficulty engaging the hindlimbs properly. The clinician must assess the relative heights of the withers and hindquarters. A horse that is taller behind than in front (rump height is greater than height at the withers) is predisposed to forelimb lameness. A horse that also is underdeveloped in the shoulders and upper forelimbs (weak up front) and heavy behind is more at risk. Limb lengths should be proportional to body size and height. In general, the body length (point of shoulder to point of rump) should be equal or slightly longer than withers height (see Fig. 4-4).

Head conformation is not relevant to lameness, but the size of the head relative to the body and the angulation between the head and neck influence the ease with which the horse can work "on the bit" (see Chapters 100 and 117). A horse's ability to see is important. A horse with ocular abnormalities may exhibit bizarre behavioral abnormalities or unusual head and neck

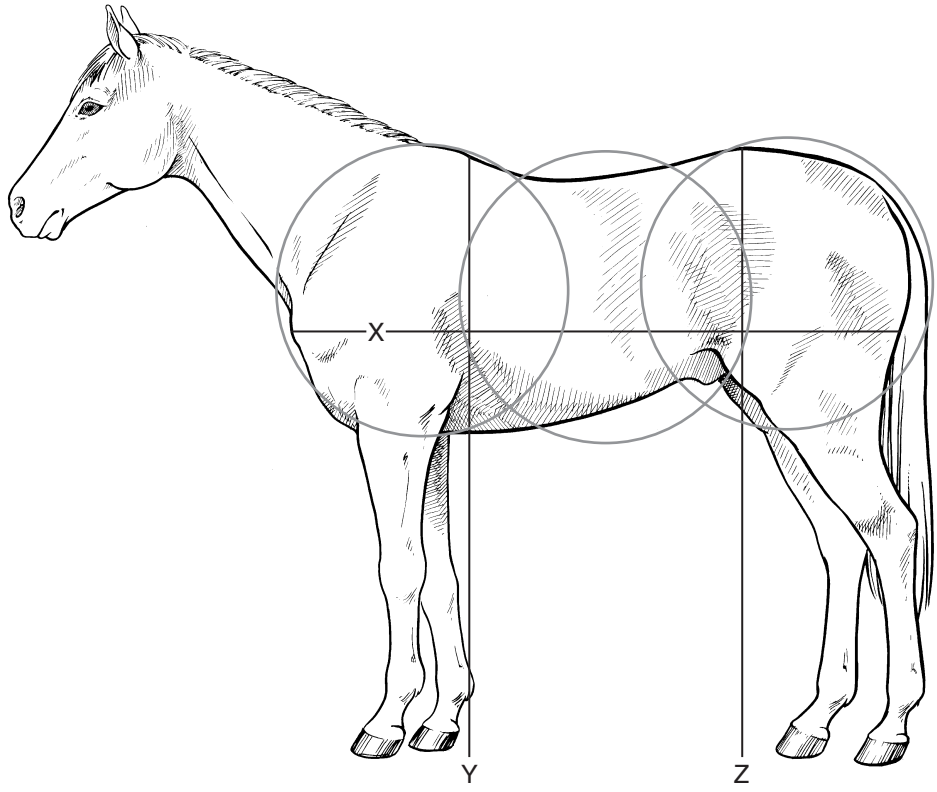

Fig. 4-4 Diagrammatic depiction of assessing balance during conformation evaluation. Three circles (from left to right: forehand, midbody, hind quarters) are visualized and should overlap by approximately one third. Excessive overlapping of circles (short coupled) or barely overlapping of circles (long, weak in back) are common conformational abnormalities. Body length (*X*) should be equal to or slightly longer than withers height (*Y*), and withers height and rump height (*Z*) should be the same.

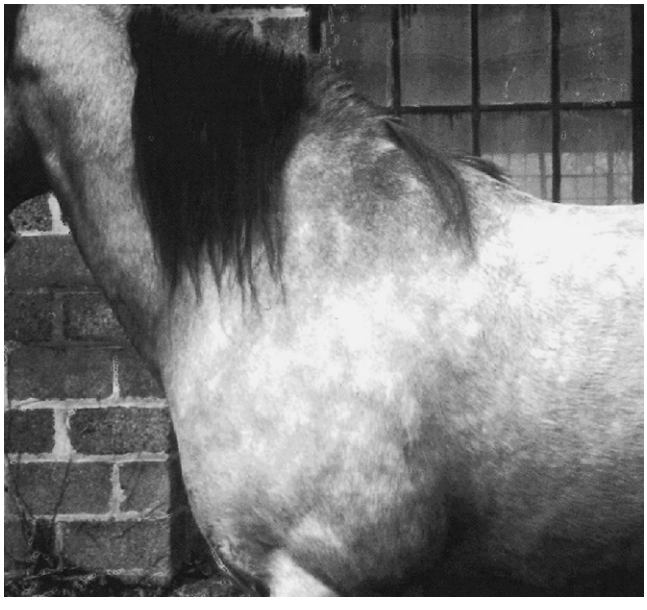

Fig. 4-5 Horse with short, heavy neck; heavy, short, and straight shoulder; and withers set forward. This horse is prone to forelimb lameness and likely to have a short stride.

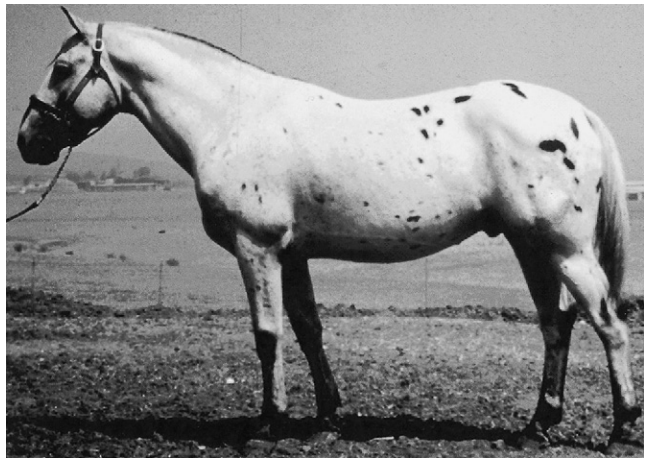

Fig. 4-6 Unbalanced Appaloosa gelding that is long and weak in the barrel (back). The rump height is slightly higher than withers height.

carriages, possibly misinterpreted as the result of pain. A rare cause of "being on a line" occurs in driving horses, such as a STB with unilateral blindness. The horse turns the head away from the blind side to see and thus is on the contralateral line (to straighten the head, the driver must pull on the contralateral line). This mimics a contralateral (to the blind eye) lameness.

Assessment of Lengths, Angles, and Heights

Body length is important in determining stride length (see Fig. 4-4). Short coupled conformation predisposes horses to short strides and problems with interference, especially in racehorses. If horses are too long, they can be weak in the back. The length of the neck is important in assessing balance and should be proportional to the overall body length. Some horses have long, weak necks. The neck may be "set on low" relative to the shoulder with a depression (ventral deviation) of the dorsal topline cranial to the withers (ewe necked), giving the appearance of prominent withers laid too far caudally. Horses should have adequate depth in the girth region (depth of girth).

Shoulder length (top of withers to the point of the shoulder) may be related directly to stride length, and horses with longer shoulders usually have longer strides (Fig. 4-7). Those with short shoulders usually have shorter strides (see Fig. 4-6). Shoulder length and shoulder angle often are related; long shoulders often are more sloping (smaller shoulder angle) and short shoulders often are straight. Good shoulder length appears to be important and desirable, but recent objective data from TB racehorses suggest that horses with long limbs may be at increased risk of lower limb lameness.[14]

In TBs particularly a long radius (forearm) and short, strong third metacarpal bone (McIII) are desirable for adequate strength and maximum stride length. Chest width should be commensurate with overall body size. A wide chest with a base-narrow (front feet close when evaluating the horse from the front) limb stance or a narrow chest with a base-wide stance are undesirable. In STB pacers a good chest width is desirable, but in trotters a narrow chest is preferred (see Chapter 109).

Rump length also is important in determining stride length, and a longer length of the rump is desirable. Many horses with long rumps have larger rump angles (flat croup) and those with short rumps have smaller rump angle (steep croup). Long, flat croup regions are desirable. The ideal horse should have a long gaskin (crus) and a short, strong metatarsal region (hocks close to the ground) to maximize stride length.

The angles of the shoulder and rump are important factors in determining stride length and balance. Undesirable shoulder and rump angles often accompany other conformational faults and may predispose to lameness. The ideal angle of the shoulder (relative to the ground) has classically been determined as 45° (see Fig. 4-7). Horses with steep shoulder angles (>50° to 55°) usually have short shoulders and short, upright pasterns, which predispose to lower limb lameness. The forelimb pastern angle should be equal to the shoulder angle. Steep shoulder angle shifts the center of gravity forward, predisposing to forelimb lameness. Horses with a flat rump or croup generally have longer rump lengths and longer strides (Fig. 4-8). Horses with short, steep rumps (goose rump), often have short, choppy gaits, and many have hindlimb lameness (Fig. 4-9). A steep rump angle shifts the center of gravity caudally, predisposing to hindlimb lameness.

Limbs

It is critical to evaluate limb conformation with the horse standing squarely on a firm, flat surface and with an experienced handler who can make the horse cooperate. If the clinician observes a fault that may result from how the horse is standing, he or she should reevaluate the horse after repositioning. Horses often stand camped out, both behind and in front, simply as the result of improper positioning.

The plumb line concept allows evaluation of each limb from the front or back and the side (Fig. 4-10). For example,

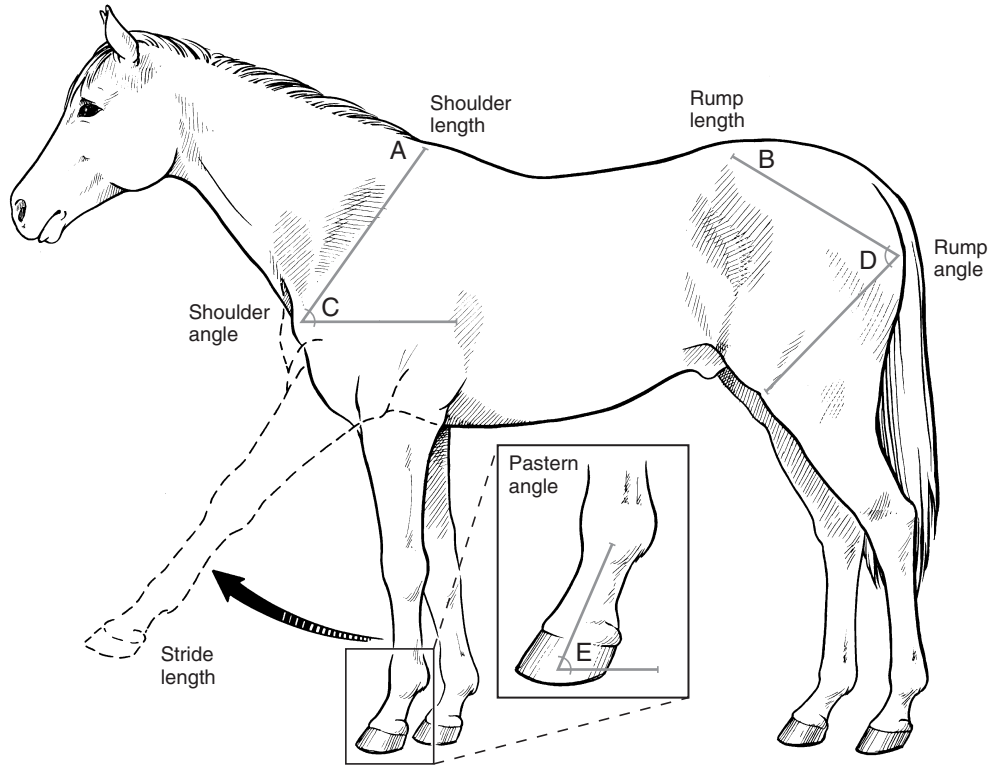

Fig. 4-7 Measurement of shoulder length (*A*), rump length (*B*), shoulder angle (C), and rump angle (*D*). The pastern angle (*E*) should be equal to the shoulder angle. Shoulder angle and length are important in determining stride length.

a vertical line from the point of the shoulder should bisect the limb. The clinician also should evaluate the horse while it is walking because some defects are dynamic. Horses that toe in or toe out, or those with fetlock or carpus varus deformities, may stand reasonably well, particularly with corrective trimming and shoeing, but the defect may be readily apparent while the horse is walking.

FORELIMB CONFORMATION

Front Perspective

Several forelimb conformational abnormalities are apparent when evaluating a horse from the front. *Base-wide* conformation may occur alone or in combination with toed-in or toed-out conditions (Fig. 4-11). Horses that are base wide stand with the forelimbs lateral to the plumb line and generally are narrow in the chest, resulting in overload of the medial aspect of the lower limb, predisposing to lameness. Horses that are *base wide, toed in* tend to wing out or paddle during protraction (Figs. 4-11, *B* and 4-12, *A*). Winging out predisposes trotters to interference with the ipsilateral hindlimb. *Base-wide, toed-out*

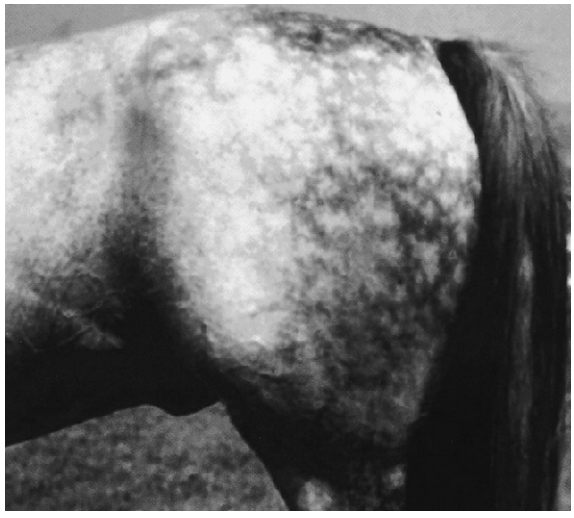

Fig. 4-8 Desirable hindlimb conformation. The flat rump angle and good rump length would likely increase stride length and allow good support and strength of the hindlimbs.

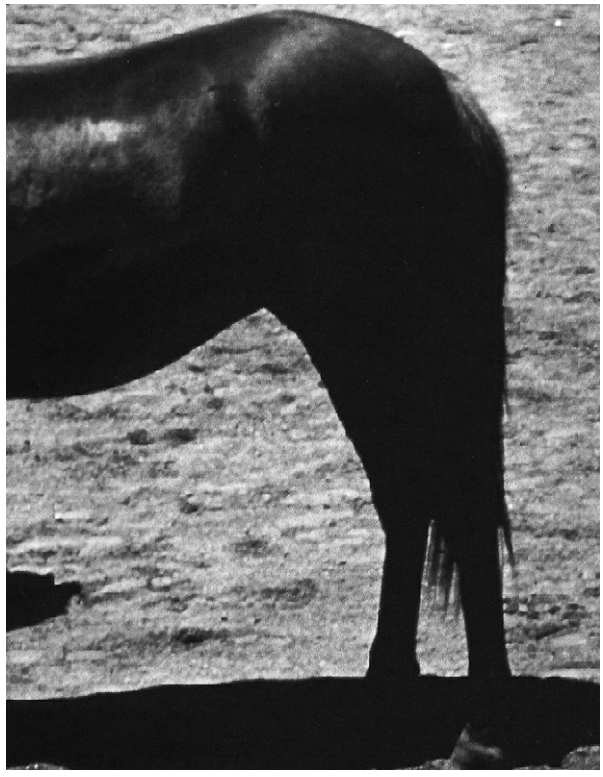

Fig. 4-9 Undesirable hindlimb conformation characterized by short, steep rump (goose rump), predisposing to hindlimb lameness.

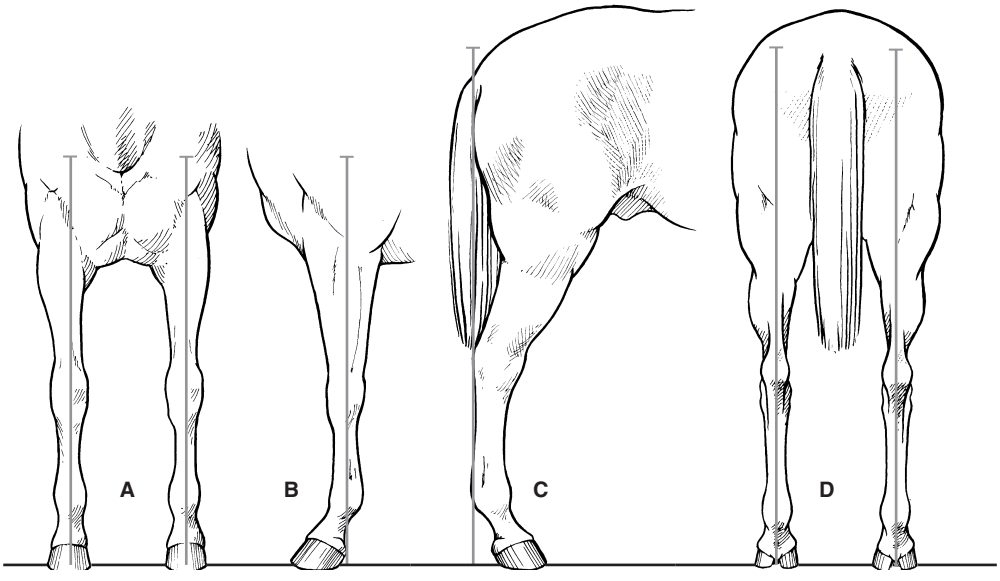

Fig. 4-10 Diagram demonstrating use of plumb lines to evaluate limb conformation from three perspectives. Vertical lines are visualized from the front (**A**) forelimb (line runs from point of the shoulder, bisecting the limb), side (**B**) forelimb (line bisects elbow joint, carpus, and fetlock joint and intersects the ground approximately 5 cm behind the solar surface of the heel), and side (**C**) hindlimb (line runs from point of rump to the ground, touching the point of the hock and plantar metatarsus and intersecting the ground approximately 7.5 to 10 cm behind the heel) and from the back (**D**) hindlimb (line drawn from point of rump, bisecting the hindlimb).

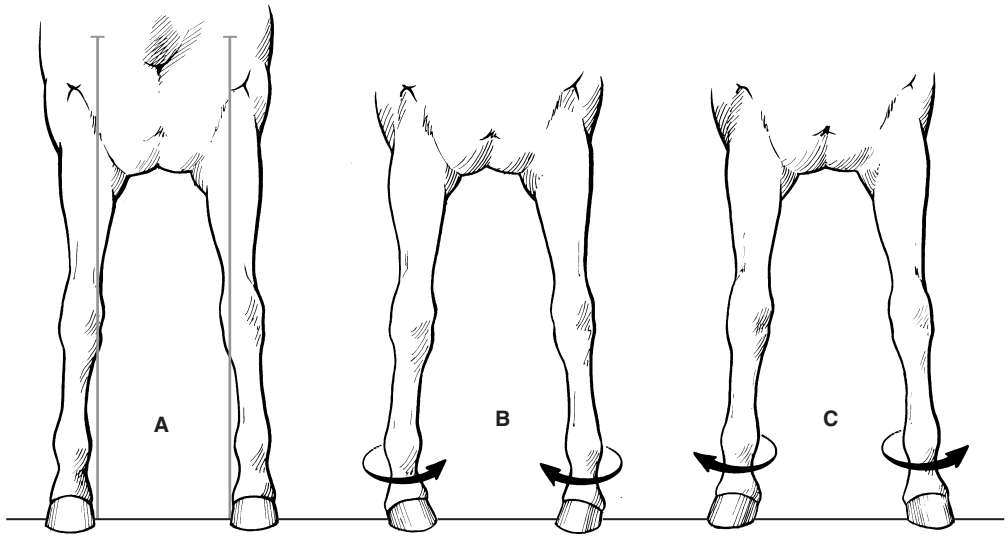

Fig. 4-11 Three variations of base-wide forelimb conformation, including (**A**) simple base wide, (**B**) base wide, toed in, and (**C**) base wide, toed out.

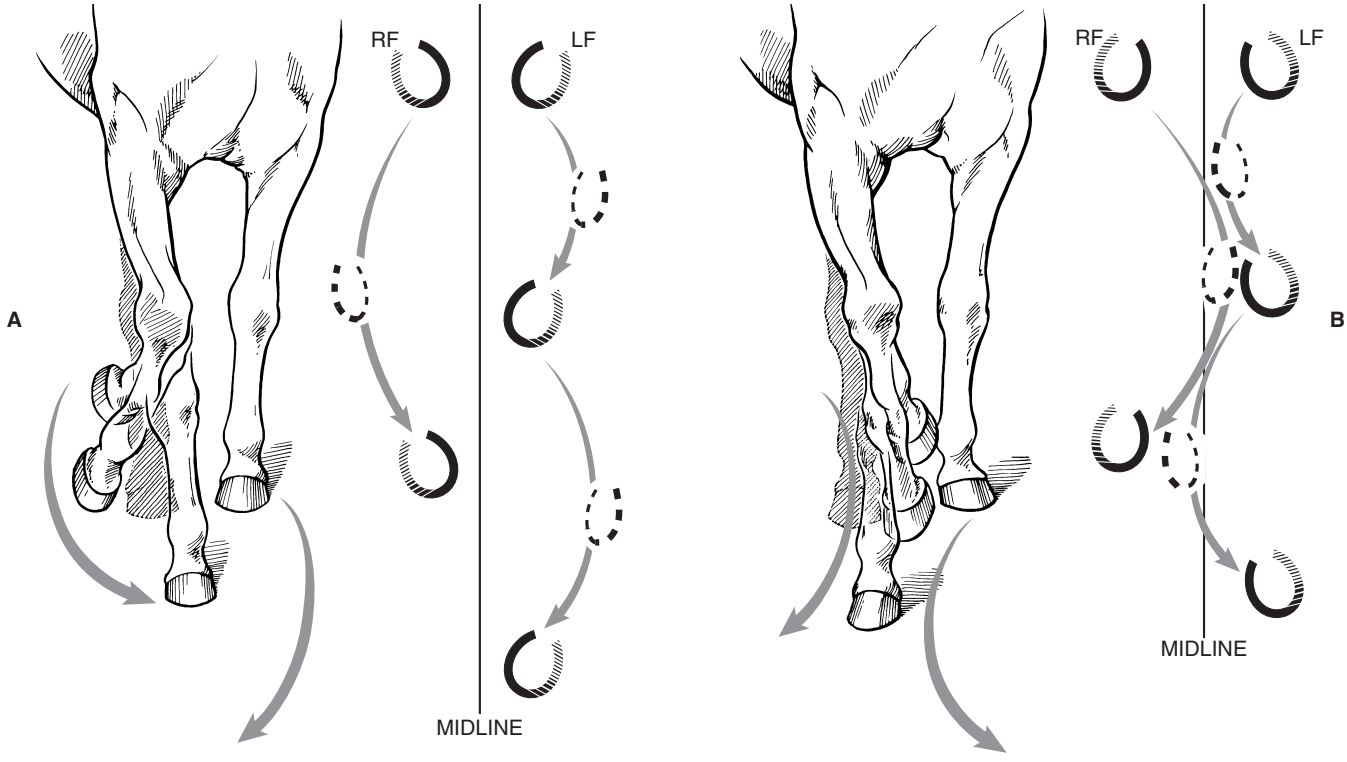

Fig. 4-12 **A,** Toed-in conformation often causes horses to wing out or paddle during advancement of the forelimb. **B,** Toed-out conformation causes horses to wing in, predisposing to interference with the contralateral forelimb.

conformation appears most often in horses with uncorrected carpus valgus deformities (Figs. 4-11, *C* and 4-12, *B*) and results in excessive loading on the medial aspect of the foot and misshapen feet. Interference with the contralateral forelimb may occur in severely affected horses.

Base-narrow conformation may occur alone or in combination with toed-in or toed-out conformation (Fig. 4-13). Horses that are base narrow stand with the forelimbs inside the plumb line and overload the outside of the lower limb and foot. Horses that are *base narrow, toed in* tend to wing out, and those that are *base narrow, toed out* tend to wing in during protraction (see Figs. 4-12 and 4-13).

With *in-at-the-knee*, knock-kneed, or carpus valgus conformation (Fig. 4-14) the carpi are medial to the plumb line, creating an angular deformity and concentrating the weight of the horse on the medial aspect of the carpus and proximal metacarpal region. This condition, if severe, may predispose the horse to carpal lameness and splints. In some horses, particularly foals, carpus valgus may be accompanied by external rotation of the entire limb or just the distal aspect (toed out). Severely affected horses wear the inside aspect of the hoof or shoe abnormally.

Out-at-the-knee (bow-legged, bandy-legged) conformation usually is a consequence of early carpus varus and often is career

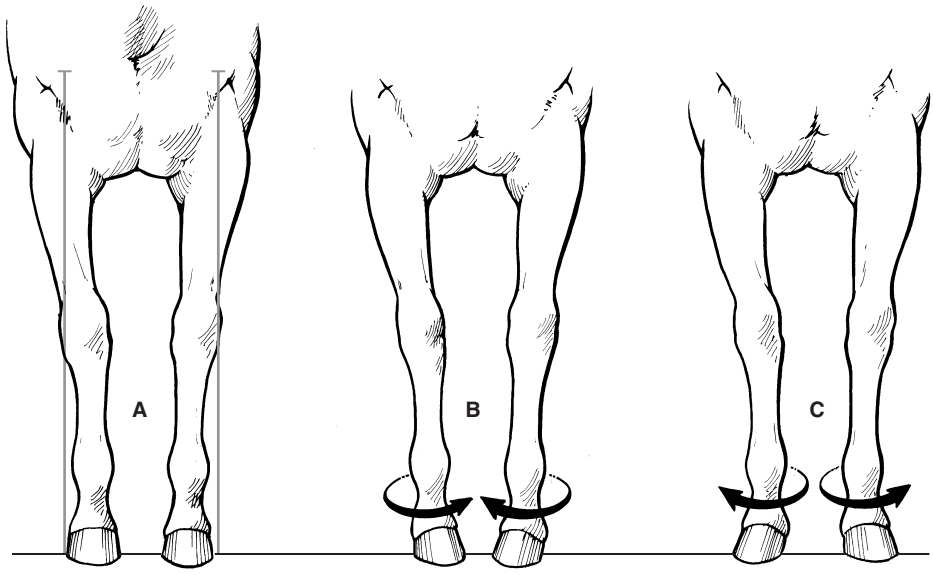

Fig. 4-13 Three variations of base-narrow forelimb conformation including (**A**) simple base narrow, (**B**) base narrow, toed in, and (**C**) base narrow, toed out.

Fig. 4-14 A horse with in-at-the-knee conformation that is worse in the right forelimb.

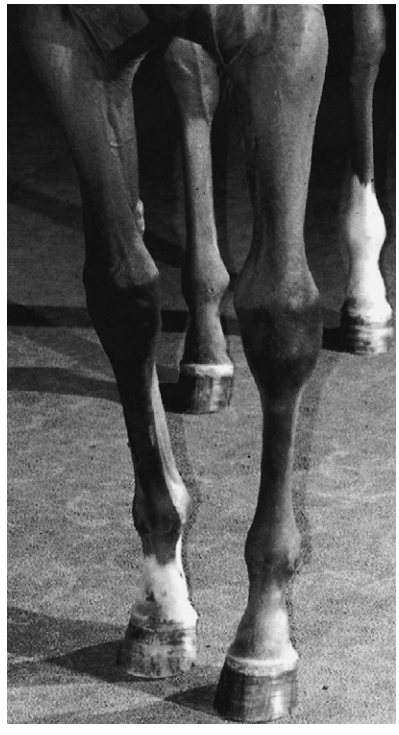

Fig. 4-15 Two-year-old Thoroughbred filly with moderate to severe carpus varus (out-at-the-knee) conformation in the left forelimb and mild deformity in the right forelimb. The filly also is toed in, a common finding in horses with this type of conformation. Another common finding is lateral deviation or bowing of the elbow, prompting clinical suspicion that a deformity also exists at this joint.

limiting, particularly if the fault is pronounced (Fig. 4-15). The carpus is bowed outward, lateral to the plumb line. Many horses are also toed in, accentuating abnormal forces on the lateral aspect of the entire distal forelimb, predisposing to osteoarthritis of the carpus or fetlock or lateral suspensory branch desmitis and sesamoiditis. In most foals with this deformity, lateral deviation of the elbow usually is present. Correction is difficult.

Offset or *bench-knee* conformation is classically defined as lateral positioning of the metacarpal region relative to the central axis of the radius (Fig. 4-16). However, radiographs demonstrate that the actual displacement usually is at the antebrachiocarpal joint. Displacement may be unilateral or bilateral with differing degrees of severity on each side. This conformation often is associated with carpal or metacarpal lameness (Fig. 4-17). Many 2-year-old STBs with offset knees are precocious during early training but often develop carpal lameness at 3 or 4 years of age. TBs with offset knees are believed to perform better on the soft turf tracks in Europe, as opposed to the firm turf or dirt tracks in the United States.

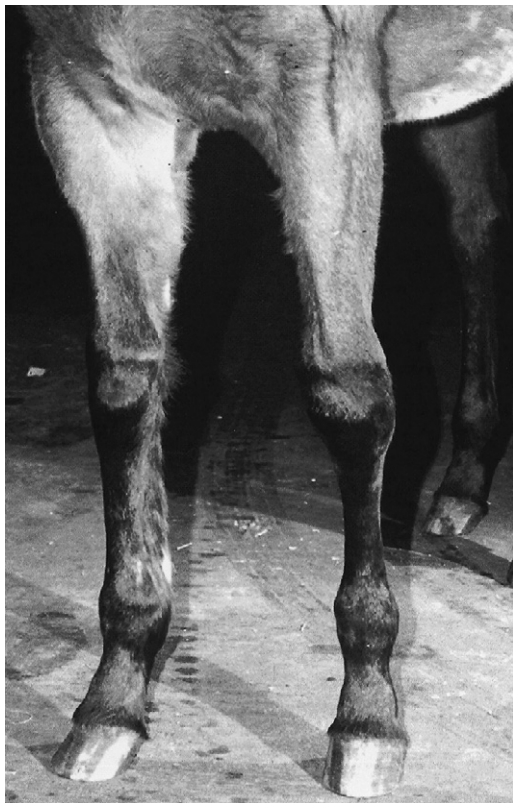

Fig. 4-16 Standard Thoroughbred with a prominently offset (bench) knee in the left forelimb. An apparent lateral deviation or shifting (offset) of the cannon bone and distal extremity occurs relative to the plumb line dropped through the left radius.

Fig. 4-17 Dorsopalmar xeroradiograph of 3-year-old STB colt with longitudinal fracture of the third metacarpal bone (*small arrow*). Medial is to the right. The lateral displacement ("step") at the antebrachiocarpal joint (*large arrow*) gives the clinical appearance of an offset (bench) knee.

Toed-in conformation, or internal rotation of the distal extremity, exists alone or in combination with abnormalities of stance (base-narrow or base-wide), other conformational faults such as carpus varus, and being wide in the chest (see Fig. 4-15). Horses that are toed in usually wing out (paddle) (see Fig. 4-12). Toed-in conformation is particularly undesirable in a trotter because of potential interference at speed. Toed-in conformation predisposes horses to lateral splints, lameness of the lateral aspect of the fetlock joint region (e.g., lateral branch suspensory desmitis), and osteoarthritis of the interphalangeal joints. Horses that are toed in wear the outside aspect of the foot.

Toed-out conformation, or external rotation of the distal extremity, is common and if mild may be considered normal or inconsequential (Fig. 4-18). Mild toed-out conformation appears in 50% of STBs and is common behind in STBs and WBLs.[9,11] It first develops in foals and, if pronounced, persists in the mature horse. In foals, toed-out conformation often accompanies carpus valgus deformities but may result from external rotation primarily from the fetlock down but, in more severe deformities, from further proximally (Fig. 4-19). Mild toed-out conformation usually resolves as a foal matures and with corrective trimming. Toed-out conformation results in abnormal wear on the inside aspect of the foot. Horses tend to wing in; if winging in is severe, particularly if accompanied by base-narrow conformation, it may interfere with the opposite forelimb (see Fig. 4-12). Exostoses (splints) on the second metacarpal bone (McII) or McIII may develop, requiring protective boots to be worn during exercise. In STBs, interference injury occurs as high as the distal radius.

Lateral Perspective

Horses camped out in front stand consistently with the entire forelimb ahead of the plumb line, but this conformation usually is a temporary problem with the horse's stance and can be corrected by repositioning the horse, or it reflects pain caused by laminitis, for example. C*amped under in front* is unusual and usually also results from temporary malpositioning of the horse (Fig. 4-20). If a horse prefers to stand camped under and is otherwise sound, however, this trait may be a sign of "extreme speed."

Back-at-the-knee or *calf-knee* (sheep-knee) conformation describes a concave dorsal aspect of the limb, with the carpus behind the plumb line (Figs. 4-21 to 4-23). On radiographs of a normal carpus the proximal and distal rows of carpal bones are aligned in a proximal to distal direction, and the dorsal faces of these bones are parallel to the radius and McIII (Fig. 4-22, *A*). With back-at-the-knee conformation the proximal row of carpal bones is set back (Fig. 4-22, *B*). Horses that stand back at the knee are considered predisposed to carpal injuries because of the natural tendency of the carpus to hyperextend (larger carpal angle) during fatigue. In my experience, TB racehorses are particularly at risk, despite limited contrary evidence (see page 16).[13]

In the STB, mild calf-knee conformation is common in pacers and acceptable, whereas in the trotter this defect is undesirable. In other breeds, mild calf-knee conformation may not directly lead to lameness. In young horses with lameness from unrelated sources such as osteochondrosis or fracture of the distal phalanx, back-at-the-knee conformation and clubfoot (small, upright foot) may accompany flexural deformity

Fig. 4-18 Trotter showing inconsequential mild toed-out conformation. Toe weights often are used in trotters to balance gait and correct interference.

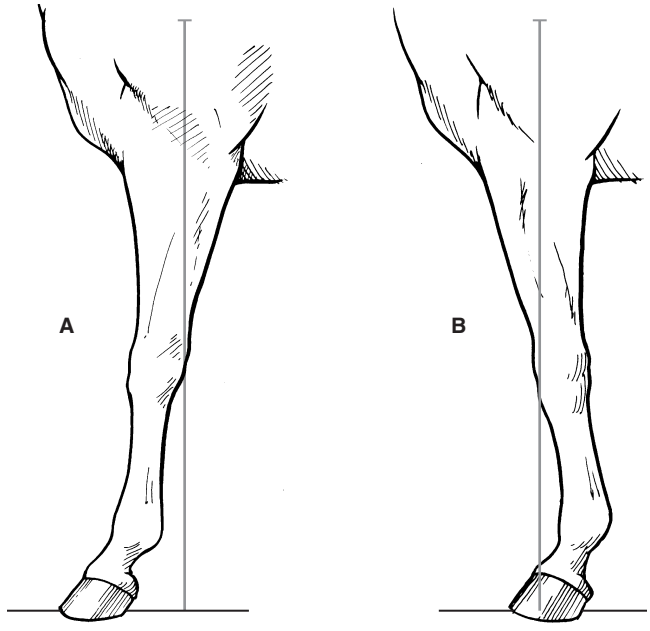

Fig. 4-20 Diagram showing (A) camped-out in front and (B) camped-under in front conformation, both in relation to plumb lines.

Fig. 4-19 Thoroughbred foal with pronounced external rotation or toed-out left forelimb limb conformation. The deformity involves the entire limb, beginning well above the carpus.

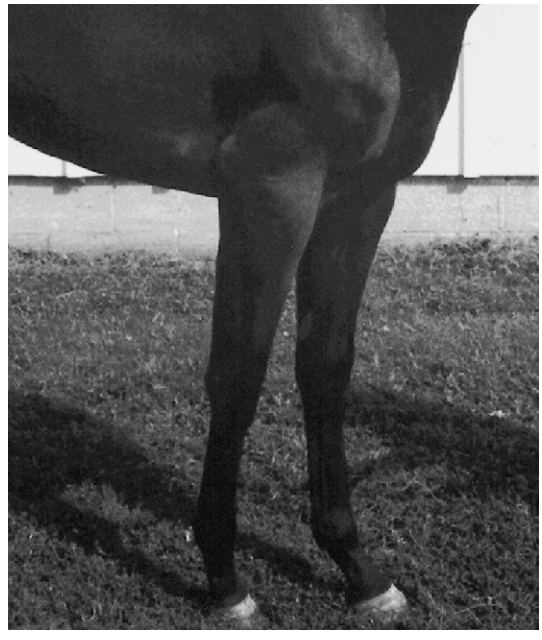

Fig. 4-21 Thoroughbred yearling with back-at-the-knee (calf-knee) conformation most noticeable in the left forelimb. This conformational fault is undesirable, particularly in racing breeds.

of the limb (see Fig. 4-23). This deformity is a combination of contraction (clubfoot) and laxity (calf knee) caused by chronic lameness and partial weight bearing and warrants a guarded prognosis.

Over-at-the-knee, bucked-knee (knee-sprung), or hanging-knee conformation describes a convex dorsal surface of the carpus, with the carpus in front of the plumb line (Fig. 4-24). In young, untrained horses, bucked-knee conformation may be a predictor of lameness, but in mature horses it appears to be an acquired characteristic and occurs primarily in horses that jump. Older cross-country horses, steeplechasers, jumpers, or field hunters are prone to buck knee and often stand over at the knee with no obvious lameness. These horses may exhibit a tendency to buck forward to such an extent that they appear on the verge of collapse or prone to stumbling yet show good stability. *Tied in below the knee* (Fig. 4-25) describes a distinct notch just distal to the accessory carpal bone on the palmar aspect of the limb. Normally, McIII and the flexor tendons are in parallel alignment from the accessory carpal bone to the proximal sesamoid bones. With tied-in conformation the flexor tendons appear to enter the carpus in a dorsoproximal direction. If the horse also is bucked kneed, the tied-in appearance

Fig. 4-22 Lateromedial radiographs of two different horses with carpal lameness. **A,** In a horse with nondisplaced slab fracture of the third carpal bone, normal carpal conformation is present: the proximal and distal rows of carpal bones are aligned and parallel to the radius and third metacarpal bone. **B,** In a horse with distal, lateral radius chip fracture, there is palmar deviation of the proximal row of carpal bones. This radiographic appearance is typical of back-at-the-knee conformation.

is accentuated. Young horses are prone to superficial flexor tendonitis. In STBs this defect is worse for a pacer than a trotter.

The junction of the carpus and McIII should be flat. C*ut out under knee* describes a notch under the dorsal surface of the carpus (see Fig. 4-25). In horses with this defect, McIII appears thin (dorsopalmar direction) and weak. Horses with this conformational abnormality also are often back at the knee, predisposing them to carpal and metacarpal problems. Some young racehorses, typically late yearlings or early 2-year-olds in training, appear to have distention of the middle carpal joint capsule or an unusually prominent distal radial epiphysis. These findings give the impression of an unusually large gap between these structures, described as open at the knee. I have not seen a correlation between this clinical observation and obvious radiographic changes, although in young horses with this conformation the distal radial physis remains visible. Whether this conformation is relevant to lameness in young racehorses is debatable.

O*ver-at-the-fetlock* usually is seen in young horses with flexor deformity of this joint (see Chapter 61). This conformational fault may persist in a mature horse, causing upright pasterns or knuckling of the fetlock joint. In some horses this condition causes a progressive, permanent deformity and severe lameness, whereas in others a dynamic, intermittent knuckling occurs and some of these horses remain surprisingly sound. Knuckling also may be a sequel to desmitis of the accessory ligament of the deep digital flexor tendon.

HINDLIMB CONFORMATION

Lateral Perspective

Hindlimb conformational faults generally are less numerous and problematic than those in the forelimb because of differences in weight distribution and center of gravity. Plumb lines also are useful in evaluating conformation of the hindlimb with the horse standing squarely, loading all limbs (see Fig. 4-10). Camped-out conformation is unusual and generally results from faulty positioning of the horse during the examination. Horses that are truly camped out usually have short strides and poor athletic ability. Camped under behind often is associated with sickle-hocked conformation but also appears in horses that are straight behind (Fig. 4-26). Horses with this type of conformation often have short, choppy strides (Fig. 4-27).

A particularly severe conformational fault that leads directly to lameness is *straight behind*, otherwise called *straight hocks* or *post* (posty) leg. Horses that are straight behind have larger stifle and hock angles but smaller fetlock joint angles compared

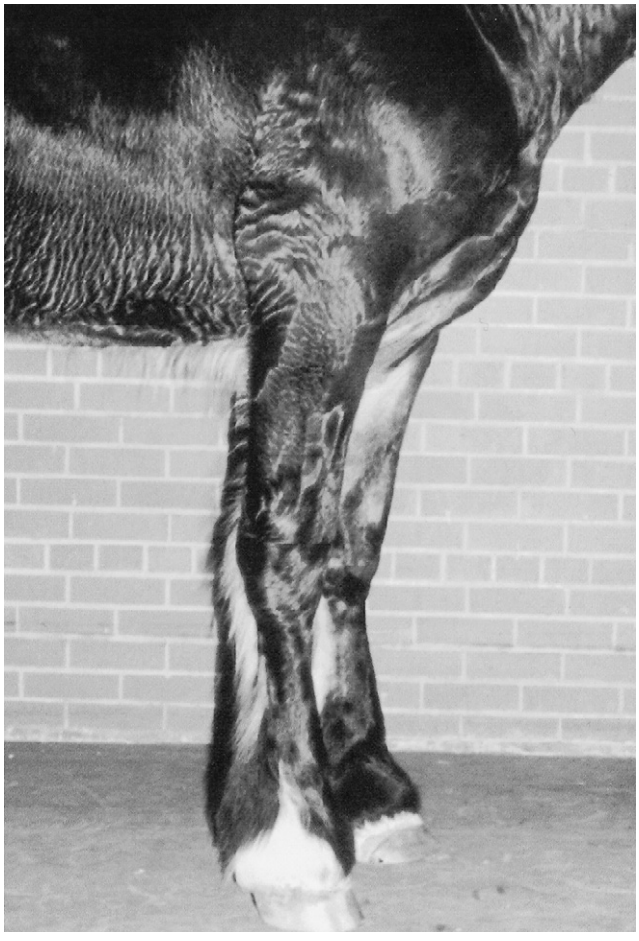

Fig. 4-23 Clydesdale yearling with calf-knee conformation and clubfoot secondary to osteochondrosis of the shoulder joint. This conformation is primarily the result of chronic lameness, decreased weight bearing, and the development of a flexural deformity.

Fig. 4-24 Older horse without obvious lameness with over-at-the-knee (bucked-knee) conformation.

with ideal hindlimb conformation (see Fig. 4-26; Fig. 4-28). Straight behind, sickle-hocked, and in-at-the-hock conformation are the three most important hindlimb conformational faults and all may lead directly to lameness. Horses that are straight behind often develop upward fixation of the patella, a condition seen most often in WBLs. Suspensory desmitis and fetlock osteoarthritis also occur frequently. Horses with normal initial hindlimb conformation may become straight behind if they develop severe suspensory desmitis and lose support of the fetlock joint.

Sickle-hocked conformation is one of the most common conformational faults, and it leads directly to lameness of the tarsus and plantar soft tissues. Horses that are sickle-hocked stand with the lower hindlimb well ahead of the plumb line, with an exaggerated concave dorsal surface of the hindlimb (resembling a sickle), creating a smaller than normal hock angle (see Fig. 4-26; Fig. 4-29). This type of conformation is often called *curby* conformation because horses frequently develop curbs (see Chapter 79). Sickle-hocked conformation concentrates load in the distal, plantar aspect of the hock, predisposing to curb and to distal hock joint pain. In foals with incomplete or delayed ossification of the tarsal bones, marked sickle-hocked conformation may occur (see Chapter 45). Sickle-hocked conformation is undesirable, particularly in racing breeds, but if mild is not detrimental. In STB pacers, some prefer a mild degree of sickle-hocked conformation because horses can extend the hindlimbs farther forward without risk of interference. In STB trotters the condition

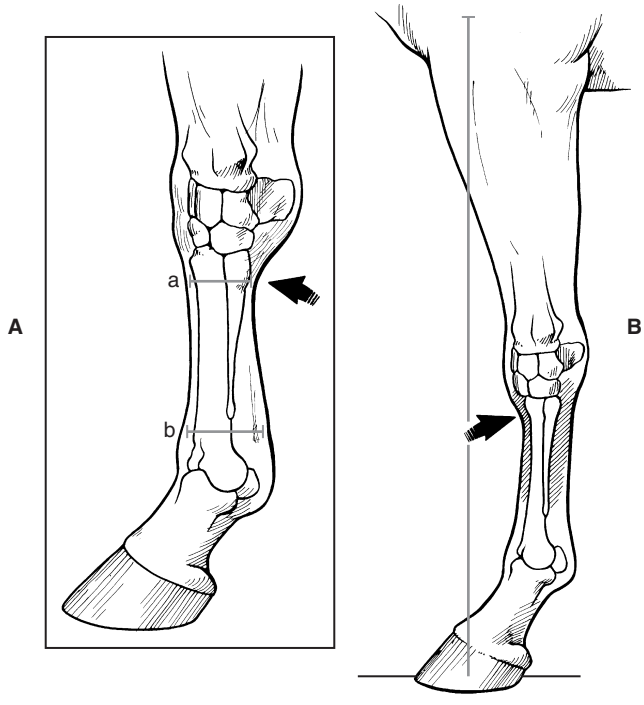

Fig. 4-25 **A,** Diagrammatic representation of tied in below the knee. The dorsal-palmar length of *a* is less than *b*, giving the appearance that the flexor tendons run obliquely, proximally to enter the distal carpal region more dorsal than expected. **B,** A horse that is cut out under the knee has a concave appearance of the dorsal aspect of the distal carpus and proximal metacarpal region.

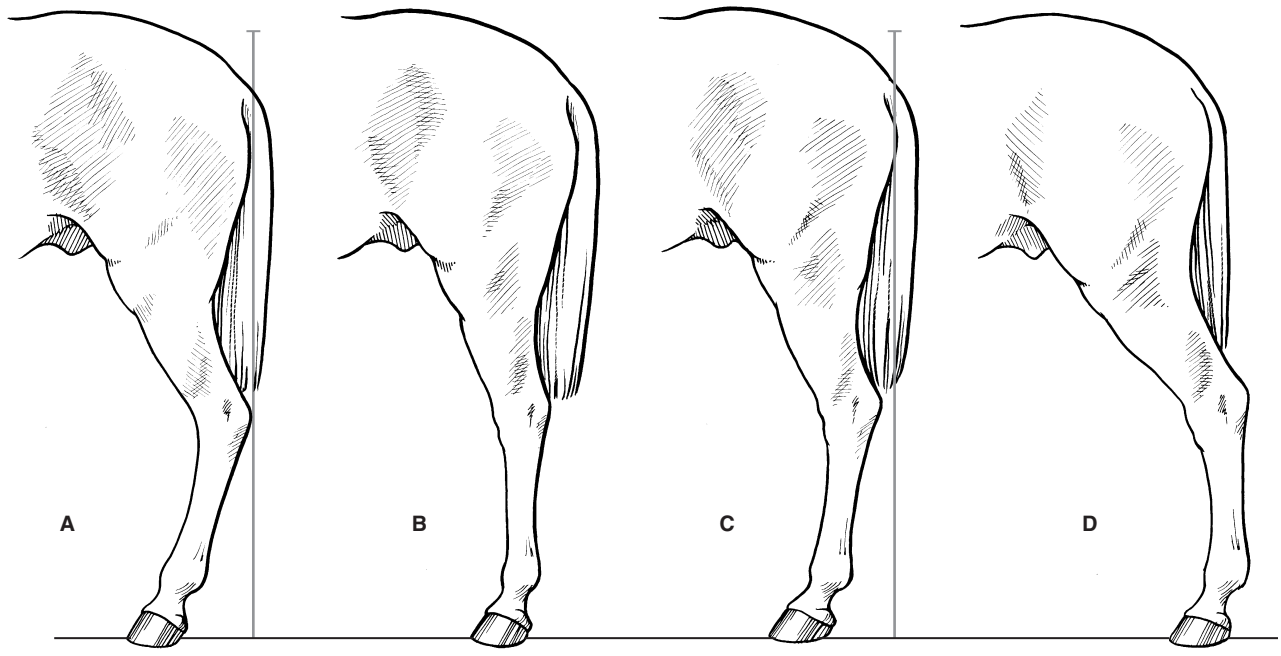

Fig. 4-26 Diagrammatic representation of conformational faults of the hindlimb from the lateral perspective. Compared with ideal conformation, horses with sickle-hocked conformation (**A**) have a concave dorsal surface of the limb with the distal extremity dorsal to the plumb line, but those that are straight behind (**B**) have large stifle and hock joint angles but smaller fetlock joint angles. Horses that are camped under (**C**) often are sickle-hocked as well. Camped-out conformation (**D**) is unusual and most often results from faulty positioning of the horse.

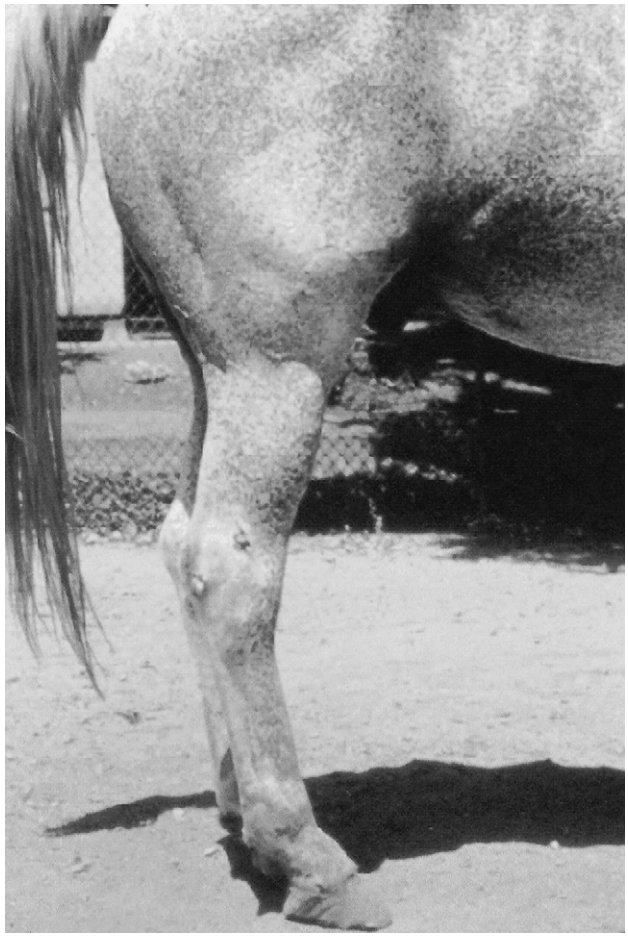

Fig. 4-27 Horse with camped-under and mild sickle-hocked conformation, a combination leading to a short, choppy gait.

Fig. 4-28 Standardbred filly with straight hindlimb conformation and suspensory desmitis.

Fig. 4-29 This 4-year-old Standardbred has sickle-hocked conformation and has developed curb, which has been treated by freeze-firing, resulting in white marks on the plantar aspect of the hock.

often predisposes to distal hock joint pain and curb, but these horses tend to be fast, although unsound. In Western reining horses, sickle-hocked horses may be able to slide better.

Rear Perspective

A majority of STB and WBL horses toe out behind, which should be considered normal. Horses with mild external rotation of the distal extremity are called toed out and usually also have external rotation of hocks, causing the points of the hocks to be closer than normal. This fault is called *cow-hocked* conformation and is a *rotational* change of the hindlimb (Fig. 4-30). Cow-hocked conformation occurs in combination with base-wide or base-narrow deformities or independently. Cow-hocked and base-narrow conformation is most common. Base-wide and base-narrow conformation may occur without cow-hocked conformation. These conformational faults seldom lead to lameness but have a substantial effect on gait in some horses. Horses that are base narrow travel close behind, particularly at a walk. Some travel close at a trot, pace, or gallop, whereas others seem to widen out when going faster, thus avoiding interference. Those that travel close at speed often interfere, causing injury to the medial aspect of the contralateral hindlimb.

Bow-legged hindlimb conformation, in which the point of both hocks is truly outside the plumb line, is uncommon (see Fig. 4-30). Occasionally horses that are base-narrow appear to be bow-legged. Unilateral bow-legged conformation occurs in foals born with windswept deformity or in those with tarsus varus deformity. Bilateral tarsus varus deformity is unusual.

In-at-the-hock or tarsus valgus is an *angular* deformity (Fig. 4-31). The deformity can be corrected in foals. If it persists in a mature horse, particularly a racehorse with other conformational abnormalities, such as sickle-hocks, abnormal forces or load occur in the tarsal region, predisposing the horse to distal hock joint pain, curb, and proximal metatarsal lameness.

Horses can be toed in or toed out behind, but in general the conformational abnormality starts above the fetlock joint, causing the lower limb abnormality to be linked with the upper limb. Thus a horse that is toed in generally is bow-legged, and one that is toed out is cow hocked. In some foals, however,

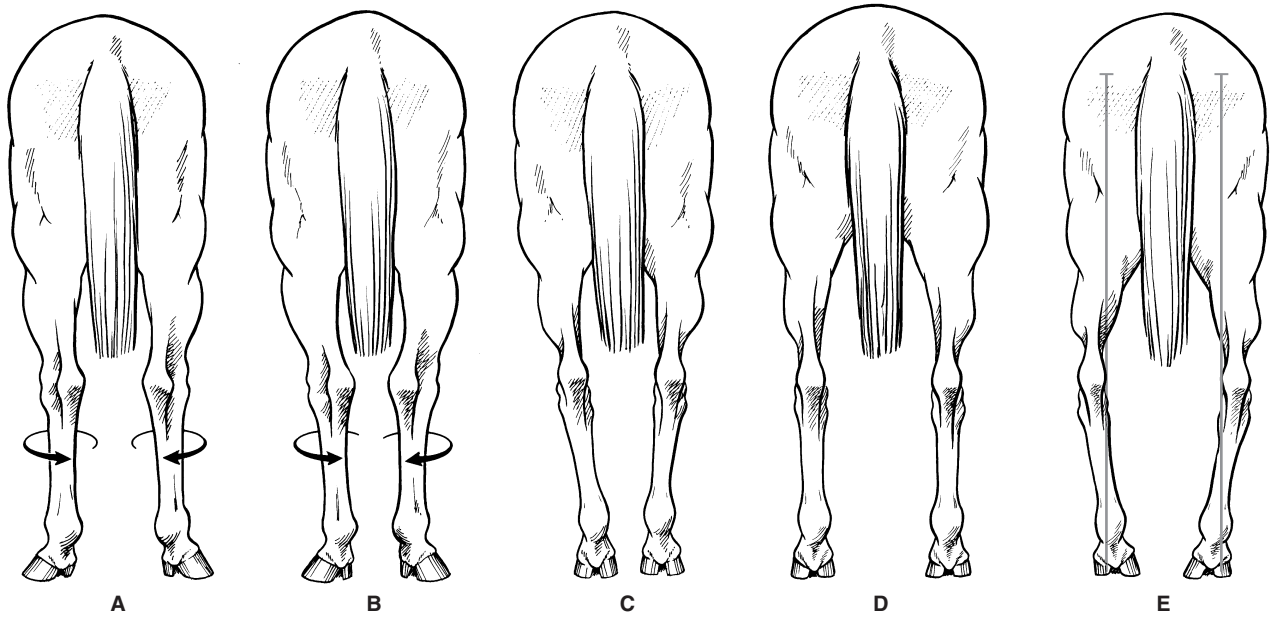

Fig. 4-30 Hindlimb conformational abnormalities viewed from the rear. **A,** Cow-hocked conformation is a common fault characterized by external rotation of the limb, usually without angular deformity, causing the hocks to be too close together. Mild external rotation of the hindlimbs is common and does not appear to cause lameness. **B,** Cow-hock, base-narrow conformation. **C,** Base-narrow conformation. **D,** Base-wide conformation is uncommon. **E,** Bow-legged conformation is uncommon and undesirable.

Fig. 4-31 Mature Standardbred racehorse with in-at-the-hock (tarsus valgus) conformation. This conformational abnormality is characterized by an angular deformity as opposed to the rotational deformity seen in cow-hocked conformation. The characteristic white marks were produced by cryotherapy for treatment of bilateral curb.

fetlock varus occurs independent of upper limb conformational abnormalities. This abnormality usually appears in windswept foals in which upper limb deformities have resolved, leaving a fetlock varus. This is an angular deformity, but with abnormal hoof wear, toed-in conformation can develop. Fetlock varus and the resulting toed-in conformational defect may cause osteoarthritis of the fetlock and interphalangeal joints and can be career limiting.

CONFORMATION OF THE DIGIT

More detailed aspects of conformation of the foot and limb flight characteristics are discussed in Chapters 5 and 7. Many of the changes in hoof growth or conformational changes in the hoof are the result of wear, shoeing, and exercise demands of training and performance and often are not present in a young horse.

The pastern angle is usually similar to the angle of the shoulder (see Fig. 4-7). The pastern foot axis should be straight. The pastern should be neither excessively sloped (low angle) nor upright (high angle). The angle of the pastern is important in determining the amount of load on the lower limb structures. In general, the more upright the pastern (steeper pastern angle), the shorter the stride and vice versa. Horses with upright pasterns appear to be prone to foot lameness and perhaps superficial digital flexor tendonitis. Those with long, sloping pasterns may be at risk to develop osteoarthritis of the fetlock joint and proximal phalangeal fractures. Horses with short, upright pasterns but relatively normal hoof angles have a broken foot-pastern axis—the foot axis is lower than the pastern axis—and are at risk of developing foot lameness (Fig. 4-32). If the pastern axis is lower than the foot axis, called *coon footed*, it causes undue strain on the soft tissue structures supporting the fetlock joint. This type of conformation may result from severe suspensory desmitis and loss of support of the fetlock joint.

Pastern length is important and usually is related to pastern angle. Horses with long pasterns commonly have more slope or lower pastern angles. The plumb line should drop approximately 5 cm behind the heel in a well-conformed horse. In horses with long, sloping, and weak pasterns, the line drops more than 5 cm behind the heel. Those with short pasterns usually have more upright pasterns, and the plumb line drops

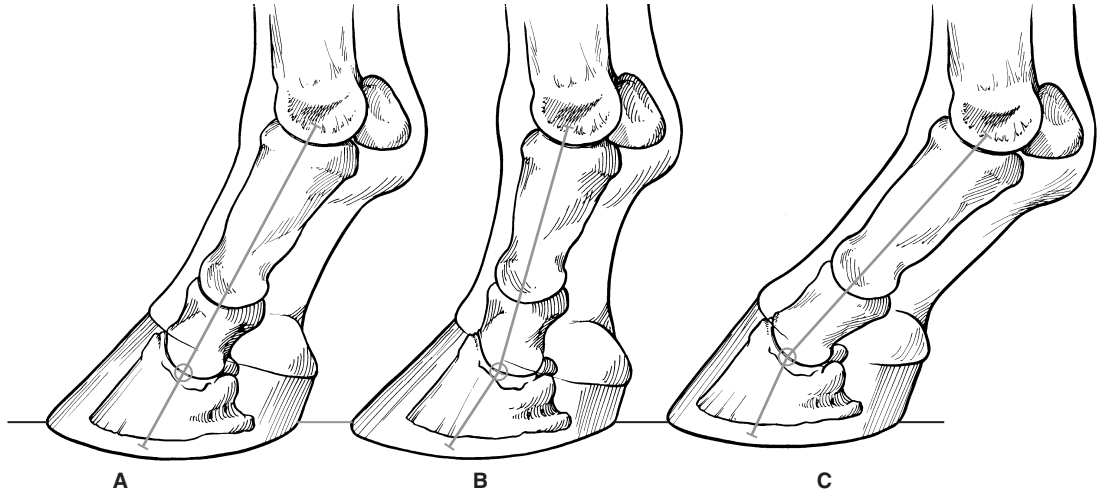

Fig. 4-32 Diagrammatic representation of ideal pastern and foot conformation and the concept of a broken pastern-foot axis. Ideally the foot and pastern angles (**A**) should be identical to allow full and even weight bearing on all aspects of the foot. A broken foot axis (**B**) occurs when pastern angle is more upright than that of the foot or vice versa (**C**). In both latter situations, uneven load distribution on the foot or soft tissue structures may cause lameness.

through the foot. A variety of pastern lengths and angles occur, but the pastern length should be in proportion to the overall length of the limb.

Viewed from the front, the plumb line may divide the pastern and foot asymmetrically with more pastern and foot laterally, which often is associated with some degree of distortion of the hoof capsule, with a steeper medial wall and some flaring laterally. This results in asymmetrical loading of the distal limb joints and may predispose to lameness.

Buttress foot is an acquired firm bulge or swelling at and proximal to the dorsal aspect of the coronary band and usually reflects osteoarthritis of the distal interphalangeal joint.

CHAPTER • 5

Observation: Symmetry and Posture

Mike W. Ross

Assessments of symmetry and posture are important aspects of a lameness examination. Comparison between the normal and abnormal sides facilitates identification of abnormalities, unless the condition is bilateral so that no recognizable differences exist between the left and right limbs. The horse should be standing squarely on a flat surface in a quiet, insect-free environment. Horses with severe lameness often are reluctant to stand correctly, but information gained about symmetry and posture of severely lame horses is valuable. The veterinarian should look carefully at size, shape, contour, heights, and widths, and compare with the opposite side.

FORELIMB SYMMETRY

Muscle Atrophy

The symmetry of skeletal muscle in the forearm, pectoral, and cervical areas should be assessed. Muscle atrophy that occurs in horses with chronic lameness conditions is called *disuse atrophy* and in those with neurological disease is called *neurogenic atrophy*. Horses with muscle atrophy and lower motor neuron disease (see Chapter 11) may be lame, sometimes the result of muscle pain or nerve root pain, complicating differentiation between these causes of muscle atrophy. In most but not all horses with neurogenic atrophy, other clinical signs suggestive of neurological disease may be present. Horses with disuse atrophy resulting from chronic lameness usually have generalized atrophy of the ipsilateral forelimb. Muscle loss usually is not pronounced but involves the forearm (extensors are most commonly affected), triceps, and shoulder muscles. Shoulder muscle atrophy involving the infraspinatus and supraspinatus muscles generally is not pronounced, and lateral subluxation of the shoulder joint during weight bearing is not present (see Chapter 41).

Development of disuse atrophy resulting from chronic lameness generally takes weeks to months unless severe lameness exists. In horses with severe or non–weight-bearing lameness, atrophy may develop within 10 to 14 days. In horses with severe forelimb lameness, carpal contraction (flexor deformity of the carpus) may occur simultaneously with muscle atrophy. The most common cause of carpal contraction because of

through the foot. A variety of pastern lengths and angles occur, but the pastern length should be in proportion to the overall length of the limb.

Viewed from the front, the plumb line may divide the pastern and foot asymmetrically with more pastern and foot laterally, which often is associated with some degree of distortion of the hoof capsule, with a steeper medial wall and some flaring laterally. This results in asymmetrical loading of the distal limb joints and may predispose to lameness.

Buttress foot is an acquired firm bulge or swelling at and proximal to the dorsal aspect of the coronary band and usually reflects osteoarthritis of the distal interphalangeal joint.

CHAPTER • 5

Observation: Symmetry and Posture

Mike W. Ross

Assessments of symmetry and posture are important aspects of a lameness examination. Comparison between the normal and abnormal sides facilitates identification of abnormalities, unless the condition is bilateral so that no recognizable differences exist between the left and right limbs. The horse should be standing squarely on a flat surface in a quiet, insect-free environment. Horses with severe lameness often are reluctant to stand correctly, but information gained about symmetry and posture of severely lame horses is valuable. The veterinarian should look carefully at size, shape, contour, heights, and widths, and compare with the opposite side.

FORELIMB SYMMETRY

Muscle Atrophy

The symmetry of skeletal muscle in the forearm, pectoral, and cervical areas should be assessed. Muscle atrophy that occurs in horses with chronic lameness conditions is called *disuse atrophy* and in those with neurological disease is called *neurogenic atrophy*. Horses with muscle atrophy and lower motor neuron disease (see Chapter 11) may be lame, sometimes the result of muscle pain or nerve root pain, complicating differentiation between these causes of muscle atrophy. In most but not all horses with neurogenic atrophy, other clinical signs suggestive of neurological disease may be present. Horses with disuse atrophy resulting from chronic lameness usually have generalized atrophy of the ipsilateral forelimb. Muscle loss usually is not pronounced but involves the forearm (extensors are most commonly affected), triceps, and shoulder muscles. Shoulder muscle atrophy involving the infraspinatus and supraspinatus muscles generally is not pronounced, and lateral subluxation of the shoulder joint during weight bearing is not present (see Chapter 41).

Development of disuse atrophy resulting from chronic lameness generally takes weeks to months unless severe lameness exists. In horses with severe or non–weight-bearing lameness, atrophy may develop within 10 to 14 days. In horses with severe forelimb lameness, carpal contraction (flexor deformity of the carpus) may occur simultaneously with muscle atrophy. The most common cause of carpal contraction because of

ipsilateral forelimb lameness is olecranon process fracture or other elbow lameness, but carpal contraction may occur in horses with severe shoulder or even lower limb lameness. Atrophy of the triceps muscles usually is recognized before other muscle atrophy in severely lame horses.

Horses with neurogenic atrophy may have profound atrophy of one or more muscles in the forearm, pectoral, or cervical regions. Atrophy often is much more pronounced than expected based on the degree of lameness, prompting suspicion of neurological disease. Pronounced, unilateral pectoral or triceps atrophy with mild atrophy of the forearm muscles suggests neurological disease. Severe atrophy localized to the infraspinatus or supraspinatus muscles without subluxation of the shoulder joint usually results from injury of the suprascapular nerve caused by external trauma. Atrophy and subluxation of the shoulder joint is associated with injury of the brachial plexus or nerve roots. Other muscles may also show atrophy.

Localized muscle atrophy or fibrosis occurs in horses with previous injury and subsequent scar tissue formation within muscle bellies. This condition is more common in the hindlimb, but occasionally occurs in the forelimb.

Swelling

Swelling, a common sign of inflammation, often causes asymmetry. Swelling within a joint capsule caused by excess joint fluid, *effusion*, is a general reaction of the joint to several traumatic or degenerative processes. Edema, cellulitis (lymphangitis), bleeding, fibrosis, and bony enlargement can cause soft tissue swelling. *Edema* usually signals acute inflammation and pits (a distinct impression is visible) when compressed by digital palpation (pitting edema). Horses develop edema around and often distal to the site of inflammation. In some horses, especially racehorses left unbandaged when accustomed to being bandaged, benign mild to moderate edema of the distal extremities develops. This process is called "stocking-up" and should not be misinterpreted as a pathological process. In these horses the edematous area is not painful and usually does not pit, and the horse is not lame.

Cellulitis describes infection within the tissue planes of the distal extremities (see Chapter 14) and is sometimes called *lymphangitis*. Lymphangitis, by definition, is inflammation of the lymphatic circulation of the limb, but the conditions are similar and the terms are used interchangeably. Swelling is firm, warm, and painful, and lameness is often pronounced. "Stove-pipe" swelling describes this condition ("the horse is all stoved-up"). Horses generally show systemic signs such as fever and elevated white blood cell count. This condition usually results from small puncture wounds that may be difficult to discover or occurs after articular, periarticular, or subcutaneous injections. Infection develops in subcutaneous tissues or deeper in the dense fascial planes and can be difficult to eradicate.

Blunt trauma or fractures may cause bleeding within tissue planes. Severe lameness and swelling accompany fractures of the scapula and humerus, because large vessels are nearby. Bleeding may be severe and cause a decrease in plasma protein and packed blood cell volume values. In horses with fractures located more distal in the limb, swelling is less pronounced but still prominent. The most likely location of injury is the swollen area, but swelling may occur distal to the site of injury because of venous and lymphatic congestion.

Fibrosis or scar tissue formation as the result of previous cellulitis or trauma causes asymmetry of the distal extremities but may not be the source of the current lameness. The veterinarian should avoid overinterpreting areas of scar tissue formation unless evidence of recrudescent inflammation exists. Horses may have scars caused by previous application of counterirritants or from healed wounds, leaving large, painless, and thus benign blemishes.

Bony swelling is a common cause of asymmetry. Proliferative change results in periosteal or periarticular new bone formation and accompanies a myriad of problems in the distal extremities. Bony changes may be active, causing the current lameness problem, or old and inactive, causing few or no clinical signs. For example, old inactive bony swelling of the shin or osselets (bony and fibrous swelling of the fetlock joint) may be prominent in ex-racehorses but have little to no relevance to current lameness.

Foot Size

Ideally both front feet should be identical in size and shape, or nearly so, and any asymmetry should be noted. Horses with chronic lameness may have disparity in foot size, usually with the smaller foot being ipsilateral to lameness. The small foot often is contracted and more upright (Fig. 5-1). Chronic reduction in weight bearing results in foot size disparity in some, but not all, horses. Mild disparity in foot size is a normal finding in some horses. Mild clubfoot conformation, acquired from previous flexor deformity, may be present incidentally in adult horses. Previous lameness may have caused contraction of the foot but has since resolved, resulting in disparity in foot

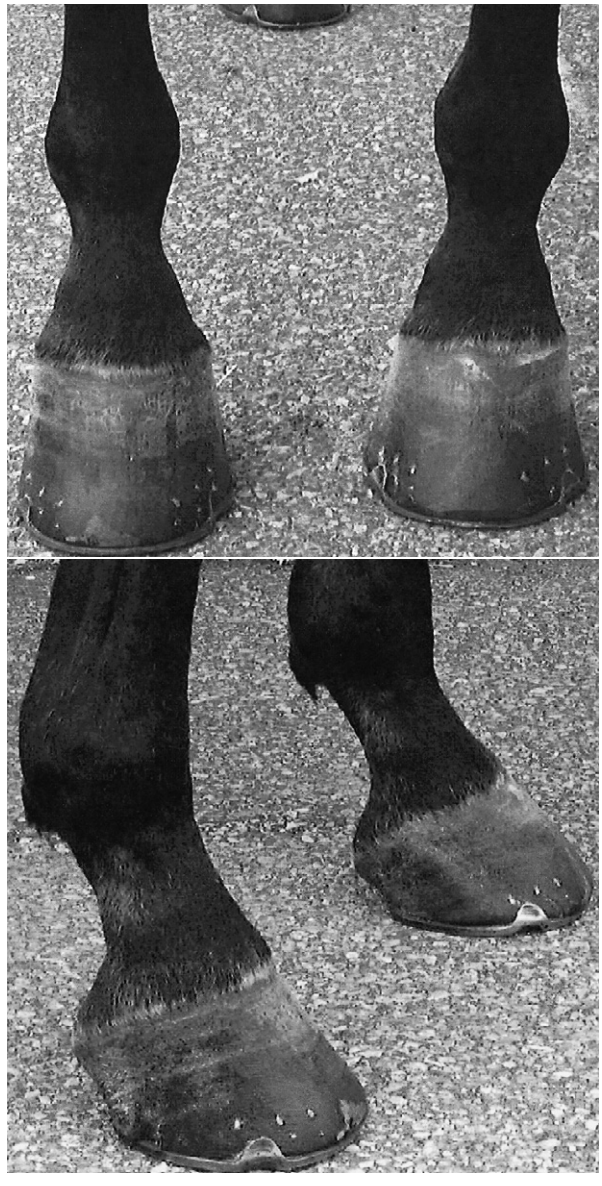

Fig. 5-1 A horse with disparity in front foot size caused by chronic lameness. The right forelimb foot is smaller compared with the normal left forelimb foot when viewed from the front **(A)** and more upright when viewed from the side **(B).**

size and shape but no residual lameness. Clubfoot conformation appears to be better tolerated in Thoroughbred (TB) than in Standardbred (STB) racehorses.

Fetlock Height

Fetlock position should be assessed in the standing horse and during movement. In a standing horse, fetlock height should be symmetrical, assuming the horse is loading the limbs equally. Horses with severe lameness commonly "point" or hold the limb in front of the opposite forelimb, thus taking weight off the limb. This standing posture obviously causes disparity in fetlock height but should be carefully interpreted. Loss of support of a fetlock in the standing horse causes the affected fetlock to drop and occurs most commonly with acute, traumatic disruption of the suspensory apparatus in racehorses but also appears with chronic, active desmitis (Fig. 5-2). Severe superficial digital flexor (SDF) tendonitis or lacerations resulting in fiber damage of the deep or superficial digital flexor tendons can cause similar clinical signs.

In horses with mild flexor deformity of the metacarpophalangeal joint, dynamic knuckling (buckling forward, flexion) of the fetlock joint may occur in the standing position (Fig. 5-3). Joint position usually returns to normal during movement. In horses with severe flexor deformity, normal fetlock position is never achieved. Knuckling of the fetlock also may result from desmitis of the accessory ligament of the deep digital flexor tendon.

Scapular Height

Disparity in scapular height is a rare clinical sign in a lame horse. The veterinarian must stand behind and above the horse to observe scapular height. The horse's mane may obscure observation from a distance, requiring closer examination by palpation. Traumatic or neurological conditions affect scapular height, causing either injury or dysfunction of the serratus ventralis muscle, respectively. With both conditions the dorsal aspect of the scapula is *higher* on the affected side. The veterinarian may place pieces of white tape or other suitable markers on both sides of the horse and stand back to compare height or may use two assistants to point to the locations.

HINDLIMB SYMMETRY

Muscle Atrophy

Asymmetry of bone and muscle mass in the hindlimbs and pelvis is a common clinical sign but must be differentiated carefully. The horse should stand squarely on a flat, even surface. The clinician must determine whether asymmetry exists, and if so, if the problem involves muscle, bone, or a combination of the tissues. Muscle atrophy is most common and, if unilateral muscle atrophy exists, easily can be confused with bony asymmetry caused by pelvic fractures or sacroiliac asymmetry.

Disuse and neurogenic muscle atrophy occur in the hindlimb. Horses with chronic hindlimb lameness develop ipsilateral gluteal muscle atrophy, but asymmetry may be subtle. Mild muscle atrophy usually first appears just lateral to the tuber sacrale. The veterinarian should differentiate muscle atrophy from disparity in height of the tubera sacrale (Fig. 5-4). Recognition of muscle atrophy helps determine the lame leg and provides some information about the duration of the problem. Severe muscle atrophy develops in horses with long-standing, severe lameness or in those with neurological disease (Fig. 5-5).

In horses with neurogenic atrophy of the gluteal muscles the degree of muscle loss is inappropriately severe compared

Fig. 5-2 A Standardbred racehorse with severe suspensory desmitis and a "dropped fetlock." The level of the right forelimb fetlock joint is lower than the left forelimb, caused by chronic, severe desmitis. Similar clinical signs and severe lameness appear in horses with acute traumatic disruption of the suspensory apparatus.

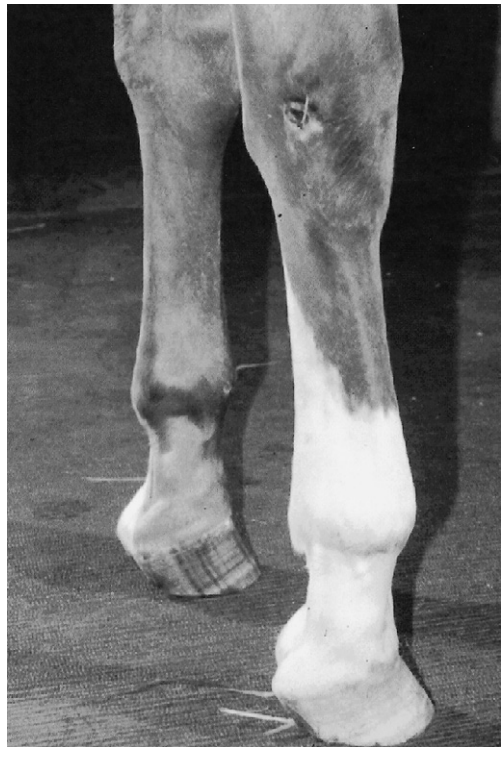

Fig. 5-3 Knuckling forward of the right front fetlock joint occurs in a standing position in this horse with mild flexor deformity of the metacarpophalangeal joint. This dynamic instability abates somewhat when the horse moves, but the left front fetlock also is straight, indicating the presence of bilateral flexor deformity.

Fig. 5-4 Three-year-old Thoroughbred filly with subtle disparity in tuber sacrale height. The left tuber sacrale is slightly lower (*arrow*) than the right, caused by a fracture at the base of the tuber sacrale. This clinical finding can easily be missed or confused with mild muscle atrophy.

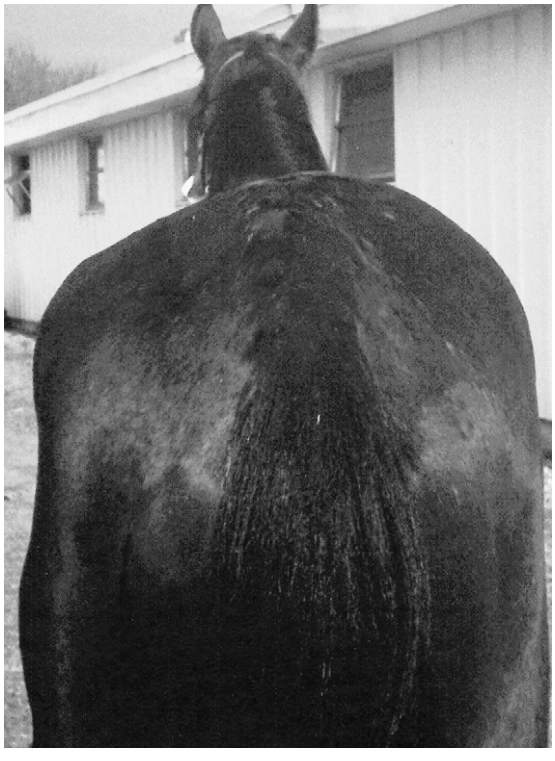

Fig. 5-5 A 4-year-old Standardbred with severe left gluteal atrophy caused by neurological disease. The presumptive clinical diagnosis was equine protozoal myelitis.

with observed lameness. Neurological signs such as weakness and proprioceptive deficits usually appear in horses with neurogenic atrophy, but early in the course of diseases such as equine protozoal myelitis (EPM) the only observable signs may be muscle atrophy and mild lameness.

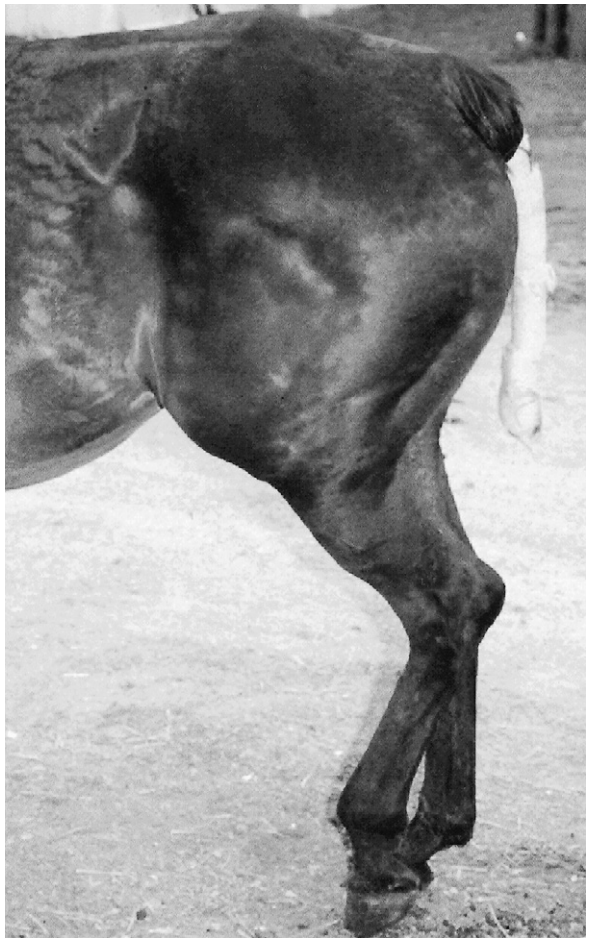

Fig. 5-6 A Thoroughbred broodmare with severe lameness and swelling of the left thigh caused by a comminuted femoral fracture.

Selective atrophy of individual muscles or muscle groups occurs in horses with neurological disease or injuries causing focal muscle loss and scarring. Horses with trauma involving fracture of the tubera ischii may develop focal muscle loss of the semitendinosus or semimembranosus muscles. A depression resulting from localized muscle atrophy replaces initial swelling of the point of the rump. Horses with *fibrotic myopathy,* which in most horses is believed to result from injury and scarring of the semitendinosus muscle, usually have palpable scars or defects of the caudal thigh muscles. Degenerative neuropathy of the nerves supplying the distal aspect of the semitendinosus muscle also may cause fibrotic myopathy[1] (see Chapter 49).

Swelling

Swelling is especially important in horses with acute, severe lameness when the clinician must differentiate between catastrophic injury, such as pelvic or long bone fracture, and more common conditions, such as cellulitis. Horses with pelvic fractures may develop mild swelling in the thigh, but swelling is not prominent in most horses. In horses with fracture of the tuber coxae or ilial wing or shaft, mild swelling may develop distally but usually is not prominent. Inappropriate lameness and lack of swelling should prompt the clinician to perform a rectal examination, checking for internal asymmetry or crepitus. Horses with femoral fractures develop acute, severe swelling of the thigh, accompanied by severe lameness, instability, and often crepitus (Fig. 5-6). Horses may develop severe swelling of the stifle and thigh resulting from trauma and secondary bleeding. Large stifle hematomas resemble the

Fig. 5-7 Moderate, fluctuant soft tissue swelling over the stifle caused by subcutaneous bleeding (hematoma). In this situation, swelling is much more pronounced than expected for the observed degree of lameness.

swelling in horses with femoral fractures, and in some horses hematomas can be confused with severe femoropatellar effusion (Fig. 5-7). Excessive bleeding from subcutaneous vessels also may involve the ventral, lateral abdominal region. In horses with stifle hematoma, lameness is not as prominent as expected, and swelling fluctuates, which is useful in differentiating this cause of lameness from femoral fractures. Generalized, diffuse soft tissue swelling appears in horses with cellulitis or lymphangitis in the hindlimb (Fig. 5-8).

Bony Asymmetry

Comparison of the height of the tubera coxae is important to determine the nature and extent of pelvic bony injury (Fig. 5-9). Two assistants, one on each side of the horse, may point to the dorsal aspect of the tubera coxae, or the veterinarian may use temporary markers to compare the height. Determining the height of the tubera sacrale may be difficult and requires careful palpation to differentiate bone, ligament, and muscle asymmetry. Accurate determination may be possible only by ultrasonography. Estimating the midline-to-lateral pelvic width also aids in diagnosing acute or chronic pelvic fractures.

Tubera Coxae

Asymmetry in height of the tubera coxae accompanies many different pelvic fractures. The most common fracture involves the tuber coxae itself, often called *knocked-down hip.* Marked ventral and medial displacement of the fracture fragment occurs because of muscle attachment to the bony prominence. The veterinarian also must palpate the actual shape of the tuber coxae, because ventral displacement occurs with other pelvic injuries. Displacement and rotation occurs in horses with fracture of the wing of the ilium caudal to the tuber coxae without an obvious change in size or shape of the tuber coxae. However, with a partial fracture of the ventral aspect of the tuber coxae, there is a change in its shape, without displacement of the dorsal aspect of the bone.

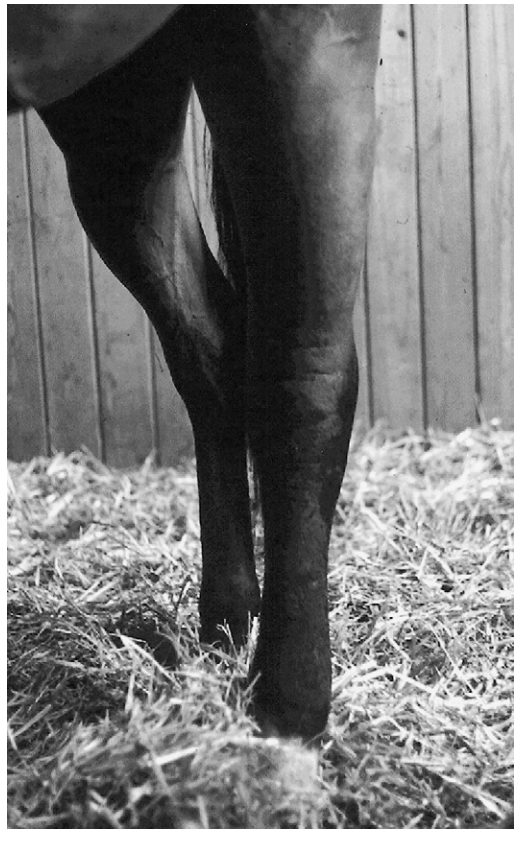

Fig. 5-8 Soft tissue swelling caused by cellulitis. Firm, painful swelling appears in the entire limb.

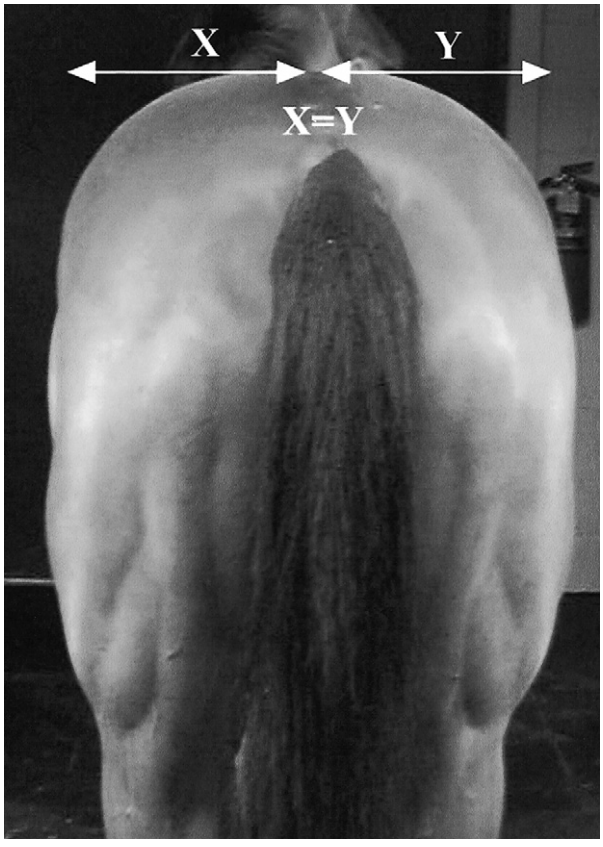

Fig. 5-9 A well-positioned horse to determine tubera coxae height and the midline-to-lateral pelvic width (*X*, *Y*). In a normal horse, *X* = *Y*.

Tubera Sacrale

The term *hunter's bump* describes the prominence of the tubera sacrale. This finding may reflect the horse's conformation, poorly developed surrounding musculature, or a change in position of one or both tubera sacrale. Increase or decrease in size of the overlying dorsal sacroiliac ligament also results in apparent asymmetry. Many clinically normal horses have slight apparent asymmetry of the tubera sacrale. Asymmetry in height of the tubera sacrale occurs in horses with acute or chronic sacroiliac joint disruption (Fig. 5-10). In horses with acute fractures of the base of the tubera sacrale, the affected side is lower[2] (see Chapter 51). Ultrasonography and nuclear scintigraphy may help identify the cause of asymmetry.

Midline-to-Lateral Pelvic Width

A change in the relative width of each hemipelvis is a subtle but important clinical sign of pelvic injury. In most horses with pelvic fractures, the injured side is narrower than the normal side. Over-riding and displacement of fracture fragments results in compression on the injured side.

Swelling over the Greater Trochanter

Mild swelling over the lateral aspect of the coxofemoral joint may be a subtle clinical sign of acetabular or proximal femoral fractures. When standing behind the horse, the veterinarian should carefully observe for enlargement over the affected hip joint. This clinical sign usually is not noticeable initially, but soft tissue enlargement is visible within 2 to 3 weeks after intra-articular fracture. The groove between the greater trochanter and the biceps femoris muscle should be compared carefully; usually a slight bulge or subtle enlargement on the affected side is visible.

Crepitus

Bone-on-bone grating is a valuable clinical sign, particularly in horses with pelvic injury. Crepitus can be heard (with or without a stethoscope) or felt (external or rectal palpation) and most often is caused by movement of bone fragments in horses with displaced fractures (see Chapter 6). In horses with pelvic fractures, crepitus usually is not observed for several days to weeks after injury because muscle tone and fracture hematoma apparently stabilize fracture fragments and delay onset. Crepitus also can be felt or heard in horses with end-stage osteoarthritis.

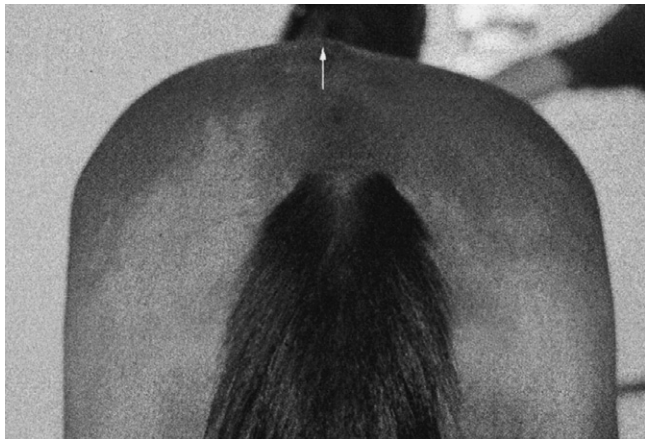

Fig. 5-10 Asymmetry of the tubera sacrale. The left tuber sacrale (*arrow*) is higher than the right. This horse has chronic left sacroiliac subluxation.

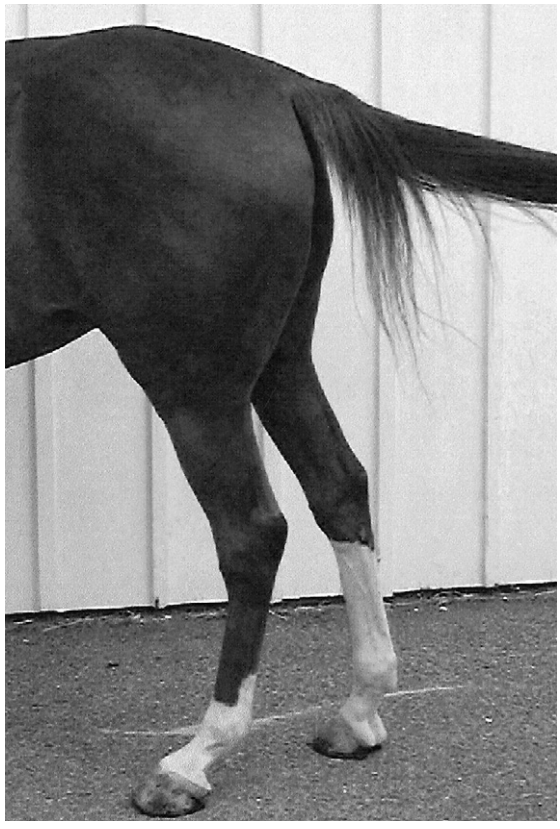

Fig. 5-11 A horse with partial disruption of the left gastrocnemius. An injury to the origin of the lateral head of the gastrocnemius muscle in this horse caused an unusual gait deficit, lameness, and mild distal displacement (drop) of the hock and fetlock.

Calcaneus

The points of the hock should be of equal height when observed from the side or from behind. There is dramatic lowering of the point of the hock with complete disruption of the

Fig. 5-12 A horse with a comminuted fracture of the left femur. The point of the left hock is higher than the right as a result of over-riding of fracture fragments and muscle contraction, effectively shortening the limb.

common calcaneal tendon or gastrocnemius tendon alone. Partial injury of the gastrocnemius muscle origin, the musculotendonous junction, or the tendon itself causes varying degrees of asymmetry in height of the point of the hock, both in a standing horse and during movement.[3] Other gait abnormalities such as unusual rotation or instability of the limb usually are present (Fig. 5-11).

The point of the hock is elevated in horses with severe pelvic fractures involving the acetabulum, luxation of the coxofemoral joint, and some femoral fractures (Fig. 5-12). Evaluating elevation is difficult because horses with severe lameness usually cannot bear weight, causing a dramatic alteration in limb position. However, in horses with true elevation in the point of the hock, the hock is extended, whereas with most non–weight-bearing conditions, the hock is flexed.

Fetlock Height

Assessment of fetlock position is as important in the hindlimb as in the forelimb. Horses with excessively straight hindlimb conformation (straight hocks) may have more obvious excursion of the fetlock (fetlock drop) while moving or shifting position during standing. Pathological fetlock drop generally accompanies suspensory desmitis (Fig. 5-13) but also occurs with partial disruption of the gastrocnemius and other ligamentous and tendonous injuries.

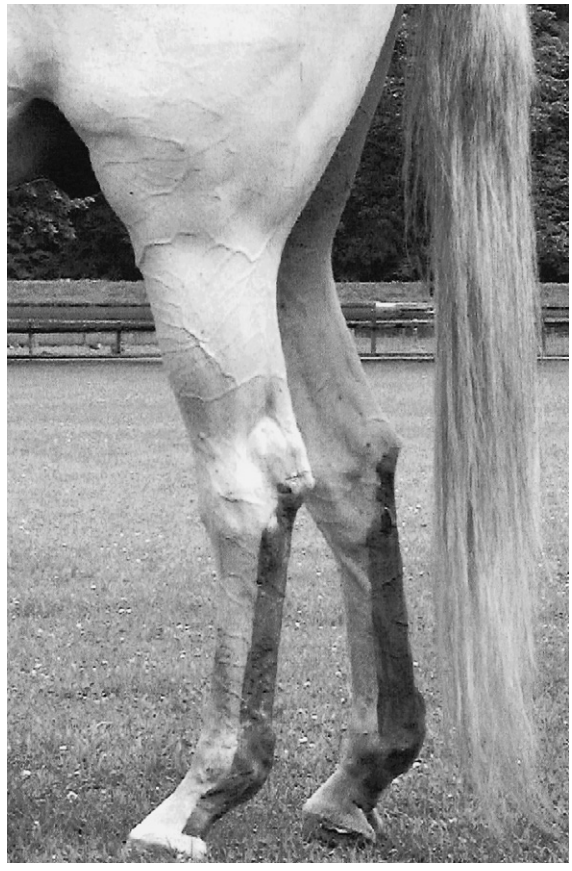

Fig. 5-13 Warmblood gelding with chronic, severe, bilateral hindlimb suspensory desmitis causing noticeable fetlock drop in the left hindlimb.

POSTURE

Body posture provides important clues to the source of lameness, but some abnormalities may be missed unless the horse is observed over long periods. Normal horses tend to rest one hindlimb and may alternate between limbs. Resting a forelimb is uncommon but does occur. Distractions in the environment may make a horse stand normally despite pain. However, abnormal posture because of mechanical or neurological dysfunction usually is evident.

The horse has a well-developed stay apparatus in both the forelimbs and hindlimbs.[4] It is assumed that the main purpose of the stay apparatus is to allow the horse to remain standing for long periods. The stay apparatus in the hindlimbs is better developed than in the forelimbs and includes ligamentous and tendonous structures dictating predictable movement of joints in the limb. If intact, the hindlimb stay apparatus demands reciprocal movement of the hock and stifle and often is called the *reciprocal apparatus*. A change in posture usually means a part of the reciprocal apparatus is broken.

FORELIMB POSTURE

Pointing

Horses that are severely lame often point or hold the affected forelimb ahead of the unaffected forelimb. These horses usually are severely lame at a walk. Horses with severe, bilateral forelimb lameness caused by laminitis may stand camped out in front, attempting to point with both forelimbs simultaneously. However, pointing is not synonymous with the presence

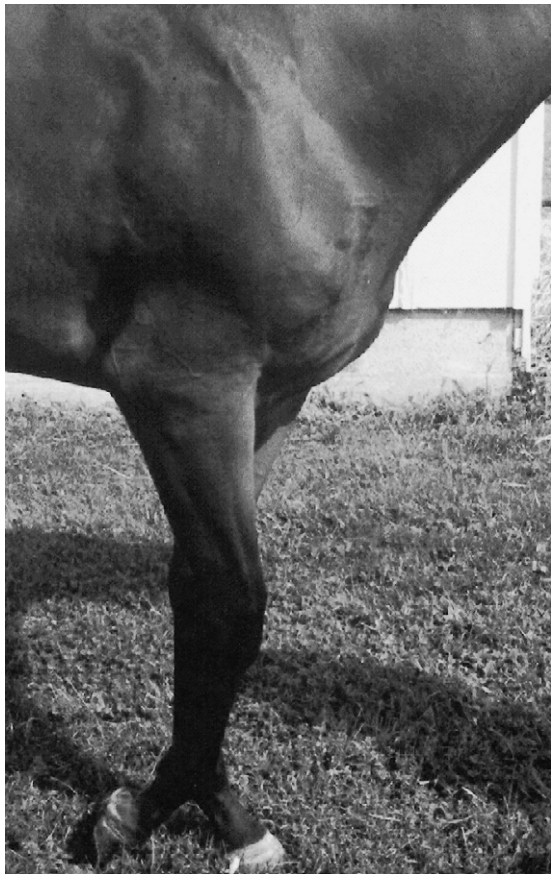

Fig. 5-14 Classic forelimb posture most often called radial nerve paresis or paralysis. The horse cannot extend or fix the elbow, causing the appearance of dropped elbow. The inability to fix the elbow (loss of triceps apparatus) commonly occurs in horses with olecranon fractures.

of pain or lameness or its degree. Some horses prefer to point one forelimb or another and walk and trot normally. In general, pointing is unusual and often signals resting pain or subtle pain relieved by adopting this posture. Some horses stack bedding under the heels to stand in a toe-down position, indicating a degree of unilateral or bilateral foot pain. These horses often are not as lame as expected based on the degree of postural change seen at rest.

Treading

Constant shifting of weight from one forelimb to the other may indicate bilateral forelimb lameness. Laminitis, severe soft tissue injuries such as tendonitis or suspensory desmitis, or severe osteoarthritis may cause treading. Horses with chronic, severe unilateral forelimb lameness often stand with little weight on the affected limb, overload the unaffected limb, and seldom tread. The development of treading in such circumstances is an ominous sign because the horse now is trying to shift weight from the previously unaffected limb, probably because of laminitis.

Buckling Forward at the Knee

Horses with bucked-knee or over-at-the-knee conformation may buckle forward at the knee while standing. In clinically normal older field hunters or other heavily used riding horses with bilateral over-at-the-knee conformation, this may be particularly obvious. The carpus is locked in extension primarily by the action of the extensor muscles. Neurological disease (e.g., EPM) affecting forelimb extensor muscles is a rare cause

Fig. 5-15 Forelimb posture in a foal with infectious osteomyelitis (scapula) and arthritis (shoulder joint). With severe lameness of the shoulder or bicipital bursa, horses are reluctant to stand or move normally and often hold the limb caudally. This posture may be difficult to differentiate from that seen with loss of the triceps apparatus (see Fig. 5-14).

of buckling forward at the knee, both at rest and during movement. Specific injury of the distal aspect of the radial nerve causes similar clinical signs. In foals, rupture of the common digital extensor tendon or other extensor tendons may cause this posture (see Chapter 78).

Dropped Elbow

A dropped elbow results from failure of the triceps apparatus to maintain elbow extension (Fig. 5-14) and usually results from fracture of the olecranon process. It also may result from injury to the radial nerve or brachial plexus. Similar clinical signs appear in horses with lesions of the nerve roots (neuritis, radiculopathy) or nerve cell bodies in the cervical intumescence, usually the result of lower motor neuron disease. A most unusual cause of this posture appears in horses with "root signature" (see "Neck Pain").

Severe Lameness of the Shoulder Region

Horses with severe shoulder pain may stand with the affected limb more caudal than usual (Fig. 5-15) and often drag the limb even with the slightest movement. This posture is similar to dropped-elbow posture, but in horses with a dropped elbow the limb is held at, or even slightly cranial to, the expected position.

Neck Pain

Horses with neck pain often hold the head and neck lower than expected at a level equal to or slightly lower than the withers (Fig. 5-16). In horses with severe pain muscle tremors or spasms are visible, especially when approaching the horse or causing the horse to move, and the horse stands in a guarded position. The horse may be reluctant to turn or move and may be unable or unwilling to eat food from the ground or an elevated position. An unusual but characteristic sign of neck pain is posturing of a single forelimb, usually on the side of the lesion. The limb is held extended or pointed in front of the other forelimb; rarely the limb is held in slight flexion (see Fig. 55-10, *A*). This sign appears in dogs with cervical pain, most commonly from intervertebral disk disease, and is

Fig. 5-16 Yearling Standardbred with neck pain on the left side showing typical stance and head and neck posture.

termed *root signature*.[5,6] Pain associated with the nerve roots supplying the brachial plexus may be the cause. Some horses with cervical pain also have unilateral forelimb lameness.[7]

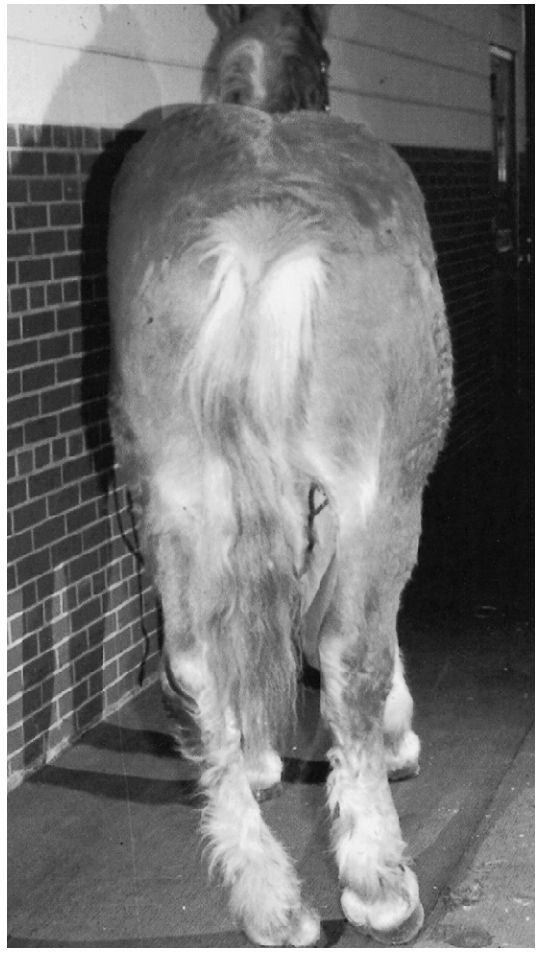

Fig. 5-17 A 2-year-old Belgian gelding with a fracture of the right femoral head and neck exhibits external rotation of the right hindlimb. Varus deformity of the left hindlimb also is visible.

HINDLIMB POSTURE

Resting a Hindlimb

Normally a horse rests one hindlimb or another, but immediately resting a hindlimb after work, or a combination of resting the hindlimb and trembling in the flank or stifle region, may indicate lameness.

Abnormal Tail Position

Horses may carry the tail in an abnormal position during movement, often alerting an observer to possible hindlimb pain. The tail usually is carried away from the lame limb, but this finding is inconsistent. Horses seldom have an abnormal tail posture at rest unless the tail has been traumatized or set, or there is severe hindlimb lameness.

External Rotation of the Hindlimb

Cow-hocked conformation is common, but unilateral external rotation may reflect pelvic injury (Fig. 5-17). The veterinarian should verify this change in posture by moving and reevaluating the horse. Horses with pronounced unilateral external rotation usually have fractures of the acetabulum or proximal femur but may have non-articular ilial shaft or wing fractures.

Hindlimb Varus Posture

Horses with chronic, severe unilateral hindlimb lameness may develop varus conformation of the contralateral limb (see Fig. 5-17). This posture most often appears in foals and may develop 7 to 10 days after onset of lameness.

Treading

Constant shifting of weight between the hindlimbs, or treading, is an unusual clinical sign and usually indicates pronounced bilateral lameness. Horses with bilateral hindlimb laminitis or severe osteoarthritis of any joint may tread. Horses with chronic, severe unilateral hindlimb lameness can endure 4 to 6 weeks or more of weight bearing on the contralateral limb, but treading may be the earliest sign of traumatic laminitis in the supporting limb.

Camped Under

Camped under appears only in horses with bilateral hindlimb laminitis and is rare. Horses often tread and exhibit an unusual hindlimb gait (shortened caudal phase of the stride) when moved.

Soft Tissue Injuries Altering Hindlimb Posture

Upward fixation of the patella causes rigid extension of all hindlimb joints in the standing horse (Fig. 5-18). Patellar dysfunction resulting in fixed extension of the stifle also causes extension of the tarsus and lower limb joints because of the hindlimb reciprocal apparatus. The horse may maintain this posture during movement, or the posture may be intermittent and resolve when the horse is moved. Occasionally a horse with severe hindlimb lameness assumes a similar posture, apparently hanging the limb, but the limb is not locked

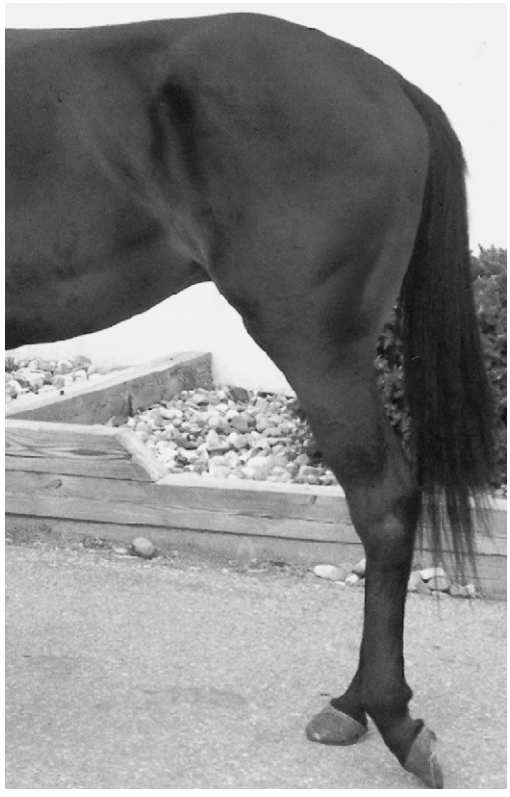

Fig. 5-18 A horse with the classic posture seen with upward fixation of the patella. All joints are held in rigid extension, and the horse is forced to rest or bear weight on the dorsal aspect of the hoof wall.

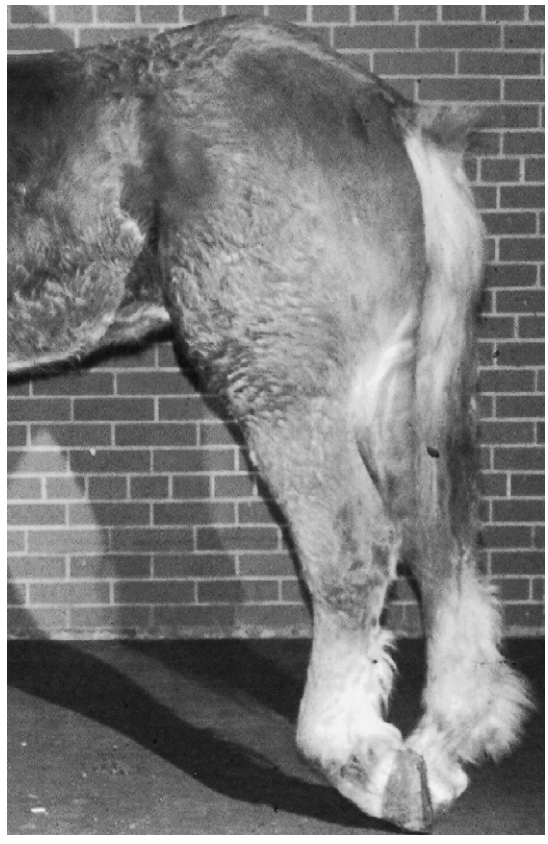

Fig. 5-19 Belgian gelding shown in Fig. 5-17. This horse occasionally rested the left hindlimb in this extended position, similar to that of upward fixation of the patella. Most normal horses, or those with severe lameness, prefer to rest the limb with the sole facing the ground.

in extension (Fig. 5-19). Normal horses simply resting a hindlimb, or those with severe lameness, usually keep the sole facing the ground.

Foals with unilateral or bilateral lateral patellar luxation have an unusual crouched hindlimb posture similar to femoral nerve paresis. The foal may have difficulty in rising if the condition is bilateral and severe or long-standing.

Disruption of fibularis (peroneus) tertius allows the hock to extend abnormally during weight bearing. Foals occasionally stand excessively straight in the hock (extended) in the affected hindlimb. In foals the injury usually causes tearing at the origin of fibularis tertius from the distal femur, but in adults injury may occur in the crus or at the distal aspect of the ligament as it courses over the hock. Swelling and excessive hock extension may occur with the latter injury (Fig. 5-20). The diagnosis is confirmed by manipulation: the hock can be extended while the stifle is flexed.

Rupture of the gastrocnemius tendon, or severe injury at any level of the muscle-tendon unit, causes mild or severe hindlimb postural change. During weight bearing, the hock flexes excessively as the stifle is held in extension, so the point of the hock drops. This injury is called *disruption of the caudal component of the reciprocal apparatus.*[8,9]

Peripheral Nerve Deficits

Sciatic nerve damage is rare. It occurs in foals as a result of injections into the thigh or rump or may occur transiently after injection of local anesthetic solution caudal to the coxofemoral joint. Horses with sciatic nerve damage support weight but appear to be crouched behind, because innervation to the gastrocnemius, flexor, and extensor muscles causes the hock to drop and fetlock to knuckle forward. Careful observation of stifle action and the ability to support weight are useful when attempting to differentiate this deficit from femoral nerve paresis.

Horses with femoral nerve paresis also assume a crouched hindlimb posture but are unable to bear weight, and the stifle drops substantially (Fig. 5-21). Because the reciprocal apparatus is intact, the inability to fix the stifle leads to hock flexion and knuckling (flexion) of the fetlock joint. If the condition is bilateral, the horse is unable to rise for more than a few seconds. Femoral nerve paresis may occur unilaterally or bilaterally after general anesthesia or may result from lower motor neuron disease or injury.

Solitary tibial nerve injury is rare. Fibular (peroneal) nerve injury usually is recognized after general anesthesia and causes characteristic knuckling of the fetlock joint. Tibial nerve injury is differentiated from sciatic injury by lack of involvement of the tibial nerve, and thus normal positioning of the hock, and from femoral nerve injury, because horses are able to support weight and fix the stifle.

Other Unusual Leg Positions

Horses with severe lameness occasionally rest a hindlimb back, forward, or abducted. Often these positions also are maintained during movement. Horses with caudal thigh or pelvic pain prefer to keep the affected hindlimb back, behind the unaffected limb. Horses with shivers may stand with the limb slightly abducted and more caudal than expected, with elevation of the tail head (see Chapter 49).

Horses with pelvic fractures, in particular those involving the acetabulum, may stand with the limb slightly forward

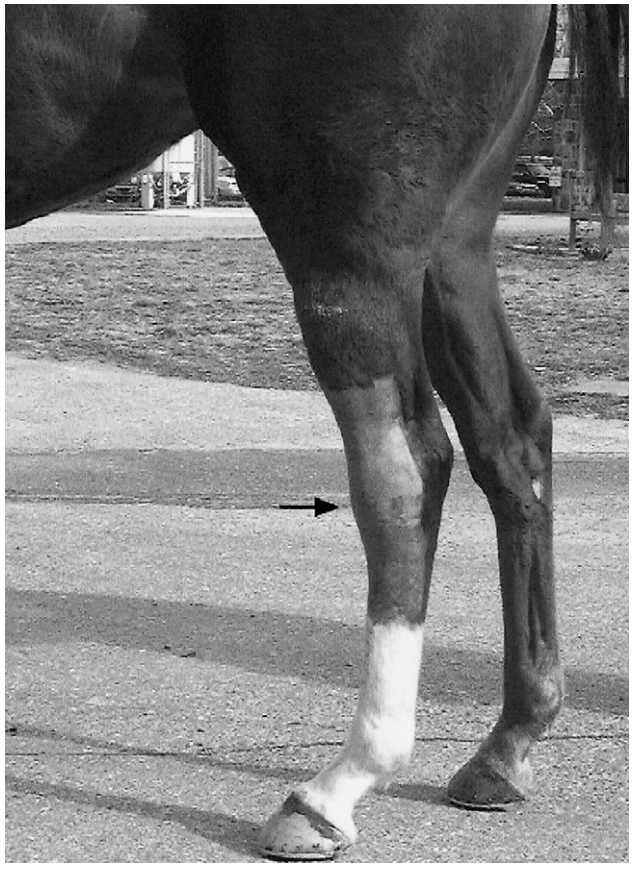

Fig. 5-20 This Thoroughbred racehorse with fibularis tertius injury has swelling over the dorsal aspect of the hock (*arrow*) and straight-in-the-hock conformation.

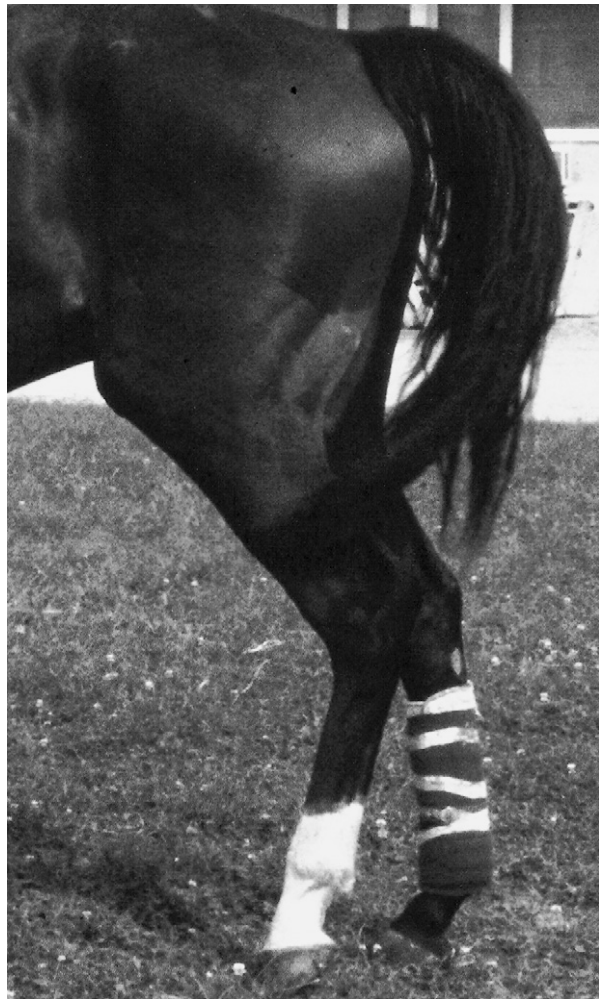

Fig. 5-21 Thoroughbred with transient, post-anesthesia, unilateral (left hindlimb) femoral nerve paresis. The crouched posture of the left hindlimb includes flexion (knuckling) of the fetlock joint.

and often are reluctant to place the limb behind the unaffected limb, thus reducing the caudal phase of the stride at the walk. Horses with pain in the medial thigh and groin area stand with the limb abducted and may travel in this manner. Adductor muscle damage, medial thigh abscessation, and scirrhous cord or other inguinal problems also cause this posture.

CHAPTER • 6

Palpation

Mike W. Ross

Palpation is an important part of a lameness examination. In some sport horses, it becomes more important because, for example, suspensory desmitis often is not associated with overt lameness but may compromise performance. The veterinarian must develop a system to evaluate comprehensively all parts of the musculoskeletal system. I palpate in order each forelimb, the neck, back, pelvic regions, and then the hindlimbs. Each limb should be assessed when bearing weight and then again with the limb elevated from the ground. Deep palpation is used to describe direct, digital palpation, with the limb in an elevated position.

If time permits, palpation should be completed *before* the horse is moved, because if the lame limb is identified first, the other limbs may be overlooked and compensatory problems may be missed. For example, in a Thoroughbred (TB) racehorse, superficial digital flexor (SDF) tendonitis is a common compensatory problem caused by contralateral limb lameness resulting in overload. If a lame horse with left forelimb (LF) lameness is first examined while the horse is moving, and subsequent palpation of the limb reveals signs of possible fetlock osteoarthritis, mild swelling of the right forelimb (RF) SDF tendon may be missed. Comprehensive palpation may allow the clinician to make predictions about lameness, to "read" the horse. Palpation before exercise also facilitates identification of localized heat or swelling, because limb temperature increases with exercise and swelling often decreases.

THE ART OF PALPATION

The veterinarian should palpate and manipulate every possible anatomical structure, using the fingers and hands to push, prod, and feel. Interpretation of an abnormal response requires appreciation of the normal response. There are nerves beneath or adjacent to many structures, and direct pressure may elicit an apparently positive response. Such false-positive responses often occur during palpation of the origin of the suspensory ligament (SL) or the proximal sesamoid bones (PSBs). Care should be taken to apply pressure only in the desired location. During palpation of the PSBs, distal aspect of the SL, and flexor tendons, it is easy to apply pressure over the dorsal aspect of the third metacarpal bone (McIII), and a painful response may actually reflect sore shins.

The clinician should look for signs of inflammation: heat, pain, redness, swelling, and loss of function. One side of the horse should be compared with the other, but it should be remembered that both sides may be abnormal. Heat is one of the earliest clinical signs to develop with articular or nonarticular problems and may be the only sign. Subchondral remodeling and sclerosis of the third carpal bone often cause lameness in young racehorses, but effusion of the middle carpal joint and a positive response to flexion are found inconsistently. Usually prominent heat is detectable on the dorsal aspect of the carpus. It is important to recognize normality. A normal horse may have disparity in foot temperature. Horses often have two or three cold feet, but the other feet feel warm. A few hours later, feet that previously were cool may feel warm. Foot temperature often reflects variations in ambient temperature, and care must be taken not to over-interpret this normal finding. In general, palpation is done with the palm side of the hand, although the back of the hand may be more sensitive to detection of warmth.

The veterinarian should assess the quality or strength of the digital pulse. In a normal horse, reliable detection of a digital pulse may be difficult, especially in cold weather or in horses with a thick hair coat. Increased or elevated digital pulse refers to the detection of increased strength or the bounding nature of the digital pulse. Inflammatory conditions in the foot or pastern region, such as abscesses, laminitis, hoof avulsions, or cracks, are the most common causes of increased digital pulse. Complete absence of hindlimb digital pulse may occur with aortoiliac thromboembolism or other vascular problems, but care should be taken when interpreting weak or near absent hindlimb digital pulses, because hindlimb digital pulses can be difficult to feel in normal horses.

Redness is difficult to perceive in the horse because of skin pigmentation, but in the foot, solar bruising or redness at the coronary band can be observed, especially in horses with nonpigmented feet. *Swelling* is often detected by observation, but subtle enlargement of structures such as the SL, or presence of effusion may be determined only by careful palpation.

Loss of function of tissues and regions can be assessed during palpation. Manipulation, flexion, and extension of the joints or soft tissues provide a better idea of function or loss of function. Static flexion and extension determines the range of motion of a joint and the horse's response to the procedure. Chronic osteoarthritis of the fetlock or carpal joints often results in reduced range of flexion. However, many horses in work but without lameness resent hard flexion of the lower limbs. Good correlation between a reduction in fetlock flexion range, lameness and severity of osteoarthritis was found in TB racehorses.[1] A reduction in fetlock flexibility in young Warmbloods may be a predictor of future lameness.[2] The response to rotation of joints also should be assessed.

Crepitus, the grating or crackling sound made by bone rubbing on bone, is an unusual and ominous clinical sign usually determined by palpation, although in horses with prominent osteoarthritis or fractures, a grating sound may be heard. A stethoscope may be useful for detection of subtle crepitus.

Other factors may confound the results of palpation. Clipped areas usually are warmer than an adjacent area with normal hair length. Blistering or freeze firing can cause localized pain for weeks after application, even if lameness has resolved. Any type of skin lesion, such as those found in horses with scratches or boot rubs, can cause extreme soreness to palpation but no signs of lameness. Some individual horses are more sensitive to palpation than others, and interpretation of apparent pain can be frustrating.

PALPATION OF THE FORELIMB

Foot

The importance of the foot cannot be overemphasized, and it is for this reason that palpation of the forelimb begins here. The feet are included in evaluation of conformation, symme-

Fig. 6-1 Instruments needed to examine the hoof, remove a shoe without tearing the hoof wall, and prepare the hoof for radiographic examination. Shown are apron, rasp, shoe pullers, nail pullers, clinch tool, hoof knife, hammer and hoof pick, and wire brush.

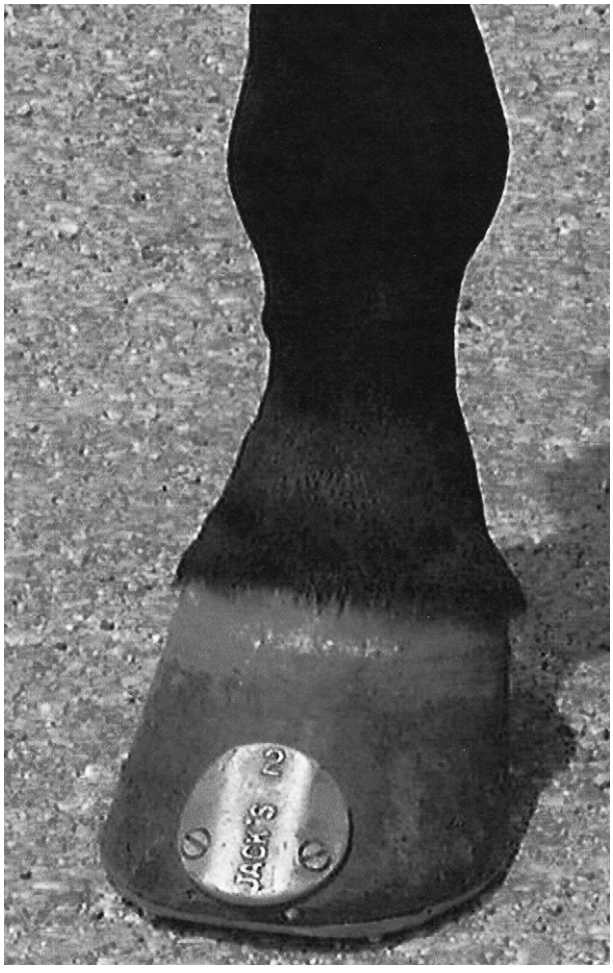

Fig. 6-2 The coronary band is uneven compared with the ground in this trotter's unbalanced hoof. The medial wall (*right*) appears to be shorter than the lateral wall.

try, and posture. Detailed static examination (examination at rest) of the foot must always be supplemented with, and correlated to, dynamic observations of foot flight and foot striking patterns. Some horses continually attempt to pick up the limb as the clinician tries to evaluate it with the horse in the

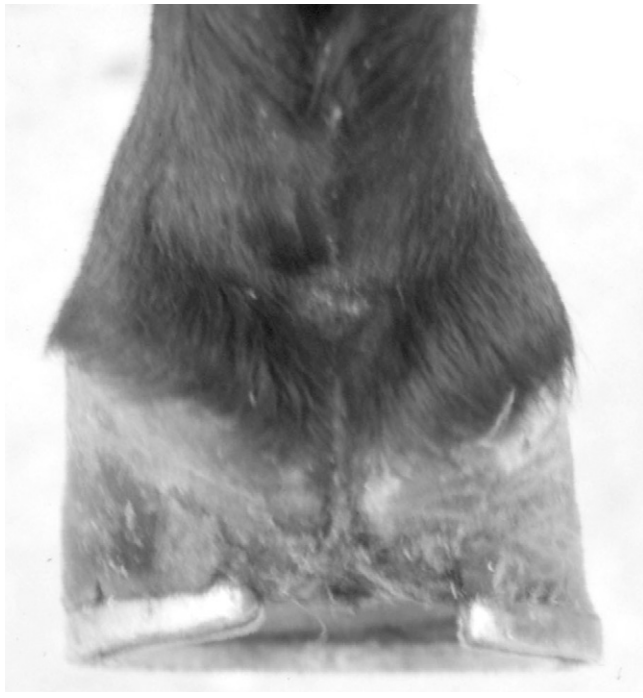

Fig. 6-3 Elevated foot viewed from the palmar aspects shows that the hairline at the medial bulb of heel (on the right) is displaced proximally compared with the lateral heel bulb. The medial wall is longer. Note also the prominent cleft between the heel bulbs. These features are typical of sheared heels.

standing position; it may be necessary to stroke the contralateral limb to divert attention. A hoof pick, wire brush, hoof knife, shoe-removing equipment, and hoof testers are required (Fig. 6-1). The sole and frog and wall of the foot should be cleaned thoroughly. Removal of the shoe at this stage in the examination usually is indicated only if a sub-solar abscess is suspected. The veterinarian should take care to preserve the hoof wall, and if cracked, protect it with tape.

Foot and hoof balance are assessed by evaluating toe and heel length, hoof capsule conformation, condition and integrity, type of shoe and shoe position relative to the hoof capsule, hoof and pastern angle (axis), medial to lateral hoof balance, coronary band conformation, and distal interphalangeal (coffin) joint capsule distention and response to hoof testers. The coronary band should normally be parallel to the ground surface. Deviation from parallel often indicates mediolateral foot imbalance (Fig. 6-2). Medial and lateral wall lengths should be assessed while the horse is standing and again with the limb off the ground, viewing the foot from palmar to dorsal along the solar aspect. The limb is lifted and held in neutral position so the solar surface is perpendicular to the ground. Sheared and underrun heels are commonly associated with lameness (Fig. 6-3). Deformation of the hoof capsule is not necessarily a cause of lameness. Many horses with proximal displacement of the medial heel bulb have level foot strikes and otherwise balanced feet. Toe and heel length should be assessed, and the hoof-pastern axis should be determined. The angle of the hoof and pastern should be equal to allow equal loading of all portions of the foot. Forelimb hoof-pastern angles normally range from 48° to 55°, but the absolute angle should not be overemphasized. A straight pastern-foot axis is more important. A long-toe, underrun heel foot conformation causes a broken foot axis and predisposes to palmar heel pain (Fig. 6-4).

The conformation, condition, and integrity of the hoof capsule should be assessed. It is easy to miss hoof wall defects on the medial aspect. Small quarter or heel cracks and defects at the

Fig. 6-4 This trotter has long toe, under-run heel hoof conformation, and broken hoof-pastern axis.

coronary band should not be overlooked. The clinician should evaluate the solar surface, bars, and frog. Thrush, although a reflection of poor management, rarely causes lameness.

The shoe type, shoe wear patterns, and the shoe size relative to the foot need to be assessed. The clinician should note the presence of pads or additions to the shoe, such as toe grabs, borium, and heel caulks. There is an association between toe grabs and suspensory apparatus failure in TB racehorses.[3] Low heel angle also has been associated with injury.[4] Shoe wear is important, because it reflects how the horse has been moving over the last several weeks. The clinician should note the breakover point and whether one branch of the shoe is worn more than the other. Shoe size should be assessed relative to foot size and the fit of the shoe. A shoe that is too small or set too close to the frog may predispose to lameness.

Careful palpation of the coronary band in the standing and non–weight-bearing position is critical in detecting foot soreness (Fig. 6-5). In horses with sore feet, heat and pain often are detected on the sore side of the foot, and a prominent digital pulse usually is present. Effusion of the distal interphalangeal joint capsule accompanies many abnormalities of the foot, from early synovitis to chronic osteoarthritis of the distal interphalangeal joint, and those with non-specific foot soreness. The clinician places one finger lateral to, and another medial to, the common digital extensor tendon and gently pushes in on the joint capsule, first laterally and then medially. *Ballottement* is a useful technique to detect effusion in many synovial structures: with effusion, pushing in on the capsule on one side of the tendon causes elevation of the capsule on the other side.

The clinician should palpate the cartilages of the foot, either with the horse standing or with the limb elevated. *Sidebone,* mineralization of the cartilages of the foot, rarely causes lameness. The cartilages of the foot normally are pliable and readily compressed axially. Fracture at the attachment of the cartilage of the foot to the distal phalanx is an occasional cause of lameness, and compression of the heel with hoof testers may elicit pain in some horses.

Fig. 6-5 Palpation of the coronary band should include assessing the dorsal joint pouch of the distal interphalangeal joint. In this horse, distal interphalangeal effusion and fibrosis appear as a bulge just proximal to the coronary band, dorsally.

Hoof Tester Examination

"…I feel naked going into a stall without my hoof testers!"[5] Hoof testers are essential for evaluation of the foot and are a basic requirement for all lameness examinations. Many types of hoof testers are available (Fig. 6-6), but I favor one that is adjustable and can be applied with one hand. A proper evaluation of the foot with hoof testers cannot be done with a pad in place, although useful information can be acquired. The instrument can be applied with or without a shoe in place. The amount of force to apply varies from horse to horse and by region of the hoof, and both false-positive and false-negative responses occur. More force is required when the instrument is used across the heels than when used from sole to quarter. The foot should be held between the clinician's legs in a relaxed manner. The clinician must be able to feel the horse react to subtle pressure, and if the leg is held too tightly or the horse is not calm during the examination, it is difficult to feel a response. The veterinarian should be careful not to place the outside jaw of the instrument too close to the coronary band, because this may cause a false-positive result. Sole sensitivity is assessed by applying the instrument to three to five sites from heel to toe, on both the medial and lateral aspects of the foot, starting from the angle of the sole (seat of the corn) and proceeding dorsally (Fig. 6-7). The responses should be compared. If the sole is readily compressible, pain from bruising, a sub-solar abscess, laminitis, fracture of the distal phalanx, and other injuries may be elicited, but in horses with hard horn the response may be negative. To evaluate sensitivity of the frog and underlying deeper structures, the hoof testers should be applied from the lateral aspect of the frog to the medial wall, and from the medial aspect of the frog to the lateral wall, each in the palmar, mid-portion, and dorsal aspects of the frog (Fig. 6-8). Pain over the middle third of the frog has been attributed to navicular disease or navicular syndrome, but the specificity of this association is questionable and there are many false-negative responses. Horses with generalized foot soreness or any other cause of palmar

Fig. 6-6 A variety of hoof testers are available for lameness examinations. I prefer hoof testers that are easily adjusted and used in one hand (*two pairs on the right*). Large hoof testers (*left*) can be applied only with two hands, and small hoof testers (*bottom*) are inappropriate for medium to large hooves.

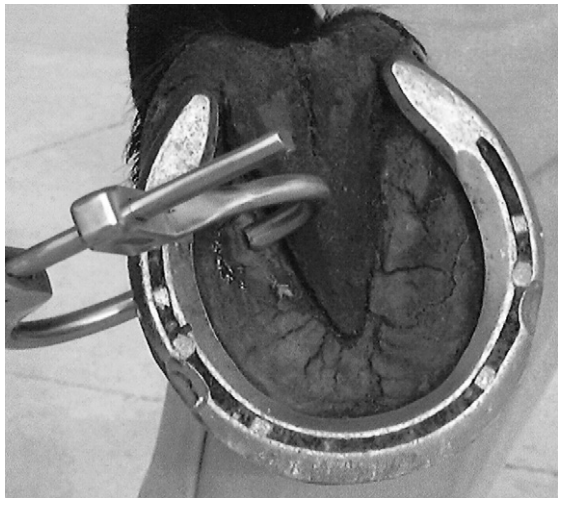

Fig. 6-7 Hoof testers should be applied from the sole to the wall, from the heel to toe, and to both sides of the hoof.

heel pain may respond positively or not at all. Only 19 of 42 horses with navicular region pain responded positively to hoof tester examination in the middle third of the frog, with 50% specificity, 50% positive predictive value, and 48% accuracy.[6] Horses with palmar heel pain caused by other conditions were as likely to respond to the test, a finding that obviously prompts questioning of the value of hoof tester examination.[6] It is difficult if not impossible to create adequate pressure to cause pain in large breed horses or if the horn is hard. Application of a poultice or soaking the foot may be necessary to soften a hard foot, and re-examination after several days may be rewarding. Hoof tester application to the small feet of foals or ponies may elicit a false-positive response, and hoof tester size or amount of compression may require adjustment.

Application of hoof testers across the heels may cause pain in horses with palmar heel pain but is not specific (Fig. 6-9). Application of the hoof tester to the area of the sole adjacent to each nail, nail hole, or defect in the sole or white line, is useful

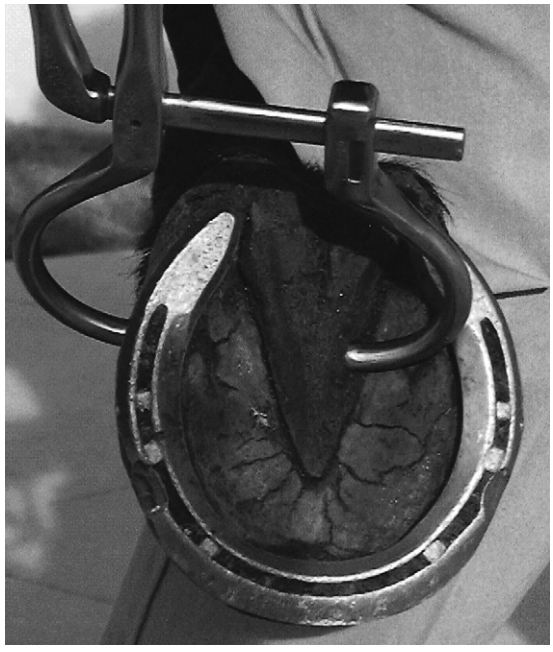

Fig. 6-8 Hoof testers applied from the middle of the frog to the contralateral hoof wall put pressure on the navicular region. Horses with many abnormal conditions of the hoof may manifest a positive response.

Fig. 6-9 Adjustable hoof testers are easily placed across the heels. I prefer to apply hoof testers in this manner to assess horses for palmar heel pain during static examination and as a provocative test for lameness.

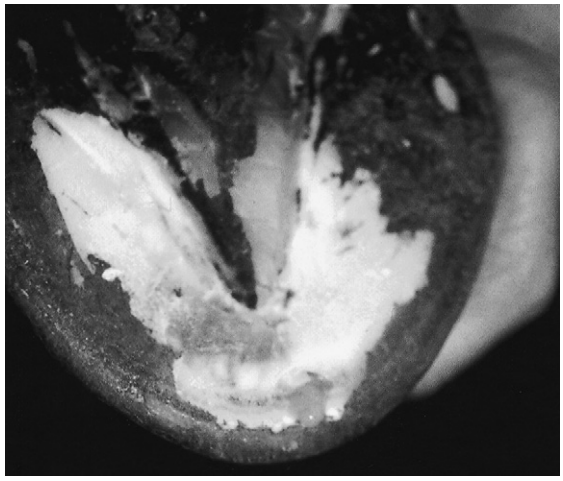

Fig. 6-10 Acute, severe lameness causing increase in digital pulse and profound hoof tester sensitivity in the toe region resulted from this hoof abscess. Exudate drains from the pared region at the toe. (Courtesy Greg Staller, Pottersville, New Jersey.)

to detect a sub-solar abscess or a close nail (Fig. 6-10). Areas of pain can be gently explored with a hoof knife, but unless clearly indicated, the veterinarian should refrain from digging too deep. The hoof tester can then be used as a hammer to percuss each nail in the shoe and the frog and toe regions.

After completing the hoof tester examination, the clinician should re-assess the digital pulses. In horses with foot pain the digital pulse may now be bounding. Horses that have recently been shod or trimmed, or have raced or performed recently, especially on hard surfaces, may have mild elevations in digital pulse and may show hoof tester sensitivity normally. Pain causing lameness may not be in the foot.

Pastern

The proximal interphalangeal (pastern) joint capsule is assessed by ballottement, although severe effusion must be present to perceive fluid distention. Bony swelling associated with this joint, proximal or high ringbone, is a classic cause of lameness yet an unusual clinical finding. Osteoarthritis of the proximal interphalangeal joint is a common diagnosis, but one made by a combination of clinical findings, diagnostic analgesia, radiography, and sometimes scintigraphy. The distal extent of the digital flexor tendon sheath (DFTS), deep digital flexor tendon (DDFT), and distal sesamoidean ligaments are palpated. Deep pain associated with the origin and insertion of these structures is assessed by palpation with the limb in flexion (Fig. 6-11). The oblique sesamoidean ligaments are difficult to differentiate from the branches of the SDFT, but injury of the SDFT is more common. Distal sesamoidean desmitis or chronic suspensory desmitis may result in subluxation of the proximal interphalangeal joint (Fig. 6-12). The proximal interphalangeal joint is manipulated in a medial to lateral direction to assess pain and collateral ligament integrity and is flexed independently of the fetlock joint. The proximal, dorsal aspect of the proximal phalanx is palpated (Fig. 6-13). Horses with short, mid-sagittal fractures of the proximal phalanx may show pain. Occasionally enthesophyte formation at the common digital extensor tendon attachment, seen most commonly in older, ex-racehorses with chronic osteoarthritis of the fetlock joint, results in prominent bony and soft tissue swelling and pain on palpation.

Fetlock

The clinician palpates the joint capsule of the metacarpophalangeal (fetlock) joint with the limb bearing weight, bearing in mind that pain associated with the joint can be present

Fig. 6-11 Palpation of oblique distal sesamoidean ligaments.

Fig. 6-12 Subluxation and osteoarthritis of the left front proximal interphalangeal joint resulted from primary suspensory desmitis.

without localizing clinical signs. The dorsal aspect is palpated using ballottement on either side of the common digital extensor tendon. The clinician should determine whether localized heat is present. *Osselets* is a North American term used to describe early osteoarthritis of the metacarpophalangeal joint in young racehorses, with firm bony and soft tissue swelling on

Fig. 6-13 Proliferative changes at the common digital extensor attachment or pain from mid-sagittal fracture of the proximal phalanx should be palpated along the dorsal, proximal aspect of the proximal phalanx.

Fig. 6-14 Digital pulse quality can be assessed easily at the level of the proximal sesamoid bones.

the dorsal, medial aspect of the proximal phalanx, and the distal aspect of McIII, caused by traumatic capsulitis and early enthesophyte formation. Occasionally in horses with prominent effusion of the metacarpophalangeal joint, a soft tissue swelling can be palpated in the proximal, dorsal aspect of the joint from excessive proliferation of the dorsal synovial pads, called *proliferative* or *villonodular synovitis*. The palmar pouch of the metacarpophalangeal joint is palpated dorsal to the SL branches, both medially and laterally. Mild effusion may be present without associated lameness, especially in older performance horses. The PSBs are palpated and assessed for mild swelling and heat, clinical signs of sesamoiditis, or SL avulsion injury. The digital pulse is re-assessed by placing fingers both medially and laterally, abaxial to both PSBs (Fig. 6-14).

The DFTS extends from the distal metacarpal region to the distal palmar pastern. Usually no palpable fluid is found. Effusion of the DFTS (tenosynovitis) causes swelling in the palmar fetlock region that must be differentiated from effusion of the metacarpophalangeal joint. Tenosynovitis causes swelling *palmar* to the branches of the SL medially and laterally. Fluid can be compressed from medial to lateral. With severe effusion, distention is found in the palmar pastern, but there may be distention proximal to the palmar annular ligament without obvious distention distally. *Wind puffs* or *wind galls* describe incidental fluid distention of the DFTS, commonly seen in older performance horses unassociated with lameness. Tenosynovitis can cause lameness, but additional diagnostic techniques are required to confirm the diagnosis.

The limb is elevated to assess range of joint motion and the horse's response to flexion. Normally the fetlock can be flexed to 90° (the angle between the proximal phalanx and McIII) or slightly more. A reduction in fetlock flexion range is indicative of chronic fibrosis but is not necessarily a cause for concern. A pronounced response to static flexion is noteworthy, but many horses resent static flexion but do not show a positive response to dynamic flexion (lower limb or fetlock flexion tests; see Chapter 8). Horses with clinically relevant tenosynovitis usually strongly resent fetlock flexion. With the limb in flexion, the clinician palpates the PSBs and the branches of the SL, avoiding compression of the palmar digital nerves.

Metacarpal Region

The clinician should assess the dorsal aspect of McIII for heat and swelling. This is a common area for traumatic injury (barked shins) or stress-related bone injury (bucked shin syndrome). Many ex-racehorses have incidental, prominent, chronic, and non-painful swelling of McIII caused by extensive modeling and remodeling of the dorsal cortex while in race training. Racehorses currently in training may have heat and pain on deep palpation (performed with the limb elevated), but prominent swelling may be lacking. Any combination of palpation findings is possible in horses with stress-related bone injury of McIII. It is difficult to apply deep pressure to the dorsal aspect of McIII without concomitant pressure to the palmar soft tissue structures or PSBs, so the responses should be assessed carefully.

The entire length (abaxial surface) of the second and fourth metacarpal bones (McII/IV) should be palpated with the horse in the standing position to detect exostoses, callus, or fractures. Swelling of the SL branches or body may make this difficult. Palpation of McII/IV should be repeated with the limb elevated, because the axial aspect of these bones is impossible to assess in the weight-bearing position. Splint exostoses are common, particularly in young horses. Therefore the presence of even large bony swellings is not unusual. Exostoses detected axially, possibly impinging on the SL (or so-called blind splints) should be carefully noted. Pain from even small exostoses of McII/IV usually is more accurately assessed immediately after training or racing, because pain and lameness resulting from these swellings can be subtle and transient. The clinician should carefully palpate the SL branches. Differentiation of branch or SL body injuries is important: the latter injuries usually are more serious and have a worse prognosis.

The medial and lateral palmar digital vein, artery, and nerve, in dorsal to palmar orientation, respectively, are located between the SL and DDFT. The accessory ligament (distal or inferior check ligament) of the DDFT (ALDDFT) normally is difficult to palpate and even when enlarged cannot easily be differentiated from the DDFT, but injuries of the ALDDFT are more common. All soft tissue structures should be palpated

Fig. 6-15 The soft tissue structures in the palmar metacarpal region should be carefully palpated with the horse in standing and flexed (shown) positions for heat, pain on compression, and swelling. Most ridden horses have mild pain, but in racehorses a painful response is an early sign of tendonitis or desmitis.

carefully, using digital compression, with the limb elevated (Fig. 6-15). Acute or chronic swelling should be assessed, as should the horse's response to deep palpation. Obvious swelling and pain indicate the presence of tendonitis or desmitis. In some horses with acute severe tendonitis or desmitis the structure feels "mushy" or soft in the area of fiber damage. This finding, especially in horses with fetlock drop, indicates near rupture of the structure. There are many false-positive and even false-negative responses to palpation of the flexor tendons and SL. In most ridden performance horses a mild painful response (false-positive) to deep palpation of the SL is normal. However, in racehorses, false-positive responses are less common, and a painful response to deep palpation may indicate the presence of early desmitis or tendonitis. In many horses with foot lameness, secondary, mild suspensory desmitis is common. There is a painful response to palpation of the body and origin of the SL. It may be difficult to decide whether this is a true or false-positive response, a determination that often is made in hindsight after the lameness examination is finished. False-positive and false-negative responses to palpation of the proximal palmar metacarpal region also occur. This is a common site of lameness and should be examined carefully. Palpation must be done with the limb in flexion, and the presence of swelling and pain must be carefully interpreted (Fig. 6-16). Horses with acute injuries, such as proximal suspensory desmitis (PSD), avulsion or longitudinal fracture of McIII, and stress reaction of McIII at the origin of the SL, may have swelling and pain. Deep palpation may create pressure on the palmar metacarpal nerves resulting in a false-positive pain response, and many horses with PSD have no localizing signs.

The proximal dorsal aspect of McIII should be palpated in a flexed position (Fig. 6-17). Occasionally, dorsomedial articular fracture of McIII results in a subtle painful swelling. Swelling (effusion) of the carpal sheath may be detected in the proximal medial metacarpal region, but large veins (medial palmar, accessory cephalic, and cephalic veins), may interfere with accurate palpation. With mild tenosynovitis, effusion may be difficult to discern.

Carpus

Detection of warmth on the dorsal aspect of the carpus is a reliable indicator of underlying inflammation. Obviously, one side should be compared with the other, but bilateral conditions exist commonly. Previous application of counterirritants interferes with the reliable detection of warmth. Carpal joint lameness without obvious signs of synovitis is common, but if present, effusion is easily palpated using ballottement. With the horse in the standing position, a finger is placed dorsolaterally between the extensor carpi radialis and common digital

Fig. 6-16 Palpation of the proximopalmar metacarpal region is essential in diagnosing proximal suspensory desmitis and other conditions of the suspensory origin and differentiating lameness in the region from carpal lameness. (Courtesy Ross Rich, Cave Creek, Arizona.)

Fig. 6-17 Careful palpation of the proximal, dorsal metacarpal region identifies pain associated with dorsomedial articular fracture or other fractures of the proximal aspect of the third metacarpal bone. (Courtesy Ross Rich, Cave Creek, Arizona.)

Fig. 6-18 Carpal tenosynovitis must be differentiated from effusion of the antebrachiocarpal joint. This horse with severe superficial digital flexor tendonitis has moderate distention of the carpal sheath (*arrow*) in the caudal, distal aspect of the antebrachium and medially in the proximal metacarpal region (not shown).

extensor tendons, and another finger is placed just medial to the extensor carpi radialis tendon. These openings are used for palpation and arthrocentesis of both the middle carpal and antebrachiocarpal joints. The middle carpal and carpometacarpal joints always communicate, but a small synovial compartment and dense overlying soft tissue structures limit palpation of the carpometacarpal joint. Both the middle carpal and antebrachiocarpal joints have a palmarolateral pouch that may be distended if effusion is severe. If swelling is detected just caudal to the radius, it is necessary to differentiate distention of the palmarolateral pouch of the antebrachiocarpal joint from the carpal sheath (Fig. 6-18). In horses with antebrachiocarpal joint effusion the dorsal outpouchings also should be prominent, whereas in those with carpal sheath effusion, fluid distention is restricted to the palmar aspect and also detected medially, both proximal and distal to the accessory carpal bone.

Tenosynovitis of the extensor carpi radialis, common digital extensor, or lateral digital extensor sheaths results in vertically oriented swellings that traverse the carpal joints, may extend proximal or distal to the carpus, and usually are multi-lobed, being divided by bands of extensor retinaculum located dorsally and laterally.

Normally the carpus can easily be flexed completely, so that the palmar metacarpal region and bulbs of the heel touch the caudal antebrachium. Reduced flexion may be caused by pain with or without chronic fibrosis associated with osteoarthritis. Pain during carpal flexion is a reliable indicator of carpal region lameness but does not indicate the cause. The carpal sheath is compressed and the extensor tendons are stretched during this maneuver, and conditions involving these structures and the accessory carpal bone can cause pain during

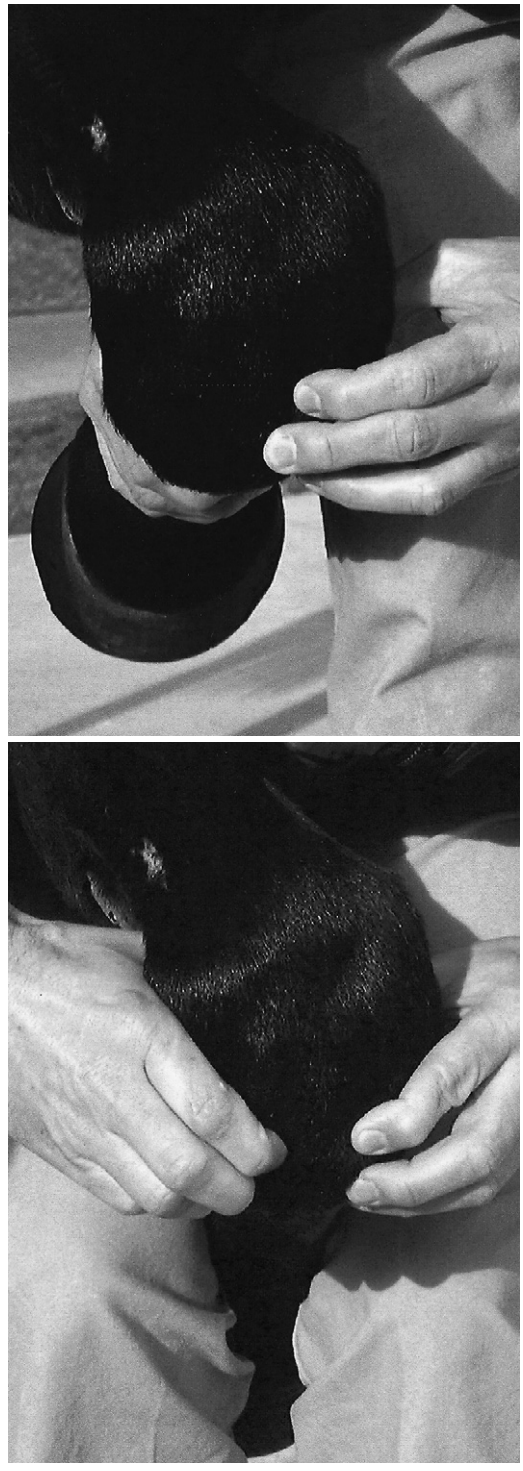

Fig. 6-19 Careful palpation of the dorsal aspect of each carpal bone can be done with one hand (**A**) or by placing the distal limb between the clinician's legs and using both hands (**B**). A painful response indicates an osteochondral fragment or an osteophyte. Occasionally a loose osteochondral fragment can be palpated.

flexion. The elbow joint is flexed simultaneously; therefore a positive response to carpal flexion can rarely result from elbow pain. The examiner should palpate the dorsal surfaces of the carpal bones with the limb in partial flexion (Fig. 6-19). Many pathological conditions associated with the carpus are manifested dorsally, and pain associated with osteochondral fragmentation, slab fractures or other severe injuries, or

osteoarthritis can be assessed with the limb in this position. Focal pain can be identified, and occasionally loose fragments associated with the third carpal bone or distal lateral radius can be identified.

Antebrachium (Forearm)

Digital palpation of the forearm usually is performed with the limb bearing weight. The examiner should look primarily for muscle atrophy, wounds, or mild swelling associated with the radius. Small wounds in the antebrachium may look innocuous, but inappropriately severe lameness and pain on palpation may reflect a spiral radial fracture. The examiner should pay particular attention to the medial aspect of the limb; this area is easily overlooked when palpating from the lateral side. Distally, fluid distention of the carpal sheath or acute swelling associated with injury of the accessory (proximal or superior check ligament) ligament of the SDFT, or the flexor muscles and tendons can occur. The amount of muscle in the extensors and flexors should be compared with the contralateral limb, because subtle atrophy may be missed during observation.

Elbow

Frank swelling and prominent lameness accompanies many injuries of the elbow region, but other problems of the elbow joint are discovered only after diagnostic analgesia has localized pain to this area or by use of advanced imaging modalities. It is nearly impossible to use diagnostic analgesic techniques to abolish pain in the distal humerus and proximal radius and ulna; therefore advanced imaging techniques are often required to identify problems in these structures. The clinician should palpate the olecranon process and the lateral and medial collateral ligaments with the limb bearing weight. Effusion is difficult to detect, but excess fluid occasionally can be found using ballottement, by placing fingers both cranial and caudal to the lateral collateral ligament. The elbow is flexed by pulling the distal limb in a cranial and proximal direction, and then extended, by pulling the lower limb in a caudal direction. The shoulder joint is undergoing the opposite reaction during this manipulation, and pain associated with that joint or the bicipital bursa can cause a positive response during elbow manipulation.

Brachium (Arm) and Shoulder

The shoulder and intertubercular (bicipital) bursa are regularly blamed as the cause of lameness yet are seldom involved. Normal horses may resent palpation of this area. Pain in the muscles surrounding the shoulder joint may develop *secondary* to primary lower limb lameness. In Standardbred (STB) racehorses with carpal lameness, secondary pain often is detected when palpating the bicipital bursa.

Palpation of the arm is limited because overlying muscles obscure much of the humerus. Horses with displaced humeral fractures usually are unwilling to bear weight and have severe soft tissue swelling. Those with humeral stress fractures usually have no localizing signs except a positive response to upper limb manipulation. A normal intertubercular (bicipital) bursa is not palpable. Horses with bicipital bursitis usually resent direct compression of the greater tubercle of the humerus and fluid distention may be palpable, but ballottement is usually limited. Effusion of the scapulohumeral (shoulder) joint is palpable only if severe and even then is easily overlooked.

Upper limb manipulation, including static flexion and extension to assess the range of motion of the shoulder and elbow joints and the presence of a painful response, should always be performed. This can be done during palpation of the elbow or later when the clinician finishes the shoulder region. Most horses with shoulder joint lameness or bicipital bursitis show a painful response when the limb is pulled back (shoulder flexion, elbow extension), whereas those with elbow lameness may show a painful response when the limb is pulled forward (shoulder extension, elbow flexion).

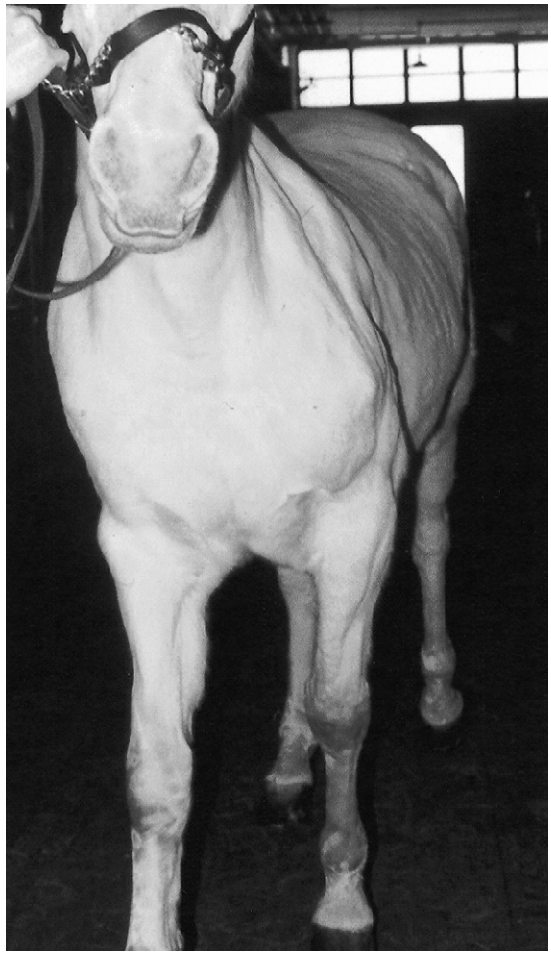

Fig. 6-20 This horse shows atrophy of the supraspinatus and infraspinatus muscles with concomitant lateral subluxation of the left shoulder joint.

The examiner should palpate the scapular area and move the mane if necessary. Atrophy of the infraspinatus and supraspinatus muscles may indicate suprascapular nerve or brachial plexus injury (Fig. 6-20). Muscle atrophy of these and other forelimb muscles can be caused by other neurogenic causes or by disuse. Upper limb palpation often is used to confirm those findings recognized during observation of the horse. Scapular height is compared manually. Although rare, damage to the innervation of the serratus ventralis muscle allows abnormal elevation of the injured side when the horse is standing or during movement. Pectoral muscle atrophy can easily be missed during observation, and the pectoral region should be palpated to assess pectoral muscle mass and identify swellings or wounds that may cause lameness.

PALPATION OF THE CERVICAL AND THORACOLUMBAR SPINE

Cervical Spine (Neck)

Palpation of the neck is limited. I usually palpate the brachiocephalicus muscle after shoulder palpation and manipulation, a procedure thought to have predictive, but non-specific value in horses with forelimb lameness.[8] The muscle is squeezed just cranial to the shoulder joint; most horses flinch, but some

horses with ipsilateral forelimb lameness show a marked painful response. The examiner should palpate both sides of the neck, noting any swelling or muscle atrophy. Cervical abscessation can cause signs of neck pain and forelimb lameness. Muscle atrophy may indicate long-standing cervical pain or ipsilateral forelimb lameness. Muscle development of the neck may be asymmetrical especially if viewed from above (the perspective of a rider).[2] Palpation of the poll region is important because undue soreness cranial to the wings of the atlas may be associated with poor performance.[2] The head should be moved from side to side to evaluate the horse's willingness to move the neck. One hand is place on the mid-cervical region to use as a fulcrum, and the other hand is used to bend the head and neck toward the examiner. Food also can be used to entice the horse to move the head and neck from side to side. Normally a horse can reach around to the girth region on either side to ingest food, and reluctance to do so may indicate neck pain. This procedure may more closely mimic the horse's natural head and neck movement than using a hand in the mid-cervical area as a fulcrum. A more comprehensive examination, including neurological or chiropractic evaluations, may be necessary after completion of the lameness examination. Up and down movement of the head also should be assessed. Although usually not a part of a routine lameness examination, evaluation of the temporomandibular joints and the mouth may be necessary in horses with poor performance.[2]

Thoracolumbar Spine (Back)

Additional detailed palpation of the back and pelvis may be necessary once the lameness examination is completed. Chiropractic manipulation and assessment of acupuncture points may be useful, but it usually is reserved for specific horses or when history and clinical signs warrant such an examination and if the clinician is qualified to complete it. The cranial thoracic spine has already been briefly evaluated during examination of the shoulder for scapular symmetry. The withers should be examined closely for conformational abnormalities, such as those seen with fracture of the dorsal spinous processes or fistulous withers. The presence of sores may indicate an ill-fitting saddle and can cause performance-related problems. Using a hand on each side of the spine the examiner should apply digital pressure to assess vertebral height, presence of pain, muscle atrophy, and to confirm symmetry (Fig. 6-21). Many horses resent deep and aggressive palpation of the epaxial muscles, and the response of normal horses should be learned before a pathological response is presumed. Most horses readily become mildly lordotic ("scootch") during deep digital palpation or by using a blunt object such as a pen. Some clinicians prefer to use the ends of the fingers to "run" (apply digital pressure while moving the fingers caudally) the muscles from cranial to caudal, parallel to the spinal column. When this is continued along the gluteal muscles and rump. most normal horses become somewhat kyphotic and move forward slightly. Aggressive use of blunt or sharp objects to assess pain should be avoided. Some horses are stoic during palpation, and it may be impossible to stimulate them to extend and flex the thoracolumbar region without the use of a blunt instrument.[2] In these horses, firmly stroking the ventral abdomen may stimulate movement.[2] With one hand on the horse's back during movement of the thoracolumbar spine, the clinician may be able to feel muscle "cracking" during the release of tension in the epaxial muscles.[2] The observation of muscle fasciculations during or after palpation usually indicates a degree of muscle pain. Failure to exhibit the normal lordotic or kyphotic responses, assuming a guarded posture, or vocalizing during the examination are further signs of back pain.

In many horses, back pain, and more specifically, muscle pain, is secondary to hindlimb lameness, resulting from altered gait and posture. Any site of pain in the hindlimb may alter the gait to cause secondary upper limb or back muscle pain. The use of diagnostic analgesia to confirm the primary source of pain (in the hindlimb or locally in the back) may be required to make the true diagnosis. Back pain often is complex and may be caused by many factors including ill-fitting saddles, poor riding, and other primary problems, such as overriding of dorsal spinous processes or other bony causes. The clinician should palpate carefully to detect localized swelling in the area of the saddle. Even small areas of hair loss without swelling may indicate a loose or ill-fitting saddle, abnormal movement of the saddle associated with hindlimb lameness, or a rider sitting crookedly.[2]

Fig. 6-21 Palpation of the thoracolumbar region should be performed in a quiet, careful manner. Many horses object to sudden or sharp stimuli applied to this region. Direct, even pressure is applied to the epaxial muscles (*shown*) and the summits of the dorsal spinous processes.

It is doubtful that muscular pain alone can cause unilateral hindlimb lameness. Back pain was induced in STB horses by injection of lactic acid into the left longissimus dorsi muscle and subsequently exercised and observed with high-speed cinematography.[8] Frank lameness was not observed, but there was slight modification of left hindlimb stride and reduced performance. This supports the clinical observation that back pain usually is the result, not the cause, of obvious hindlimb lameness, although it may result in slight alterations in gait. Severe vertebral abnormalities or an abscess in the epaxial muscles may result in lameness or neurological dysfunction.

PALPATION OF THE LATERAL AND VENTRAL THORAX AND ABDOMEN

History or observation of lameness, performance, or behavioral abnormalities seen only when a horse is ridden or wearing tack should prompt examination of the thoracic region. Irritation from an ill-fitting girth or other sores or wounds can contribute to poor performance, and injury of the sternum or ribs can cause pain associated with saddling or being ridden. Traumatically induced hernias of the ventral abdomen can cause gait deficits or guarding of the abdomen.

PALPATION OF THE EXTERNAL GENITALIA

Testicular or inguinal pain should be considered as a cause of gait modification. Swelling, infection from previous castration, scirrhous cord, and mastitis can cause a change in gait. The veterinarian should determine the sex of the horse and the presence of one or both testicles.

PALPATION OF THE PELVIS

Palpation of the pelvis is performed to confirm previous observations. The horse should stand as squarely as possible. The clinician should palpate all bony protuberances, including the tubera coxae, tubera sacrale, and tubera ischii. The examiner stands behind the horse and palpates these paired protuberances simultaneously if it is safe to do so (Fig. 6-22). Fracture of a tuber coxae or ilial shaft may result in asymmetry, but if the ventral aspect of the tuber coxae is fractured, the height of the dorsal aspect may be equal to the contralateral side, but the anatomy of the ventral aspect is distorted. Small muscle defects may be associated with fracture or enthesopathy of the tubera ischii, but even with a displaced fracture, palpation of this area may be unrewarding (Fig. 6-23). If a pelvic injury or fracture is suspected, the clinician should gently rock (move) the horse from side to side. Subtle crepitus may be detected, but with many pelvic fractures this is not apparent until days to weeks after injury and only during the initial portions of the examination before muscle guarding supervenes. The veterinarian should grasp the tail and elevate it. Many horses resist this, but in those with fractures of the base of the tail (most commonly from sitting in the starting gate or trailer), a true painful response is elicited. Subtle swelling also may be present. Lack of tail tone may indicate neurological disease.

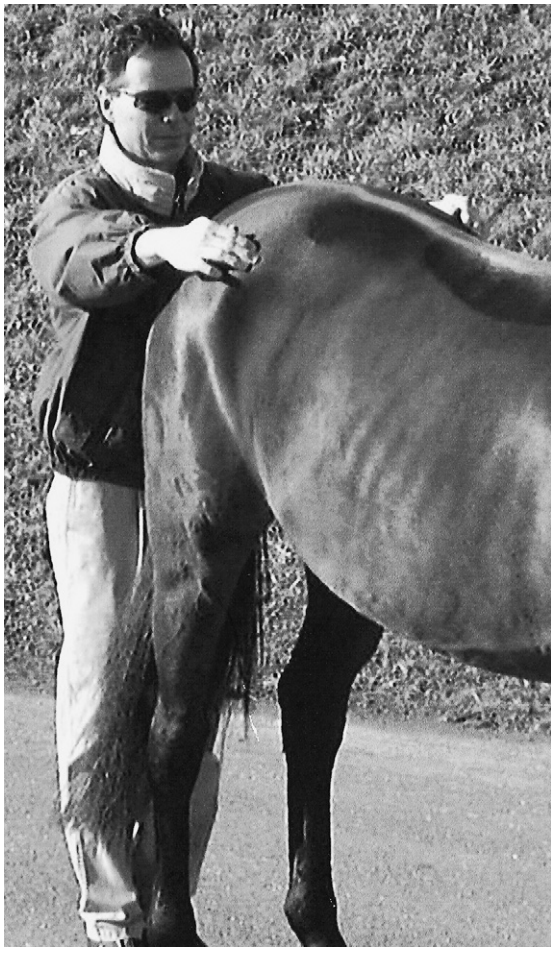

Fig. 6-22 Although the veterinarian must take care when standing behind any horse, this perspective is crucial in determining pelvic heights and widths. The height of each tuber coxae is compared in this photograph. Alternatively, an assistant on each side can be asked to point to a comparable location, or tape can be applied.

Muscle pain and muscle atrophy should be assessed. The clinician carefully examines the gluteal musculature, the origin of the caudal thigh muscles, and the tensor fascia lata (see Chapter 46 for further discussion of muscle assessment and palpation of the greater trochanter of the femur). Pain or soreness noted during palpation of the semimembranosus and semitendinosus muscles may be associated with injury of the ipsilateral tuber ischium.[2]

PALPATION OF THE PELVIS PER RECTUM

Rectal examination is not part of the routine lameness examination and should be reserved as a special examination procedure if pelvic fracture or aortoiliac thrombosis is suspected. With the wrist just inside the anus the veterinarian should palpate the medial and dorsal aspects of the acetabulum, comparing sides. In young horses, there is a membranous junction between pelvic bones in the center of the acetabulum; a defect and a small amount of motion normally can be felt. Just cranial to the acetabulum is the cranial aspect of the pubis (brim of the pelvis). With the arm at elbow depth the examiner should sweep the arm dorsally on each side to palpate the medial aspect of each ilium. The ventral aspect of the sacrum and sacroiliac region are compared. The clinician should compare the pulse quality between the right and left external iliac arteries and evaluate conformation and pulse quality of the terminal aorta and branches. Horses with aortoiliac thromboembolism have abnormal conformation and altered pulse quality. Crepitus may be felt more easily by gently rocking the horse from side to side, picking up one hindlimb, or walking the horse a short distance with the veterinarian's arm still within the rectum.

Asymmetry, swelling, actual fracture lines, fragments or callus, and crepitus are assessed. In horses with acute pelvic fractures, crepitus, fracture fragments or lines, and callus usually are not detectable, but hematoma and soft tissue swelling usually can be felt. In horses with ilial wing or shaft

Fig. 6-23 The tubera ischii (*shown*) and third trochanters are palpated carefully. Enthesopathy or fracture causes lameness that is difficult to locate without careful palpation or scintigraphic examination. Occasionally, horses with small muscle defects located distal to the tubera ischii have chronic lameness from previous fracture. (Courtesy Carolyn Arnold, Kennett Square, Pennsylvania.)

fractures, large fracture hematomas often are present, but the absence of swelling does not preclude presence of ilial fractures. These horses are at risk to develop fatal hemorrhage. Edges of fracture fragments may be evident with comminuted or grossly displaced fractures. With chronic pelvic fractures, crepitus and callus may be more obvious.

PALPATION OF THE HINDLIMB

For safety reasons, I prefer to start proximally and work distally in a hindlimb, allowing the horse to become accustomed to palpation. Horses often object to palpation of the flank and stifle regions, and this should not be misinterpreted as a sign of pain. The clinician should grasp the tail and pull it gently toward himself or herself to keep the ipsilateral hindlimb bearing weight and reduce the chance of the horse kicking. It may be useful to pick up the ipsilateral forelimb. In the large majority of horses the entire limb can be safely examined while bearing weight, but pain in the lame limb or contralateral limb or the horse's behavior may make it difficult or impossible to pick up the limb. Reluctance to pick up the hindlimbs has been attributed to unilateral or bilateral sacroiliac pain.[2] Horses with shivers often are reluctant or anxious to pick up one or both hindlimbs. It may be necessary to spend a small amount of time coaxing the horse to elevate the hindlimb, at first just high enough to examine or pick out the hind foot and then progressing to full flexion. Although historically the hock and stifle joints have been regarded as the principal sources of pain causing hindlimb lameness, there are many other potential sites, and the metatarsal and fetlock regions in particular should be examined with care.

Thigh

The clinician should assess the thigh for swelling, muscle atrophy, or scarring. Horses with femoral fractures usually have obvious severe swelling, crepitus, and instability of the limb. The third trochanter of the femur is difficult to feel, and clinical abnormalities associated with enthesopathy of the insertion of the superficial gluteal muscle or a fracture usually are impossible to detect. Scarring associated with the semitendinosus, semimembranosus, and rarely, the biceps femoris can lead to mechanical gait deficits, known as *fibrotic myopathy*. The gastrocnemius muscle arises from the distal caudal femur, and acute tearing of this muscle may cause swelling in the caudal stifle area. This is difficult to perceive, but severe muscle injury results in a marked postural change, which should provoke more careful assessment of this region.

Stifle

Palpation of the stifle is limited to the cranial, lateral, and medial aspects; unfortunately, the caudal and proximal aspects of the joint are inaccessible. Many horses, especially fillies, object to palpation of the stifle, a normal response often misinterpreted as a painful reaction.

The veterinarian should palpate the stifle with the limb bearing weight. The foot should be flat on the ground. This may be impossible if the horse has severe pain prohibiting complete assessment of the stifle. The limb should be in a neutral and not in an abducted position, and should be perpendicular to the spine or slightly ahead of the other hindlimb. If the limb is retracted, it is more difficult to palpate the patellar ligaments and joint outpouchings. The middle patellar ligament is identified and followed proximally to the distal aspect of the patella. The clinician should feel the femoropatellar joint capsule between either the middle and medial or the middle and lateral patellar ligaments and should determine the presence of effusion. In horses with osteochondrosis dissecans (OCD), fluid distention can be pronounced. However, normal young horses (weanlings to early 2-year-olds) often have prominent bilateral fluid distention of the femoropatellar joint capsules.

The clinician should find the medial patellar ligament and follow it proximally and distally. At the proximal extent, the medial fibrocartilage of the patella can be felt medial to the medial trochlear ridge of the femur. It is this normal arrangement of the medial aspect of the patella and the medial trochlear ridge that allows the veterinarian to determine whether a horse has patellar luxation. The position of the patella is difficult to confirm if the horse is standing with the stifle flexed. True patellar luxation is rare. The examiner should determine if the medial patellar ligament is enlarged, which usually reflects previous desmotomy. Usually a distinct depression is present between the medial patellar ligament and the medial collateral ligament, but effusion of the medial femorotibial (MFT) joint may result in a substantial "bulge" (Fig. 6-24). This may be the only clinical sign indicative of MFT joint injury.

The lateral patellar ligament is palpated from its origin to insertion. Patellar desmitis is unusual, but does occur; it usually involves the middle patellar ligament and may cause mild swelling. Previous injection with counterirritants causes firm, fibrous areas over the patellar ligaments, a common finding in racehorses. Gently rocking the horse from side to side to assess motion of the patella may give some indication of the potential for intermittent upward fixation of the patella (IUFP). In horses prone to IUFP, jerky rather than the normal smooth motion of the patella sometimes is detected.[2] The

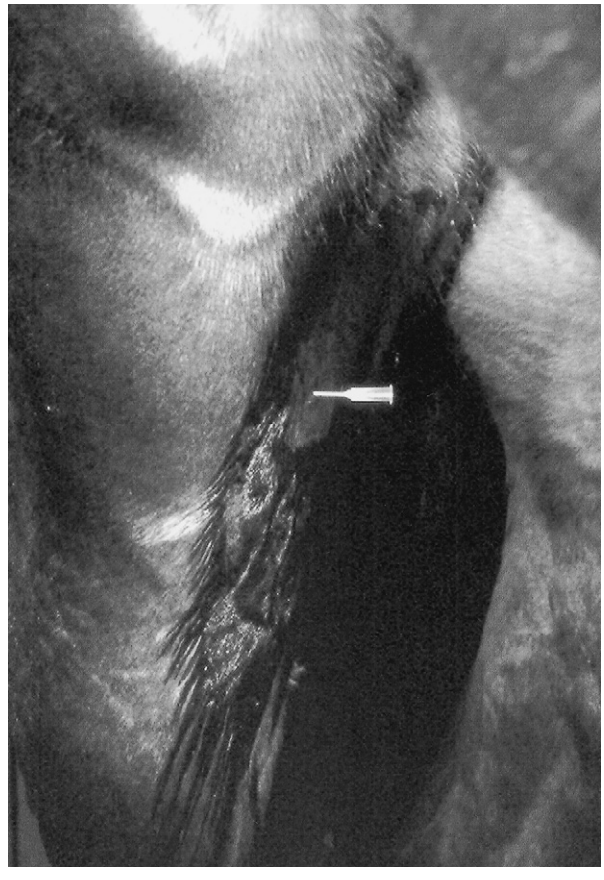

Fig. 6-24 The medial femorotibial joint (right stifle, cranial view) is the most common location for osteoarthritis of the stifle joint and is palpated medially (*needle in joint*) between the medial patellar ligament and the medial collateral ligament. Normally a depression is present at this location, but a bulge from effusion can be palpated.

lateral femorotibial joint capsule is accessed between the lateral patellar and lateral collateral ligaments, but even with severe effusion it is difficult to palpate. Overlying and adjacent soft tissue structures obscure palpation.

Deep palpation of the medial collateral ligament and the medial patellar ligament with the limb in flexion may elicit a painful response in horses with stifle lameness, but it probably is not specific for the source of pain in the stifle. The medial collateral stress test is perhaps the most reliable manipulative test of the stifle, although horses with lower limb lameness also may respond. With the leg in partial flexion, the shoulder or one hand is used as a fulcrum on the lateral aspect of the stifle, and the distal extremity is pulled laterally, thus placing valgus stress on the stifle (Fig. 6-25). Care should be taken because horses may resent this manipulative test. If possible, the valgus motion should be applied by using the shoulder as a fulcrum and both hands on the crus, thus eliminating possible false-positive results from the lower limb. Patellar manipulation may cause a painful response, particularly in horses with femorotibial joint disease. During this procedure, caudal movement of the femur also may exacerbate cruciate injuries. With the limb on the ground in a weight-bearing position, the clinician's hand is placed on the distal aspect of the patella, and the patella is forced upward (Fig. 6-26). Theoretically during this test, multiple movements of the stifle are induced. The patellar ligaments are stretched, the patella is forced proximally, and on release the patella rapidly moves distally against the trochlear ridges, and the femur is forced caudally. Tests to assess cruciate ligament damage have been described but are dangerous to perform, and I have not found them particularly useful.[9] Complete tearing of the cruciate or collateral ligaments is rare, and partial tearing does not cause clinically detectable instability. In horses with severe lameness and gross stifle instability, it is obvious that the stifle is the source of lameness and pain usually prohibits manipulation.

Fig. 6-25 The valgus stress test of the stifle is difficult to perform and is accomplished by using a hand (*shown*) or shoulder as a fulcrum. This test can be done during static examination or a provocative test followed by trotting (see Chapter 8).

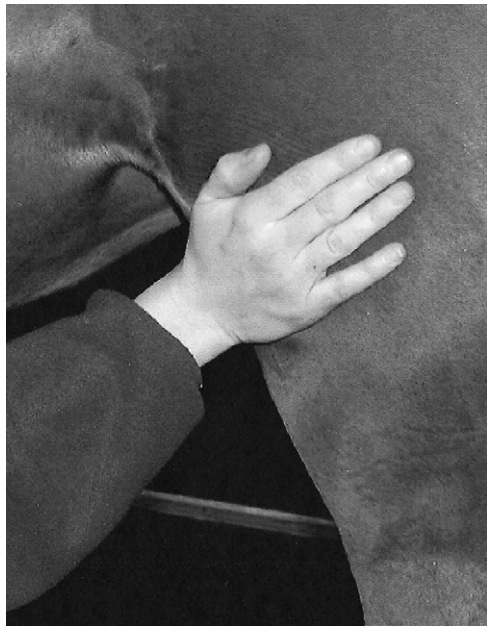

Fig. 6-26 Used as a static or provocative test, patellar manipulation is performed by placing the palm of the hand over the cranial aspect of the patella and manually forcing the patella proximally several times in succession. This maneuver can exacerbate pain from conditions of the patella and femoropatellar joint and forces the distal femur in a caudal direction. Pain from soft tissue injuries such as patellar, cruciate or collateral ligament tears, and osteoarthritis of the femorotibial joints can be exacerbated, but false-negative and false-positive results are common. (Courtesy Carolyn Arnold, Kennett Square, Pennsylvania.)

Crus

The examiner should palpate the crus using both hands with the limb bearing weight. Subtle swelling of the medial aspect of the tibia can be palpated, but palpation of the caudolateral aspect of the tibia, the area in which stress fractures are diagnosed most frequently, is limited. Often no palpable abnormality is associated with a stress fracture. Any small wound or any form of swelling should be thoroughly investigated for the possibility of underlying bone damage, such as an occult tibial fracture. The veterinarian should palpate the caudal soft tissues. Proximally, the musculotendonous junction of the gastrocnemius muscle is a rare site of pain. The common calcaneal tendon is assessed. Swelling may indicate damage to any one of the contributing tendons. Effusion of the tarsal sheath causes swelling just proximal to the tarsus, at the caudal aspect of the crus, and should be differentiated from bog spavin. Deep palpation of the medial and caudal aspects of the crus is performed with the limb elevated (Fig. 6-27). Horses with tibial stress fractures or those with spiral fracture or other tibial trauma may show a painful response, but false-positive responses are frequent. Tibial percussion, performed medially by using a clenched fist (knuckles) as a hammer, may elicit a painful response in horses with stress fractures, but many normal horses resent this test.

Tarsus

Five common swellings of the hock are important to differentiate, but hock swelling is not synonymous with hock pain. *Capped hock* is swelling located at the point of the hock (the proximal aspect of the calcaneus) and usually is an incidental finding, but in some horses the condition does cause lameness (Fig. 6-28). The most common form involves the development of firm, fibrous subcutaneous tissue in the false bursa that lies over the point of the hock. This is a common area for abrasions and excoriation, and fibrous tissue formation results in a blemish but usually no lameness. Horses may be sensitive to palpation if the area has been traumatized recently. Infection or trauma leading to osteitis of the calcaneus can cause a clinically important capped hock and severe lameness. In these horses the problem involves the calcaneal bursa, located between the common calcaneal tendon and the calca-

Fig. 6-27 **A,** Palpation of the medial aspect of the tibia in a flexed position or **B,** tibial percussion in the standing position sometimes elicits pain in horses with tibial stress fractures, but false-positive results are common.

neus. If surrounding soft tissue swelling is minimal, fluid distention of the calcaneal bursa may be felt by ballottement. The bursa can be felt both medially and laterally at the proximal aspect of the calcaneus. Lateral, or less commonly, medial dislocation (luxation) of the SDFT results in similar swelling, but in the acute situation, lameness is present. Careful palpation may reveal the SDFT coursing laterally (Fig. 6-29), unless excessive soft tissue swelling is present.

Effusion of the tarsal sheath, *thoroughpin*, must be differentiated from bog spavin (see following text). Tarsal tenosynovitis causes swelling both medially and laterally in the depression between the calcaneal tendon and caudal tibia (Fig. 6-30). With severe effusion of the tarsal sheath, fluid distention can be palpated distal to the hock on the medial aspect. Thoroughpin usually is an incidental finding, seen most commonly in Western performance horses, but acute lameness accompanied by tarsal tenosynovitis can indicate strain or injury of the sheath, often associated with adjacent bony injury. Unusually, swelling in the distal, caudal crus identical to that seen with classic thoroughpin is seen, but communication with and concomitant swelling of the tarsal sheath is absent.

The term *spavin* refers to "any disease of the hock joint of horses in which enlargements occur, often causing lameness…the enlargement may be due to collection of fluids or to bony growth."[10] *Bog spavin* is fluid distention of the tarsocrural joint capsule. The tarsocrural joint has four outpouchings: dorsolateral, dorsomedial, plantarolateral, and plantaromedial. All joint pouches may be distended, although the dorsomedial and plantarolateral pouches are large and most prominent (Fig. 6-31). Using ballottement, fluid can be pushed between pouches on the dorsal or plantar aspects, thus differentiating this condition from thoroughpin.

Bone spavin refers to fibrous and bony swelling that results from chronic osteoarthritis of the proximal intertarsal, centrodistal, and tarsometatarsal joints. This swelling usually is seen in older horses and can be palpated and observed on the medial side of the hock (Fig. 6-32). Although the bony enlargement is the result of proliferation, it does not necessarily mean the horse is lame as the result of the condition. Most horses with distal hock joint pain do not have palpable enlargement medially, and based on radiographic evaluation, the most common area of proliferation and bony change is dorsolateral. Blood spavin is an old term usually meaning enlargement of the saphenous vein,[3] but it also may have been used to describe a prominent saphenous vein in horses with bog spavin. Saphenous distention is rare and the term is not used today. *Occult* or *blind spavin* is an obsolete term used to describe horses with clinical signs of hock lameness but no observable

Fig. 6-28 Capped hock, a firm fibrous swelling of the proximal aspect of the calcaneus (point of the hock), is considered a blemish, but with effusion of the calcaneal bursa (not shown), lameness is substantial.

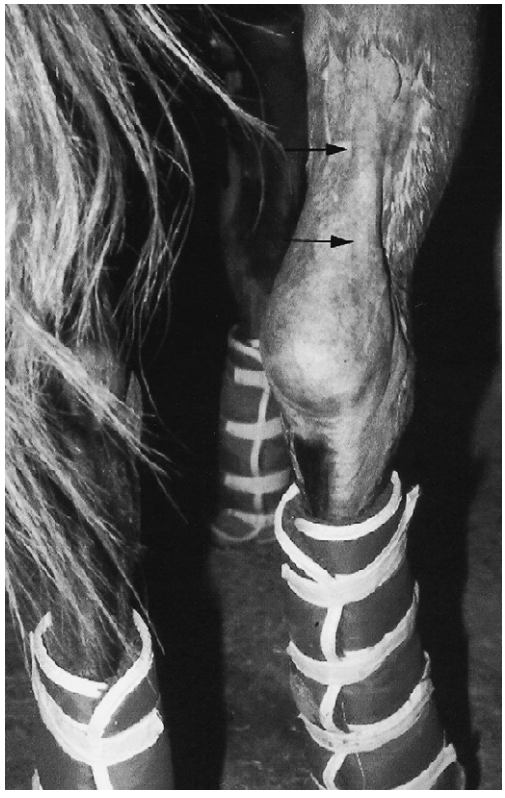

Fig. 6-29 Lateral dislocation (luxation) of the superficial digital flexor tendon. Instead of attaching to the tuber calcanei, the superficial digital flexor tendon (*arrows*) is now located lateral to the point of the hock. Initial swelling makes this diagnosis difficult.

Fig. 6-31 Moderate to severe tarsocrural effusion, bog spavin, in this draft filly was caused by osteochondritis dissecans of the distal intermediate ridge of the tibia. Distention of the large dorsomedial pouch and swelling of the dorsolateral, plantarolateral, and plantaromedial pouches was present.

Fig. 6-30 Thoroughpin, swelling located in the distal, caudal crus, usually is caused by distention of the tarsal sheath and must be differentiated from effusion of the plantarolateral pouch of the tarsocrural joint (bog spavin).

bony swelling.[3] High spavin is also an obsolete term used to describe bone spavin located close to the tarsocrural joint.[3]

Curb describes swelling along the distal, plantar aspect of the hock and has often erroneously been blamed on long plantar desmitis. In most horses the swelling is actually enlargement of the SDF tendon or subcutaneous tissues. The swelling is often firm, but in some horses subcutaneous fluid can be present (see Fig. 79-1). In horses with acute severe injury the swelling may feel soft and mushy. In some normal horses the proximal aspect of MtIV is prominent and should not be confused with curb.

Swelling restricted to the medial or lateral aspect of the hock may reflect collateral ligament injury. Localized heat on the medial aspect of the hock or on the proximal aspect of the metatarsus may be important findings.

THE CHURCHILL HOCK TEST

• Dan L. Hawkins

The Churchill hock test was developed by Dr. E.A. Churchill in the 1950s as a rapid, non-invasive, specific method to screen and identify distal tarsal pain in athletic horses. Although the test has been used by Dr. Churchill and me primarily in STBs, TBs, and Three-Day Event horses, it is equally reliable when applied to other equine athletes.

Digital pressure is applied on the plantar aspect of the head of the second metatarsal bone (MtII) and fused first and second tarsal bones with the limb in a non–weight-bearing position. Abduction of the limb is a positive response. To

Fig. 6-32 Bone spavin (*arrows*), fibrous and bony swelling on the medial aspect of the distal hock joint (left hindlimb) caused by chronic osteoarthritis of the distal hock joints, sometimes appears in older sport horses but is rare in young racehorses. The presence of bone spavin should be noted and this area should be palpated carefully, but horses can have distal hock pain without bone spavin, and horses with bone spavin can have lameness elsewhere in the limb. Previous cunean tenectomy causes chronic fibrosis in this region.

examine the left tarsus, the clinician approaches the horse facing caudally. The left hindlimb is picked up and brought forward, supported by the clinician's right hand cupped under the fetlock or hoof. Holding the limb so that the hoof is approximately 25 to 30 cm above the ground is most comfortable for the horse. The heel of the left hand is positioned on the proximodorsal surface of the third metatarsal bone (MtIII) while the third phalanges of the index and middle or middle and ring fingers are placed around the medial side of the tarsus to engage the bony ridge formed by the head of MtII and the first and second tarsal bones (the area of insertion of the cunean tendon) (Fig. 6-33). The thumb is rested on the dorsal lateral aspect of the tarsus and proximal MtIII. Gentle, firm pressure is applied to the bony ridge by flexing the phalanges of *only the index and middle fingers* (Fig. 6-34). The hand does not squeeze the hock. Pressure is applied three times approximately 1 second apart, each time with increasing intensity to a maximum effort on the third time.

Proficiency requires patience and routine practice. Consistent diagnostic information can be obtained safely from

Fig. 6-33 Correct left hand placement in the left proximal metatarsal region to perform the Churchill hock test. (Courtesy Dan Hawkins, Dubai, United Arab Emirates.)

Fig. 6-34 The Churchill test is demonstrated on an anatomy specimen. The index and middle fingers are flexed and positioned on the bony ridge formed by the third metatarsal bone and the fused first and second tarsal bones, and the heel of the hand rests on the proximodorsal aspect of the third metatarsal bone. The thumb rests against the dorsolateral aspect of the tarsus. (Courtesy Dan Hawkins, Dubai, United Arab Emirates.)

more than 90% of fit racehorses. If the limb cannot be picked up, the test cannot be performed. Fussing and repeatedly flexing the hock and limb in an agitated manner while the procedure is performed should not be misinterpreted as a positive response.

The Churchill hock test is useful for horses that are not visibly lame, but the trainer or rider has a complaint that the horse is doing something uncharacteristic during work or competition associated with decreased performance. The horse may have a changed attitude toward work, lugs in, is rough in the turns, refuses to change leads, stops at jumps, jumps to one side, or is stiff going in one direction. Although these horses cannot be blocked out at a slow gait, the Churchill hock test may suggest hock pain.

SAPHENOUS FILLING TIME

• **Mike W. Ross**

The veterinarian should assess the saphenous vein filling time. Blood flow in the saphenous vein is prevented using digital compression in the proximal metatarsal region, and the blood accumulated in the vein over the tarsocrural joint is pushed proximally to completely collapse the vein. The finger compressing the vein distal to the hock is then removed, and the time it takes for the saphenous vein to fill is observed. Normally, it takes less than 1 second for the vein to fill, but in horses with reduced circulation, prolonged filling time is seen. Pulse quality of the dorsal metatarsal artery, located on the dorsolateral aspect of MtIII just dorsal to the fourth metatarsal bone (MtIV), can be useful, especially if the history suggests lameness is caused by vascular compromise. The arterial pulse quality is compared with the contralateral limb.

The Metatarsal Region

The veterinarian should palpate the flexor tendons and SL. Tendonitis is unusual in the hindlimb, but occasionally SDF tendonitis occurs in the proximal metatarsal region. This is most common in horses with curb, and tendonitis progresses distally to involve the metatarsal area. The hock angle is evaluated carefully. Occasionally horses with severe curb or those with SDF tendonitis of the metatarsal region have reduced hock angle (obvious unilateral sickle-hocked conformation), indicating loss of support in the SDFT. Once a general palpation for the presence of heat, swelling, exostoses associated with the MtIII, MtII, MtIV, and the proximal aspect of the DFTS is completed, the limb is lifted and deep palpation is performed. The clinician should carefully palpate the origin and body of the SL, keeping in mind that both false-positive and false-negative responses can occur (Fig. 6-35). Much of the palpation of the SL laterally is indirect, since MtIV hides the origin and proximal body. Because the presence of the splint bones and dense metatarsal fascia prevents substantial swelling, or at least the clinical recognition of swelling of the SL, even mild swelling in the proximal, medial metatarsal region should be carefully interpreted. With the limb in flexion, the axial borders of splint bones are palpated. The dorsal aspect of MtIII should also be assessed with the limb in flexion, because bony injury of MtIII does occur and includes dorsal cortical trauma from external injury or interference, dorsal cortical and spiral fractures, and proximal dorsolateral fractures.

Metatarsophalangeal Joint

Many of the common problems of the metatarsophalangeal joint, such as short, mid-sagittal fractures of the proximal phalanx, sesamoiditis, stress or non-adaptive remodeling of MtIII, and osteochondrosis, cause very few clinical signs and while palpation is quite important, diagnostic analgesia is often needed to localize pain to this area. Nonetheless, careful

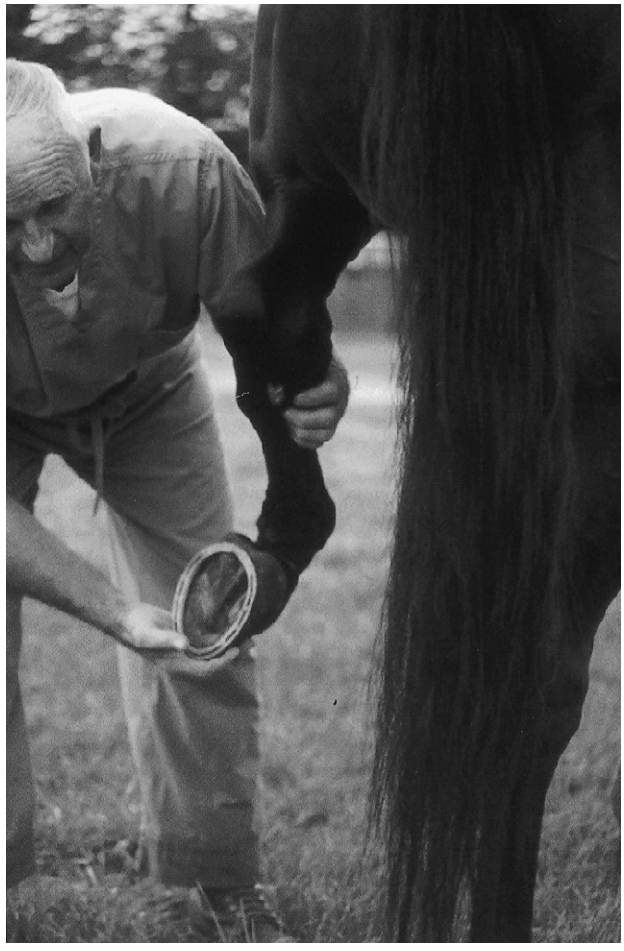

Fig. 6-35 Deep palpation of the proximal suspensory ligament can be performed only with the limb in flexion. The close association of the suspensory origin to the Churchill site explains the need to differentiate proximal plantar metatarsal pain from distal hock joint pain using diagnostic analgesia. (Courtesy Howard "Gene" Gill, Pine Bush, New York.)

palpation of the fetlock region is mandatory. Some horses have concurrent metatarsophalangeal joint and stifle pain and when suspicious findings exist in one site, the veterinarian should look carefully at the other for additional, secondary, or complimentary problems.

The metatarsophalangeal or hind fetlock joint, is evaluated with the limb bearing weight and in flexion. The clinician should assess the metatarsophalangeal joint capsule and the DFTS for the presence of effusion or fibrosis (Fig. 6-36). Incidental effusion of both the metatarsophalangeal joint and DFTS is common in the hindlimb of older performance horses therefore this finding should not be over-interpreted. In younger horses, particularly racehorses, the presence of effusion can be an important clinical sign associated with osteoarthritis or other problems and should be interpreted accordingly. The clinician should carefully palpate for the presence of heat and mild swelling over the surface of both PSBs, subtle but important signs of sesamoiditis. This problem is more prevalent in the hindlimb and causes few clinical signs. The digital pulse should be assessed.

With the fetlock joint in flexion, the veterinarian should palpate the proximal, dorsal aspect of the proximal phalanx for the presence of pain or exostoses (Fig. 6-37) and should apply pressure to the PSBs, avoiding aggressive compression

Fig. 6-36 The metatarsophalangeal joint region often is overlooked during lameness examination. This joint should be palpated carefully with the limb in the standing and flexed (*shown*) positions. (Courtesy Ross Rich, Cave Creek, Arizona.)

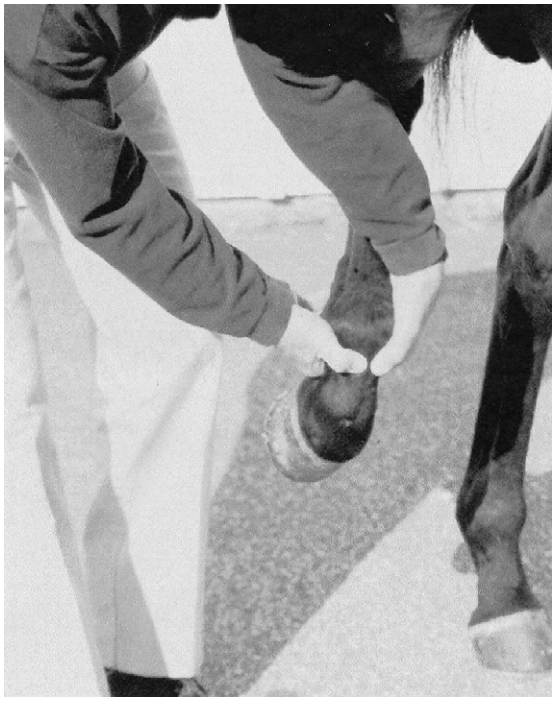

Fig. 6-37 Palpation of the proximal, dorsal aspect of the proximal phalanx can elicit pain in horses with incomplete mid-sagittal fracture of the proximal phalanx. In trotters, interference injury from the ipsilateral front foot causes pain and swelling in this region. (Courtesy Ross Rich, Cave Creek, Arizona.)

that may cause false-positive results. The range of motion of the metatarsophalangeal joint is noted.

Pastern

When the limb is elevated, the reciprocal apparatus causes constant flexion of the digit, which makes palpation of the plantar aspect of the pastern exceedingly difficult. Subtle swelling in the plantar pastern is easy to miss. Bony and soft-tissue structures should be palpated with the horse in the standing position and the veterinarian should note the same clinically important areas that were pointed out for the forelimb. High and low ringbone (osteoarthritis of the proximal interphalangeal and distal interphalangeal joints, respectively), osteochondrosis of the pastern joint, and soft tissue problems such as SDF branch tendonitis, distal sesamoidean desmitis, and plantar injury of the pastern joint occur, but with reduced frequency when compared with the forelimb.

Foot

A similar approach to the evaluation of the hind foot as that described for the front foot is used. I spend considerably less time evaluating the hind foot than the front foot, unless the history or horse type dictates otherwise, because this area is relatively infrequently the source of pain. In the Draft horse, hind foot pain is as common as in the forelimb, and therefore the hind feet merit considerable attention. Unless specifically indicated by the lameness history, or the horse is severely lame without an obvious cause in the upper limb, I do not routinely perform a hoof tester examination of the hind foot. Pressure with hoof testers over the frog and across the heels in the hind foot often causes a false-positive response in normal horses. The position needed to perform an unassisted hoof tester examination in the hindlimb can be dangerous. The presence of an assistant to elevate the limb may obviate some of the risk.

The examiner should assess the shape, balance, and contour of the foot, and observe the shoe (or lack of one) carefully. Hoof angle in the hindlimb ranges from 48° to 58°, and the hoof and pastern axis should be straight. A common finding is low or under-run heels. An interesting relationship between low heels and the presence of PSD has been noted.[2] In these horses a lateral radiograph of the foot shows the plantar aspect of the distal phalanx is lower than the dorsal aspect.[2] Shoe wear is extremely important in the hindlimb and can give clues to the source of lameness. For instance, horses with distal hock joint pain tend to stab the lower hindlimb during advancement, causing excessive wear of the lateral branch of the shoe (Fig. 6-38). Other lower hindlimb lameness, such as osteoarthritis of the metatarsophalangeal joint, can cause a similar gait, but usually abnormal shoe wear is less pronounced. Horses with stifle lameness often wear the medial branch of the shoe. The presence of heel and toe caulks or borium cause additional shear stress on many of the lower limb joints and can exacerbate lameness.

THE ROLE OF PHYSICAL EXAMINATION IN THE LAMENESS EXAMINATION

Body temperature may assist with a clinical diagnosis. The normal temperature range is 37.5° to 38.6° C (99.5 to 101.3° F), although in a foal the upper limit may normally be slightly higher. Body temperature in foals rises more abruptly than in adult horses in response to stress, infection, and inflammation. Thus transport of a foal may cause transient low-grade pyrexia, but fever in an adult horse after transport is abnormal. Localized infection in a foal usually causes pyrexia but rarely does in an adult. The examiner should not *exclude* infectious arthritis in an adult horse simply because fever is *not* present. However, adult horses usually are pyrexic during the early stages of cellulitis or lymphangitis.

Elevation in the pulse and respiratory rates often accompanies severe lameness because of pain. Systemic diseases such as endotoxemia may cause abnormal vital parameter findings in any horse and can lead to conditions such as laminitis.

It is important to remember that diseases of other body systems can cause clinical signs that mimic lameness or cause true gait deficits. For instance, abnormal or stiff gaits can be seen in horses with pleuritis and peritonitis, abdominal, sublumbar, inguinal, thoracic inlet, and pectoral abscesses or

Fig. 6-38 It is imperative to observe the hind shoes for wear during lameness examination. This right hind shoe (lateral is to the right) has wear along the dorsal and lateral aspects (lateral aspect of toe grab and fullering are worn) consistent with a lower hindlimb lameness, such as distal hock joint or proximal metatarsal region pain.

tumors. Proliferative new bone associated with hypertrophic osteopathy may be associated with a thoracic or abdominal mass. If an unusual situation arises, the veterinarian should step back and think of the exception rather than the rule, because the "red herring" may be just around the corner.

Movement

Mike W. Ross

"The best time for examining a lame horse is while he is in action. An attendant should lead him on a trot, preferably on hard ground, in a straight line, allowing him freedom of his head, so that his movements may all be natural and unconstrained."

A. Liautard, 1888[1]

It would be difficult to improve on Liautard's insistence that the lame horse be examined during movement or his description for how it is best accomplished. Although all parts of the lameness examination are important, the key is the determination of the limb or limbs involved. Not all horses with musculoskeletal problems exhibit lameness that is perceptible under normal conditions, or even by use of high-speed or slow-motion cinematography, gait analysis, or other sophisticated imaging devices. Under most circumstances, however, lameness from pain or a mechanical defect in gait is discernible, and the essence of the lameness examination is to determine the source of the pain. This discussion includes relevant experimental findings to support clinical observations, but sometimes experimental finds are confusing rather than informative.

GAIT

Gait, defined as the "manner or style of walking"[2] or "the manner of walking or stepping,"[3] is used to describe the speed and characteristics of a horse in motion. The *natural gaits*, those exhibited when a horse is free in a field, are the walk, trot, and gallop.[4] The canter is a collected gallop. Other gaits including the pace, running walk, rack (a singlefoot or broken amble), fox trot, and amble are *artificial gaits*, although some

"The best time for examining a lame horse is while he is in action. An attendant should lead him on a trot, preferably on hard ground, in a straight line, allowing him freedom of his head, so that his movements may all be natural and unconstrained."

A. Liautard, 1888[1]

It would be difficult to improve on Liautard's insistence that the lame horse be examined during movement or his description for how it is best accomplished. Although all parts of the lameness examination are important, the key is the determination of the limb or limbs involved. Not all horses with musculoskeletal problems exhibit lameness that is perceptible under normal conditions, or even by use of high-speed or slow-motion cinematography, gait analysis, or other sophisticated imaging devices. Under most circumstances, however, lameness from pain or a mechanical defect in gait is discernible, and the essence of the lameness examination is to determine the source of the pain. This discussion includes relevant experimental findings to support clinical observations, but sometimes experimental finds are confusing rather than informative.

GAIT

Gait, defined as the "manner or style of walking"[2] or "the manner of walking or stepping,"[3] is used to describe the speed and characteristics of a horse in motion. The *natural gaits*, those exhibited when a horse is free in a field, are the walk, trot, and gallop.[4] The canter is a collected gallop. Other gaits including the pace, running walk, rack (a singlefoot or broken amble), fox trot, and amble are *artificial gaits*, although some

pacers pace "free-legged" (without the use of hobbles) while on the track, either at a slow speed or racing speed, and occasionally a Standardbred (STB) paces free-legged in a field. In some instances a trotter switches from a trot to the pace, but this change usually is exhibited while the horse is performing at speed and may be associated with lameness or interference.

The term *beat* describes the number of foot strikes in a single stride cycle regardless of whether one or more feet strike the ground simultaneously. The following abbreviations are used for limbs: left forelimb (LF), right forelimb (RF), left hindlimb (LH), and right hindlimb (RH). The walk is a four-beat gait in which all four feet strike the ground independently without a period of suspension (in which no feet are on the ground). Depending on the part of the stride during which observations begin, the walk can appear to be lateral or diagonal. In general, in a lateral gait, both feet on one side strike the ground before the feet on the contralateral side. In a diagonal gait, one foot strike is followed by a strike of the foot located diagonal and contralateral to the initial foot (e.g., LF followed by the RH).

Lame horses should always be evaluated at the walk. Stride length should be evaluated and compared with observations at the trot. Stride length and sequence of footfalls are easier to see while horses are walking than while trotting. Horses with hindlimb lameness may be admitted for evaluation for failure to track up.[5] Horses normally track up, or over track. The hind foot is placed in or in front of the imprint of the ipsilateral front foot. Failure to track up usually is caused by hindlimb lameness or poor impulsion, and the hind foot imprint is seen behind that of the ipsilateral front foot.[5]

Backing is a diagonal, two-beat gait. Horses seldom back up naturally, but backing commonly is required of horses during performance events, while exiting from a trailer, or while driving. Backing is useful during lameness examination to evaluate certain gait deficits, such as shivers, stringhalt, and neurological disease.

The trot is a diagonal, two-beat gait and diagonal pairs of limbs move simultaneously. The trot is theoretically a symmetrical gait, meaning both "halves" (beats) of the stride are identical, and at low speed in a sound horse, symmetry is likely achieved. However, at speed perfect balance and fine management of weight (of the shoes) are necessary for a trotter to be perfectly symmetrical. There is a moment of suspension between impact of each diagonal pair of limbs. Hindlimb lameness is present in a higher percentage of horses that perform at speed at the trot compared with galloping horses because of differences in weight distribution in the trot and gallop. Compensating lameness develops in the diagonal paired limb. LF lameness predisposes to RH lameness.

The pace is a symmetrical, lateral, two-beat gait predominantly in STB racehorses and is characterized by movement of lateral pairs of limbs simultaneously (LH and LF; RH and RF), with a moment of suspension between lateral pairs. Pacers also have a high percentage of hindlimb lameness, but compensatory lameness usually develops in the lateral paired limb. RH lameness predisposes to RF lameness.

The gallop or run is a four-beat gait. In the gallop and the canter the horse leads with the left or right forelimb, the forelimb that strikes the ground last in the stride sequence. An unrestrained horse usually leads with the LF turning to the left, or the RF turning to the right. Fatigue also plays a role. A Thoroughbred (TB) racehorse racing counterclockwise leads with the LF on the turns, but immediately after entering the stretch, switches to the right lead. Failure to switch leads, or constantly switching leads in the gallop or canter, may reflect fatigue or lameness.

In a *left* lead gallop, the RH strikes the ground first, followed in sequence by the LH, RF, and LF followed by a period of suspension. When a horse is on the right lead, the RF strikes the ground last, propelling the horse into the suspension phase of the stride. It is often assumed that a horse with RF lameness is reluctant to take the right lead. However, bone stress measured in the radius and McIII is greater on the non-lead (trailing) forelimb, and thus a lame horse may change leads to protect the non-lead forelimb.[6] Ground reaction forces are greater in the trailing (non-lead) forelimb, a fact that supports the clinical observation that horses with forelimb lameness may select leads to protect the lame forelimb. A horse with a RF lameness may prefer the right lead, allowing the LF to assume the greater forces and bone stress.[5]

The canter (lope) is a three-beat gait. In left lead canter the RH strikes the ground first, then the LH and RF land simultaneously, followed by the LF and then a period of suspension. A horse reluctant to take a lead may be trying to compensate for hindlimb lameness. In the right lead the LH must absorb a considerable amount of concussion and then generate propulsive forces. Proneness of this limb to fatigue seems logical, but a consistent change in stride characteristics of fatigued horses to protect the LH was not seen.[7] Although the LH strikes the ground first, stance time, flexion of the upper limb joints, and ground reaction force are greater in the RH.[5] It could be assumed that a horse lame in the RH would be reluctant to take the right lead and may prefer the left lead.[5] Lead and stride characteristics of fatigued and lame horses are complex because of asymmetry of the gait, and forelimb and hindlimb problems could account for failure or reluctance to take a particular lead and inappropriate lead switching.

Young horses early in training or trained horses that are lame may exhibit a disunited canter. The horse may spontaneously change legs behind, but not in front. In changing from left to right lead canter, or vice versa, the forelimbs and hindlimbs should change simultaneously. Horses with back pain or hindlimb lameness may be reluctant to change leads, or may change in front, but not behind.

The Lameness Examination: Which Gait Is Best?

The trot is the most useful gait to determine the location of the lame limb or limbs. Forelimb lameness in particular is difficult to observe at the pace, especially in horses that are led in hand. Lame trotters may pace, supporting the supposition that the pace is an easier gait in a lame STB. I have seen horses with severe forelimb lameness at the trot that looked barely lame when pacing.

Relevance of Lameness at a Trot in Hand

Is lameness seen at a trot in hand the same lameness that compromises performance at speed? Is the lameness seen at a trot in hand in a jumping horse the same problem that causes the horse to refuse fences? The answer is usually, but not invariably, yes. For instance, I have seen many STBs show subtle unilateral hindlimb lameness at a trot in hand, but when the horse was later examined at the track and hooked to a cart, pronounced contralateral hindlimb lameness was noted. Differences include the track surface, pulling a cart, the additional weight of the driver, and a faster gait. Lameness often is evaluated on a smooth hard surface useful in exacerbating even subtle problems, but most horses perform on softer surfaces, when other problems may be apparent. More than one lameness problem may exist, one evident at a trot in hand and another while the horse is ridden or driven. Horses can show lameness from one problem when trotted in a straight line, but lameness from an entirely different problem while being trotted in a circle.

Horse Temperament and Lameness Examination

Safety of the handler, observers, and the horse must always be considered throughout a lameness examination, and with a difficult horse the examination may need to be modified,

especially on cold, windy days. In some female horses and geldings, judicious use of the tranquilizer acetyl promazine (0.02 to 0.04 mg/kg, IV) permits continuation of the examination. I avoid use of this tranquilizer in stallions, although the possibility of paraphimosis is remote. Low doses of sedatives such as xylazine can be used (0.15 to 0.30 mg/kg, IV) in stallions or other horses but can produce mild ataxia. Detomidine may be a better choice than xylazine, since the drug lasts longer, thus allowing diagnostic analgesic procedures to be performed.[5]

I try to avoid using tranquilization and sedation, although some clinicians use them frequently and report that lameness in most horses may be more pronounced and easier to observe. Mild muscle relaxation may reduce the tendency of the horse to guard the lame leg. In big moving, exuberant Warmblood horses, especially dressage horses (particularly stallions), sedation may be essential to accurately assess lameness.[5]

Leading the Horse during Lameness Examination

The horse must be led with a loose lead shank so that it can move the head and neck freely. It is impossible to see a head nod in a fractious or excited horse that is held tightly. Use of a chain lead shank over the nose facilitates control but is resented by some horses, and use of a bridle with a lunge line attached may be preferable.[5]

Horses should move at a consistent speed, not too fast and not too slow. A lazy horse may need encouragement with a whip. Constantly changing speed can make assessment of lameness difficult, but occasionally, assessing a horse during deceleration may reveal useful information about the existence of subtle lameness.[5] A horse may have to be trotted up and down many times. It is sometimes useful for the examiner to lead the horse to assess subtle forelimb lameness, since gait abnormalities may become more obvious.

Surface Characteristics and Lameness Examination

The horse should be examined on a smooth, flat surface. I prefer a hard surface, such as pavement or concrete, that creates maximal concussion and may exacerbate subtle lameness. However, the clinical relevance of mild lameness seen on hard surfaces, especially on turns, should not be over-interpreted. Many horses that are actively competing successfully show mild lameness on hard surfaces; it is important to understand that the horse does not perform on a surface of pavement, and foot strike patterns and gait could be much improved if the horse performs on firm, but forgiving surfaces. Crushed rock, cobblestone, deep sand, or undulating grassy areas and potentially dangerous slippery surfaces should be avoided.

It is important that the surface is non-slip because some horses appear to lack confidence while moving on hard surfaces and alter the gait. In these situations, horses may shorten the stride for protection rather than from lameness.[5] Horses with studs or caulks on the shoes may develop induced lameness unrelated to the baseline lameness when trotting on hard surfaces.[5]

Ideally the gait on hard and soft surfaces should be compared to help differentiate soft tissue from bony problems. Horses with foot pain usually perform worse on a hard surface. Lameness from soft tissue injuries, such as suspensory desmitis or tendonitis, tends to be worse on soft or deep ground.

DETERMINATION, GRADING, AND CHARACTERIZATION OF LAMENESS

Six basic steps are necessary to determine, grade, and characterize lameness. The clinician should determine the following:

1. Primary or baseline lameness or lamenesses
2. Possibility of involvement of more than one limb and presence of compensatory lameness
3. Classification of lameness as a supporting, swinging, or mixed
4. Grading of lameness or lamenesses
5. Alteration of the cranial or caudal phase of the stride
6. Presence of abnormal limb flight

The *primary or baseline lameness* is the gait abnormality before flexion or manipulative tests are used. The practitioner attempts to abolish baseline lameness using analgesic techniques. Lameness in more than one limb may complicate determination of the worst affected limb. It is important to trot a horse even if it is quite lame at a walk, unless an incomplete or stress fracture is suspected. A horse may take a short step with a limb at walk, or can appear very lame, but trot reasonably sound. Horses with scratches (palmar/plantar pastern dermatitis) or superficial wounds in the palmar or plantar pastern may appear quite lame at walk but trot well. A STB pacer may walk extremely short both in front and behind but pace or trot without lameness. However, only the degree of lameness usually differs between a walk and trot. A horse may appear sound at walk and trot in hand, but lameness may be apparent trotting in a circle, in hand or on the lunge, or while being ridden. *This lameness now becomes the baseline lameness*, and under these conditions, the results of nerve blocks should be evaluated. The clinician should try to recognize if the horse has bilateral forelimb or hindlimb lameness, which is manifest as shortness of stride or poor hindlimb impulsion, or if concurrent forelimb and hindlimb lameness is present. Moderate to severe hindlimb lameness can mimic ipsilateral forelimb lameness, although ipsilateral forelimb and hindlimb lameness also occurs. In these horses the veterinarian should perform diagnostic analgesia in the hindlimb first.

Compensatory Lameness

Compensatory (secondary or complimentary) lameness results from overloading of the other limbs as a result of a primary lameness. It must be differentiated from the stride-to-stride compensation by a horse to avoid interference injury because of a gait deficit, or lameness, or to shift weight (load) during examination. A compensatory problem develops as the result of predictable compensation a horse may make *over time* for a primary lameness in a single limb. However, a horse may compensate for lameness in one limb by shortening the stride in another, a stride-to-stride change in gait that is not the result of lameness. A horse with severe LF lameness is reluctant to extend the LF and must shorten the cranial phase of the LH limb, creating what appears to be a hike in the LH. If the veterinarian looks only at the hindlimbs, LH lameness may be diagnosed. A trotter performing at speed with a LF lameness is likely to develop compensatory lameness in the RF or RH, but not in the LH. However, the horse may appear to be hiking (lame) in the LH to avoid interfering with the LF. Elimination of obvious unilateral forelimb lameness usually resolves an ipsilateral pelvic hike. Experimental results appear to contradict this clinical impression. In 6 of 10 horses with stance phase forelimb lameness, compensatory movements of horses created a false lameness in the *contralateral* hindlimb (see following text).[8]

It is often difficult to know which lameness came first, but it is important to understand how horses compensate for lameness and which limbs are at risk to develop compensatory problems. Compensatory problems range from obvious lameness to only mild palpable abnormalities that may still compromise performance. Several predictable patterns of compensatory lameness are possible; the most common is bilateral forelimb or hindlimb lameness. Horses with a specific lameness in one forelimb are at risk to develop the same condition in the opposite forelimb. This tendency may not always be compensation for the primary lameness but may be simultaneous injury or degeneration of bone or soft tissue of both limbs. Abnormal loading of forelimbs or hindlimbs, faulty

bilateral conformation, and the same shoeing or foot conditions all likely contribute to bilateral, simultaneous lameness. In horses with bilateral lameness, eliminating lameness in one limb usually results in contralateral limb lameness. Bilateral lameness may affect both limbs equally, resulting in a short, choppy gait. The horse may be lame in one limb while being circled in one direction and lame in the contralateral limb in the opposite direction.

Racehorses that gallop are most likely to develop compensatory lameness on the contralateral limb or the ipsilateral forelimb or hindlimb. A TB racehorse with a left metatarsophalangeal joint lameness is most likely to develop a similar problem in the RH but may also develop LF lameness. In a trotter the contralateral limb is most at risk, followed by the diagonal forelimb or hindlimb. If a trotter has a right carpal lameness, the left carpus should be examined carefully; compensatory lameness also may occur in the diagonal LH limb. In a pacer the ipsilateral forelimb or hindlimb should be considered after the contralateral limb. In a pacer with LH lameness the RH and LF are at risk.

The most common compensatory lameness is the same problem in the contralateral limb. However, suspensory desmitis is a common compensatory problem in both the contralateral and other limbs. In a TB racehorse or a jumper with LF lameness, RF suspensory desmitis is common. Primary RH lameness may result in suspensory desmitis in the RF. It is logical that soft tissue structures are particularly vulnerable to the effects of over-load. Superficial digital flexor tendonitis may develop secondary to a primary problem in the contralateral limb. In trotters a common pattern is primary carpal lameness and compensatory osteoarthritis of the medial femorotibial joint in the diagonal hindlimb, or vice versa.

Compensatory lameness also can develop in the same limb. In horses with front foot lameness the suspensory ligament (SL) often is sore, and some horses have suspensory desmitis. In horses with lameness abolished by palmar digital analgesia, most with navicular syndrome, scintigraphic examination revealed increased radiopharmaceutical uptake (IRU) in the proximal palmar aspect of the third metacarpal (McIII) bone in 30% of horses, indicating possible abnormal loading of the proximal SL (Fig. 7-1).[9] Complete resolution of lameness may not be achieved until high palmar analgesia is performed.

Horses with primary metatarsophalangeal joint lameness often have associated ipsilateral stifle pain.[10] Determination of the primary site of lameness may be difficult without use of diagnostic analgesia and observing that blocking one site abolishes the majority of lameness. This phenomenon may be most common in trotters, but I have recognized it in all types of sport horses.

Supporting, Swinging, and Mixed Lameness

Lameness has classically been divided into three categories in an attempt to characterize the motion associated with the lame leg and to assign etiology to the lameness condition. These categories are described and discussed, but I firmly believe that adequate characterization of most lameness conditions is impossible and may be unnecessary.

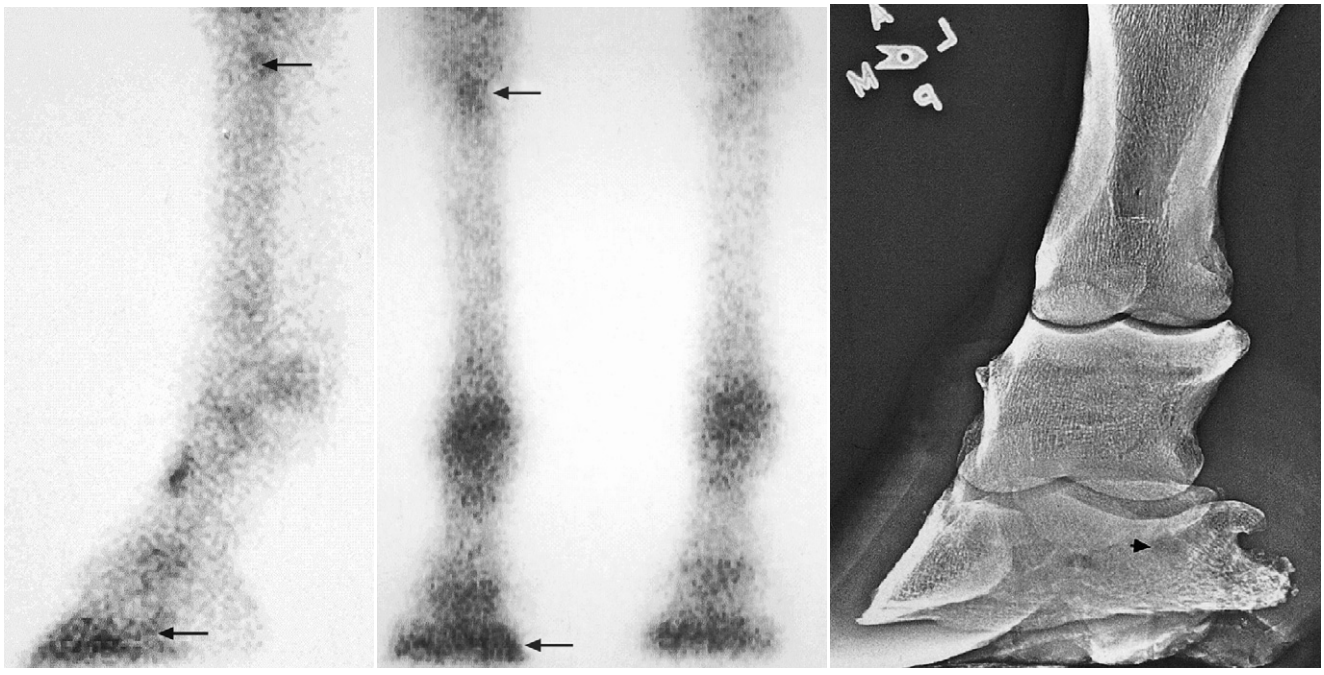

Fig. 7-1 **A,** Lateral delayed-phase scintigraphic view showing focal, mild increased radiopharmaceutical uptake (IRU) of the navicular bone *(bottom arrow)* and proximal aspect of the third metacarpal bone (McIII; *top arrow*). Normal modeling is seen in the dorsal aspect of the proximal phalanx. **B,** Dorsal delayed-phase scintigraphic image, and **C,** dorsomedial palmarolateral oblique xeroradiograph of a dressage horse with lameness abolished by palmar digital analgesia. IRU of the medial aspect of the distal phalanx *(bottom arrow)* corresponds to the area of subchondral radiolucency seen in the xeroradiographic projection (C, *arrowhead)*. Notice the focal area of mild IRU involving the proximal aspect of McIII *(top arrow, A* and *B)*. Abnormal loading of the suspensory ligament may occur as a compensatory problem in some horses with navicular syndrome or other sources of palmar heel pain.

Supporting limb lameness describes a lameness that is painful during the weight-bearing phase of the stride. Most lameness conditions are of this type. Supporting limb lameness also has been referred to as *stance phase lameness*, but this term is inappropriate because the swing phase of the stride is also altered.

Swinging limb lameness describes lameness that primarily affects the way the horse carries the lame limb. However, most horses with painful lameness conditions alter the swing phase of the stride in a typical and repeatable fashion, and it is difficult to make a clear separation between supporting and swinging limb lameness. Swinging limb lameness should be a term reserved for mechanical defects of gait, such as fibrotic myopathy, upward fixation of the patella, stringhalt, or other lameness conditions causing a mechanical restriction of gait. In these horses, lameness is manifested in the swing phase of the stride with no apparent pain. Unfortunately, the term swinging limb lameness often is used inappropriately to describe the gait deficit in horses with painful, supporting limb lameness. Lameness associated with osteochondrosis of the scapulohumeral joint is often described as a swinging limb lameness because of a marked shortened cranial phase of the stride. Dramatic improvement in the shortened cranial phase of the stride can be achieved by diagnostic analgesia, eliminating pain associated with lameness. Thus the gait deficit is the direct result of pain and no clear differentiation between supporting and swinging limb lameness can be made. Horses with painful forelimb lameness almost always shorten the cranial phase of the stride, although perhaps not to the extreme as in a horse with authentic scapulohumeral joint lameness. Because the terminology is confusing and often erroneous, I prefer to avoid use of these terms and simply describe lameness as accurately as possible. For instance, describing a horse as grade 2 of 5 LF lame, with a marked shortening of the cranial phase of the stride reminiscent of other horses I have seen with shoulder region lameness, gives the most accurate and useful information.

There is an erroneous tendency to equate a swinging limb lameness with one that is more evident when the lame limb is on the outside of a circle. Upper limb lameness is often presumed, yet not confirmed by diagnostic analgesia. It is logical that if a horse is reluctant to swing a limb forward, the lameness may be most prominent when the lame limb is on the outside of a circle. However, many horses with painful weight-bearing lameness show more pronounced lameness with the limb on the outside of the circle, a finding that neither suggests that lameness originates from the upper limb nor indicates the presence of swinging limb lameness (see following text). The outer limbs must stretch further and cover a larger circumference circle than the inside limbs. Slight temporal differences in the stance and swing phases of the inside and outside limbs are necessary to maintain gait symmetry.[5]

The results of cinematographic analysis of gait in lame horses seem to support reservation of the term swinging limb lameness for horses with authentic mechanical gait deficits, rather than those induced by painful lameness. In a horse with a supraglenoid tubercle fracture examined at a trot in hand, a marked decrease in the cranial phase of the stride (protraction) was observed, along with a marked head and neck nod. A markedly shortened stride could be equated with swinging leg lameness, but high-speed cinematography showed that the cranial and stance phases of the stride were shorter than in the sound limb.[11] A horse with unilateral semitendinosus fibrotic myopathy had a shortened stride length and a shortened cranial phase of the stride, but the stance phase did not differ from that of the unaffected contralateral limb.[12]

In my experience, most lameness conditions can be considered *mixed lameness*, with changes in gait during weight bearing or the stance phase and during the swing phase of the stride. With the exception of mechanical defects in gait, I have not been able to categorize the clinical characteristics of most lameness conditions into swinging or supporting limb types. However, it has been suggested that swinging limb lameness is caused by muscle injury, supporting limb lameness is caused by bone, tendon and ligament injury, and mixed lameness is caused by joint, tendon sheath and periosteal injury.[13] A shortened cranial phase of the stride is a common characteristic in forelimb and hindlimb lameness and should not be considered pathognomonic for the location or type of lameness.

DETERMINING THE LOCATION OF LAMENESS

The horse should be observed at both the walk and the trot from the front, behind, and side. I spend most of my time watching the horse move away and then back toward me. Medial-to-lateral limb flight and foot strike can be evaluated only from this perspective, although cranial and caudal aspects of the stride can be evaluated only from the side. Most important, evaluation of lameness from this perspective allows the veterinarian to use the horse as a frame of reference. I find it quite useful to evaluate forelimb lameness when the horse is traveling away from me and hindlimb lameness when the horse is traveling toward me. This perspective allows use of the horse's top line to see a subtle head and neck nod or pelvic hike. Only by observing the horse from the side can the cranial and caudal phases of the stride be determined. When first learning to assess lameness from the side, a linear frame of reference, such as a fence or wall in the background, may be helpful to notice head nod and pelvic hike against a non-moveable background. Application of pieces of tape or other markers to the horse's head or a fixed point on the pelvis can assist recognition of upward and downward movement of that body part.

Independent observation of the forelimbs and hindlimbs is needed to understand whether a horse has forelimb or hindlimb lameness or a combination. These observations then are amalgamated to form a final clinical impression.

Recognition of Forelimb Lameness

Forelimb lameness often is easier to recognize than hindlimb lameness. *Understanding the concept of the head nod is vital to the correct interpretation of equine lameness.* The head and neck elevate or rise when the lame forelimb is bearing weight or hits the ground and nod down or fall when the sound forelimb hits the ground. "…When the [forelimb] is the lame one, the movements of the foot and head occur somewhat in unison. When the lame foot is raised, the head is elevated, but only to fall when the sound leg is brought to a rest."[1] Some clinicians find it easier to appreciate the head nod, while others find it easier to recognize elevation of the head.

When evaluating slow-motion videotape of lame horses, it is immediately obvious that the elevation of the head and neck is much easier to see than the head nod down. In slow motion the horse appears to be elevating the head and neck just before the lame limb hits the ground, and then, during the later portion of the support or stance phase, the head and neck nod down. The head and neck nod occurs as the contralateral limb begins the support or stance phase. Both head elevation and falling are present, but head elevation is much easier to detect when it occurs in unison with the lame limb hitting the ground. It is likely that a combination of visual clues allows the clinician to decide the primary forelimb lameness. Quantification of lameness and description of the actions of the lame and compensatory limbs have been attempted using gait analysis systems. In horses with amphotericin-induced carpal lameness, head movements were the most consistent indicator of lameness, followed by sinusoidal

motion, or a rising and falling action, of the head and withers.[14] The motion of the lame limb was assessed, and a falling of the head and withers during the support phase of the lame limb was noted, contrary to clinical perception and evaluation of slow-motion videotape of lame horses. It was suggested that an uncoupling of the weight from the lame forelimb and a "free fall–like" phenomenon occurred during weight bearing.[14] The problem with this description is that it considers only the lame limb and is confusing. When evaluating a lame horse, the observer "sees" both forelimbs. During the later portion of the support phase of the lame limb, the sound limb is in the later portion of the swing phase and beginning the support or stance phase. Thus the head and withers drop described experimentally appears to occur concomitant with the sound limb hitting the ground. The observer perceives the early portion of the stance or support phase.

In general a good correlation between clinical evaluation of forelimb lameness and that described using motion analysis has been observed. There was complete agreement between clinical determination of location of forelimb lameness and that detected by motion analysis using a computerized three-dimensional motion measurement system. However, the degree of lameness differed in 6 of 29 horses.[15] The maximal vertical acceleration of the head was the best indicator of forelimb lameness.[16] Although horses with forelimb lameness shifted weight in a caudal direction to the diagonal hindlimb, the amount of withers motion was minimal. The authors reasoned that the tremendous mobility of the head and neck, allowing the horse to asymmetrically elevate the neck and thus load the non-lame forelimb, accounted for the lack of withers movement and the horse's adaptation to forelimb lameness.[16] A similar compensatory ability is not present in the hindlimb. Vertical displacement of the tuber coxae and forward motion or translation of the pelvis occur in horses with hindlimb lameness, since a mechanism such as head and neck movement does not exist.[16] In a computer-generated model of a trotting horse the dynamic effects of head and neck movement accounted for the majority of load shift to the contralateral forelimb and diagonal hindlimb in horses with unilateral forelimb lameness.[17] Load shift and compensation by the diagonal hindlimb in horses with unilateral forelimb lameness lends support to the clinical findings of compensatory lameness in the diagonal limbs in trotters.

Instrumented shoes have been used experimentally to study motion in horses by quantifying ground reaction forces (GRF) but have had limited clinical use.[18,19] Although this system is not currently widely available, in the future this or similar systems may be useful to objectively assess lameness and the response to diagnostic analgesic techniques in clinical patients.

Recognition of Hindlimb Lameness

Historically descriptions of hindlimb lameness have been confusing. An important principle in the recognition of hindlimb lameness is the *concept of the pelvic hike* or asymmetrical movement of the pelvis. This has also been termed *hip hike*, but I prefer the term *pelvic hike* because it accurately describes how the pelvis moves in a horse with unilateral hindlimb lameness. The entire pelvis, not just the lame side of the pelvis, appears to undergo elevation. Because the horse has two "hips" and only one pelvis, the term pelvic hike seems preferable. Pelvic hike is the vertical elevation of the pelvis when the lame limb is weight bearing. In other words, the pelvis "hikes" upward when the lame limb hits the ground and moves downward when the sound limb hits the ground. "… the haunch settles downward when the sound leg touches the ground…".[1] Some clinicians find it easier to see the downward movement of the pelvis, on the side of the lame limb, rather than the pelvic hike.[5] It may be simpler to determine which side has the most movement, rather than looking for either a hike or a drop.[5] The clinician must keep in mind that the pelvic hike is the clinical impression of *the change in height of the pelvis*, not the absolute or measured height. It is the shifting of weight or load that occurs as the horse tries to reduce weight bearing in the lame limb and transfer weight to the sound limb.

Another explanation for asymmetrical movement of the pelvis involves one of the protective or compensatory mechanisms used by the horse to assist in break over and minimize load on the lame limb. Many horses with hindlimb lameness drift away from the lame limb toward the sound limb. Drifting may decrease the magnitude of the observed pelvic hike, but more important, makes the lame side look lower than the sound side. This is why it is important to watch the entire pelvis as a unit rather than the individual sides of the "hips."

In most horses with hindlimb lameness, particularly those without a substantial tendency to drift away from the lame limb, the elevation of the pelvis (pelvic hike up) when the lame limb hits the ground surpasses that when the sound limb is weight bearing. This elevation can be seen readily in real-time and slow-motion videotape analysis, but it may not be as obvious during clinical examination. Observing horses with hindlimb lameness from the front as the horse trots toward you may be useful. This approach allows the pelvic hike to be seen clearly using the horse's top line as a frame of reference. Subtle pelvic elevation is best seen from this perspective. The use of markers on a fixed part of the pelvis can help to identify asymmetry. Stride length characteristics, height of foot flight, sound, and fetlock drop are also helpful (see following text).

Horses with bilateral hindlimb lameness may have a short, choppy gait that lacks impulsion, but they may have no pelvic hike. Other methods to exacerbate the baseline lameness should be performed, such as circling the horse at a trot in hand or while on a lunge line. Lameness may be accentuated when the lame or lamer limb is on the inside or outside of the circle (see following discussion).

Hindlimb Lameness Confused with Forelimb Lameness

It is important to understand how a horse with unilateral hindlimb lameness modifies its gait so that *hindlimb lameness can mimic forelimb lameness at the trot*. When the lame limb hits the ground, the horse shifts its weight cranially to transfer load away from the lame limb. This causes the head and neck to shift forward and nod down at the same time. The contralateral forelimb bears weight simultaneously with the lame hindlimb and the head nod coincides, thus mimicking lameness in the forelimb ipsilateral to the lame hindlimb. Head and neck movement in horses with hindlimb lameness is not always observed. Horses generally must have prominent (≥3 out of 5, see later grading discussion) hindlimb lameness before compensatory head and neck movement develops. At the pace, a lateral gait, LH lameness mimics RF lameness and RH lameness mimics LF lameness.

Horses can have a head and neck nod at the trot caused by singular forelimb lameness, singular ipsilateral hindlimb lameness, or concurrent forelimb and ipsilateral hindlimb lameness. A prominent head nod is seen in horses with simultaneous LF and LH lameness. The examiner first must determine whether both limbs are affected. Problems arise because a horse with only LF lameness may shorten the LH stride at the trot, leading the veterinarian to question whether LH lameness also exists. Horses with only LH lameness can have a rather pronounced head nod, and thus the veterinarian may question the existence of LF lameness. Although a horse with LF lameness may have a compensatory shortened stride of the LH, in the absence of lameness a marked pelvic hike should not be

present. A head nod consistent with a LF lameness may be inappropriately severe to be caused by mild LH lameness. If a horse has simultaneous LF and LH lameness, it is essential to perform diagnostic analgesia in the hindlimb first, because moderate to severe hindlimb lameness produces head and neck nod that is not abolished unless the hindlimb lameness is resolved. Resolution of the pelvic hike and reduction in the head nod should be expected with resolution of the hindlimb lameness.

Simultaneous lameness of a diagonal pair of limbs is less common than simultaneous ipsilateral lameness, except in trotters, because many horses perform at gaits that induce compensatory lameness either in the contralateral or ipsilateral limb. With simultaneous LH and RF lameness the head nod reflects the forelimb component, a mandatory clinical sign for perception of RF lameness. The horse may drift away from the LH with shortening of the cranial phase of the stride. The horse may have a short, choppy stride in the forelimbs and hindlimbs. The horse may have a rocking gait. It cannot shift weight or compensate from stride to stride in the usual manner and thus tends to rock back and forth from the hindlimbs to the forelimbs.

Reasonable agreement generally exists between clinical recognition of hindlimb lameness and that found experimentally. The use of markers placed on each tuber coxa of 13 horses with unilateral hindlimb lameness showed a consistent increase in vertical displacement of the pelvis during early weight bearing of the lame limb.[20] Although the rise and fall of the pelvis was readily apparent and occurred consistently with weight bearing of the lame and sound limbs, respectively, the absolute height of the pelvis on the lame side did not rise above that of the lame limb.[20] These findings are consistent with my clinical impressions. A head nod down when the diagonal forelimb was bearing weight further confirmed clinical observations that hindlimb lameness can mimic lameness of the ipsilateral forelimb.[21] In a kinematic study using a three dimensional optoelectronic locomotion system, hip acceleration quotient increased in horses with hindlimb lameness.[21] Vertical displacement corresponded to the pelvic hike up on the lame leg, with a simultaneous forward movement of the head and neck during the stance phase of the lame limb.[21]

GRF has been measured in normal horses and those with forelimb and hindlimb lameness.[22-25] GRF is reduced in the lame forelimb or hindlimb with compensation by the other limbs. In horses with unilateral forelimb lameness, decreased horizontal GRF in the lame limb is compensated by increased GRF in the contralateral forelimb and ipsilateral hindlimb.[26] Decreased vertical GRF in the lame limb is compensated by increased vertical GRF in the contralateral forelimb during the swing phase of the lame limb, and increased vertical GRF in both the ipsilateral and contralateral hindlimbs during the stance phase of the lame limb.[26] During unilateral hindlimb lameness the decreased GRF in the lame limb is compensated by increased GRF in the contralateral hindlimb and the contralateral and ipsilateral forelimbs.[26] These experimental data support the clinical impression that a lame horse adapts by shifting load to the contralateral limb or by shifting load in a caudal direction for forelimb lameness and in a cranial direction for hindlimb lameness.

A study using an optoelectronic motion measurement system and expert vision analysis high-speed video system for motion analysis confirmed that horses with hindlimb lameness show false lameness in the ipsilateral forelimb. However, contrary to my clinical observations, 6 of 10 horses with severe forelimb lameness showed "false" lameness of the diagonal (contralateral) hindlimb.[8] Review of videotape of lame horses reveals false lameness in the diagonal or ipsilateral hindlimb depending on several factors. Horses with pronounced forelimb lameness may look lame in the diagonal hindlimb. Horses with marked shortening of the cranial phase of the stride may appear lame in the ipsilateral hindlimb. Horses with forelimb lameness circled with the lame limb on the inside may look lame in the ipsilateral hindlimb. Thus analysis of lameness can be complex, and determination of the lame limbs may not become clear until diagnostic analgesia is performed.

Bilaterally Symmetrical Forelimb or Hindlimb Lameness

Bilateral lameness is a common cause of poor performance and may go unrecognized without additional movement, such as circling, lunging or riding. Horses with bilaterally symmetrical forelimb lameness may have a short, choppy gait when trotted in straight lines. Horses with hindlimb lameness may lack lift to the stride, have a subtle change of balance, or reduced hindlimb impulsion.[5] If bilaterally symmetrical lameness is suspected, the veterinarian should select one limb and begin diagnostic analgesia. Horses often show pronounced lameness in the contralateral limb when the source of pain is desensitized.

THE LAMENESS SCORE: QUANTIFICATION OF LAMENESS SEVERITY

I believe it is important to have a standardized lameness scoring system that allows the clinician to quantify lameness within and between horses. Ideally it should be consistent worldwide, but currently a scale from 0 to 5 generally is used in North America, and a scale from 0 to 10 is often used in Europe. Definitions vary within the grading systems. The system adopted by the American Association of Equine Practitioners (AAEP) provides a framework.[27]

- Grade 1 lameness is difficult to observe and not consistently apparent regardless of circumstances (such as weight carrying, circling, inclines, hard surfaces).
- Grade 2 lameness is difficult to observe at a walk or trotting a straight line but is consistently apparent under certain circumstances (such as weight carrying, circling, inclines, hard surfaces).
- Grade 3 lameness is consistently observable at a trot under all circumstances.
- Grade 4 lameness is obvious lameness with marked nodding, hitching, or shortened stride.
- Grade 5 lameness is characterized by minimal weight bearing in motion or at rest and the inability to move.

The AAEP system is potentially confusing because it grades lameness at both the walk and trot. It does not account for a horse that has a shortened stride at walk that trots sound. In my experience, many lame horses show consistently observable lameness at a trot and therefore would have to be scored at least 3, leaving only grades 3 and 4 for use for the majority of lame horses. Horses with bilateral lameness and a shortened stride but no obvious head nod or pelvic hike are difficult to score based on this system.[5] It does not permit grading under different circumstances, such as straight lines, circles on the soft in each direction, and circles on the hard.[5]

An alternative lameness scoring system is listed in Box 7-1. Lameness is only scored at a trot, and the grading system is used most often to describe lameness at a trot in hand. The system is useful for both forelimb and hindlimb lameness and is based on a range of 0 (sound) to 5 (non–weight-bearing). In this system a horse with unilateral hindlimb lameness of grade 3 or worse would have a head nod that mimics ipsilateral forelimb lameness. There is a practical difference between this scoring system and that put forth by the AAEP. A horse with lameness grade 1 in this modified scoring system would have a lameness grade between 2 or 3 in the AAEP system. The

Box • 7-1

Lameness Scoring

Lameness grades from 0 to 5 are based on observation of the horse at a trot in hand, in a straight line, on a firm or hard surface.

0 Sound
1 Mild lameness observed while the horse is trotted in a straight line. When the lame forelimb strikes, a subtle head nod is observed; when the lame hindlimb strikes, a subtle pelvic hike occurs. The head nod and pelvic hike may be inconsistent at times.
2 Obvious lameness is observed. The head nod and pelvic hike are seen consistently, and excursion is several centimeters.
3 Pronounced head nod and pelvic hike of several centimeters are noted. If the horse has unilateral singular hindlimb lameness, a head and neck nod is seen when the diagonal forelimb strikes the ground (mimicking ipsilateral forelimb lameness).
4 Severe lameness with extreme head nod and pelvic hike is present. The horse can still be trotted, however.
5 The horse does not bear weight on the limb. If trotted, the horse carries the limb. Horses that are non—weight bearing at the walk or while standing should not be trotted.

modified scoring system is more flexible and allows clear differentiation between most lameness conditions. However, it does not account for a bilaterally symmetrical gait abnormality and may be difficult to apply in a horse with lameness in more than one limb. Many horses evaluated for subtle lameness or poor performance have a score between 0 and 1 because consistent lameness is not observed. Use of half grades provides greater flexibility and supports adoption of a scoring system from 1 to 10, assuming 0 denotes soundness.

LAMENESS DETECTION

Fetlock Drop

Assessment of fetlock drop, or extension of the metacarpophalangeal and metatarsophalangeal joints, may be helpful in recognition of the lame limb. In general, *the fetlock joint of the sound limb drops farther when this limb is weight bearing than does the fetlock joint of the lame limb*, because the horse is attempting to spare the lame limb by increasing load in the sound limb. This may be easier to detect by video analysis than in a clinical situation and may be more recognizable at the walk than a trot. However, in some horses with moderate or severe unilateral suspensory desmitis or tendonitis, the fetlock drops markedly on the lame limb when the horse is walking, but at a trot fetlock drop usually is more pronounced in the sound limb. With bilateral suspensory desmitis or severe tendonitis the fetlock may drop further in the lamer limb.

Use of Sound

Sound can be useful in lameness evaluation. *A lame horse usually lands harder on the sound limb, resulting in a louder noise.* To appreciate this sound, the horse must be trotted on a firm or hard surface such as pavement or concrete. However, the sound a horse makes while landing depends greatly on symmetry of the front or hind feet, and the loss of one shoe, different shoe types, or disparity in foot size confounds interpretation. Listening for regularity of rhythm and sound of footfall are important, especially when evaluating the response of lame horses to diagnostic analgesia, particularly in horses with subtle lameness.[5]

Drifting

Horses with hindlimb lameness generally *drift away from the lame limb.* Drifting is one of the earliest adaptive responses of a horse with unilateral hindlimb lameness, allowing the horse to break over easier or reduce load bearing. Drifting may alleviate the need for extensive pelvic excursion (hike). It may make pelvic drop on the lame side more obvious. The horse may mask the lameness by reducing pelvic excursion. In some horses a pelvic hike is undetectable or subtle, but consistent drifting away from the lame side indicates the presence of hindlimb lameness. Many driven STBs with hindlimb lameness drift away from the lame limb, or are "on the shaft." Horses with LH lameness have a tendency to be on the right shaft and vice versa. Drifting away from the lame limb may be most evident when horses have pain from the tarsus distally, although some clinicians have different experiences.[5] Drifting may result in the horse moving on three tracks.

Horses with severe forelimb lameness also tend to drift away from the lame limb, but this tendency usually is less obvious than in horses with hindlimb lameness. Drifting is most common with carpal lameness when the horse tends to abduct the limb during the swing phase of the stride and appears to push-off with the limb, forcing the horse away from the lame side. Racehorses with either forelimb or hindlimb lameness tend to drift away from the lame limb while training or racing at speed. This finding is an important piece of the lameness anamnesis.

Drifting toward the lame hindlimb is an unusual but important clinical sign. In horses that drift toward the lame limb, I suspect weakness and lameness exist simultaneously, suggesting a neurological component to the gait abnormality. However, a jumping horse at takeoff may push off more strongly with the non-lame hindlimb and drift across the fence toward the lame limb.[5]

EVALUATION OF LIMB FLIGHT

Observation and characterization of limb flight can be useful in determining the lame limb or limbs and possibly the location of lameness within the limb. Abnormal limb flight also may predispose to lameness, especially in horses with faulty conformation. In my opinion, it is impossible to predict the site of lameness accurately based on limb flight and other characteristics, although some abnormalities lead to a high index of suspicion. I believe strongly that the location of pain should always be confirmed by diagnostic analgesic techniques whenever possible. Some abnormalities are consistently associated with specific lameness conditions, whereas others are general patterns of limb flight seen with many different conditions.

Cranial and Caudal Phases of the Stride

Changes in limb flight in the cranial and caudal phases of the stride can be seen only when the horse is evaluated from the side. In a normal horse the length of the stride of the paired forelimbs and hindlimbs, measured from hoof imprint to hoof imprint, is nearly identical from side to side. Extension and flexion of the limbs is also similar. From a clinical perspective the length of the stride of the affected limb cranial to the stance position of the contralateral limb is called the *cranial phase* of the stride, and the length of the stride caudal to the stance position of the contralateral limb is called the *caudal phase* of the stride. Obviously in a normal horse these individual parts of the

stride are symmetrical. In a lame horse the overall stride length does not appear to change. If stride length changed, the horse could not trot in a straight line. Drifting is associated with lameness and could be explained by a change in stride length, but shorter stride length would be expected in the lame limb, causing the horse to drift toward the lame side, in contrast to the usual observation, drifting away from the lame limb. In racehorses, some of the tendency to drift away or toward the inside of the track could be easily explained by mild differences in stride length. However, at a trot in hand we can assume that total stride length does not change.

In many lame horses the cranial phase of the stride of the affected limb is shortened. The caudal phase is lengthened to maintain a near equal overall stride length side to side. Shortening of the cranial phase of the stride appears to be a learned response of the horse to reduce the time spent during the stance phase and to help during break-over. Loss of propulsion, or an unwillingness to push off with the lame limb, could also explain reduction in the cranial phase of the stride. Because most lame horses have a shortened cranial phase of the stride, this finding is not particularly useful in localizing or classifying lameness and is not synonymous with swinging limb lameness. It is also important to recognize that pain causing lameness results in altered proprioceptive responses, to protect the painful area, and these responses may persist for some time after pain has resolved.[5] A classic example of attenuation of the cranial phase of the stride in the hindlimbs occurs mechanically in horses with fibrotic myopathy. This authentic swinging limb lameness causes a marked abrupt change in the later portion of the protraction phase of the affected hindlimb, shortening the cranial phase and causing a sudden downward and backward action of the limb.

The caudal phase of the stride is lengthened in most lame horses since, to maintain overall equal stride length, this portion of the stride must compensate. I generally have not found evaluation of the caudal phase of the stride at the trot in hand clinically useful, but it is sometimes a useful observation in horses at a walk (see following text). Some horses with severe palmar foot pain have a shortened caudal phase of the stride at both walk and trot.[5]

Contrast of the cranial and caudal phases of the stride in the lame limb at a walk and a trot is useful. In most horses with forelimb lameness the cranial phase of the stride is slightly shortened at the walk but markedly shortened at a trot. Obviously, in horses with subtle lameness, this clinical sign is absent at the walk and only mildly apparent at the trot. Horses with pain in the dorsal aspect of the foot, such as hoof abscessation or laminitis, may have a shortened caudal phase of the stride at a walk. This response is an attempt to protect the painful area and to shorten during break-over. These horses walk with a marked camped-out appearance in the forelimbs. At the trot, however, the cranial phase of the stride is likely to be shortened, a clinical contrast useful in localizing lameness to the dorsal aspect of the hoof.

Most horses with hindlimb lameness have a reduction in the cranial phase of the stride at the walk and the trot. Horses with pelvic fractures involving the acetabulum prefer to keep the lame limb ahead of the contralateral limb at the walk and have marked shortening of the caudal phase of the stride, but at the trot the horse has a shortened cranial phase of the stride. Horses with hoof abscessation, most commonly of the dorsal aspect of the hoof, walk similarly, only to trot with a pronounced shortening of the cranial phase of the stride. Unilateral or bilateral laminitis is rare in the hindlimbs and can cause similar clinical signs.

Shortening of the cranial phase of the stride does not always indicate that lameness is present in that limb. At speed a trotter with forelimb lameness shortens the cranial phase of the stride in the ipsilateral hindlimb to avoid interference with the lame limb. This observation sometimes is also made in horses being trotted in hand. This compensatory movement gives the impression that the horse may be lame in the ipsilateral hindlimb, with a subtle pelvic hike. Lameness of the foot and carpus in trotters most often causes this compensatory ipsilateral hindlimb pelvic hike. Once lameness is abolished in the ipsilateral forelimb, the pelvic hike and shortened cranial phase of the stride in the hindlimb abate. In trotters a shortened cranial phase of the stride and a pelvic hike may be related to faulty weight distribution and interference problems and not to lameness at all.

ABNORMALITIES OF LIMB FLIGHT

Abnormalities of limb flight can cause interference of one limb with another, particularly in trotters and pacers (Fig. 7-2). However, horses performing at speed at any gait and those with faulty conformation also are at risk to develop interference injuries. In some horses, interference is of no consequence, but in others, especially trotters, it causes gait deficits. Skin lacerations, bruising, and underlying bone and soft tissue damage (interference injury) may occur. Various boots and other protective devices have been developed to protect the limbs from potential trauma. It is important to assess the presence and location of interference injuries. In some horses, only mild evidence of hitting is found, but other horse may have many painful areas. Chronic interference can be the sole reason for lameness or poor performance.

Front Foot Interference

Front foot hitting the contralateral forelimb. Horses with toed-out conformation tend to wing-in during movement, predisposing to interference injuries. Horses with base-narrow conformation or those with a combination of base-narrow and toed-out conformation also are at risk. However, many horses with these conformational abnormalities do not interfere.

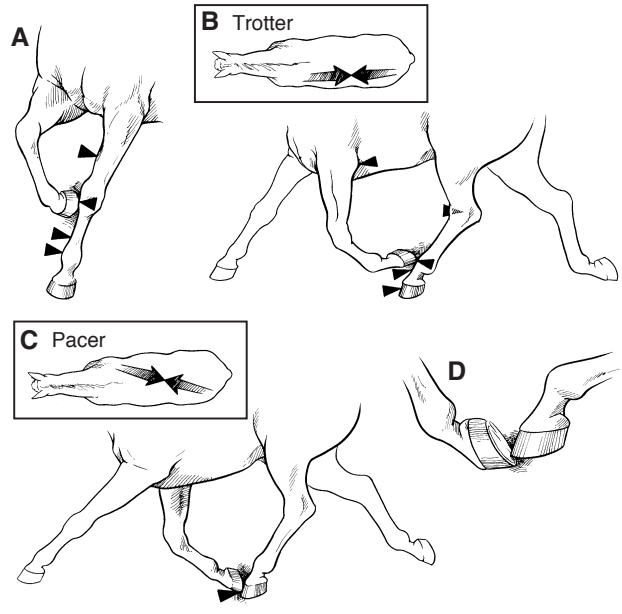

Fig. 7-2 Types of interference. **A,** Horses at any gait can be injured by interference of a forelimb with the opposite side. **B,** Interference is common in the trotter and usually involves the ipsilateral forelimb and hindlimb. Interference within a forelimb can be seen in horses that hit the elbow of the same limb. This usually occurs because of high action, excessive weight of the shoes, or a combination of these factors. **C,** Interference in the pacer can involve the forelimb and diagonal hindlimb, commonly called cross-firing. **D,** Forging occurs during trotting when the toe of the hind foot strikes the bottom of the ipsilateral front foot.

Some horses walk very closely but widen out at faster gaits. Interference injury from one hind foot hitting the medial side of the contralateral hindlimb occurs infrequently.

All types of horses, especially STB racehorses, are at risk of interference. Interference can involve any level of the limb from the foot to the proximal antebrachium. Mild interference of this type is called *brushing*. STBs often "hit their knees," which causes swelling, bruising, and lacerations of the skin on the distal medial aspect of the radius. In some horses, large, chronic swellings develop; these consist of mostly fibrous tissue. In others, osteitis of the distal radius or abscessation occurs. Even with protective gear, horses may be reluctant to perform at maximal speed to avoid injury or disruption of gait, or pain caused by interference induces the horse to go off-stride.

Interference within the same limb. Horses can develop interference injuries within a limb when the hoof or shoe hits the ipsilateral elbow. This type of interference sometimes is seen in trotters with high action (excessive carpal flexion) and is common in gaited horses that perform with heavy shoes intended to cause high action of the forelimbs (Fig. 7-2, *B*).

Front foot hitting the ipsilateral hindlimb. Interference in trotters usually involves the toe of a forelimb interfering (hitting) with the dorsal aspect of the ipsilateral hindlimb (see Fig. 7-1). Various names are given to the type of interference based on the location in which the injury occurs. Interference injury at the dorsal aspect of the hind foot or coronary band is called *scalping;* in the pastern region it is called *speedy cutting;* in the metatarsal region (shin) it is called *shin-hitting;* and in the dorsal or medial aspect of the tarsus, it is called *hock-hitting*. Because interference is common in trotters, it is important not to over-interpret signs of pain on palpation. Speedy cutting results in pain over the dorsal aspect of the proximal phalanx that should not be misinterpreted as pain associated with a mid-sagittal fracture.

Front foot hitting the contralateral (the diagonal) hindlimb. Cross-firing, or the striking of the contralateral (diagonal) hindlimb by the front foot, usually occurs only in pacers (Fig. 7-2, C).

Hind Foot Interference

Interference as a result of a hind foot hitting the foot of the ipsilateral forelimb *(forging)* is common and usually does not result in injury. Many horses forge at a trot in hand or while being ridden. In horses with shoes the sound is unavoidable but may not be a sign of a pathological condition. Forging is most common in horses that are trotted in deep footing. Forging may reflect imbalance, lack of strength, incoordination, or poor foot trimming.[5]

Forelimb: Common Abnormalities of Limb Flight

Winging In and Winging Out

Common limb flights observed during lameness examination include winging in and winging out movement of the front feet and are often related to conformation (see Fig. 4-12). Horses that are toed out tend to wing in, whereas those that are toed in tend to wing out. Such abnormalities do not necessarily compromise performance. However, such movement may result in uneven loading of the soft tissue structures and uneven hoof wear, leading to chronic imbalance. Horses that wing in tend to develop interference injuries and wear the medial aspect of the shoe excessively. Horses that wing out tend to develop lateral branch suspensory desmitis and wear the lateral aspect of the shoe excessively.

Lateral Placement of the Foot during Advancement (Abduction)

Horses normally advance the forelimbs straight ahead. When advancing the limb, horses with articular carpal pain, and in some with pain in the proximal metacarpal region, the foot is placed lateral to the expected foot position. This action has been described as *abduction* of the limb, but this term may infer swinging the limb, and horses with carpal lameness seem to place the limb laterally rather than swing the limb. However, ankylosis associated with severe osteoarthritis of the carpus does necessitate swinging the limb during advancement.

Horses with this abnormality of flight almost always have a shortened cranial phase of the stride. They tend to push off with the affected limb from the lateral location, resulting in a wide or peg leg type of motion at walk, and sometimes at trot. With bilateral carpal lameness the horse moves wide bilaterally. Not all horses with carpal pain move wide, and this gait change is seen more often in horses with middle carpal or carpometacarpal joint pain than in those with pain in the antebrachiocarpal joint. Some horses with upper limb lameness may carry the limb wide while walking, although this characteristic is not typical of horse with shoulder pain. A horse with a humeral stress fracture sometimes may travel wide, similar to a horse with carpal lameness, but the latter is more likely. A horse with pain in the lateral aspect of a foot may move wide in the affected limb to reduce load laterally. This characteristic is seen in STB and TB racehorses with subchondral bone trauma or early stress fractures of the distal phalanx in the LF.

Plaiting

The verb *to plait* means to braid or pleat, or to make something by braiding.[3] The term is used to describe horses that walk or trot by placing one foot directly ahead of the other foot. Plaiting in the forelimbs is not nearly as common as in the hindlimbs and usually is the result of base-narrow, toe-out conformation. Old horses (usually broodmares) with severe carpus osteoarthritis and carpus varus limb deformities occasionally may swing the limb laterally and place the foot far enough medially to end up in front of, or lateral to, the opposite foot. Some horses with shoulder region lameness guard the limb and travel very close in front. Plaiting in the forelimbs can be seen in horses with recent fractures of the thoracic dorsal spinous processes at the withers.[5] Horses with neurological disease occasionally plait.

Limb Flight in Horses with Shoulder Region Lameness

I include this section principally because the shoulder often is erroneously incriminated as the source of pain. Horses with moderate to severe lameness of the scapulohumeral joint or bicipital bursa have a marked shortening of the cranial phase of the stride. They also have an unusual motion of the shoulder joint that is difficult to describe. Since the cranial phase of the stride is shortened, during break-over the affected shoulder joint seems to drop or buckle forward, more so than the opposite side (assuming lameness is unilateral). There may be prominent lifting of the head and neck. Limb flight is either straight ahead or somewhat close to the opposite forelimb. However, racehorses with humeral stress fractures may travel wide in front. With mild lameness there are no typical gait characteristics.

Hindlimb: Common Abnormalities of Limb Flight

Stabbing or "Stabby" Hindlimb Gait

A common abnormality of limb flight seen in horses with hindlimb lameness is described as a *stabbing* or "*stabby" gait*. During protraction of the lame hindlimb or limbs the limb travels medially, close to the opposite hindlimb, and then moves laterally during the later portion of the swing phase and is placed lateral to the expected foot placement. This motion results in excessive wear of the lateral or dorsolateral aspects of the shoe. Although this gait often is seen in horses with distal hock joint pain, it can be seen with many other sites of pain from the distal tibia to the foot. Therefore diagnostic analgesia is required to localize the pain. However, horses with the most marked shoe wear consistent with this abnormality of limb flight are most likely to have tarsal

lameness. Exaggerated stabbing hindlimb motion often is seen in horses with neurological disease.

Abduction of the Hindlimbs during Advancement

In some horses with hindlimb lameness the limb is carried forward in a position lateral to the expected position (i.e., abducted). In some horses with this limb flight the limb swings outside the expected line of limb flight, only to strike the ground near the expected position. Lateral swinging of the limb begins immediately after the lame limb leaves the ground. I have observed this abnormality most consistently in horses with stifle lameness, but it also occurs with some other upper limb lameness conditions. Care must be taken when evaluating horses that normally travel wide behind, such as trotters.

I have recognized lateral swinging of the hindlimb most commonly in pacers with articular lesions of the stifle, because the normal gait in these horses is to swing the hindlimb more than would be expected from other horses. Many horses with stifle lameness carry the limb forward lateral to the expected position, but just before impact may actually stab laterally. Therefore the veterinarian must pay close attention to limb flight directly after the lame limb leaves the ground and while it is passing the contralateral limb. Another common characteristic of horses with stifle lameness is a shortened cranial phase of the stride. The stifle joint also may appear unusually prominent and be carried somewhat away from the flank and slightly externally rotated.

Plaiting

Plaiting is more common in the hindlimb than in the forelimb and usually results from lameness rather than faulty conformation, although plaiting can occur in a horse with severe base-narrow conformation. Plaiting can be seen in horses with unilateral or bilateral lameness. In horses with unilateral lameness, it appears that limb flight actually may be altered in both hindlimbs, resulting in both hind feet being placed ahead, or in some horses, lateral to the opposite foot. In horses with severe hindlimb lameness, it appears that the affected foot is being swung around and placed directly in front or lateral to the unaffected foot. Alternatively, the horse may be trying to support most of its weight on the unaffected limb and moves this limb inside to support the lame side. In horses with bilateral lameness, it is equally difficult to determine what exactly is causing the plaiting. The horse may be reluctant to bring either hindlimb along the expected line of flight, leaving the limb medially and forcing the opposite limb to the outside to avoid interference. A horse may swing each hindlimb around the other, ultimately ending placing one foot ahead or lateral to the other. An unusual rocking-type of gait is observed in horses with bilateral hindlimb lameness and plaiting. I have observed plaiting most commonly in horses with osteoarthritis of the coxofemoral joint or pelvic fractures, but I also have seen it in horses with bilateral distal hock joint pain or suspensory desmitis. Plaiting also is observed in some horses with sacroiliac joint pain.[5]

Mechanical Lameness of the Hindlimb and Limb Flight

Mechanical conditions of the hindlimb can cause profound abnormalities of limb flight. These are termed lameness conditions because of the gait abnormality exhibited, although in many horses pain is not characteristic.

Stringhalt

Stringhalt, an ill-defined neuromuscular disorder of the hindlimb, causes mild-to-severe hyperflexion of the tarsus. The condition can be unilateral or bilateral and usually is most obvious at a walk but can also be seen at the trot. In horses with severe stringhalt the dorsal aspect of the hoof comes close to or hits the ventral aspect of the abdomen. Horses may exhibit the clinical signs more prominently during backing or when initially moved after previous standing.

Fibrotic Myopathy

Fibrotic myopathy is characterized by a sudden downward and backward motion of the limb (slapping motion) that occurs during, and restricts the length of, the cranial phase of the stride. Hyperflexion of the hock is not a clinical feature of this gait deficit, but the restriction of the cranial phase of the stride and the slapping motion and sound can be confused with the clinical signs of stringhalt. It is most obvious at the walk.

Upward Fixation of the Patella

Upward fixation of the patella is a classic hindlimb gait deficit and one that displays the function of the stay or reciprocal apparatus. It can be intermittent or permanent and unilateral or bilateral. When the patella is locked in position over the medial trochlear ridge of the femur, the stifle and hock joints are held in extension, whereas the digit is held in partial flexion.

Shivers

Shivers is an ill-defined neuromuscular disease and is most common in Warmbloods and Draft breeds; it can occur unilaterally or bilaterally. Clinical signs usually are most obvious when a horse is backed or first moves from the stall. Horses elevate and abduct the limb, and the limb may actually shiver or shake. The tail often is elevated. Signs may be accentuated if the horse is tense.

Other Hindlimb Gait Deficits

Other unusual unexplained gait deficits affecting one or both hindlimbs are observed occasionally, and they often have characteristics similar to those seen with stringhalt, fibrotic myopathy, upward fixation of the patella, and shivers. However, some distinction usually prevents easy recognition and diagnosis. A gait deficit characterized by marked hindlimb abduction seen most prominently at the walk has been recognized. This is most similar to fibrotic myopathy, since a consistent abduction of the limb is observed, and signs tend to abate when the horse is trotted. It may be related to scarring, abnormal function of the biceps femoris and gluteal muscles, or neurological disease.

Neurological disease can cause many different gait deficits, most commonly recognized in the hindlimbs but also in forelimbs. A complete neurological evaluation usually is not performed during lameness examination unless certain abnormalities are observed. Abnormal or excessive circumduction of the hindlimbs, a bouncy, stabby hindlimb gait noticed when the horse is trotted, knuckling over behind or crouching, stumbling, and lethargy are signs that should prompt further investigation.

EVALUATION OF FOOT PLACEMENT

It is important to critically evaluate foot placement. Ideally, both the front and hind feet should land flat and level on a firm surface. Foot strike patterns change on soft footing. Evaluation of foot strike is most important in horses with lameness localized to the foot, but it can also give clues to other causes of lameness. Abnormal foot placement can be the result of a current lameness problem but may also cause lameness.

In the forelimbs, horses commonly land on the lateral side of the foot first before rocking medially. This can be the result of abnormal conformation or hoof imbalance and can predispose to lameness in the digit and suspensory branch desmitis. Landing abnormalities in the dorsal-to-palmar direction are common but are difficult to recognize unless severe. Horses with profound pain in the toe caused by laminitis or hoof abscessation land heel first, giving a camped-out appearance, and have a shortened caudal phase of the stride. Horses with palmar heel pain may compensate by landing toe first and cause abnormal stress on the dorsal structures of the foot, but this characteristic is difficult to see, except in slow motion.

In the hindlimbs, several patterns or abnormal landing or motion are recognized; not all of which are a cause or the result of lameness. Landing on the toe is commonly considered the result of heel pain, but many horses with severe hindlimb lameness land on the toe. This tendency is particularly prominent when the horse is first moved, and most horses warm out of the lameness. Horses may land on the toe when walking up an incline or at the walk on the flat, but generally place the heel on the ground when trotted. The most consistent lameness I see in horses that land on the toe is distal hock joint pain, but any cause of lameness from the tarsus to the foot can cause a horse to exhibit this abnormal landing pattern. Horses with lameness of the metatarsophalangeal joint region, including osteoarthritis, tenosynovitis of the digital flexor tendon sheath, or desmitis of the accessory ligament of the deep digital flexor tendon, have a tendency to land on the toe. Horses with adhesions within the digital flexor tendon sheath may have severe mechanical restriction that causes toe-first landing. Old Western performance horses with deep digital flexor tendonitis have severe toe-first landing and may stand on the toe and even rise up in the heels during the examination. The condition can be bilateral or unilateral and is difficult to manage. Mild or moderate tendency to land on the toe also has been attributed to stifle lameness.[5]

Abnormal movement of the lower or entire hindlimb occasionally is noted when horses are watched from behind. Horses may place one or both hind feet in an axial position and collapse or break-over the lateral aspect of the fetlock region.[5] Another uncommon hindlimb motion is characterized by excessive rotation of the hindlimb. The horse plants the hind foot and rotates the heel laterally, causing abnormal loading or twisting of the distal limb.[5] Although this movement can lead to lameness, it sometimes is seen in horses that are successful in various sporting endeavors. I have seen this type of hindlimb motion most often in TB racehorses.

ADDITIONAL MOVEMENT DURING LAMENESS EXAMINATION

Further information about the character of lameness often can be obtained by observing the horse as it move in circles and is ridden or driven. Some lameness conditions are apparent only under these circumstances.

Hard and Soft Surfaces

Comparison of movement on hard and soft surfaces is valuable. Foot lameness usually is worse when the horse is trotted on hard surfaces and better on a soft surface, such as grass or sand. Horses with suspensory desmitis or flexor tendonitis are more likely to show lameness on a soft surface. Deep sand may accentuate some lameness conditions, but an extended lameness examination under these conditions could cause proximal suspensory desmitis.[5] A slight downward incline or an uneven, rough surface may make subtle lameness more apparent.[5]

Circling

Lameness often is much more pronounced when a horse is circled. Horses should be circled in both directions: to the left (counterclockwise, LF and LH on the inside) and to the right (clockwise, RF and RH on the inside). Lameness may be more pronounced when circling at either the walk or the trot. In some horses with incomplete fractures, baseline lameness at a trot in straight lines in hand may be subtle or absent. Lameness may be readily apparent during circling, even at the walk. The additional forces of torsion and bending during circling are added to those of compression and tension. In horses with incomplete fractures, such as those involving the proximal or distal phalanges, torsion or bending forces during circling likely cause mild separation of the fracture fragments and exacerbate lameness. In horses with other lameness conditions, exacerbation of lameness may be caused by a change of load on the affected soft tissue structure or bone, redistribution of the forces of compression and tension in a medial to lateral direction, or additional forces of bending and torsion.

From a clinical perspective the force of compression may be dominant to other forces in determining a horse's response to circling, but it is not the only factor. Extension of the limb is also influential.[5] When the lesion is on the outside of the circle and undergoing compression, exacerbation of the lameness occurs. For instance, lameness in horses with medially located lesions of the distal phalanx or of the third carpal bone is worse when the limb is on the outside of the circle and the lesion is being compressed. For some soft tissue injuries, tension forces may be more important. Lameness in horses with proximal suspensory desmitis often is worse with the limb on the outside of the circle, suggesting that tension is important in the expression of lameness. The same observation is not seen in horses with more distally located suspensory desmitis.

Is lameness seen when in the horse while circling the same lameness seen while walking or trotting in straight lines? In most instances, circling exacerbates the primary lameness seen in straight lines. If lameness is subtle or non-existent when the horse is evaluated in a straight line, the lameness seen when circling becomes the baseline lameness. The clinician must recreate the same conditions of circling when evaluating the results of diagnostic analgesic techniques. There is always the possibility that lameness seen while circling may be different from the baseline lameness seen in straight lines. A horse may have a grade 1 RF baseline lameness when it moves in straight lines that increases to 3 when trotted in a circle to the left, but still has grade 1 lameness when trotted to the right. Lameness in straight lines and when trotting to the right is absent after palmar digital analgesia, but still is rated 3 when the limb is on the outside of the circle. The horse has two problems in the RF: palmar foot pain and an additional carpal lameness that becomes evident when the horse is trotted to the left (RF on the outside of the circle). With bilateral forelimb or hindlimb lameness, primary lameness often is seen in a single limb in straight lines, but while circling lameness is seen in whichever limb is on the inside (or outside) of the circle. Circling is useful in exacerbating the primary lameness problem and identifying an additional lameness not previously noted. This additional lameness must be recognized and treated separately from the baseline lameness.

Good correlation usually exists between the cause of lameness seen on the straight and that seen while circling the horse; thus it is helpful to circle the horse to try to exacerbate lameness. Circling can be done at the walk and trot in hand and while lunging or riding the horse. Horses often move more freely and naturally when lunged rather than when being led.[5] However, lunging is not possible in some horses, particularly racehorses, and circling while being led is better than no circling. The surface should be non-slip because horses may be hesitant to move freely on slippery surfaces and shorten or alter the stride even when lameness is not present.[5] Soft footing is best when the horse is first being lunged, since the horse can buck and play without risk of injury. Hard or firm surfaces are best to exacerbate many lameness conditions, but the surface must be non-slip to avoid possible injury.

That lameness of the upper forelimb or hindlimb is worse when the limb is on the outside of the circle is a common misconception. This is true in some horses, but a generalization cannot be made (see following text). Shortening of the cranial phase of the stride may appear more obvious with the limb on

the outside of the circle, but exacerbation of lameness judged by the degree of head nod may not be observed. Another misconception is that horses with lameness of the foot are lamest when the limb is on the inside of the circle. Although a majority (65%) of those with lameness localized to the foot are most lame when the limb is on the inside of a circle, lameness can be worst with the lame limb on the outside of a circle. This depends in part on the location of pain within the foot.

Forelimb

Lameness worsened with limb on the inside of the circle. In many horses, lameness originating from the fetlock region to the foot is worse with the affected limb on the inside of the circle. Comparison of circling on hard and soft surfaces is useful. Baseline lameness associated with foot pain usually is dramatically increased when the horse is circling on a hard surface, but a less obvious response is seen when circling on softer surfaces. However, lameness in horses with medially located lesions can be worse with the limb on the outside of the circle.

Horses with lameness of the metacarpal region vary in response to circling. Lameness in those with lameness related to metacarpal bony injury and distally located lesions in the suspensory ligament or digital flexor tendons tend to be worse with the limb on the inside of the circle, whereas lameness in those with proximal suspensory desmitis is worse with the limb on the outside. Horses with suspensory branch desmitis may show a different response depending on lesion severity and whether the injured branch is undergoing tension or compression.

In my experience, in horses with lameness of the forearm, elbow joint, arm, and shoulder joint region, the lameness tends to be worse with the limb on the inside of the circle, but opinions and experiences do vary.[5] Lameness in some horses with mechanical restriction of movement that dramatically decreases the cranial phase of the stride may be worse with the limb on the outside of the circle.

Lameness worsened with limb on the outside of the circle. Horses with medially based lesions of the lower limb, especially foot lameness, proximal metacarpal lesions (proximal suspensory desmitis or avulsion injury to McIII at the suspensory origin), or carpal pain often are more lame with the limb on the outside of the circle. Horses with lesions in the antebrachiocarpal joint are less consistent in response to circling compared with those with middle carpal joint lesions, since most of the common injuries involve the medial aspect of the latter. Upper limb lameness is accentuated in some horses.[5]

Lameness Improved when Circling

Lameness that appears better on a circle than in straight lines is uncommon. Lameness in horses with medially located lesions in the foot or carpus may improve when the limb is on the inside of a circle. Baseline lameness in horses with middle carpal disease involving the third and radial carpal bones improves with the limb on the inside of the circle. A STB racehorse with grade 2 or 3 RF baseline lameness that increases to grade 3 or 4 when circled to the left, but is only grade 1 or 2 when circled to the right, may have lameness associated with the middle carpal joint, but pain in the medial aspect of the foot also is possible.

A horse with bilateral forelimb lameness (e.g., a horse with grade 3 RF baseline lameness in straight lines) may show grade 3 to 4 RF lameness when trotting to the right, but grade 1 LF lameness when trotting to the left. The primary lameness is in the RF, and lameness is worse when the limb is on the inside of the circle. Circling to the left induced lameness in the LF, masking the RF lameness, because bilateral lameness existed that was not recognized when the horse was trotting in a straight line.

Hindlimb Lameness and Circling

In my experience, baseline lameness in most horses with any hindlimb lameness is worse when the limb is on the inside of the circle. Exceptions do exist, and some have different experiences and thus opinions.[5] Lameness associated with proximal suspensory desmitis often is worse with the affected limb on the outside of the circle, and the horse may stumble or take bad steps. Lameness in some horses with stifle lameness appears worse with the affected limb on the outside of a circle, but in others it appears similar to the left and the right. Many conditions of the stifle involve the medial femorotibial joint, a location that would be compressed with the limb on the outside. Lameness in any horse with a medially located lesion involving the distal hindlimb could be worse with the limb on the outside of the circle. Circling may be useful in exacerbating a primary lameness but generally is not helpful in localizing lameness.

Observation during Riding

Lameness may not be apparent when the horse is evaluated in hand in straight lines and circles but is obvious when the horse is ridden. This lameness becomes the baseline lameness for further investigation. The additional weight of a rider can exacerbate both forelimb and hindlimb lameness. Lameness in horses with primary back pain or those with substantial muscle pain secondary to hindlimb lameness usually is worse when they are ridden. Hindlimb gait restriction can occur in horses with back pain but may be apparent only when a horse is ridden.[5] Problems related to an ill-fitting saddle or girth, behavioral problems, head shaking, abnormal posture or carriage of the head and neck, and refusal to take a lead or bend in certain directions may be evident only when a horse is ridden.

A horse may be easier to control when ridden than when in hand or on the lunge. Performance of specific maneuvers by the horse may accentuate lameness. A collected trot that forces more weight onto the hindlimbs may exacerbate hindlimb lameness. An extended trot may reveal the horse's inability to extend on limb compared with another and reveal lameness that was completely imperceptible under all other circumstances. The primary complaint, such as poor-quality flying changes of lead at canter, may require a riding assessment regardless of whether baseline lameness is evident under other circumstances.

However, it is important for the veterinarian to separate his or her observations from those perceived by the rider. Identification of the lame limb may be difficult for a rider, although he or she may have a very strong opinion. If the veterinarian's observations differ, the rider may be difficult to convince. It is also essential to recognize that bad riding can actually induce a false lameness that is completely unapparent if the horse is ridden well. Nonetheless, an experienced rider, trainer, or driver can be quite helpful in assessing the horse's response to diagnostic analgesia or therapy, particularly in horses with thoracolumbar pain, subtle hindlimb lameness manifested only when ridden, and poor performance related to a musculoskeletal problem. Working regularly with a skilled, experienced, and reliable rider can be very helpful.

Subtle differences in weight distribution of the rider may exacerbate or mask the presence of forelimb and especially hindlimb lameness. When the horse is performing the posting (rising) trot, lameness may be more or less prominent depending on which diagonal the rider is using. In the rising trot the rider sits on either the left or right diagonal. On the left diagonal the rider is sitting when the LF and RH are bearing weight and rising during the swing phase of these limbs. On the right diagonal the rider is sitting when the RF and LH are bearing weight. The correct diagonal is the outside diagonal (i.e., left diagonal on the right [clockwise] rein). Hindlimb lameness often is worse when the rider sits on the diagonal of the lame limb.[5] Therefore if the horse is lame in the RH, the lameness appears and feel worse when the rider sits on the left diagonal.

Horses with hindlimb lameness may try to force or throw the rider to sit on the more comfortable (for both horse and rider) diagonal.[5] A horse with bilateral hindlimb lameness may appear lame in the RH when the rider sits on the left diagonal and lame in the LH when the rider sits on the right diagonal.[5] Forelimb lameness is influenced less by the diagonal on which the rider sits, but a similar pattern exists. RF lameness is worse with the rider sitting on the right diagonal.[5] This difference in lameness expression may be perceptible only by an experienced rider.

Observation of Inclines

Walking or trotting a horse uphill or downhill may exacerbate lameness or identify previously unapparent lameness. Lameness in horses with suspensory desmitis may be worse when they walk uphill or downhill. Lameness associated with palmar heel pain may be worse when the horse walks downhill and the horse may show a tendency to stumble. Horses that tend to stumble or knuckle behind while walking downhill may have loose stifles (inability to maintain the position of the patella, usually caused by lack of muscle tone). Horses with neurological disease usually show more pronounced clinical signs when walking uphill or downhill.

A superficially flat, hard surface may actually slope; this can influence lameness because the horse's feet will be tilted with one side lower than the other. Thus the horse may appear different when trotting away from the observer than when returning.

EVALUATION OF LAMENESS WITH A TREADMILL OR GAIT ANALYSIS

The use of a treadmill for poor performance evaluation is well recognized, and its use in lameness assessment is discussed in detail in Chapter 101. The clinical relevance of lameness apparent only on a treadmill is open to debate. I do not find lameness examinations on a treadmill at high speed particularly useful unless slow-motion videotape is available. I prefer to assess the horse while training or performing. A horse may modify its normal gait on a treadmill. Good correlation was demonstrated between gait regularity in horses exercised on a track and a treadmill, but treadmill strides and steps were shorter, and the swing phase of the stride was reduced.[28] Horses require at least two training sessions on a treadmill before the gait becomes consistent.[29] Stride characteristics of horses galloping on a treadmill change as the slope of the treadmill increases from 0% to 8%; horses reduced the suspension phase to maintain overall stride length.[30]

Gait analysis is discussed in Chapter 22. To date, assessment by an experienced, skilled observer has been more reliable in the identification of the lame limb or limbs than other more sophisticated methods of gait analysis.

CHAPTER • 8

Manipulation

Mike W. Ross

Flexion or other manipulative tests often are used to induce or exacerbate lameness during lameness or pre-purchase examinations.

INDUCED AND BASELINE LAMENESS

It is important to understand the concept of *induced lameness* and the possible difference between lameness seen at this stage and baseline lameness. During lameness examination, baseline lameness is established before any form of manipulation is performed. This may be difficult if more than one limb is involved, if lameness is subtle or sub-clinical, or if lameness is bilaterally symmetrical, which causes a gait abnormality without overt lameness. Lameness provocation is performed to exacerbate the baseline lameness or to provoke a hidden gait abnormality and attempt to localize the source of pain within a limb or limbs.

Provocative tests create induced lameness that may not have any clinical relevance to the baseline lameness observed during initial movement. These tests are not sensitive or specific, and many times result in false-positive and false-negative findings. Many horses with palmar heel pain respond positively to the "fetlock flexion test" (or lower limb flexion test, see following text) and could erroneously be thought to have lameness of the metacarpophalangeal joint. A racehorse with baseline lameness as the result of a carpal chip fracture may have pre-existing low-grade osteoarthritis of the metacarpophalangeal joint and respond positively to lower limb flexion, but response to carpal flexion may be equivocal. Diagnostic analgesia is essential to localize the source or sources of pain. In the hindlimb, hock flexion, the so-called spavin test, causes many false-positive reactions.

FLEXION TESTS

Flexion tests were first described early in the twentieth century, but information regarding the degree of flexion, force, or duration of the tests was lacking.[1] Variations in technique persist and produce variable responses that can be misleading. There appear to be more false-positive reactions to flexion than there are false negatives, but the latter do occur. Flexion tests are useful during pre-purchase examinations because the horses being examined usually are relatively sound, and the tests are useful at uncovering hidden sources of pain. Flexion tests may be useful in exacerbating lameness, particularly when the primary or baseline lameness is in the region being flexed, but sensitivity is doubtful. Horses judged to be clinically sound underwent a "normal" and then a "firm" lower limb flexion test (fetlock flexion).[2] Of the 50 horses tested, 20 had a positive response to normal flexion, and 10 of these horses were judged to be lame while trotting for about 15 m (50 ft) or more. Forty-nine of 50 horses had a positive response to firm flexion, and 35 of these remained lame for a minimum of 15 m. In this study the force applied was not calibrated, 7 of the 50 horses developed lameness within 60 days of completion of the study, and 24 horses had radiographic abnormalities that could have contributed to a positive response to flexion.[2] Although there may be an explanation for a positive response in some horses, the high percentage of positive results in the study is in agreement with my clinical impression. In a study using the Flextest (Krypton Electronic Engineering NV, Leuven, Belgium), an apparatus designed to control traction force and time during a lower limb flexion test, the optimal force and time for flexion were 100 N and 1 minute, respectively. There was a positive response to flexion in many horses that were considered sound, and a positive response in sound horses was more likely in those in active work than in horses that had been rested or turned out on pasture. Horses were more likely to manifest a positive response to flexion as the force used in the test was increased.[3] A false-positive response to flexion can be observed in clinically normal horses and in those with unimportant low-grade problems. Lameness induced by flexion in these horses may have little clinical relevance.

However, other evidence suggests that a positive response to lower limb flexion in sound horses may be useful to predict future lameness. In a retrospective study, 151 initially sound horses were followed for 6 months. Twenty-one percent of horses with a positive forelimb flexion test result developed lameness in the area being flexed, whereas only 5% of horses with a negative flexion test result subsequently developed lameness. In young Swedish Warmbloods there was a positive correlation between a positive response to flexion and a subsequent insurance claim related to lameness.[4]

Flexion tests lack specificity because it is nearly impossible to flex a single joint without flexing other joints or nearby tissues, particularly in any hindlimb or distal forelimb flexion tests. Elevation of a limb without flexion in severely lame horses may exacerbate the baseline lameness, since horses guard the limb or need to warm-out of the lameness for a number of steps while trotting, thus complicating interpretation. Hindlimb flexion tests are less specific than forelimb tests because the reciprocal apparatus prevents flexion of any joint without concomitant flexion of other joints. Hindlimb flexion tests are useful in exacerbating baseline lameness, but positive responses to individual lower limb and upper limb tests, in my opinion, only localize lameness to the entire hindlimb. I believe that flexion tests are useful in exacerbating lameness, and in some horses it is the baseline or relevant lameness that is being worsened. In general, unless the horse's response is clearly pronounced and different from that of other manipulation, lameness cannot be localized based on response to flexion alone. Diagnostic analgesia should always be used, when possible, to localize pain.

Order, Duration, Force, and Venue during Flexion Tests

Consistency in technique is essential. Although force exerted by individuals varies, the flexion technique of experienced practitioners is sufficient to objectively assess response to

flexion.[5] Response to flexion can and should be compared with the contralateral limb. Ideally the flexion test should be performed in the contralateral sound limb first, before performing the test in the suspect limb, to determine the horse's response. Accurate assessment of response to flexion in the contralateral non-lame limb may not be possible if the horse is severely lame after flexion of the lame limb and lameness persists. In some instances, baseline lameness is actually increased by forcing the horse to stand for the contralateral flexion test, a useful observation seen most commonly in horses with forelimb lameness (see following text).

Duration of flexion is somewhat controversial and may be an individual choice. In a study evaluating lower limb flexion, duration of 1 minute was considered ideal, because normal horses that underwent flexion at 100 N for 1 minute had few false-positive responses.[3] Maintaining firm flexion for 1 minute while performing all flexion tests and repeating the tests in the contralateral limbs can make this portion of the lameness examination time-consuming. On the other hand, if the clinician takes the time to perform these tests, optimum chances of success are desired. A false-positive result is more useful than a false-negative test result. Some clinicians prefer to perform flexion tests with more force but for a shorter duration. This technique works well for lower limb flexion tests. Seldom is it possible to maintain some upper limb manipulative procedures for 1 minute. Thus some latitude is necessary. I believe that duration of flexion of 45 seconds to 1 minute is enough to elicit an accurate response in most horses.

Force used during flexion varies considerably, but excessive force induces lameness in most normal horses. Forces in the range of 100 to 150 N represent a moderate degree of force for lower limb flexion tests. In studies using a dynamometer, the maximum amount of force that could be used without a consistent withdrawal response in normal horses was 150 N.[6] The amount of force also depends on the size of the horse or the joint being flexed. The amount of force used in adult horses cannot be used in foals. Horses with obvious osteoarthritis or articular fracture, or those with substantial soft tissue injury likely to be affected by the flexion test, do not tolerate the same force as horses with more mild conditions. In a study of healthy and injured Thoroughbred (TB) racehorses, a positive correlation existed between decreased range of motion and joint injury.[7] Loss of joint motion was most likely caused by joint capsule fibrosis, but pain associated with increased intra-articular pressure from effusion or flexion also may have limited joint motion.[7] I recommend flexing a joint as much as possible with an amount of force just slightly less than that which consistently causes a withdrawal response.

Proper evaluation of the results of flexion tests requires that the horse be observed while trotting in a straight line on a firm, non-slip surface. Horses usually are trotted in hand, although occasionally a horse's response to flexion is evaluated while it is being ridden. The horse should be trotted immediately after the limb is placed to the ground, with care taken to avoid scaring the horse or providing any excessive encouragement to trot, because many horses will slip initially, gallop off, or balk, all of which necessitate test repetition. If possible, the horse should be trotted away from the examiner for a minimum of 12 to 15 m.

Causes of Pain during Flexion and Positive Flexion Test Results

Forced flexion of a joint can induce pain in many potential sites. Force is being applied to both articular structures and surrounding soft tissues. The tissues on the flexion side of the joint are being compressed, whereas tissues on the extension side are under tension. During flexion, intra-articular pressure and intra-osseous pressure in subchondral bone are increased.[3,7] Stretching or compression of the joint capsule, vascular constriction, and activation of pain receptors in the joints and surrounding soft tissues also can occur during flexion.[3] It is rarely possible to attribute pain on static flexion or during movement after flexion to an individual articular surface. The "fetlock flexion test" is a misnomer because as it is commonly performed, it includes the interphalangeal joints and stresses surrounding soft tissue. Thus the names *lower limb flexion test* or *fetlock region flexion test* are more appropriate.

Positive Responses to Flexion

Positive responses to flexion can be seen with static flexion (see Chapter 6) and when movement follows flexion. A positive flexion test result is defined as obvious lameness or an increase over baseline lameness that is observed for more than three to five strides while the horse trots in a straight line after flexion. A mild response, even in sound horses, often is seen in the first few strides, a finding that should be compared with the contralateral limb. Sound horses warm-out of this mild response quickly. A persistent, one- to two-grade increase over baseline lameness for several steps is a positive response. In horses with hindlimb lameness a marked positive response often is accompanied by reluctance to place the heel on the ground, and the horse may land only on the toe for several strides.

Forelimb Flexion Tests

Lower Limb Flexion Test

The lower limb flexion test often has been equated erroneously with the fetlock flexion test. The fetlock region can be flexed independently of interphalangeal joints (see following text). The lower limb flexion test is the most common test performed in the forelimb and involves placing a hand on the toe and forcing the fetlock and both interphalangeal joints into firm flexion (Fig. 8-1). A positive response to flexion can be observed with any condition of the distal interphalangeal, proximal interphalangeal, and metacarpophalangeal joints; navicular bone or bursa; other causes of palmar heel pain; digital flexor tenosynovitis; any soft tissue problem in the palmar pastern region; and lameness associated with the

Fig. 8-1 The lower limb flexion test often is erroneously called the fetlock flexion test. During the lower limb flexion test the fetlock, proximal interphalangeal, and distal interphalangeal joints are flexed; the palmar pastern and fetlock region soft tissue structures are compressed; and the dorsal structures are stretched.

branches of the suspensory ligament (SL) or proximal sesamoid bones (PSBs). Horses with lesions of the PSBs usually have markedly positive responses to this test. *This test is not specific for lameness of the metacarpophalangeal joint*. I have seen marked responses in horses with navicular disease or osteoarthritis of the interphalangeal joints. However, horses with osteoarthritis, fractures of the metacarpophalangeal joint, or tenosynovitis usually also show a marked positive response. In a recent study of clinically sound horses in which lameness could consistently be induced by flexion with 250 N for 1 minute, lameness was alleviated by intra-articular analgesia of the metacarpophalangeal joint, but not by intra-articular analgesia of the proximal interphalangeal or distal interphalangeal joints or intra-thecal analgesia of the navicular bursa.[8]

The limb should be held as close to the ground as possible, and forced carpal flexion should be avoided (see Fig. 8-1). All soft tissue and bony structures in the palmar aspect of the distal limb are severely compressed, resulting in low specificity for the metacarpophalangeal joint. Some people use a hand as a fulcrum or grab the toe with both hands (Fig. 8-2), but this technique may result in application of excessive force, although it otherwise produces similar results.

Fetlock Flexion Test

The specificity of the lower limb flexion test can be improved by applying force to the metacarpophalangeal joint and avoiding forced flexion of the interphalangeal joints. The fetlock flexion test is performed by placing one hand along the dorsal aspect of the pastern region and one hand along the dorsal aspect of the metacarpal region, while avoiding flexion of the carpus (Fig. 8-3). This test is more difficult to perform because it requires more force and the clinician's effort to maintain a similar degree of flexion. The test is not specific for articular lameness of the metacarpophalangeal joint and horses with soft tissue problems respond positively.

Flexion of Interphalangeal Joints

In my opinion, flexion of either the proximal interphalangeal or distal interphalangeal joint without concomitant flexion of the other, or of the metacarpophalangeal joint, is impossible. Varus or valgus stress can be applied to the interphalangeal joints, and when followed by trotting, this stress can be a suitable provocative test in horses with osteoarthritis or soft tissue injuries of these joints.

Carpal Flexion Test

The carpal flexion test is the most specific of all forelimb flexion tests, and a positive response usually reflects baseline lameness associated with the carpal regions. Few false-positive results occur. A positive response may reflect intra-articular pain, but a positive response also is seen in horses with carpal tenosynovitis, accessory carpal bone fractures, proximally located superficial (SDF) and deep digital flexor (DDF) tendonitis, proximal suspensory desmitis (PSD), or avulsion fracture of the third metacarpal bone (McIII) at the SL insertion. Rarely, a horse with a problem in the scapulohumeral and cubital joints or the antebrachium responds positively. A negative response does not preclude an articular lesion of the carpus, including incomplete fractures or sclerosis of the carpal bones.

The limb is elevated and the carpus is forced into full flexion by pushing the metacarpal region directly underneath the radius (Fig. 8-4). The distal limb can be pulled laterally to place the carpal joints in valgus stress or torsion.

Horses sometimes trot off lame on the contralateral limb after the carpal flexion test is performed. I have seen this most commonly in young Standardbred or TB racehorses with subchondral bone pain in the middle carpal joint and call it the "Ross crossed-extensor phenomenon." I believe that this reflects bilateral lameness, and flexion of the ipsilateral carpus causes less pain than making the horse stand for 1 minute on the contralateral limb. I have observed this response most commonly in horses with bilateral carpal lameness, but exacerbation of contralateral lameness is not restricted to carpal lesions. Dyson[9] has called this a "paradoxical response to flexion" and has observed exacerbation of contralateral lameness in horses with navicular syndrome and distal hock joint pain.

Fig. 8-2 Extreme lower limb flexion can be achieved by using both hands on the toe with the limb cradled between the clinician's legs. With such extreme flexion even normal horses may manifest a positive response.

Fig. 8-3 A true fetlock flexion test can be performed by carefully flexing only the fetlock joint. The clinician's hand grasps only the pastern and not the toe of the hoof while avoiding forced flexion of the proximal and distal interphalangeal joints (see Fig. 8-1).

Upper Limb Manipulation

Because of the inverse but simultaneous movement of the elbow and shoulder joints, it is difficult to accurately name the

Fig. 8-4 The carpal flexion test is the most specific of all flexion tests, but it applies concomitant mild flexion of the elbow and shoulder joints. Although false-negative results are possible, a positive carpal flexion test result usually means that lameness originates from the carpal region.

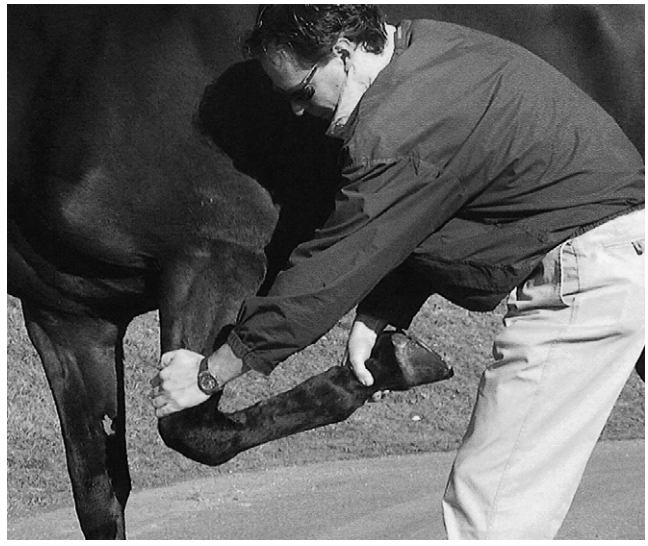

Fig. 8-5 Upper forelimb flexion is performed by grasping the antebrachium and pulling the entire limb caudally and slightly proximally. This maneuver flexes the shoulder joint and extends the elbow joint. Horses with shoulder region lameness often respond positively to this manipulative test.

flexion tests of these joints. For instance, when the limb is pulled in a caudal direction, the shoulder joint is flexed, but the elbow joint is extended. I call this manipulation *upper limb flexion* (Fig. 8-5). This maneuver requires both hands, one hand grasping the pastern region and one grasping the cranial aspect of the antebrachium to force the entire limb in a caudal direction. When the limb is pulled in a cranial direction, resulting in *upper limb extension*, the shoulder joint is extended, but the elbow joint is flexed (Fig. 8-6). Both hands are placed around the pastern region while forcing the entire forelimb into maximal extension. Maintenance of upper limb extension or flexion for even 45 seconds is difficult, so I try to maintain this position for as long as possible and then evaluate the horse while trotting. Many normal horses resist upper limb manipulation, and an alternative is to force the limb into hard flexion or extension in a rhythmical fashion six to eight times and then trot the horse. Even though the entire limb is being manipulated, there are few false-positive test results. However, false-negative test results can occur, probably because of the inability to place either the shoulder or the elbow joints in hard flexion. In my experience, horses with lameness originating from the elbow region are more likely to respond to upper limb extension, whereas those with lameness originating from the shoulder region are more likely to respond to upper limb flexion.

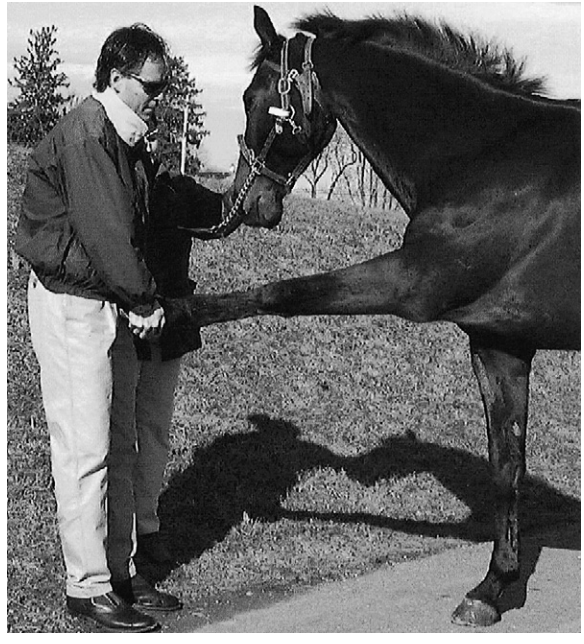

Fig. 8-6 The upper limb extension test is performed by pulling the forelimb out in front of the horse and forcing it proximally. This places the elbow joint in flexion and the shoulder joint in extension. In my experience, lameness of the elbow region is exacerbated by this technique, but occasionally shoulder joint lameness also is worsened.

Hindlimb Flexion Tests

Hindlimb flexion tests are not specific, but they may be useful to exacerbate the baseline lameness or detect hidden sources of potential lameness. I do not believe that hindlimb flexion tests are useful in differentiating the source of lameness in most horses, unless the response is dramatic, and diagnostic analgesia usually is required in all horses.

Lower Limb Flexion Test

The lower limb flexion test is performed similarly to the forelimb flexion test, but with similar force the metatarsophalangeal joint can be flexed more extremely. The veterinarian should try to keep the limb as low as possible to avoid placing hard flexion on the upper limb, although all joints are flexed to a degree. The lower limb flexion test also affects the proximal interphalangeal and distal interphalangeal joints and the surrounding soft tissues (Fig. 8-7). Horses with digital flexor tenosynovitis or DDF tendonitis show a marked response to the lower limb flexion test. False-positive results can occur, but these are less common in a hindlimb than in a forelimb, even in horses in active work. Horses with pain in the upper limb may show a mild or moderate response to lower limb flexion. This test is not specific for pain located in the lower limb, and lameness in horses with stifle pain often is worse after the lower limb flexion test.[9] Horses with subchondral

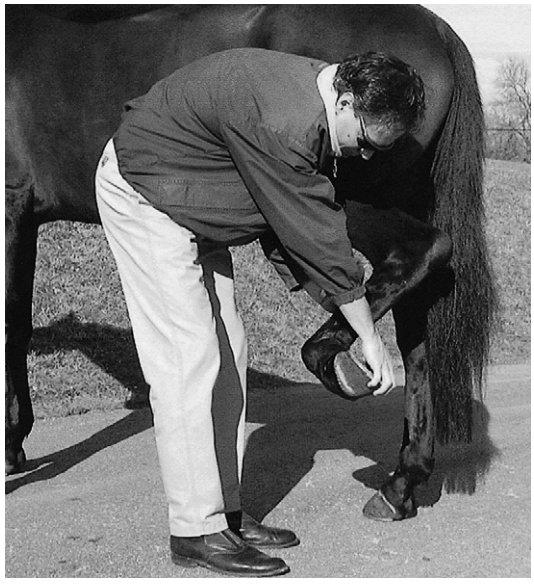

Fig. 8-7 The lower limb flexion test in the hindlimb is performed with the limb as close to the ground as possible. Flexion of one portion of the hindlimb is impossible without flexing the entire limb, a finding that explains many false-positive hindlimb flexion tests.

bone pain from non-adaptive or stress remodeling of the distal third metatarsal bone (MtIII) or those with incomplete fractures of MtIII or incomplete, mid-sagittal fractures of the proximal phalanx may show little response to this test (false-negative result).

Fetlock Flexion and Interphalangeal Joint Tests

The metatarsophalangeal joint region can be flexed independently of the interphalangeal joints in the hindlimb, or the interphalangeal joints can be flexed independently, but these tests are difficult to perform and of limited value.

Upper Limb Flexion Test

The so-called spavin or hock flexion test *is not specific for lameness of the hock*, because the stifle and coxofemoral joints also are stressed hard, and mild flexion of the lower joints is inevitable.

The limb is held in hard flexion for at least 1 minute, but additional time for this test may improve its clinical value (Fig. 8-8). It may be necessary to have an assistant place a hand on the contralateral hip to steady the horse, because proper performance of this test requires that the limb be elevated substantially and the horse may lose its balance. The position of the hands in the metatarsal region is important to consider, since the force required to hold the hindlimb in this position may cause compression and pain in structures along the plantar aspect, potentially contributing to a false-positive response.

Hindlimb Flexion Test

Alternatively, the entire hindlimb can be flexed simultaneously. This test is useless in differentiating potential sources of pain in a limb, but it is quite useful in exacerbating baseline lameness or uncovering occult lameness conditions. The clinician's hands are placed on the toe and the entire limb is held in extreme flexion (Fig. 8-9). An assistant may be necessary to steady the opposite hip while the limb is elevated.

"Hock" Extension Test

Hock extension may be useful in placing selective stress on the hock, independent of the stifle. Forced extension causes tension on the soft tissue structures on the dorsal, medial, and lateral aspects of the hock. Seldom is it possible to perform this test for 1 minute; six to eight attempts at forced extension followed by trotting the horse can be substituted for more lengthy manipulation (Fig. 8-10). False-positive and false-negative responses occur, which are caused mostly by the inelastic reciprocal apparatus. This maneuver can reveal laxity of a damaged fibularis (peroneus) tertius.

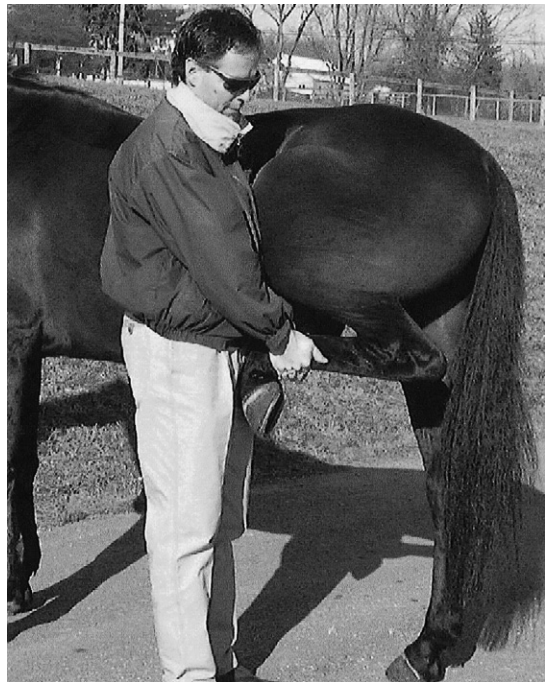

Fig. 8-8 The hindlimb upper limb flexion test is demonstrated. This test has been called the spavin or hock flexion test, but it is not specific for lameness of the hock. The hock and stifle joints are in forced flexion, the lower limb joints are flexed, the metatarsal region is compressed, and a small amount of forced flexion of the coxofemoral joint is induced.

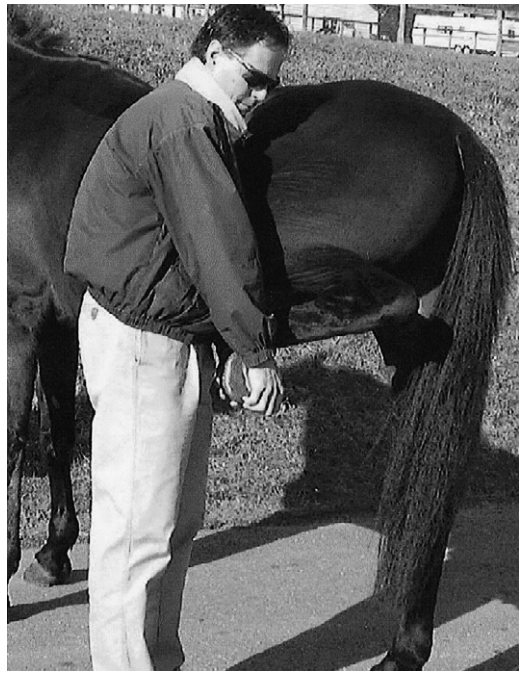

Fig. 8-9 A hindlimb flexion test is a combination of the lower limb flexion and upper limb flexion tests.

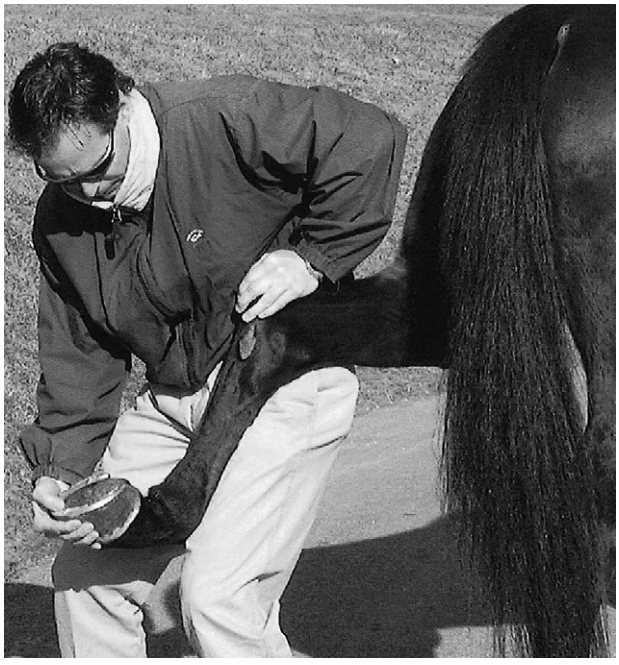

Fig. 8-10 During the hock extension test the clinician forces the hock into extension by pushing down on the calcaneus while pulling up on the distal limb by using both the right arm and left leg. Pain from hock lameness can be exacerbated, but false-positive results from pain in other locations also can occur.

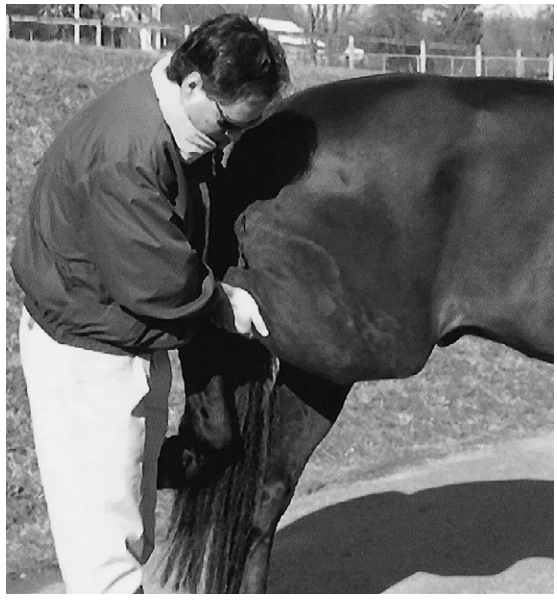

Fig. 8-11 A seldom-used test is the stifle flexion test. This test can be difficult and dangerous to perform in fractious horses. The forced flexion of the stifle joint used in this test attempts to differentiate stifle and hock joint pain.

"Stifle Flexion" Test

A modification of the upper limb flexion test can be used to place hard flexion on the stifle, independent of the hock (Fig. 8-11). This test can be somewhat difficult to perform but may exacerbate lameness in horses with osteoarthritis or other conditions of the stifle. Other proximal limb joints are also in flexion; therefore some false-positive results occur.

DIRECT OR LOCAL PALPATION FOLLOWED BY MOVEMENT

Static palpation, in which the horse's response to compression during palpation while standing is assessed, reveals useful information (see Chapter 6). Additional information can be gained by evaluating movement after palpation, dynamic provocation to induce lameness. Dynamic provocation usually is performed by digital palpation or use of hoof testers. Many horses manifest a positive response during static palpation, but the primary pain is located elsewhere. However, if lameness can be induced or baseline lameness can be increased by one or two grades by deep palpation, then the area may be relevant to the current cause of lameness. False-positive results do occur, but in my opinion, these are less frequent than with most flexion tests. There are few false-negative results.

Digital Compression of a Painful Area

The veterinarian should elevate the limb and compress the painful or otherwise inflamed area for 15 to 30 seconds and then evaluate the horse at a trot in hand. Exacerbation of the baseline lameness by one or more grades is considered a positive response. This procedure is useful in differentiating the cause of lameness in both the forelimb and hindlimb. In the forelimb, I find it useful to compress the dorsal proximal aspect of the proximal phalanx (if a mid-sagittal fracture is suspected), the dorsal cortex of the McIII (for bucked shins or a dorsal cortical fracture), exostoses involving the small metacarpal bones (for splints), the suspensory branches or digital flexor tendons, and the proximal palmar metacarpal region (for PSD or longitudinal or avulsion fracture). In horses with mild tendonitis of the superficial digital flexor tendon (SDFT), baseline lameness usually is mild or non-existent, but obvious lameness after digital compression suggests tendonitis as a substantial problem.

In the hindlimbs, compression of the dorsal proximal aspect of the proximal phalanx can increase lameness from mid-sagittal fracture, but trauma from interference injury (of particular importance in trotters) or other forms can lead to a false-positive response. A *dynamic Churchill test*, compression followed by trotting (see Chapter 6), is useful in the diagnosis of lameness of the proximal metatarsal region and tarsus. In the hindlimb, compression of the proximal aspects of both the second and fourth metatarsal bones puts indirect pressure on the origin of the SL, and a positive response may indicate PSD. Compression of a "curb" followed by trotting may increase lameness.

In some horses with tibial stress fractures, an induced lameness can be seen after deep palpation of the caudal tibial cortex. With the limb elevated, the veterinarian should apply deep pressure to the caudal cortex by wrapping the fingers around the tibia from the medial aspect. Most horses object to this maneuver, but in those with tibial stress fractures, the positive static response is followed by an exacerbation of the baseline lameness.

Axial Skeleton

Application of direct local pressure to many parts of the axial skeleton is difficult, but in some instances this procedure can lead to the detection of pain both statically and while the horse is trotting (see Chapters 6, 94, 98, and 100). In the cervical area, forced lateral bending followed by walking or trotting may exacerbate neurological signs or gait deficits in horses with cervical instability or proliferative changes. Deep palpation over the thoracolumbar spine followed by trotting

can induce hindlimb stiffness or other mild gait abnormalities. Direct and deep palpation over the tubera sacrale and tubera coxae can induce hindlimb lameness in horses with stress fractures or those with chronic lameness as a result of pelvic asymmetry from old fractures. Sacroiliac compression, or manipulation of the sacrum or tail head, can induce hindlimb stiffness or lameness in horses with injuries in these areas.

INDUCED LAMENESS AFTER HOOF TESTER EXAMINATION

The hoof testers are applied in a suspected area for 15 to 30 seconds and the horse is evaluated for lameness while trotting. False-positive test results are quite common, but a marked difference between limbs can be an important clinical sign. Shoes and pad combinations may preclude complete hoof tester examination of the sole, so I often apply pressure across the heels. I have found this position to yield the most useful information in horses with palmar heel pain from most causes, but it also induces a positive response in horses with non-specific foot pain (sore feet). Most normal horses object to firm pressure placed across the heels using hoof testers, and mild lameness on the initial few steps is common, but severe lameness after this test is a useful indication that the foot is the source of baseline lameness.

THE WEDGE TEST

The *wedge test* is a form of manipulation similar to the flexion or other varus or valgus stress tests, but it is used specifically to evaluate the digit and associated soft tissues. The wedge can be used to dramatically change the dorsal-to-palmar (heel) or medial-to-lateral hoof angles. Collateral ligaments, joint capsules, subchondral bone and articular surfaces, and surrounding soft tissues can be stretched or compressed when the horse stands on the wedge. Changes in hoof angles of this magnitude can greatly change the stress placed on the deep digital flexor tendon (DDFT), SDFT, and SL. Raising the heel reduces stress on the DDFT but increases stress on the SL. Raising the toe reduces stress on the SL but increases stress on the DDFT, navicular bone, and associated ligaments and bursa. The number of tissues affected by the wedge accounts for the lack of specificity of this test, and it likely accounts for many false-positive results. The wedge is placed in the desired position and the horse is made to stand in this position for 30 to 60 seconds with the contralateral limb elevated (Fig. 8-12). The horse is then trotted in a straight line on a firm surface. The test can be used in any limb but is performed most commonly in the forelimbs. In some horses, it is difficult to attain the desired duration regardless of whether they are lame. The horse's response to simply standing on the wedge may not give an accurate indication of how lame it will be when it is trotted. In horses content to stand in such an abnormal position, a dramatic lameness may be seen at the trot. Horses with navicular syndrome or sore feet from many causes of palmar heel pain are most likely to manifest a positive response. In my experience, the direction of the wedge that elicits the most positive response from horses with palmar heel pain is with the apex (low end) directed medially (see Fig. 8-12). This substantial change in the medial-to-lateral hoof angle is likely to cause stretching of the suspensory apparatus of the navicular bone and collateral ligaments of the distal interphalangeal joint or compression on articular structures. Horses with palmar heel pain may show severe lameness, but diagnostic analgesia is required to confirm the foot as a source of pain. Horses with injuries of the DDFT, SDFT, and SL may show a milder response.

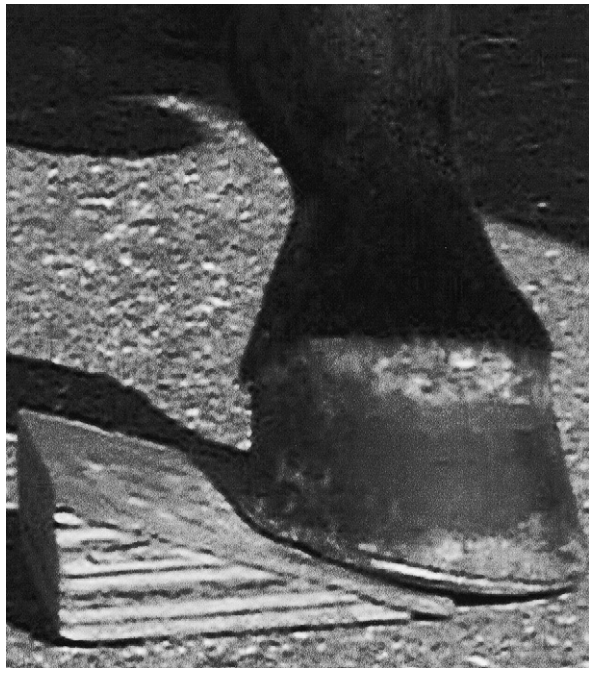

Fig. 8-12 A 15° to 20° wedge can be used to manipulate the joints and soft tissue structures of the digit. The most consistent response is elicited by directing the apex (low end) of the wedge medially (as shown). The wedge also can be used to raise the heel and toe. (Wedge courtesy Norman Ducharme, Ithaca, New York.)

VARUS OR VALGUS STRESS TESTS

Evaluation for lameness after placing varus or valgus stress on an individual joint may incriminate this area as a potential source of pain and is used most commonly in the stifle. To perform the stifle valgus stress test, the clinician's shoulder (or hand) is used as a fulcrum against the distal femur, and the distal limb is pulled laterally several times before the horse is trotted (see Fig. 6-24). False-positive results can be obtained because the entire distal extremity is manipulated during this test. Valgus or varus stress tests can be used in many joints in the distal limb, particularly the interphalangeal joints.

Patellar manipulation followed by trotting (see Fig. 6-26) may be helpful but can be difficult to perform when horses resist forced proximal movement of the patella (frequently, the veterinarian's wrist is forced into hyperextension). Although cranial and caudal drawer tests can be used to exacerbate stifle lameness, I have not found them particularly helpful, and they are dangerous to perform.

FLEXION TESTS AND DIAGNOSTIC ANALGESIA

I do not generally recommend combining the results of flexion tests and diagnostic analgesia. I often hear that baseline lameness abated after a block, but the horse still had positive flexion test results. My usual comment is, "Why bother to flex the horse if baseline lameness has been abolished?" Flexion tests induce lameness that may be unrelated to the baseline lameness. Thus it is not unusual that a horse might have residual lameness after flexion, even if the baseline lameness has been eliminated.[4] I usually do not recommend further investigation once baseline lameness has been eliminated.

If baseline lameness is not obvious, but a low-grade gait deficit is present, or if a horse has bilaterally symmetrical lameness, flexion tests or other forms of manipulation or

provocation may be the only way of "seeing" lameness. In this instance, induced lameness from manipulation can be assumed to be the baseline lameness, and diagnostic analgesia can proceed. All involved parties should be well informed about the potential for misdiagnosis, but in certain circumstances this pathway may lead to a successful diagnosis.

CHAPTER • 9

Applied Anatomy of the Musculoskeletal System

Matt Durham and Sue J. Dyson

It is beyond the scope of this book to describe all aspects of musculoskeletal anatomy in depth, yet a detailed knowledge of anatomy is fundamental to a lameness diagnostician, as highlighted in the chapters on observation and palpation (Chapters 5 and 6). Some aspects of anatomy are considered in depth in individual chapters dealing with conditions of specific areas. This chapter considers some philosophical aspects of the importance of anatomical knowledge and describes some basic principles. It also provides illustrations that we hope will help the reader to understand better the three-dimensional aspects of anatomy.

Accurate interpretation of what we see and feel during an examination requires knowledge of what structures we are looking at and palpating. For example, a swelling is noted over the dorsal aspect of the carpus. Is the swelling diffuse and possibly related to a hygroma, periarticular edema or cellulitis, or is there a discrete swelling, horizontally oriented, reflecting distention of the middle carpal joint? Or is it a longitudinal swelling reflecting distention of the common digital extensor tendon sheath or the tendon sheath of extensor carpi radialis? If the swelling is longitudinal, are any compressions in the swelling caused by normal retinaculum or adhesions within the sheath (Fig. 9-1)? If we examine the sheath by ultrasonography, is the echogenic band extending from the sheath wall to the enclosed tendon normal mesotendon, or is it an adhesion? If diffuse swelling is present around the dorsal aspect of the carpus associated with lameness, how can we tell if the middle carpal joint capsule is distended? We need to know that there is a palmar outpouching of the middle carpal joint on the palmarolateral aspect of the carpus, just distal to the accessory carpal bone. Thus during visual inspection and palpation the clinician should be constantly asking "what

Fig. 9-1 Sagittal anatomical section through the carpus, transecting the extensor carpi radialis tendon *(ECRT)*. *ICB,* Intermediate carpal bone; *C3*, third carpal bone.

provocation may be the only way of "seeing" lameness. In this instance, induced lameness from manipulation can be assumed to be the baseline lameness, and diagnostic analgesia can proceed. All involved parties should be well informed about the potential for misdiagnosis, but in certain circumstances this pathway may lead to a successful diagnosis.

CHAPTER • 9

Applied Anatomy of the Musculoskeletal System

Matt Durham and Sue J. Dyson

It is beyond the scope of this book to describe all aspects of musculoskeletal anatomy in depth, yet a detailed knowledge of anatomy is fundamental to a lameness diagnostician, as highlighted in the chapters on observation and palpation (Chapters 5 and 6). Some aspects of anatomy are considered in depth in individual chapters dealing with conditions of specific areas. This chapter considers some philosophical aspects of the importance of anatomical knowledge and describes some basic principles. It also provides illustrations that we hope will help the reader to understand better the three-dimensional aspects of anatomy.

Accurate interpretation of what we see and feel during an examination requires knowledge of what structures we are looking at and palpating. For example, a swelling is noted over the dorsal aspect of the carpus. Is the swelling diffuse and possibly related to a hygroma, periarticular edema or cellulitis, or is there a discrete swelling, horizontally oriented, reflecting distention of the middle carpal joint? Or is it a longitudinal swelling reflecting distention of the common digital extensor tendon sheath or the tendon sheath of extensor carpi radialis? If the swelling is longitudinal, are any compressions in the swelling caused by normal retinaculum or adhesions within the sheath (Fig. 9-1)? If we examine the sheath by ultrasonography, is the echogenic band extending from the sheath wall to the enclosed tendon normal mesotendon, or is it an adhesion? If diffuse swelling is present around the dorsal aspect of the carpus associated with lameness, how can we tell if the middle carpal joint capsule is distended? We need to know that there is a palmar outpouching of the middle carpal joint on the palmarolateral aspect of the carpus, just distal to the accessory carpal bone. Thus during visual inspection and palpation the clinician should be constantly asking "what

Fig. 9-1 Sagittal anatomical section through the carpus, transecting the extensor carpi radialis tendon *(ECRT)*. *ICB,* Intermediate carpal bone; *C3*, third carpal bone.

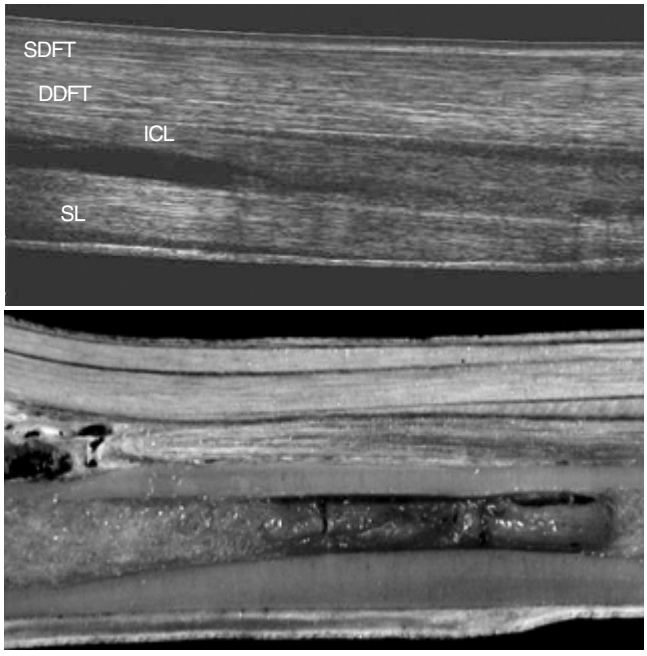

Fig. 9-2 Sagittal views of the palmar metacarpal region. (Courtesy Alamo Pintado Equine Medical Center, Los Olivos, California.)

structure am I seeing or palpating, what are its functions, and what would be the consequences of loss of function?" If it has abnormal contour or size, is this the result of swelling of that structure or an adjacent or underlying structure? Having established what structure is abnormal, the clinician then must consider the best imaging modality. If it is a tendonous or ligamentous structure, ultrasonography probably will provide the most information, but we must remember that it has bony attachments, and damage at those attachments might best be assessed by either radiography or nuclear scintigraphy. So we need to know not only what each structure is, but also the structures to which it is attached.

During visual inspection and palpation, we also need to think logically. We know that the superficial and deep digital flexor tendons (SDFT, DDFT), the accessory ligament of the DDFT (ALDDFT), and the suspensory ligament (SL) lie on the palmar aspect of the third metacarpal bone (Fig. 9-2). Swelling confined to just the medial aspect of the metacarpal region is far more likely to reflect direct trauma to the medial aspect of the limb than sprain or strain of any of the ligamentous or tendonous structures. We need to know that the proximal aspect of the SL lies between the bases (heads) of the second (McII) and fourth (McIV) metacarpal bones and therefore is inaccessible to direct palpation, and that desmitis often may be present without discernible soft tissue swelling (Fig. 9-3).

We must be aware of anatomy to realize the possible consequences of trauma to an area. The paucity of soft tissues over the cranial aspect of the stifle makes the patella and the tibial tuberosity vulnerable to direct trauma, hence the risk of fracture after hitting a fixed fence. The lack of soft tissues also means that if the horse hits a thorn hedge, the possibility of a thorn penetrating the femoropatellar joint capsule, resulting in contamination and infection, is quite high. We also need to think how structures move relative to one another while the horse is in motion. If a steeplechase horse sustains an interference injury on the palmar aspect of the metacarpal region while galloping, the position of the skin laceration probably will not coincide with the level of the laceration in the SDFT (Fig. 9-4). We also need to know the relative positions of the laceration and the digital flexor tendon sheath (DFTS) to be aware of the likelihood that the sheath may have been traumatized, and thus the risk of infectious tenosynovitis. Faced with a contaminated wound on the dorsal aspect of a hind fetlock and severe lameness, and the possibility of infection of

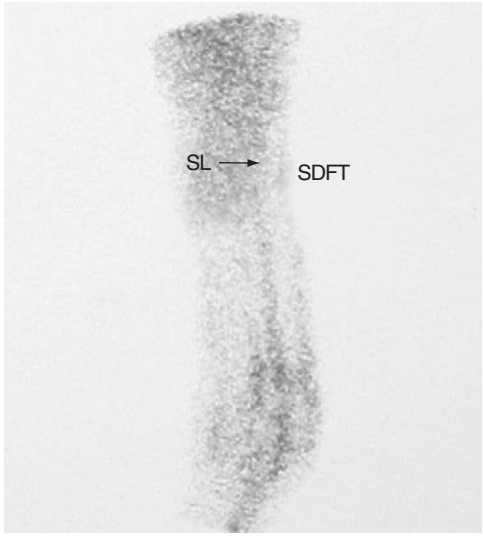

Fig. 9-4 Lateral scintigraphic image of the metacarpal region acquired before the end of the vascular phase and at the beginning of the pool phase. This jumper had a history of low-grade chronic proximal suspensory ligament *(SL)* desmitis, and mild diffuse superficial digital flexor *(SDFT)* tendonitis. An acute interference injury to the mid-metacarpal region was evident on the skin. Note the proximal location of the acute injury to the SDFT. The linear area of uptake between the SL and SDFT is vascular artifact related to the time of acquisition. (Courtesy Alamo Pintado Equine Medical Center, Los Olivos, California.)

the metatarsophalangeal joint, we need to know where to expect to see distention of the plantar pouch of the joint capsule and to know that this site is safely accessible for arthrocentesis.

A fundamental principle of lameness investigation is the identification of the source or sources of pain. Although this may be possible through detailed clinical examination, in many instances it is essential to perform diagnostic analgesia (see Chapter 10). A detailed knowledge of the anatomy of nerves, joint capsules and the various out-pouchings, tendon sheaths, and bursae is fundamental to safe, accurate performance of perineural and intra-synovial injections.

Given the knowledge of the close relationship among the distal interphalangeal joint capsule, the distal sesamoidean impar ligament, the collateral ligaments of the navicular bone and the distal phalanx, and the close proximity of branches of the palmar digital nerve, it is not surprising that intra-articular analgesia is not specific and that other structures can be affected, especially if interpretation of the response is delayed or an excessively large volume of local anaesthetic solution is used. Knowledge that the medial and lateral femorotibial joints do not normally communicate and that the cruciate ligaments usually are extra-articular structures is crucial for an understanding of why these joint compartments must be injected separately, and why the response to intra-articular analgesia may be both incomplete and delayed if a cruciate ligament is damaged.

Knowledge of functional neuroanatomy also is important for interpretation of specific gait abnormalities. Inability to bear weight on a hindlimb after general anesthesia may be due to myopathy, but in the absence of marked pain and distress, it is more likely that the horse has lost extensor function and is unable to extend any of the hindlimb joints because of femoral nerve paresis. Loss of ability to extend the elbow may be due to loss of triceps function associated with a fracture of the olecranon but may also be due to radial nerve paresis.

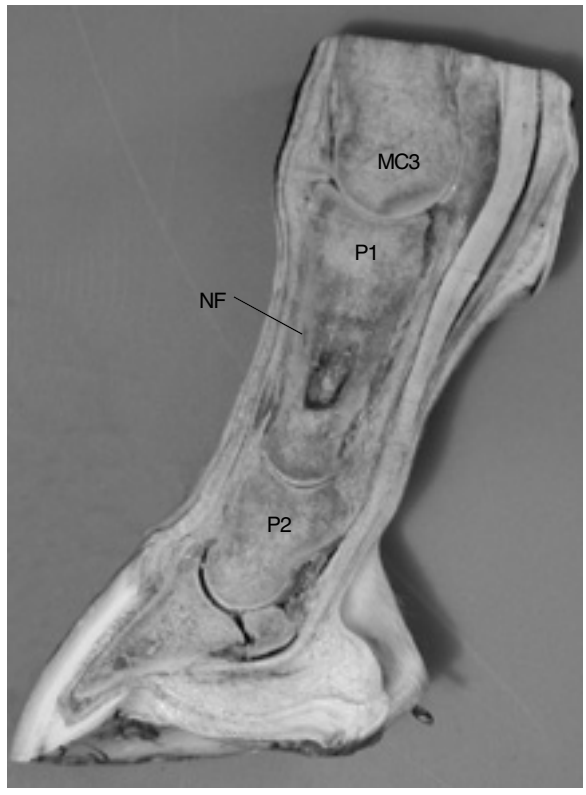

Fig. 9-5 Sagittal anatomical section through the pastern demonstrating a common location for the nutrient foramen *(NF)* entering the proximal phalanx *(P1)*. *MC3*, Third metacarpal bone; *P2*, middle phalanx.

Vascular anatomy is important because many nerves lie close to vessels. With superficial nerves and vessels, identification of the vessel may facilitate palpation of the nerve and thus aid accurate perineural injection. Avoiding penetration of the vessel and causing hematoma formation also is desirable. With regard to deeper nerves the veterinarian may benefit by knowing that the needle must be in close proximity to the nerve if blood appears in the needle hub. This information can be helpful when performing perineural analgesia of the deep branch of the fibular nerve.

Assessment of digital pulse amplitudes is an integral part of palpation. Increased pulse amplitude usually signifies a site of inflammation at, or distal to, the region of palpation, especially in association with inflammatory conditions of the foot, such as subsolar abscessation or laminitis. Palpation of the pulse in the dorsal metatarsal artery and assessment of saphenous vein filling can be helpful in the evaluation of a horse with suspected aortoiliac thrombosis.

Knowledge of the sites of major vessels is important when considering the consequences of major laceration to an area and possible avascular areas, and in planning a surgical approach to an area. All bones have one or more nutrient foramina through which major vessels enter. These usually are in standard locations (Fig. 9-5). Knowledge of these sites is critical for accurate radiological interpretation because a nutrient foramen appears as a radiolucent area, which should not be confused with a pathological lesion. The position of these intra-osseous vessels also has important consequences in considering repair of major long bone fractures.

Thermography relies on the detection of surface heat and is obviously greatly influenced by the position of superficial vessels. Interpretation may be misleading without knowledge of location. Thus it should be absolutely clear that anatomy is

a dynamic subject and is not merely a function of knowing the origins and insertions of numerous structures.

We also need to know some fundamentals of biomechanics. What is the biomechanical function of the SL? What are the implications of loss of function? For example, how may function be altered by a change in foot angle after application of a heel wedge? How is load in the distal limb joints affected by mediolateral foot imbalance? If the accessory ligament of the SDFT is cut (superior check desmotomy), how does this alter the function of not only the SDFT but also other tendonous and ligamentous structures? Does consequent overload of the SL predispose to an increased risk of suspensory desmitis? When orthopedic surgery is being considered, which is the tension side of the bone, to which a dynamic compression plate should be applied to take advantage of the tension band principle?

In more general terms, how will lameness in the left hindlimb alter forces in the other limbs, and does this vary with the gait? Given the reciprocal apparatus of the hindlimb and the inability to flex and extend the limb joints independently, it is not surprising that the gait characteristics of hindlimb lameness are so similar, irrespective of the source of pain causing lameness. Understanding the reciprocal apparatus, in addition to the results of loss of its function (e.g., after damage to the fibularis tertius) are hugely important for an understanding of hindlimb lameness.

After the source of pain causing lameness is isolated, then it is necessary to establish what is causing pain; this requires one of a number of imaging modalities: radiography, ultrasonography, nuclear scintigraphy, magnetic resonance imaging (MRI), computed tomography (CT), and exploratory arthroscopy, bursoscopy, or tenoscopy. Accurate interpretation of any of these techniques requires specialist anatomical knowledge. With radiographic images, various structures are superimposed, resulting in potentially confusing radiolucent lines that can mimic a fracture (e.g., in the relatively complex carpus and tarsus). A frog shadow superimposed over the navicular bone may mimic a fracture. We must be cognizant of anatomical variations, for example, the shape and size of the crena of the distal phalanx. We have to know how best to image a specific anatomical location, such as the sustentaculum tali of the calcaneus (fibular tarsal bone) using a skyline projection. To interpret the significance of periosteal or entheseous new bone, detailed knowledge of the soft tissue structures that do (or do not) attach in that area is vital. Particularly in the fetlock and pastern areas, numerous ligamentous structures have discrete areas of attachment (Fig. 9-6).

Radiography requires the awareness that we are looking at a three-dimensional structure in two dimensions, and thus images of the area must be obtained from several different angles. With ultrasonography, and more particularly with MRI and CT, structures can be imaged in three dimensions; this requires detailed knowledge of the shape, size, and relationships between structures. In the proximal metatarsal region the DDFT lies more medial than the SDFT and SL, and thus these structures cannot be imaged adequately by ultrason-

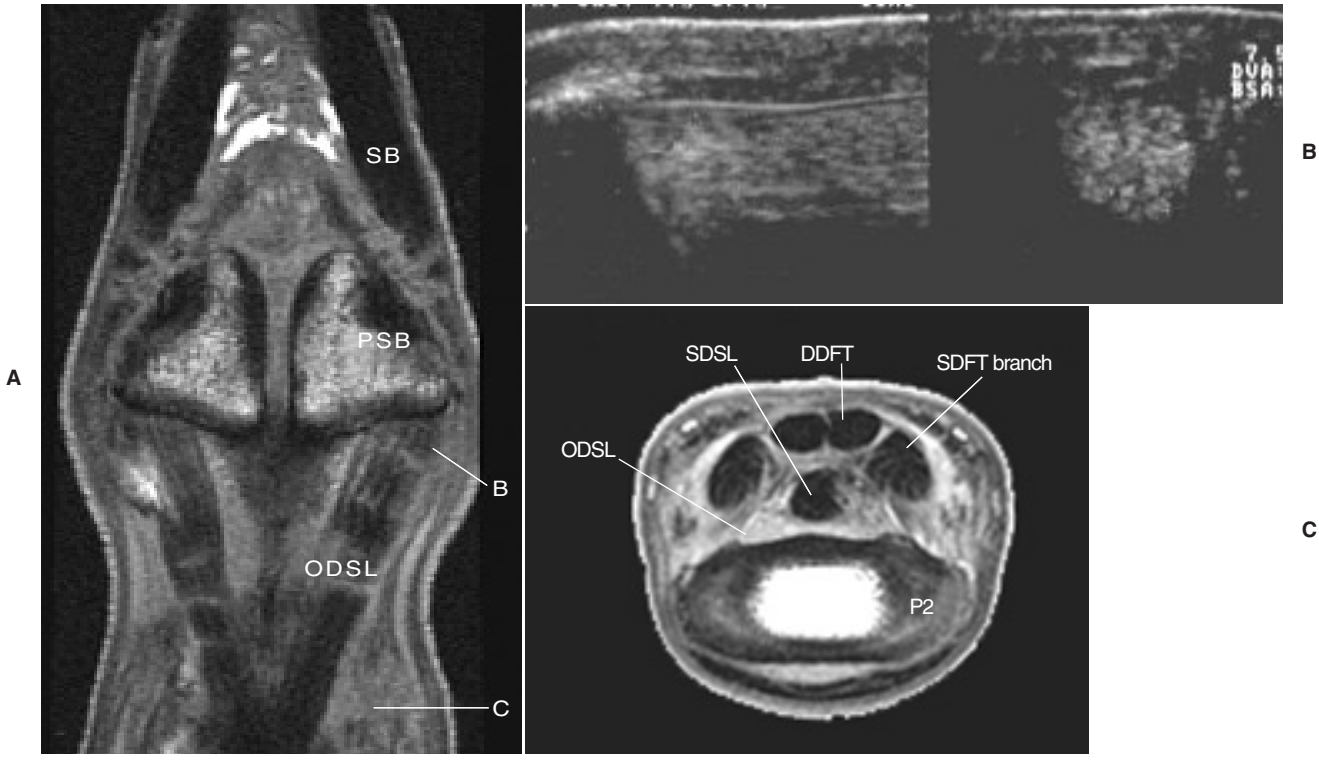

Fig. 9-6 The oblique distal sesamoidean ligaments. **A,** Frontal magnetic resonance imaging (MRI) scan of the pastern showing the origins and insertions of the oblique distal sesamoidean ligaments *(ODSL)*. *SB*, Suspensory branch; *PSB*, proximal sesamoid bone. (Courtesy Alexia L. McKnight, University of Pennsylvania, Philadelphia, Pennsylvania.) **B,** Frontal *(left)* and transverse *(right)* ultrasonographic images of the ODSL obtained at point *B* in part **A.** Proximal and dorsal are to the left. **C,** Transverse MRI scan obtained at point C in part **A.** *DDFT*, Deep digital flexot tendon; *SDFT*, superficial digital flexor tendon; *SDSL*, straight distal sesamoidean ligament; *P2*, middle phalanx.

ography at the same time from the plantar aspect of the limb (Fig. 9-7). The transducer must be moved to a plantaromedial site to evaluate the DDFT in its entirety. A large vessel on the plantarolateral aspect of the SL can cause shadowing artifacts in the SL.

The internal architecture of the joint becomes important during exploratory arthroscopy. What are the normal variations in cartilage thickness? Where do you expect to see a synovial fossa? Which parts of the synovial membrane are usually more vascular? Is it normal that the cranial cruciate ligament can be seen without synovial covering from the medial femoral tibial joint?

A textbook of this type cannot possibly provide detailed descriptions of all aspects of anatomy, functional anatomy, and biomechanics, nor answer all of the questions posed earlier in this chapter. It is hoped that this overview will stimulate readers to have a thirst for more knowledge of these subjects, in the knowledge of their huge importance.

Lameness clinicians are encouraged to acquire a set of boiled-out bones for reference and perform detailed dissections of cadaver limbs to improve knowledge of anatomy. Practicing nerve block techniques on cadaver limbs is very important for inexperienced clinicians or those performing a new block for the first time. If a lame horse must be humanely destroyed, clinicians should take the opportunity, whenever possible, to perform a post-mortem examination to correlate clinical findings with the actual lesions and revise anatomy at the same time. Each time a dissection is performed, new anatomical detail becomes apparent that had previously been missed.

The remainder of this chapter provides some basic definitions of anatomical terms used elsewhere in the book, describes the reciprocal apparatus of the forelimb and hindlimb, and presents correlative illustrations of anatomical specimens and images of those areas to assist in the understanding of three-dimensional anatomy.

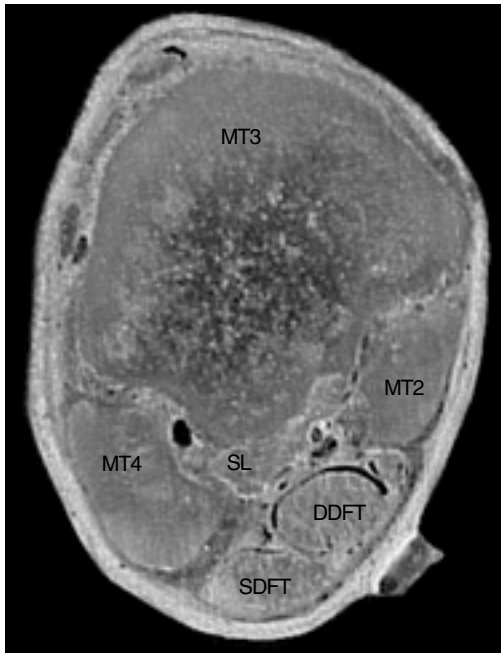

Fig. 9-7 Transverse anatomical section of the proximal metatarsal region demonstrating the lateral position of the superficial digital flexor tendon *(SDFT)* relative to the deep digital flexor tendon *(DDFT)*. Lateral is to the left and dorsal to the top of the image. This arrangement is the opposite of that seen in the forelimb (compare with Fig. 9-3). *SL*, Suspensory ligament; *MT2*, *MT3*, and *MT4*, second, third, and fourth metatarsal bones, respectively.

The Language of Anatomy

The system described in the *Nomina Anatomica Veterinaria* (NAV) according to the guidelines of the International Committee on Veterinary Anatomical Nomenclature has been used so that anatomical terminology is universal. English translations of NAV terms have been used whenever possible according to these guidelines.

Forces

The interaction of anatomical structures allows for the conversion of chemical energy into purposeful movement. It is often useful to think of complex anatomical structures in terms of interactions between simplified structural units. The interaction of forces within these anatomical units dictates the abilities and the potential weaknesses of the equine athlete. In simple terms, the stresses acting on the body are compression, tension, shear, torsion, and bending.

Compression is the force applied between two points to move them together. Examples of compression are seen in joints, such as within the middle carpal joint at the interface between the radial and third carpal bones, or that sustained by the digital cushion between the sole, frog, and the distal phalanx. Compression also is sustained within most bones, such as the third carpal bone, or the dorsal cortex of the third metacarpal bone (McIII).

Tension is the force that tends to stretch or elongate a structure. Examples of tension are most obvious in tendons and ligaments, but bones such as the olecranon or within the palmar cortex of McIII also sustain tensile strain.

Shear is a stress at the interface between two structures moving in opposite directions. Examples of shear are seen in the femoropatellar and tarsocrural joints, within bone, and within the hoof capsule.

Torsion is the stress produced when a twisting motion is applied to an object. Examples of torsional strain are seen within joints, such as the distal hock joints, or within individual bones, such as McIII.

Bending is a combination of compression on one side of a structure and tension on the other side. Structures submitted to bending are long bones such as McIII, where the dorsal cortex is submitted to compression, whereas the palmar cortex is submitted to tension.

Specialized Structures

Synovial Structures

Synovial bursae, tendon sheaths, and joints have a similar function and generally similar structure. All are sacs containing synovial fluid produced by the lining of the sac. In simple terms, synovial structures facilitate the movement between independent structures by providing a hydraulic cushion of viscous fluid that limits the effects of friction to help dissipate compressive and shear forces. (For a more complete discussion on synovial structures, see Chapters 63 and 80.)

A diarthrosis is a mobile joint containing a synovial membrane. This membrane is flexible enough to allow for movement of the joint. The synovial fluid lubricates, hydraulically equalizes pressure between cartilage plates, and nourishes the articular cartilage.

A synovial sheath is a sac that completely surrounds a tendon, forming a synovial lining on the surface of the tendon and the lining of the sheath. The synovial reflection between these visceral and parietal layers is termed the *mesotendon*. This structure is similar to the mesentery in the abdominal cavity. Nerve and blood supply to the tendon is found within the mesotendon. In areas of great mobility within the synovial sheaths, the nerve and blood supply to the tendons is through

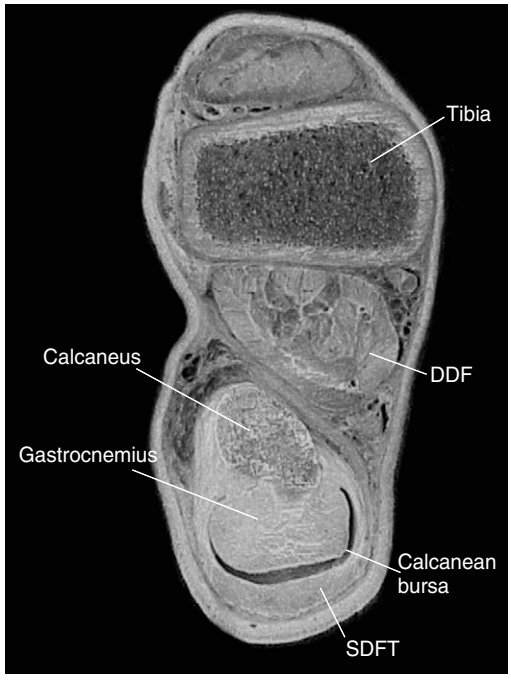

Fig. 9-8 Transverse anatomical section through distal tibia and proximal calcaneus demonstrating the distinct calcanean bursa bounded by the collateral ligaments of the superficial digital flexor tendon *(SDFT)*. *DDF,* Deep digital flexor muscle.

a vinculum, which is a modified mesotendon in the form of a narrow band connecting visceral and parietal layers.

A synovial bursa is a simple sac lying between a tendon or muscle and an adjacent bony prominence. A bursa does not surround the tendon but acts as a cushion at the interface where pressure is concentrated (Fig. 9-8).

Intercalated Bones

Intercalated bones are bones that arise within tendons or ligaments allowing for the interface between the tendonous structure and the underlying bone at an area of focal pressure, typically at the level of a joint. The interface between these bones is within a synovial sac. The navicular bone, proximal sesamoid bones (PSBs), and patella are intercalated bones. These bones allow for smooth movement and dissipation of focal pressure between the tendon or ligament and the underlying joint (Fig. 9-9).

Fibrocartilaginous Structures

In general terms, there are four functional arrangements of fibrocartilage: interarticular, connecting, circumferential, and stratiform.

Interarticular fibrocartilage. *Menisci* are fibrocartilaginous structures located between the articular cartilages of a diarthrosis. Menisci are not directly attached to the joint surfaces but are held in place by ligaments immediately adjacent to the articular surfaces. They provide congruency between the condyles, allow for a greater range of movement of the joint, and absorb concussion. Menisci are found in the stifle and temporomandibular joints of the horse.

Connecting fibrocartilage. A *symphysis* is a fibrocartilaginous joint that allows minimal movement. The pelvic symphysis and intersternebral and intervertebral joints are examples of fibrocartilaginous joints.

Circumferential fibrocartilage. In the coxofemoral joint the acetabular lip (labrum acetabulare) is a fibrocartilaginous ring extending the articular surface in a firm, semi-flexible manner. The transverse acetabular ligament is the portion of

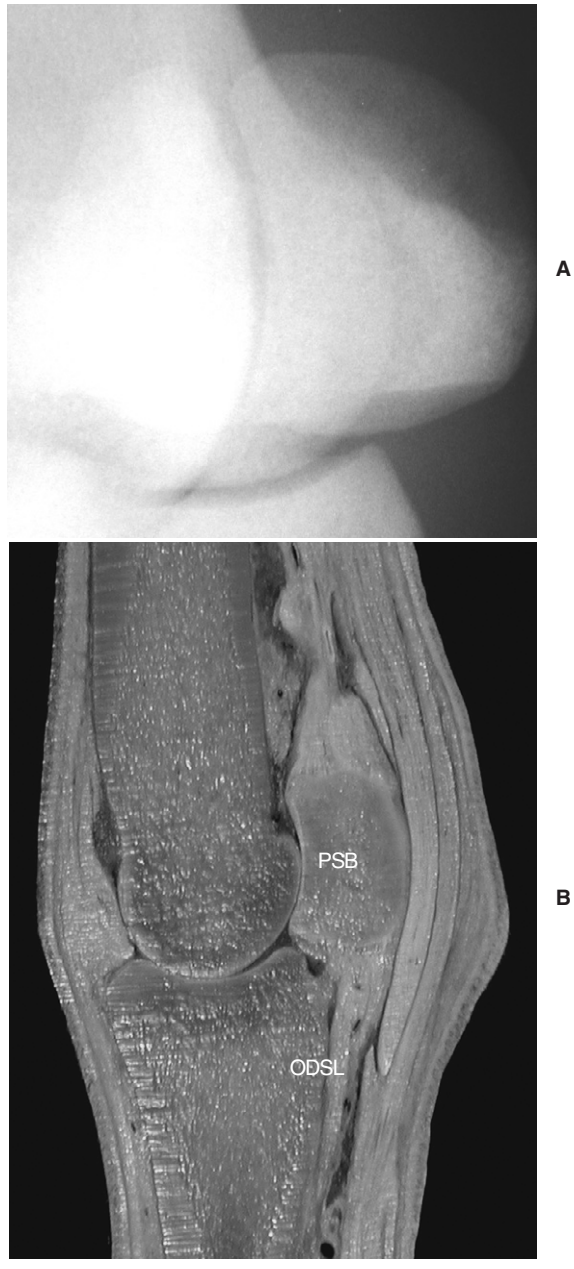

Fig. 9-9 **A,** Oblique radiographic projection of a normal proximal sesamoid bone *(PSB)*. **B,** Parasagittal anatomical section through suspensory branch, PSB, and oblique distal sesamoidean ligament *(ODSL)*.

the labrum crossing the acetabular notch. The glenoid labrum seen in other species is a poorly developed fibrous band in the shoulder of the horse.

Stratiform fibrocartilage. Stratiform fibrocartilages arise within ligamentous structures at an interface with high focal pressure between soft tissue and bone, either within a ligament or as an extension of a bony surface. These structures are similar to intercalated bones in that they typically provide rigidity to help dissipate compressive forces, but the moderate elasticity allows for some flexibility of the structures.

The parapatellar fibrocartilage on the medial aspect of the patella, portions of the biceps brachii tendon of origin within the intertubercular (bicipital) bursa, the manica flexoria, and portions of the DDFT adjacent to the proximal aspect of the middle phalanx are examples of stratiform cartilage formation

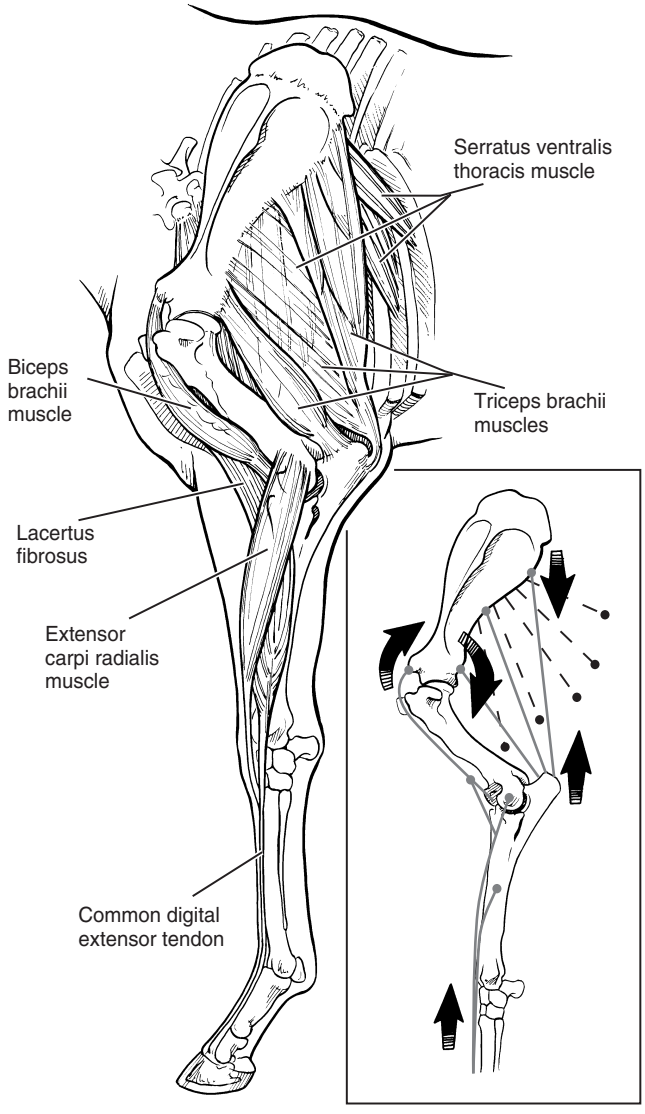

Fig. 9-10 The passive stay apparatus of the forelimb.

within tendonous structures. The proximal, middle, and distal scuta are stratiform fibrocartilaginous structures associated with the intersesamoidean ligament, the palmar aspect of the middle phalanx, and the collateral ligaments of the navicular bone, respectively. These structures serve as semi-rigid pulleys primarily for the DDFT.

Passive Stay Apparatus

Distal Limb

The horse is uniquely equipped to be able to stand at rest while expending minimal muscular effort. In the forelimb and hindlimb the fetlock is prevented from over-extension by a combination of structures providing passive resistance. The suspensory apparatus is the main contributor, forming a sling that maintains the fetlock in extension. In addition, the SDFT, DDFT, and the associated accessory (check) ligaments (in the forelimb) act as tension bands providing passive support. The suspensory apparatus consists primarily of the SL and branches, PSBs, and distal sesamoidean ligaments. The intercalated PSBs provide a broad face at the point where focal pressure is high at the palmar/plantar aspect of the fetlock joint, enabling the ligamentous tension band to support the fetlock. Dorsal branches of the SL join with the common/long digital extensor tendon, helping to stabilize the dorsal aspect of the digit. The axial and abaxial palmar/plantar ligaments of the proximal interphalangeal joint, the SDFT branches, and the straight distal sesamoidean ligament support the palmar/plantar aspect of the proximal interphalangeal joint. The navicular bone and its suspensory apparatus, in combination with the distal sesamoidean impar ligament, stabilize the palmar/plantar aspect of the distal interphalangeal joint.

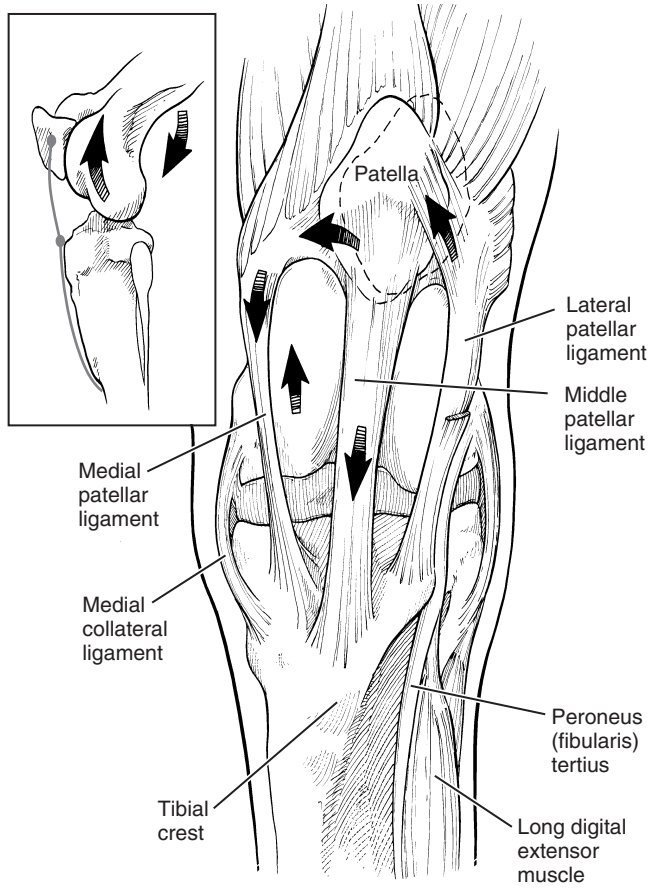

Fig. 9-11 The patellar locking mechanism.

Forelimb

In the forelimb the fibrous portion of the serratus ventralis thoracis acts as a sling suspending the thorax from the forelimb by its attachment to the scapula. The downward force applied by the serratus ventralis on the caudal aspect of the scapula causes slight flexion of the scapulohumeral joint, applying tension to the biceps brachii. A fibrous band of the biceps brachii extends from the supraglenoid tubercle of the scapula and continues as the lacertus fibrosus, which joins with the extensor carpi radialis to passively extend the carpus. Minimal muscular effort by the triceps on the olecranon maintains the elbow in extension (Fig. 9-10).

Hindlimb

The stifle is maintained in extension by the patellar locking mechanism with minimal muscular effort. Slight muscular effort by the quadriceps and tensor fascia lata rotates the patella medially, where the cartilaginous process of the patella is caught caudal to the large prominence of the medial trochlear ridge of the femur. Slight relaxation of the quadriceps as a whole allows slight flexion of the stifle, which "locks" the patella in place by applying tension primarily to the medial and middle patellar ligaments (Fig. 9-11). When the stifle is extended, the hock is passively extended by the superficial digital flexor and the fibrous component of the lateral head of the gastrocnemius muscles, which extend from the femur to the tuber calcis.

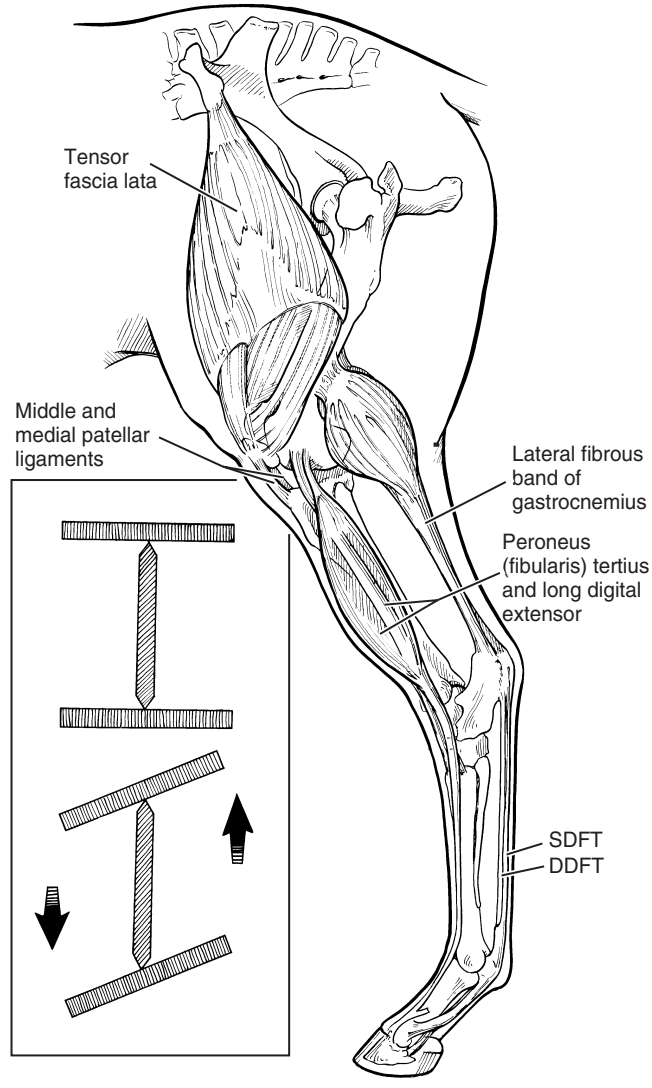

Fig. 9-12 The reciprocal apparatus. *SDFT,* Superficial digital flexor tendon; *DDFT,* deep digital flexor tendon.

The reciprocal apparatus forces the hock to flex and extend in unison with the stifle. The reciprocal apparatus transfers mechanical energy to the distal limb from the massive muscular structures of the upper limb without adding mass to the lower limb. The superficial digital flexor and the fibrous portion of the gastrocnemius serve as the caudal component of the reciprocal apparatus, along with the long plantar ligament, which acts as a tension band to make the calcaneus, distal tarsus, and metatarsal region a single functional lever arm. The fibularis (peroneus) tertius serves as the cranial component of the reciprocal apparatus, extending from the femur to the dorsal and lateral aspects of the tarsus (Fig. 9-12). Although the fibularis tertius is important as part of the reciprocal apparatus, it is not essential for function of the passive stay apparatus, as its function is flexion of the tarsus.

A second reciprocal mechanism has been described for the lower limb of the hind limb, where the fetlock and digit are flexed at the same time as the stifle and hock. The long digital extensor tendon and DDFT were the dorsal and plantar components suggested, but the SDFT probably also contributes.

Three-Dimensional Anatomy

Major advances in lameness diagnosis are being made with the assistance of advanced imaging techniques. Radiography, nuclear scintigraphy, and ultrasonography are well established, whereas CT and MRI are growing in importance. CT and MRI in particular require a detailed knowledge of three-dimensional anatomy. It is beyond the scope of this text to provide detailed correlative images of the entire musculoskeletal system. Figs. 9-13 through 9-18 give a flavor of what is possible. Figs. 9-13 through 9-16 highlight the complex anatomy of the navicular bone region, showing the close relationship between the collateral ligaments of the navicular bone, the distal sesamoidean impar ligament, the DDFT and the navicular bursa and distal interphalangeal joint capsule. Figs. 9-17 and 9-18 demonstrate the relationship between some aspects of the complex anatomy of the carpal region.

CHAPTER • 10

Diagnostic Analgesia

Lance H. Bassage II and Mike W. Ross

Despite the many technological advances in equine sports medicine over the past two decades, diagnostic analgesia arguably remains the most valuable tool in the equine clinician's arsenal to localize lameness. Although the technique requires a thorough understanding of anatomy, basic technical skill, and clinical experience, the equipment and expense are minimal. In addition, diagnostic analgesia can be performed on site, with the outcome immediately obvious. In this way, any lingering concern that a suspected "shoulder problem" exists is convincingly erased when the response to local analgesia of the digit is observed. This chapter reviews the various perineural, intrasynovial, and local (regional) infiltration techniques for application of local analgesia in the diagnosis of lameness in horses.

CHAPTER • 10

Diagnostic Analgesia

Lance H. Bassage II and Mike W. Ross

Despite the many technological advances in equine sports medicine over the past two decades, diagnostic analgesia arguably remains the most valuable tool in the equine clinician's arsenal to localize lameness. Although the technique requires a thorough understanding of anatomy, basic technical skill, and clinical experience, the equipment and expense are minimal. In addition, diagnostic analgesia can be performed on site, with the outcome immediately obvious. In this way, any lingering concern that a suspected "shoulder problem" exists is convincingly erased when the response to local analgesia of the digit is observed. This chapter reviews the various perineural, intrasynovial, and local (regional) infiltration techniques for application of local analgesia in the diagnosis of lameness in horses.

LOCAL ANESTHETICS: PHARMACOLOGY AND TISSUE INTERACTIONS

Pain is transmitted specifically in the small, lightly myelinated, A-delta and non-myelinated C nerve fibers.[1] All commonly used local anesthetics, regardless of the specific molecular structure, share the same basic mechanism of action, specifically, the ability to block or inhibit nociceptive nerve conduction by preventing the increase in membrane permeability to sodium ions.[2] These agents consist of a lipophilic and a hydrophilic group, connected by an intermediate chain containing a carbonyl group of an amide or ester linkage, and have traditionally been categorized as either amide- or ester-type local anesthetics.[3] Common local anesthetics used in horses—2% solutions of lidocaine, mepivacaine, and bupivacaine—are of the amide type.

Compared with most local anesthetics, lidocaine and mepivacaine are considered relatively fast-acting and have a reported duration of action of 1½ to 3 hours and 2 to 3 hours, respectively. In contrast, bupivacaine is intermediate in onset but has a much longer duration of action (3 to 6 hours).[4] Bupivacaine is most suited for providing therapeutic rather than diagnostic analgesia. The results in clinical practice vary, because in *severely* lame horses the degree and duration of local analgesia are decreased, regardless of the agent used.

When local anesthetics are injected, tissue damage can occur but is extremely rare.[3,4] Soft tissue swelling occurs occasionally and is likely caused by needle trauma or hematoma formation and not from a direct drug-tissue interaction. We suggest that alcohol and a clean wrap be applied to the injection sites when the diagnostic evaluation is complete to prevent or minimize swelling at injection sites. Cellulitis or other forms of infection are rare potential complications.

Acute synovitis, or *flare*, is a rare complication that can occur after intrasynovial (most commonly intra-articular) injection of anesthetics. Synovitis from intrasynovial injection of local anesthetics is much less common than from injection of other medications. Mepivacaine is less irritating than lidocaine when administered intra-articularly, but we have not recognized this difference.[3] However, Dyson reported that lidocaine may be considerably more irritating than mepivacaine, and clinical data documenting differences was used successfully in the licensing of mepivacaine in the United Kingdom.[5] Like cellulitis after perineural injections of local anesthetics, infectious synovitis is a rare but possible sequela. To mitigate the possibility of contaminated solution, we use a new vial of local anesthetic solution when performing intrasynovial analgesic procedures.

Systemic side effects from diagnostic analgesic techniques are exceedingly rare. Cardiovascular or central nervous system signs, including muscle fasciculation, ataxia, and collapse, were reported.[3] Systemic intoxication would require a dose much higher than is commonly used, even for an extensive diagnostic evaluation. For example, the maximum single infiltration dose of lidocaine that can be safely administered to a 500-kg horse is about 6.0 g, or 300 ml of a 2% solution.[6]

Strategy, Methodology, and Other Considerations

A few basic principles must be followed to ensure success. A thorough working knowledge of regional anatomy is required. Even for seasoned veterans a review of anatomy may be required before performing less common techniques. A most important principle when performing perineural analgesia is to *start distally in the limb and work proximally* (Figs. 10-1 to 10-4). If possible, sequential blocks from distal to proximal should always be used, but in certain circumstances a different strategy can be successful. Sequential blocking requires a fair amount of time, and in certain horses, selective intra-articular or local blocks can be performed without following this "golden rule." However, in most situations, blocking a large portion of the distal limb at a proximally located site may preclude accurate determination of the source of lameness and may require an additional visit to perform additional diagnostic procedures.

It is important to test the efficacy of a perineural block before reevaluating the horse's degree of lameness. If any question exists, the block should be repeated rather than assuming deep pain has been abolished, when skin sensitivity persists. If a horse shows *partial* improvement only minutes after injection, an additional few minutes should be allowed to achieve complete analgesia before proceeding with the next block. Alternatively, the block can be repeated. In so doing, the clinician minimizes the potential for misinterpretation and the tendency to ascribe the residual lameness to a "second problem" that does not exist.

During this portion of the examination, we are attempting to eliminate baseline rather than induced lameness, and care must be taken when adopting the practice of "blocking out a positive flexion test" (see Chapter 8). Once baseline lameness has been eliminated, we rarely perform additional flexion tests or attempt to eliminate all induced lameness.

How is the efficacy of the block assessed? Several methods are available, but the following points should be considered. Individual horses react differently to noxious stimuli applied to the skin. Therefore it is helpful to test the contralateral (unblocked) limb to establish the horse's baseline response to the test. Similarly, covering a horse's eye or feigning a few gestures with an instrument (pen tip, hemostatic forceps) without actually contacting the skin can help differentiate between a random or anticipatory response by an apprehensive horse and a true painful response. Positioning oneself on the contralateral side of the patient when testing for sensation also can help in making this determination. The clinician should avoid using sharp instruments that can penetrate the skin and cause hemorrhage, a situation not well understood by a concerned horse owner. Hemostatic forceps, used to pinch the skin, are ideal, because they are blunt and appear to consistently induce an appropriate amount of pain. Forceps are only useful in assessing superficial or skin sensation, however.

Perineural blocks must be assessed for the amelioration of deep and not just superficial pain. To assess whether deep pain in the hoof has been ameliorated after palmar digital analgesia or other techniques, hoof testers can usually be applied with enough force to cause a painful response, even in the most stoic of horses. Physical strength of the operator must be considered. Extreme or hard joint flexion (combined with varus or valgus stress) can be used to assess whether deep pain has been abolished in more proximal locations. In some instances, however, it is impossible to avoid contacting the skin proximal to the site of anesthetic administration, leading the clinician to assume that the block has not worked. The application of firm digital pressure in the blocked area may be a viable alternative to flexion or manipulation to help avoid these potentially confounding factors.

It is important to understand that the region of the limb that is *actually* desensitized may, in fact, differ from that which the clinician has *intended*.[7] Proximal diffusion of local anesthetic solution appears to be the most likely cause, but other intangible factors may play a role. Using a small volume of anesthetic (1 to 5 ml for most perineural blocks) can minimize but not abolish this phenomenon. To further minimize the potential for diffusion of anesthetic, the horse should be reevaluated no more than 10 minutes after the injection (exceptions apply in certain situations).

Complete analgesia, and thus 100% improvement in lameness score, is the goal when performing diagnostic analgesia, but in many horses this level of pain relief is never achieved. Improvement in degree of lameness greater than 70% to 80%

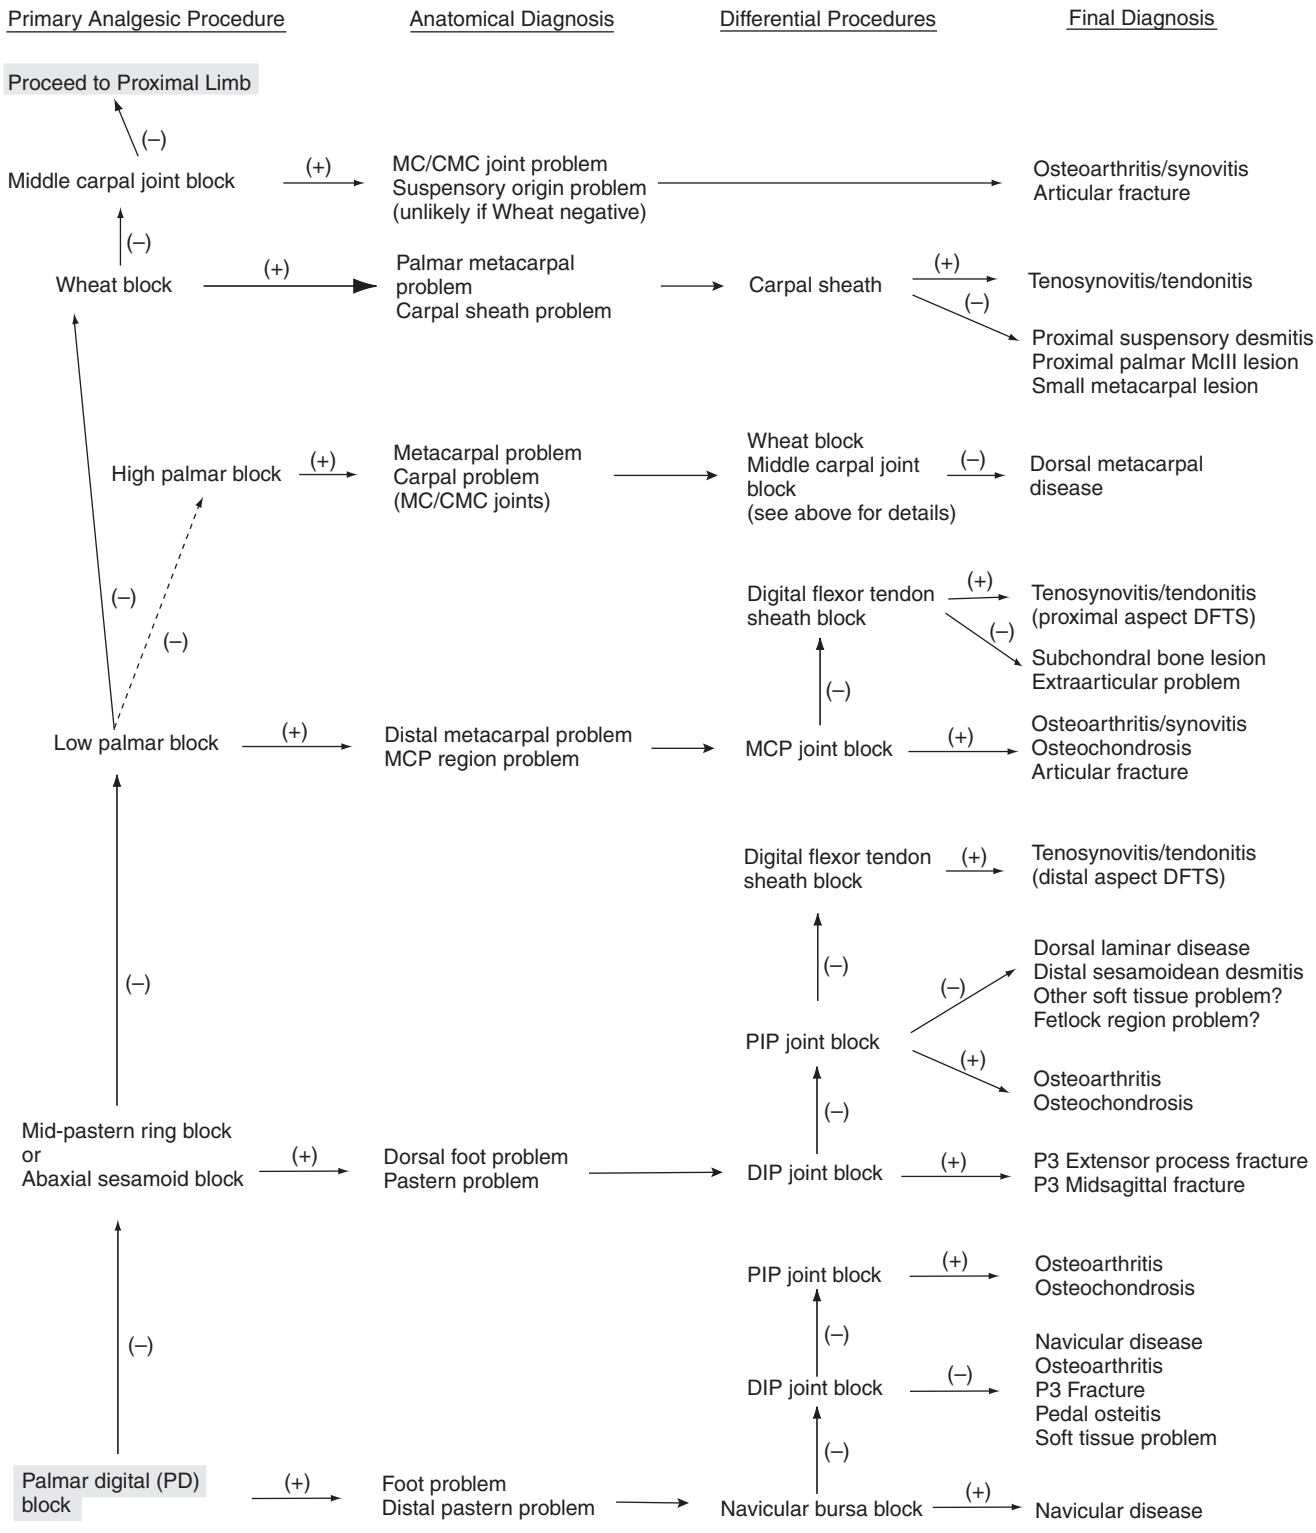

Fig. 10-1 Blocking strategy in the forelimb: foot to carpus. *CMC,* Carpometacarpal; *DFTS,* digital flexor tendon sheath; *McIII,* third metacarpal bone; *MC,* middle carpal; *MCP,* metacarpophalangeal; *PIP,* proximal interphalangeal; *Mc3,* third metacarpal bone; *P3,* distal phalanx.

after most perineural or intra-articular techniques should be considered a positive response in most horses. The quintessential response is the horse "switching lameness" to the contralateral limb, indicating that now, pain arising from the opposite limb is greater than that originating from the baseline lameness. However, complete response may not occur, and the clinician must decide when to stop sequential blocks or when the horse has "blocked out." The clinician hopes for an obvious difference in lameness score when the horse is blocked, but in some horses, serial improvement occurs with each successive block, a situation that makes assessing the primary source of lameness difficult.

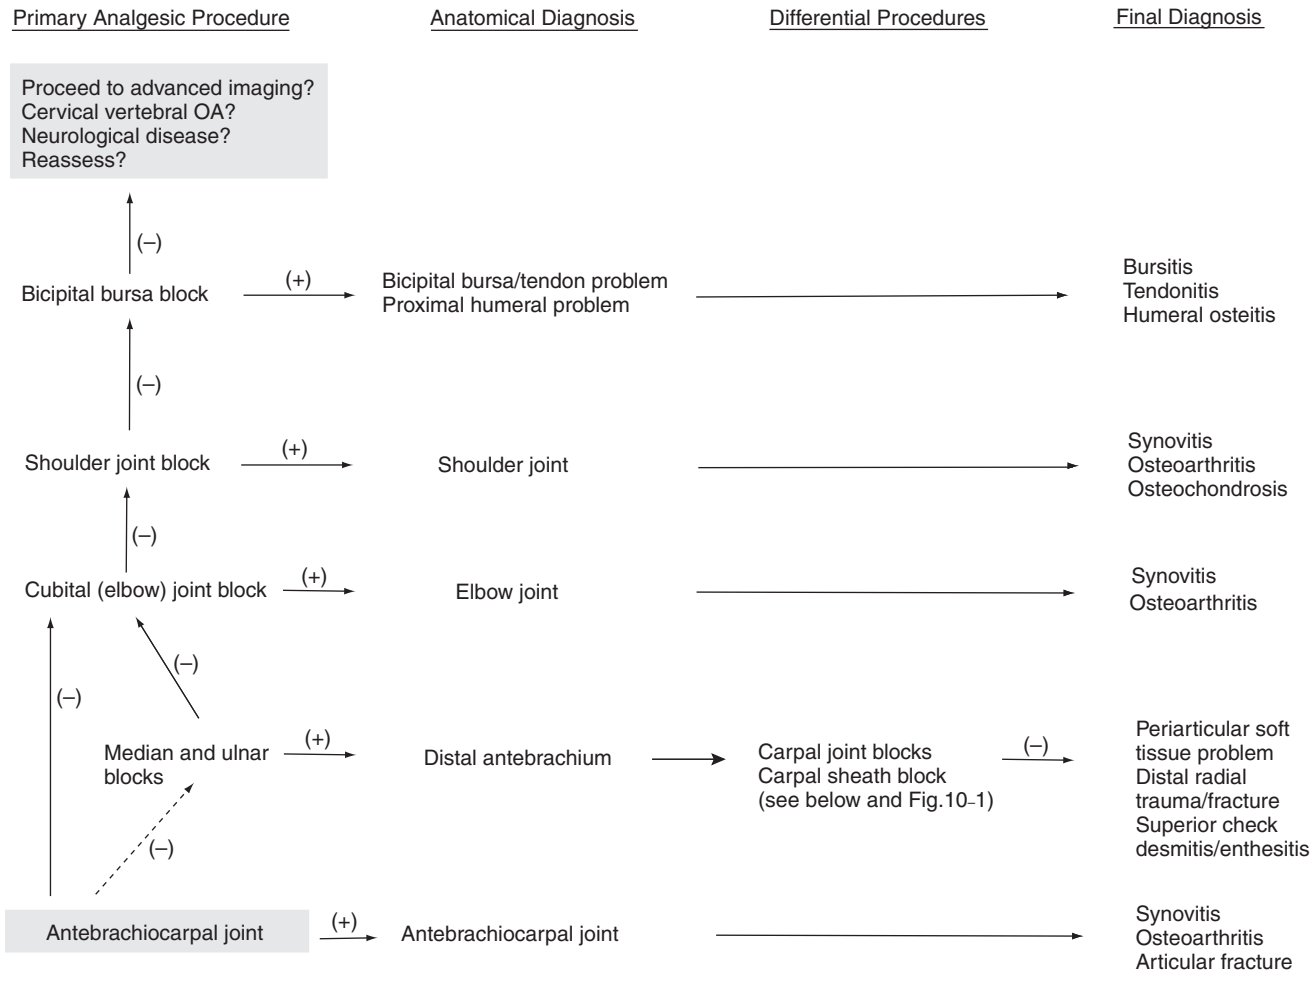

Fig. 10-2 Blocking strategy in the forelimb: antebrachium to shoulder joint, *OA*, Osteoarthritis.

Incomplete response to local analgesics in some horses may be explained by the fact that chronic pain, particularly deep bone pain, may remain resistant to complete analgesia when perineural techniques are used. For example, horses with laminitis tend to remain lame despite blocking many times at the appropriate level. Mechanical gait deficits do not improve after diagnostic analgesia because pain is minimal. Horses may continue to show lameness even with pain abolition, a situation that appears to be caused by habit. These horses tend to show mild residual lameness initially, only to warm out of it quickly during examination. Other factors affecting response to diagnostic analgesia include individual variation in neuroanatomy, the intermittent nature of certain lameness conditions, and the inherent difficulty in assessing and abolishing pain in horses with subtle lameness.[8] Articular lesions may not be desensitized by intra-articular analgesia.

Sensory innervation of joints is complex and involves three classes of neurons that transmit information from four receptor types, each of which has a specific distribution throughout the joint.[9-12] Articular pain can arise from several sources, including the synovium (inflammation, effusion), fibrous joint capsule (increased intra-articular pressure), articular and periarticular ligaments, periosteum, and subchondral bone (injury, osseous vascular engorgement).[8,10,13] Other than small branches in the perichondrium, articular cartilage is devoid of innervation. In osteoarthritic joints, however, erosion channels, formed in the calcified layer of cartilage, are invaded by subchondral vasculature.[10] Putative nociceptive neurotransmitters were identified in these areas, and therefore it is plausible that in horses with advanced osteoarthritis, pain could be emanating from the deep cartilage layers.[14,15]

On occasion, lameness from an articular lesion abates after perineural analgesia but shows minimal or only partial response after intra-articular analgesia. In some horses, this can be explained by the fact that pain is originating from articular and periarticular tissues.[8] Subchondral bone pain—caused by stress or non-adaptive remodeling, cystic or erosive lesions, incomplete fractures, and osteoarthritis—is inconsistently abolished by intra-articular analgesia. In fact, subchondral bone pain is abolished much more consistently by perineural techniques. Subchondral bone receives innervation from endosteal branches of peripheral nerves that enter the medullary cavity through the nutrient foramen.[8,9,16,17] Intra-articularly administered local anesthetic solutions may not penetrate subchondral bone sufficiently to completely block these nerves. This shortcoming is presumably even more likely in situations in which the overlying articular cartilage is intact.

Unfortunately, intra-articular analgesia, although easier to perform, inconsistently abolishes pain from many of the common articular problems. This fact, however, is either overlooked or misunderstood by many practitioners. Whenever possible, perineural analgesia should be performed, particularly in the distal limbs, because this type of analgesia more consistently abolishes pain from all aspects of the joint and surrounding soft tissue structures.

Perception of Diagnostic Analgesia by Laypersons

One of the intangible factors that can complicate the lameness examination is the layperson's perception of diagnostic analgesia or nerve blocking. In many instances the opportunity for an owner or trainer to observe the outcome of diagnostic analgesia provides the concrete evidence that finally convinces him or her of the diagnosis. The classic example is the acute shoulder injury that is actually chronic navicular disease. However, for many reasons, misunderstanding about diagnostic analgesia can lead to frustration for everyone involved. Many laypersons are not fully able to recognize the baseline lameness and therefore may not be capable of seeing that the horse's lameness improves after the block. Another difficulty is trying to explain why lameness in a horse with an articular problem is better after a perineural block but no better when local anesthetic solution is placed directly into a joint. Similarly, many laypersons do not understand why a horse with an articular lameness may "block sound" but does not respond satisfactorily to therapeutic injection. This finding that a horse blocks sound but does not inject sound is quite common in young racehorses with subchondral bone pain. Most experienced practitioners have learned to deal with these issues, but the new graduate may need fortitude and ingenuity when explaining the results of diagnostic analgesia is difficult.

Role of Chemical Restraint

Whenever possible, use of physical (nose or shoulder twitch) rather than chemical restraint is best when performing diagnostic analgesia. This is particularly important in horses with low-grade lameness. The analgesic properties of α_2-agonists (xylazine, detomidine) and synthetic opiates (e.g., butorphanol) are well recognized and may lead to false-positive

results. Ataxia after sedation can complicate lameness interpretation. However, in some horses mild sedation or tranquilization may be necessary to perform diagnostic analgesia and may improve the clinician's ability to evaluate the baseline lameness. Acetylpromazine (0.02 to 0.04 mg/kg intravenously) can calm a highly strung horse and facilitate the lameness examination. Extra care must be taken when performing hindlimb procedures, and the safety of everyone involved and the horse must be considered. In horses with moderate or severe lameness, xylazine (0.15 to 0.30 mg/kg intravenously) may not interfere appreciably with lameness interpretation. Similarly, extremely fractious horses can be sedated with an α_2-agonist, which then is reversed with the prescribed α_2-antagonist (e.g., yohimbine) before reevaluation. Alternatively, sedation can simply be allowed to wear off before reevaluating the horse, but diffusion of anesthetic may occur or the effect may wear off, both of which may potentially cause misinterpretation of results.

Patient Preparation

Before perineural analgesia is performed, the skin and hair should be cleaned of any gross debris such as mud, bedding, feces, or poultice. Clipping usually is not necessary unless the hair coat is long and prohibits accurate palpation of anatomical landmarks or adequate cleaning of the site. The site should then be scrubbed with an antiseptic, such as povidone-iodine or chlorhexidine, using clean gauze sponges or cotton. If the clinician has any concern about inadvertent penetration of a synovial cavity, a 5-minute aseptic preparation should be performed. This is followed by isopropyl alcohol administration over the site using cotton or gauze sponges.

Aseptic preparation should always be performed before any intrasynovial injection. Considerable debate and variation exists among clinicians regarding the need to clip the hair over the site. Some clinicians always clip the hair, whereas others never do. Still others shave the hair in a small area directly over the injection site. The results of a recent study indicated no significant difference in the number of post-scrub colony-forming units (bacterial flora) between clipped and unclipped skin over the distal interphalangeal (DIP) and carpal joints.[18] Nonetheless, we still clip the hair over all proposed intrasynovial injection sites before undertaking a 5-minute aseptic preparation. The only time we deviate from this policy is when we are specifically asked not to clip the hair, a situation that arises in some sport horses actively competing, in claiming horses, or in those being sold.

Similar variation among clinicians exists regarding wearing of sterile latex gloves when performing an intrasynovial injection. However, we recommend wearing sterile gloves during these procedures. Science aside, clipping hair and wearing sterile gloves project a positive impression to all in attendance.

How does, or should, the practitioner attempt perineural or intrasynovial analgesia in a horse with contact or chemical dermatitis (scurf) over the proposed injection site? A superficial wound or abrasion with a localized infection presents a similar quandary. For obvious reasons, these areas are difficult, if not impossible, to clean effectively. If possible, an alternative site, away from the area of dermatitis, should be used. If not, then the procedure should be delayed until the skin condition (or wound) has resolved. In many instances, dermatitis can be treated with topical medications (medicated sweats such as nitrofurazone-dimethylsulfoxide) for a few days to facilitate resolution of the problem.

Injection Techniques

Perineural injections are typically performed using needles ranging in size from 25 gauge, 1.6 cm (⅝ inch) to 20 gauge, 2.5 or 4 cm (1 to 1½ inches). Small needles cause less pain but carry the risk of breaking off within tissues if the horse kicks out or otherwise misbehaves. For this reason, we recommend using 18-or 19-gauge needles for injections or blocks within the proximal metatarsal or plantar tarsal regions. In the distal limb the needle is inserted subcutaneously directly over and parallel to the nerve. We generally direct the needle proximally rather than distally, although this portion of the procedure differs among clinicians. The needle is inserted before the syringe is attached. To avoid excessive manipulation once the needle is inserted, a slip-type syringe hub is preferred. Syringes with screw-on hubs can be difficult to attach, requiring additional manipulation in a sometimes fractious horse, and are not generally used. However, when dense tissue requires that additional force be used for injection, the seal between the hub and the needle can be broken, a complication minimized by using a screw-on hub (see the following discussion of lateral palmar block).

Volume of local anesthetic solution varies, but for a majority of blocks in the distal limb 1 to 5 ml is injected at each site. Larger volumes are used to perform the median/ulnar and fibular (peroneal)/tibial techniques and when infiltrating the proximal palmar (plantar) metacarpal (metatarsal) region. After injection, we briefly massage the sites with gauze sponges or clean cotton soaked in alcohol. Skin sensation and deep pain are assessed between 5 and 10 minutes after injection. More time is allowed under certain circumstances (see specific comments throughout the chapter). At the completion of the examination an alcohol wrap should be applied to minimize swelling, a common sequela resulting from local irritation and bleeding from nearby vessels.

For "ring" blocks, circumferential subcutaneous infiltration of local anesthetic solution, and other local or regional infiltration techniques, we most commonly use 18- to 22-gauge, 4-cm needles. To perform a ring block, the needle is inserted perpendicular to the long axis of the limb, and local anesthetic solution is injected as the needle is advanced, leaving a clearly visible wheal or subcutaneous bleb in most locations. The needle then is reinserted at the leading edge of this wheal, a practice that minimizes the number of injections and the horse's discomfort. However, most horses object to needle insertion even when it is performed well within the bleb. The injection is continued around the limb in this manner. For most ring blocks in the distal limb, 10 to 15 ml of local anesthetic solution is used, but larger volumes may be preferred for surgical procedures. Ring blocks can be done as a substitute for or in combination with perineural injections (see the specific blocking techniques discussed in the chapter). However, simply placing anesthetic in a subcutaneous location is not a substitute for the preferred approach, direct perineural injection.

To block a local area such as a splint or curb, the needle is typically inserted in one or two locations, and local anesthetic solution is deposited in a fan-shaped pattern. As with the perineural analgesia, the sites are massaged briefly and the horse is reevaluated in 5 to 10 minutes.

Intrasynovial injections typically are performed using needles ranging in size from 22 gauge, 2.5-cm to 18 gauge, 4-cm. If marked effusion is present, drainage of synovial fluid is advised, either by allowing the fluid to drip from the hub of the needle or by aspirating with a sterile syringe before proceeding with injection. We prefer the former procedure unless fluid analysis is necessary. The manipulation required to attach the syringe may cause the horse discomfort and potentially dislodge the needle but, if successful, may hasten withdrawal of synovial fluid. Brief evaluation of the color and viscosity of synovial fluid can shed some light on the disease process within and is expected practice among most racehorse trainers. Volume of local anesthetic solution varies considerably between synovial cavities, but the clinician should keep in mind that small volumes might contribute to a false-negative result. False-negative results are common in horses with

severe osteoarthritis, and larger volumes of local anesthetic solution should be used. We routinely spray or wipe antiseptic solution over the injection site. After the examination a light bandage is applied over the injection sites from the metacarpophalangeal/metatarsophalangeal joint, distally. Initial reevaluation is done 5 to 10 minutes after injection. Additional evaluations may be necessary depending on the response during the initial time period. General practice is to have the horse walked in hand or with a rider after perineural or intrasynovial analgesia is administered, a procedure thought to hasten local distribution of anesthetic solution and potentially improve success. Excessive diffusion of local anesthetic solution is a potential drawback to this practice, particularly with techniques such as distal interphalangeal or middle carpal analgesia (see the following discussion), although it would be a complication difficult to quantify.

Another issue to consider when performing diagnostic analgesia is whether riding or driving a horse after blocks have been performed is safe. In general, riding on the flat or driving a horse at slow speed after any of the common blocks are performed is safe. Stumbling or knuckling can be a concern after upper limb perineural techniques, such as the median/ulnar and fibular (peroneal)/tibial techniques. Common sense should prevail, however, with regard to the horse and rider negotiating fences or performing at high speed. Horses at risk of lameness from stress or incomplete fracture are candidates for imaging before evaluation at speed after diagnostic analgesic techniques have been performed.

PERINEURAL ANALGESIA IN THE FORELIMB

Palmar Digital Analgesia

Palmar digital analgesia (or palmar digital block) is the most common diagnostic analgesic procedure performed. The medial and lateral digital neurovascular bundles, consisting, in a dorsal to palmar direction, of the digital vein, artery, and nerve, course in an abaxial location to the digital flexor tendons. With the exception of small breeds or Draft horses with exceptionally long-haired pasterns (feathers), the palmar digital nerve is easily palpable between the proximal sesamoid bones and the cartilages of the foot. The palmar digital block can be performed with the horse in a standing position or with the limb held off the ground. We prefer the latter. If held by an assistant, the limb should be grasped in the mid-metacarpal region, with the fetlock and digit hanging in neutral position. The palmar digital nerve is easily palpated in this extended position. Alternatively, the clinician performing the block can hold the limb, a technique that requires practice. The clinician can stand facing backward with a hand grasping the mid-pastern region or can stand behind the limb and clutch the hoof between both legs.

A 25-gauge, 1.6-cm needle is inserted subcutaneously, directly over the nerve, just proximal to the cartilages of the foot (Fig. 10-5). One of us (L.H.B.) directs the needle in a distal direction, whereas the other (M.W.R.) directs the needle in a proximal direction to avoid deeper penetration or laceration of digital vessels if the horse withdraws the limb. Alternatively, a 22-gauge, 4-cm needle can be inserted on the palmar midline in the mid-pastern region, and local anesthetic solution is then infiltrated in a V-shaped pattern. This modification of the PD block is quite difficult to perform in the hindlimb, but when done in the forelimb, provides maximal analgesia to the bulbs of the heel and minimizes the potential of depositing local anesthetic solution dorsal to the nerve. Loss of skin sensation in the midline between the bulbs of the heels should be assessed, because this area seems most recalcitrant to palmar digital analgesia. Deep pain is assessed using hoof testers.

Traditionally the PD block was felt consistently to desensitize only the palmar (plantar) one third to one half of the foot.[19] However, in clinical practice, this block desensitizes 70% to 80% of the foot. Most of the distal interphalangeal joint is affected, with the exception of the proximodorsal aspect. Horses with fractures of the extensor process of the distal phalanx may show partial improvement after palmar digital analgesia, however. Our clinical observations have been substantiated in a recent study. Setscrews were placed near the medial and lateral aspects of the toe to simulate pain from the sole. Lameness in these horses was abolished using palmar digital analgesia performed just proximal to the heel bulbs.[20]

Classically, most horses that responded positively to palmar digital analgesia were thought to have navicular syndrome, but this block desensitizes many lameness conditions within and outside the hoof capsule (Table 10-1). This is an important and common misconception. Lameness in horses with mid-sagittal fracture of the proximal phalanx or other conditions involving the fetlock joints can be abolished using palmar digital analgesia.[7] Although using small volumes of anesthetic solution and performing the block just above the cartilages of the foot may help to minimize the area of analgesia, these procedures do not prevent inadvertent diagnosis in some horses. Diffusion of anesthetic solution is the most likely explanation, and even a small volume can readily spread in a proximal direction, but the normal anatomy of the digit prevents distal placement of anesthetic solution (Fig. 10-6).

The concept that palmar digital analgesia abolishes lameness in an area considerably more than the palmar (plantar) one third of the foot appears to be difficult for many to accept. Although results of studies are widely published and this finding has been emphasized at international meetings, most veterinary students still graduate today armed with this common misconception. Diffusion of anesthetic solution easily explains why lameness conditions in the proximal aspect of the pastern or fetlock regions are desensitized by palmar digital analgesia. But what about the innervation of the hoof itself? Skeptics should consider the anatomy of the palmar digital nerve. Most practitioners have severed the palmar digital nerve while performing neurectomy. Can the clinicians recall any instance of having identified a large dorsal branch, or for that matter, any branching of the nerve at all? The lack of nerve branches in the mid-pastern region is circumstantial evidence that important innervation to the structures located dorsally within the hoof capsule occurs farther proximally (ill-defined dorsal branches) or after the nerve courses deep to the collateral cartilages of the foot. It makes little sense that ill-defined dorsal branches would innervate the dorsal two thirds of the foot, leaving the robust palmar digital nerve to innervate only the palmar one third.

Accurately quantifying the contribution of the palmar digital nerve to the innervation of the foot or, for that matter, the exact percentage of structures desensitized by palmar digital analgesia may be impossible. Clinical experience will undoubtedly convince practitioners of the broad nature of palmar digital analgesia. Finally, it is imperative to develop expertise in diagnostic imaging of the entire digit, because the many lameness conditions affected by palmar digital analgesia require detective-like differential diagnostic skills.

Mid-Pastern Ring Block

Traditionally the diagnostic blocks performed after palmar digital analgesia are the basisesamoid or abaxial sesamoid techniques. The basisesamoid block provides little additional information compared with palmar digital analgesia, unless, of course, the dorsal branch, originating from the digital nerve at the level of the proximal sesamoid bone, is blocked. If, however, the dorsal branch is blocked, then the basisesamoid block is in reality an abaxial sesamoid block. For this reason, we rarely

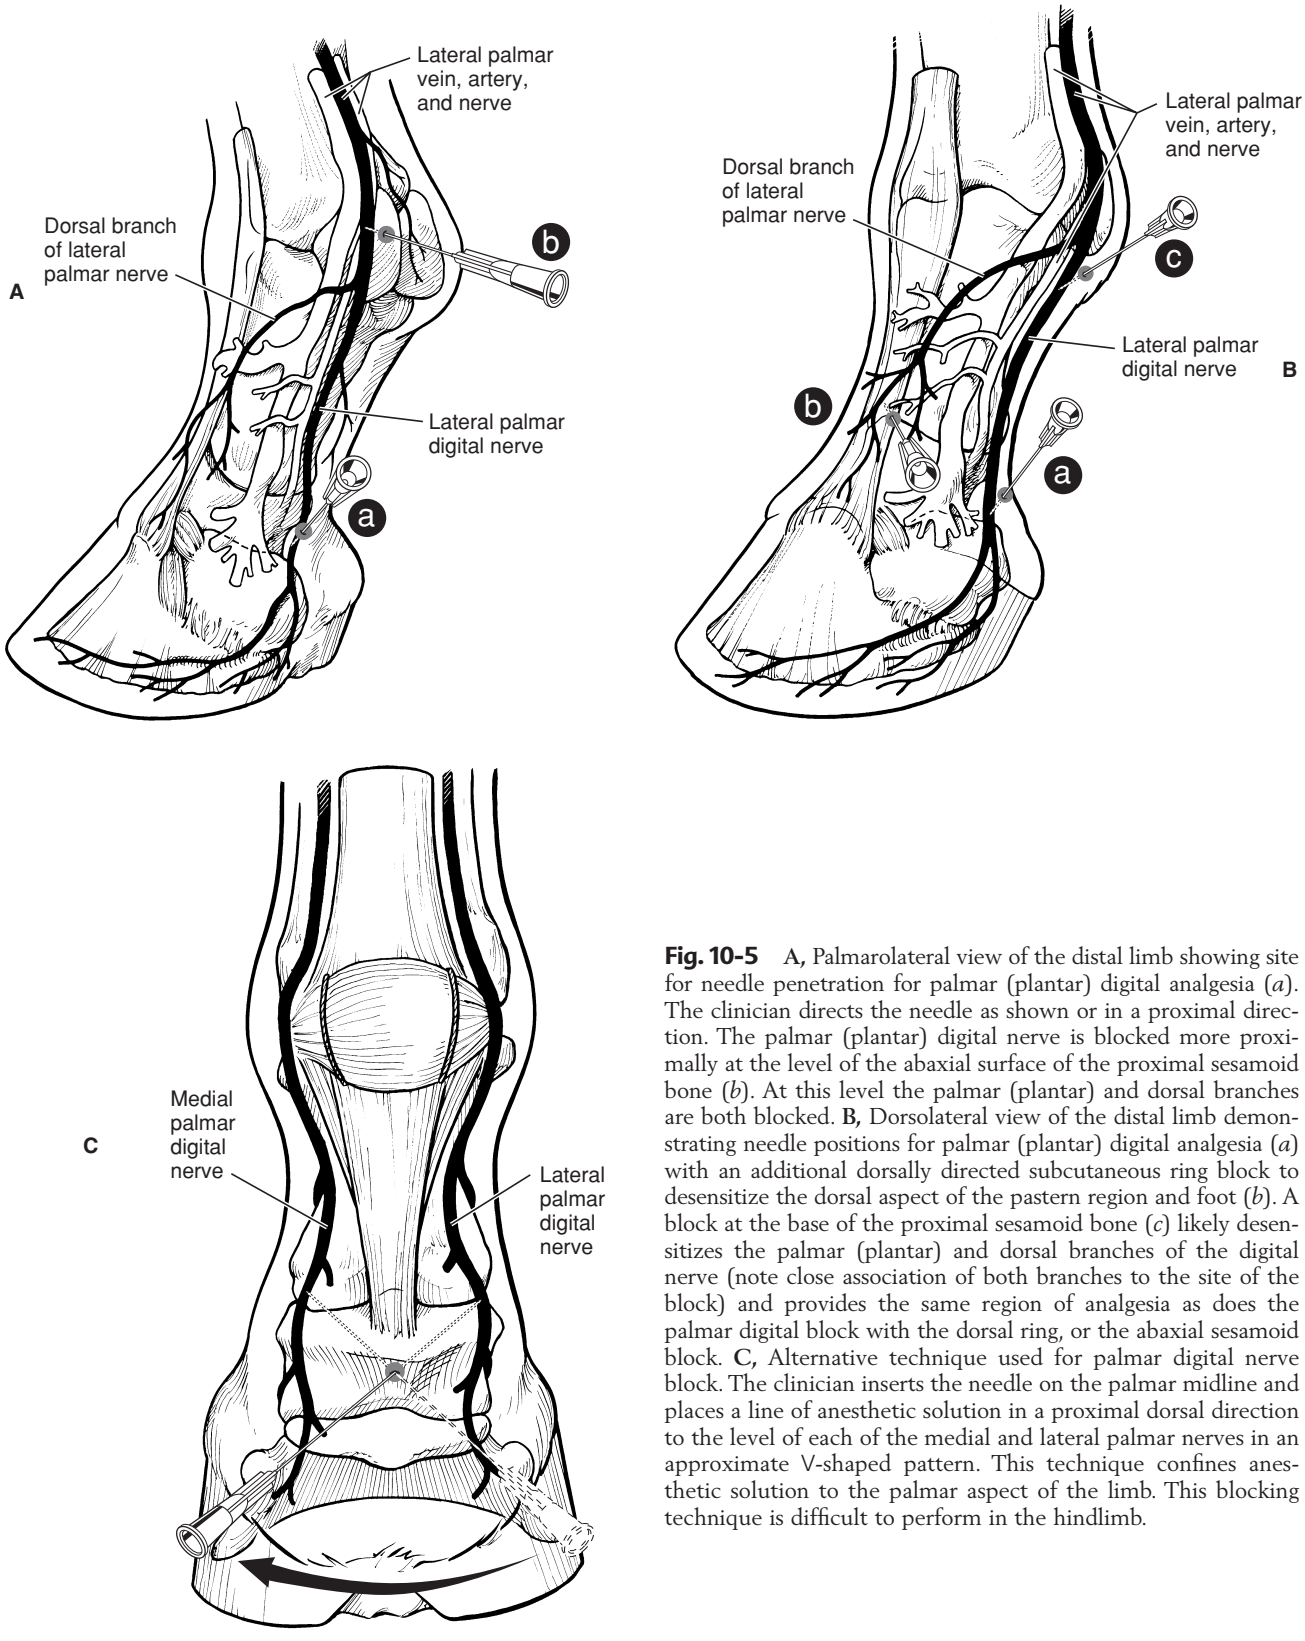

Fig. 10-5 **A,** Palmarolateral view of the distal limb showing site for needle penetration for palmar (plantar) digital analgesia (*a*). The clinician directs the needle as shown or in a proximal direction. The palmar (plantar) digital nerve is blocked more proximally at the level of the abaxial surface of the proximal sesamoid bone (*b*). At this level the palmar (plantar) and dorsal branches are both blocked. **B,** Dorsolateral view of the distal limb demonstrating needle positions for palmar (plantar) digital analgesia (*a*) with an additional dorsally directed subcutaneous ring block to desensitize the dorsal aspect of the pastern region and foot (*b*). A block at the base of the proximal sesamoid bone (*c*) likely desensitizes the palmar (plantar) and dorsal branches of the digital nerve (note close association of both branches to the site of the block) and provides the same region of analgesia as does the palmar digital block with the dorsal ring, or the abaxial sesamoid block. **C,** Alternative technique used for palmar digital nerve block. The clinician inserts the needle on the palmar midline and places a line of anesthetic solution in a proximal dorsal direction to the level of each of the medial and lateral palmar nerves in an approximate V-shaped pattern. This technique confines anesthetic solution to the palmar aspect of the limb. This blocking technique is difficult to perform in the hindlimb.

perform the basisesamoid block. When performing the abaxial sesamoidean technique in racehorses or, for that matter, any sport horse with a propensity to develop lameness of the metacarpophalangeal or metatarsophalangeal joints, the veterinarian runs the risk of an additional misdiagnosis. When local anesthetic solution is deposited in a location abaxial to the proximal sesamoid bones, pain from the metacarpophalangeal or metatarsophalangeal joints can be inadvertently blocked, explained most likely because of anesthetic diffusion, leading the clinician to assume the horse has a problem in the foot or

Fig. 10-6 Radiograph showing palmar digital anesthesia performed with positive contrast material. The clinician performed palmar digital anesthesia as far distal as possible, but the injection site is still at the level of the proximal interphalangeal joint, explaining why palmar digital anesthesia desensitizes most of the foot and the pastern region in some horses.

digit, but in reality the pain originated from these joints. For these reasons, we prefer to use a blocking sequence as follows: palmar digital nerve, followed by a dorsally directed subcutaneous ring block, followed by the low palmar or plantar block.

The mid-pastern ring block affects the dorsal branches of the digital nerves and desensitizes any remaining areas of the foot and pastern region that were not affected by palmar digital analgesia. In most horses, this includes the dorsal 20% of the foot (dorsal laminar and extensor process regions of the distal phalanx), and dorsal pastern region (middle phalanx, proximal interphalangeal joint, and distal portions of the proximal phalanx). Although desirable, performing the dorsal ring block just above the cartilages of the foot usually is not possible. Instead the block is performed at the level of the mid-pastern region.

A 20- to 22-gauge, 4-cm needle is used to deposit subcutaneously 10 to 12 ml of local anesthetic solution, beginning near the injection site used for palmar digital analgesia over the lateral neurovascular bundle and continuing dorsally and medially, ending over the medial neurovascular bundle (see Fig. 10-5). Resistance to needle advancement and injection of local anesthetic solution will invariably be encountered dorsally, if the block is done just proximal to the coronary band, because of the dense tissue (proximal interphalangeal joint capsule, extensor branches of the suspensory ligament, and extensor tendons). Performing the block in the mid-pastern region minimizes this problem and mitigates the potential for inadvertent penetration of the proximal interphalangeal joint.

Abaxial Sesamoid Block

Desensitizing the medial and lateral palmar nerves at the level of the proximal sesamoid bones is commonly referred to as the abaxial sesamoid block but may provide the same information as the basisesamoid block, if the dorsal branch of the palmar digital nerve is blocked. To avoid redundancy, we rarely perform the basisesamoid technique before progressing to the

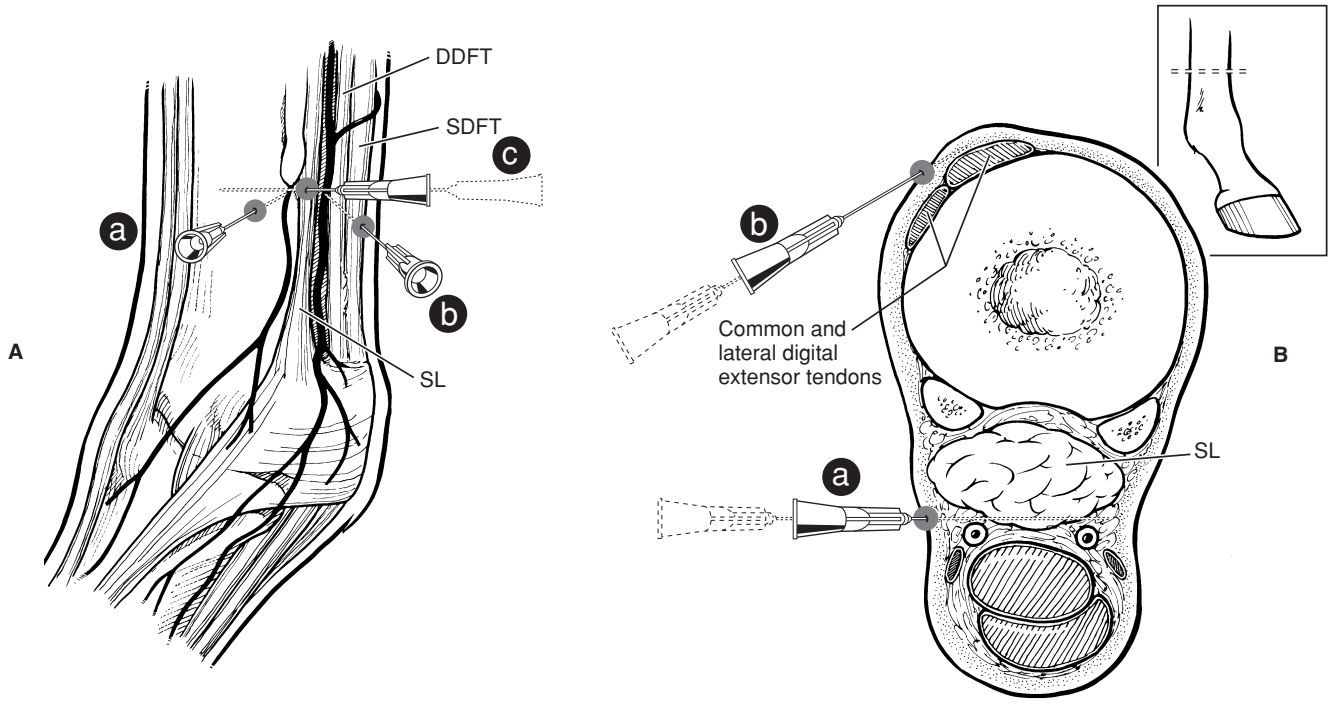

Fig. 10-7 **A,** This lateral view shows needles positioned for a low palmar (plantar) nerve block. The clinician inserts a needle (*a*) just distal to the distal aspect of the fourth metacarpal or metatarsal bone and directs it axially to block the lateral palmar (plantar) metacarpal (metatarsal) nerve. The clinician then inserts a needle (*b*) between the suspensory ligament (*SL*) and deep digital flexor tendon (*DDFT*) to block the lateral palmar (plantar) nerve. The clinician repeats the two injections on the medial side. A subcutaneous ring block from the first injection site around to the dorsal midline (*c*) completely abolishes skin sensation. **B,** Transverse view of the distal left metacarpal region demonstrating an alternative technique for low palmar (plantar) analgesia. The clinician inserts a needle (*a*) in a lateral-to-medial direction between the deep digital flexor tendon and the SL to block the lateral and medial palmar (plantar) nerves. The palmar (plantar) metacarpal (metatarsal) nerves are blocked as depicted in **A** (not shown in this diagram), which also shows the subcutaneous ring block. The clinician inserts a needle (*b*) in a lateral-to-medial direction dorsal to the digital extensor tendons to block the dorsal metatarsal nerves of the hindlimb.

abaxial sesamoid block (see previous comments). A block done at this level essentially provides analgesia of the entire digit, because the block is performed at the level of or just proximal to the origin of the dorsal branch of the palmar digital nerve. Response to this block may vary, however. Some horses retain skin sensation in the dorsoproximal aspect of the pastern region. In others, pain arising from lesions involving the fetlock joint or peri-articular tissues is abolished. In part, these phenomena can be explained by proximal diffusion of anesthetic, affecting the palmar digital nerves proximal to the fetlock joint. Branches of the palmar digital nerves supplying the proximal sesamoid bones, the sesamoidean nerves, could easily be blocked using an analgesic technique in this abaxial position.[21]

The abaxial sesamoid block can be performed in the standing horse or with the limb held by the clinician or an assistant. The palmar digital nerve can easily be palpated over the rigid proximal sesamoid bones and in fact is in its most superficial position in this location. A 25-gauge, 1.6-cm needle, directed in a proximal or distal direction, and typically 1 to 3 ml of local anesthetic solution is used for the medial and lateral injection. Deep pain is assessed by hard flexion of the interphalangeal joints.

Low Palmar Analgesia

Analgesia of the metacarpophalangeal joint region and distal limb is induced using the low palmar block or low palmar analgesia (low four-point). This technique blocks the medial and lateral palmar nerves and the medial and lateral palmar metacarpal nerves. In the forelimb a subcutaneous, dorsally directed ring block and block of the dorsal branch of the ulnar nerve completely abolishes skin sensation. Disagreement exists about whether abolishing skin sensation is necessary when performing perineural techniques. Abolition of skin sensation does not necessarily mean deep pain is abolished, which is particularly relevant when a nerve responsible for skin sensation is blocked independently from nerves contributing to deep pain sensation, as in the case of the low palmar technique. When using these techniques for diagnostic purposes, it may be best to avoid blocking nerves that only contribute skin sensation, thus minimizing the number of needle insertions. For therapeutic interventions, however, these nerves need to be blocked.

The low palmar block is performed at the level of the distal end (button) of the second and fourth metacarpal bones (splint bones), with the limb in a standing position or held off the ground (Fig. 10-7). A 20- or 22-gauge needle is used to inject 1.5 to 5 ml of local anesthetic solution at each injection site. To block the palmar metacarpal nerves, the needle is inserted perpendicular to the skin, just distal to the end of the splint bones, to a depth of 1 to 2 cm. It is important to deposit anesthetic solution deep in the injection site, rather than simply in a subcutaneous location. While continuously injecting local anesthetic solution, the needle is slowly withdrawn, leaving a visible bleb in the subcutaneous space. To block the medial and lateral palmar nerves, the needle is inserted subcutaneously, in the palmar aspect of the space between the

suspensory ligament and deep digital flexor tendon (DDFT) at the level of or slightly more proximal to the distal end of the splint bone. To improve the accuracy of the injection, using a fan-shaped injection technique is helpful. To complete this block, local anesthetic solution is placed in the subcutaneous tissues from the bleb at the distal end of the splint bone to the dorsal midline.

Alternatively, some clinicians prefer to use a longer needle first to deposit local anesthetic solution over the palmar metacarpal (metatarsal) nerves. The needle is then pushed subcutaneously to deposit local anesthetic solution over the palmar nerves (see Fig. 10-7). When performing this modification, incompletely blocking the palmar metacarpal (metatarsal) nerves or lacerating the digital vessels is possible. The lateral and medial palmar nerves can be blocked using only the lateral injection site by advancing the needle in a medial direction, palmar to the DDFT. Although each of these modifications may theoretically decrease the number of injections needed to perform this technique, they have the disadvantages of potential hemorrhage and incomplete analgesia.

High Palmar Block

To provide analgesia to the metacarpal region, the high palmar block (high four-point, sub-carpal block) is the most common technique, but a modified block (lateral palmar or Wheat block) can be performed. Inadvertent penetration of the carpometacarpal joint is a potential complication with the high palmar block. A similar complication can occur in the hindlimb but is less frequent (see the following discussion). Inadvertent penetration of the carpometacarpal joint occurred in 17% of specimens, in which a conventional high palmar block was performed, because of extensive distopalmar outpouchings (Figs. 10-8 and 10-9). However, when the high palmar block was performed within 2.5 cm of the carpometacarpal joint, inadvertent penetration of this joint occurred in 67% of specimens. The carpometacarpal joint always communicates with the middle carpal joint, and therefore penetration of the carpometacarpal joint during high palmar analgesia would lead the clinician to diagnose a metacarpal problem, when in reality, the authentic lameness condition exists in the carpus. Moving the injection site in a distal direction decreases the possibility of entering the carpometacarpal joint but also narrows the scope of the technique. Two ways around this likely complication are these: first, the clinician could perform middle carpal analgesia before performing high palmar analgesia; second, the clinician could perform a lateral palmar block in lieu of the conventional high palmar technique. In an experimental study, it was unlikely to enter the carpal joints inadvertently when performing the lateral palmar block, although in every specimen, local anesthetic solution would have entered the carpal canal.[22] Unless the clinician is familiar with the lateral palmar block, the most straightforward approach to reduce the possibility of misdiagnosis in this region is to perform middle carpal analgesia before proceeding to the high palmar block. When local anesthetic solution is placed in the middle carpal joint, not only is the carpometacarpal joint blocked, but also the possibility exists of providing local analgesia to the proximal palmar metacarpal region. Using this approach, abolishing pain associated with proximal suspensory attachment avulsion injury (desmitis, fracture), stress remodeling, and longitudinal fracture is possible (see Chapter 38). The palmar metacarpal nerves and suspensory branches from the lateral palmar nerve are closely associated with the distopalmar outpouchings of the carpometacarpal joint, and anesthetic diffusion from this area could explain in part this clinical finding (Fig. 10-10).

It is important for the clinician to understand that interpretation of analgesic techniques in the proximal palmar metacarpal region or carpus can be somewhat complex.

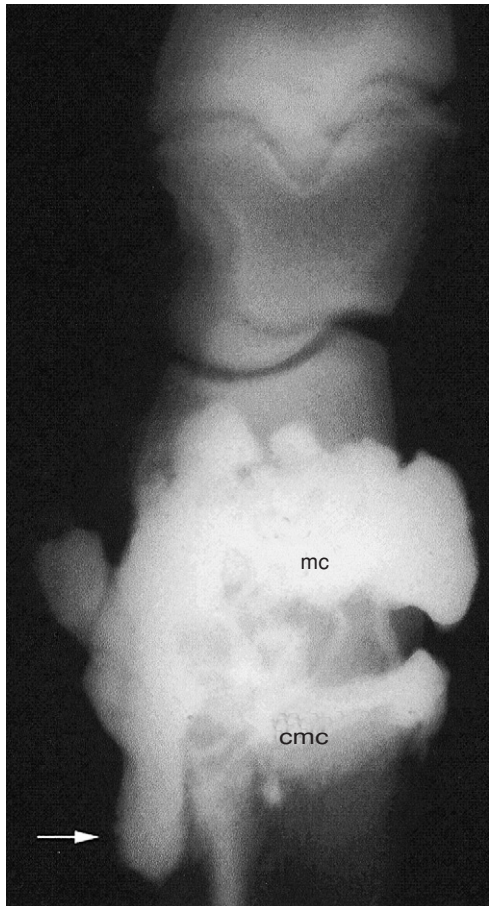

Fig. 10-8 Positive contrast arthrogram of the middle carpal (*mc*) and carpometacarpal (*cmc*) joints (dorsal is to the right). Contrast material injected into the middle carpal joint flows freely distally into the carpometacarpal joint and fills the extensive distopalmar outpouchings of the joint *(arrow)*.

Correct diagnosis is always the key, and comprehensive evaluation using multiple imaging modalities is a must in differentiating lameness in this region. From the clinical perspective, one is more likely to assume incorrectly that one is dealing with a carpal problem, when the authentic lameness condition resides in the proximal palmar metacarpal region, than vice versa. Numerous techniques are used to perform high palmar analgesia; some provide partial and others provide complete analgesia to the metacarpal region. For complete analgesia, blocking the following nerves is necessary: the medial and lateral palmar nerves, the medial and lateral palmar metacarpal nerves, the suspensory branches, and nerves providing skin sensation along the dorsum (dorsal branch of ulnar nerve and musculocutaneous nerve). To block these nerves effectively, one must use a site close to the carpometacarpal joint, at the level where the splint bones begin to taper (Fig. 10-11). If the block is done at a lower level, the region of the suspensory attachment will be missed. A 20- or 22-gauge needle at least 2.5 cm long is necessary to reach the palmar metacarpal nerves in this location. The needle is inserted axial to the splint bones just abaxial to the suspensory ligament and then guided to the palmar cortex of the third metacarpal bone (McIII). Five milliliters of local anesthetic solution is deposited, first deep within the tissues, and continued as the needle is withdrawn, ending with a bleb in the subcutaneous tissues. To block the medial and lateral palmar nerves between the suspensory ligament and DDFT, a smaller gauge needle can be used to deposit 3 to 5 ml of local anes-

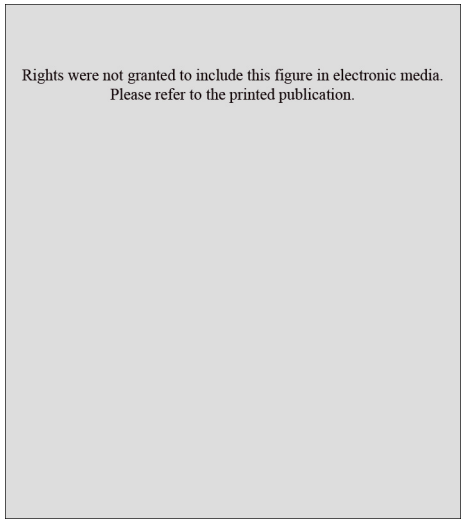

Fig. 10-9 Liquid acrylic injected into the middle carpal joint and allowed to harden created this specimen showing the lateral (*A*) and medial (*B*) distopalmar outpouchings of the carpometacarpal joint. Secondary fingerlike outpouchings ramify in the proximal palmar metacarpal region.

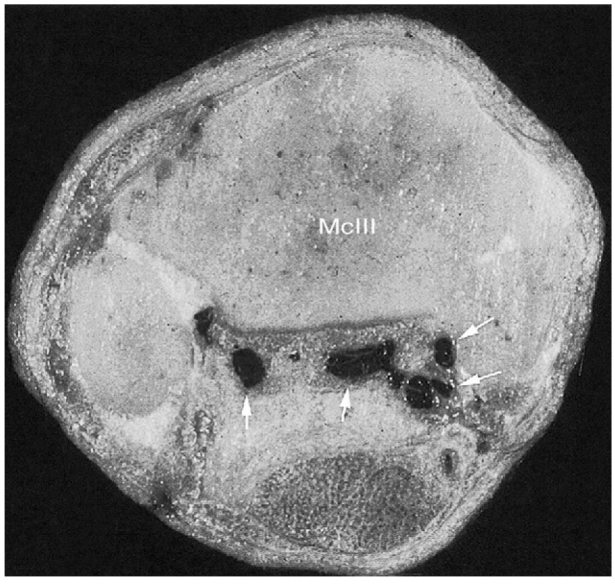

Fig. 10-10 Transverse section of the proximal metacarpal region just distal to the carpometacarpal joint after latex injection into the middle carpal joint showing primary and secondary distopalmar outpouchings of the carpometacarpal joint (*dark areas, arrows*) interdigitating with the proximal aspect of the suspensory ligament (dorsal is up; lateral is left). This anatomical arrangement explains inadvertent analgesia of the carpus and proximal palmar metacarpal region during high palmar and middle carpal analgesia, respectively. *McIII*, Third metacarpal bone.

thetic solution at each of two sites. To complete this block, a circumferential subcutaneous ring block is performed to abolish skin sensation dorsally. Alternatively, the subcutaneous nerves can be blocked on either side of the common digital extensor tendon, but small zones of sensation may persist using this technique. It is necessary to complete the dorsal portion of this block to provide complete analgesia when performing procedures in the dorsal metacarpal region, such as laceration repair or standing osteostixis.

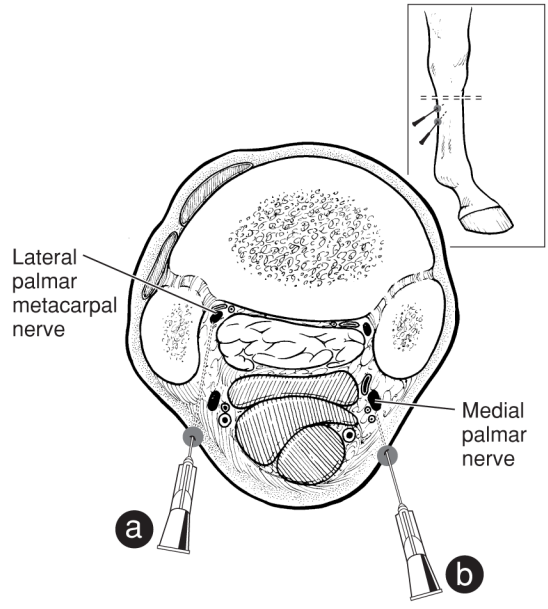

Fig. 10-11 Transverse view of the left metacarpal region showing the technique for high palmar analgesia. The clinician inserts a needle (*a*) axial to each second and fourth metacarpal bone and uses two separate injections (*b*) to block the medial and lateral palmar nerves. The location of the high palmar technique appears in the lateral view (*inset*).

A modification of the high palmar block is performed by locally infiltrating the suspensory origin from a lateral injection site in a fan-shaped pattern. This procedure, along with one specifically to block the medial and lateral palmar metacarpal nerves, improves specificity of this complex block, because only pain from a limited number of structures is eliminated. The medial and lateral palmar nerves can also be blocked from a single lateral injection site.

Lateral Palmar Block

An alternative method of providing analgesia to the metacarpal region is to perform what is known as the *lateral palmar* (high two-point) or *Wheat block*.[23] To provide complete analgesia, however, combining this block with an independent injection over the medial palmar nerve and with a dorsal subcutaneous ring block is necessary. Originally proposed as an alternative method for analgesia of the suspensory ligament origin, this technique involves blocking the lateral palmar nerve just distal to the accessory carpal bone (Fig. 10-12). The lateral palmar nerve is formed as the median and deep ulnar nerves join, proximal to the accessory carpal bone (see Fig. 10-12).[24] At the level of the block, just distal to the accessory carpal bone, the lateral palmar nerve is blocked before it branches to form the medial and lateral palmar metacarpal nerve, the suspensory branches, and continues distally (see Fig. 10-12). The high two-point block is completed with the separate but concurrent block of the medial palmar nerve.

This technique has at least three advantages compared with conventional high palmar analgesia. Inadvertently penetrating the distopalmar outpouchings of the carpometacarpal joint is virtually impossible, although local anesthetic solution will likely enter the carpal canal.[22] Lateral palmar analgesia requires fewer needle penetrations than does conventional high palmar analgesia. Finally, only a small volume of local anesthetic solution is necessary to desensitize a number of nerves

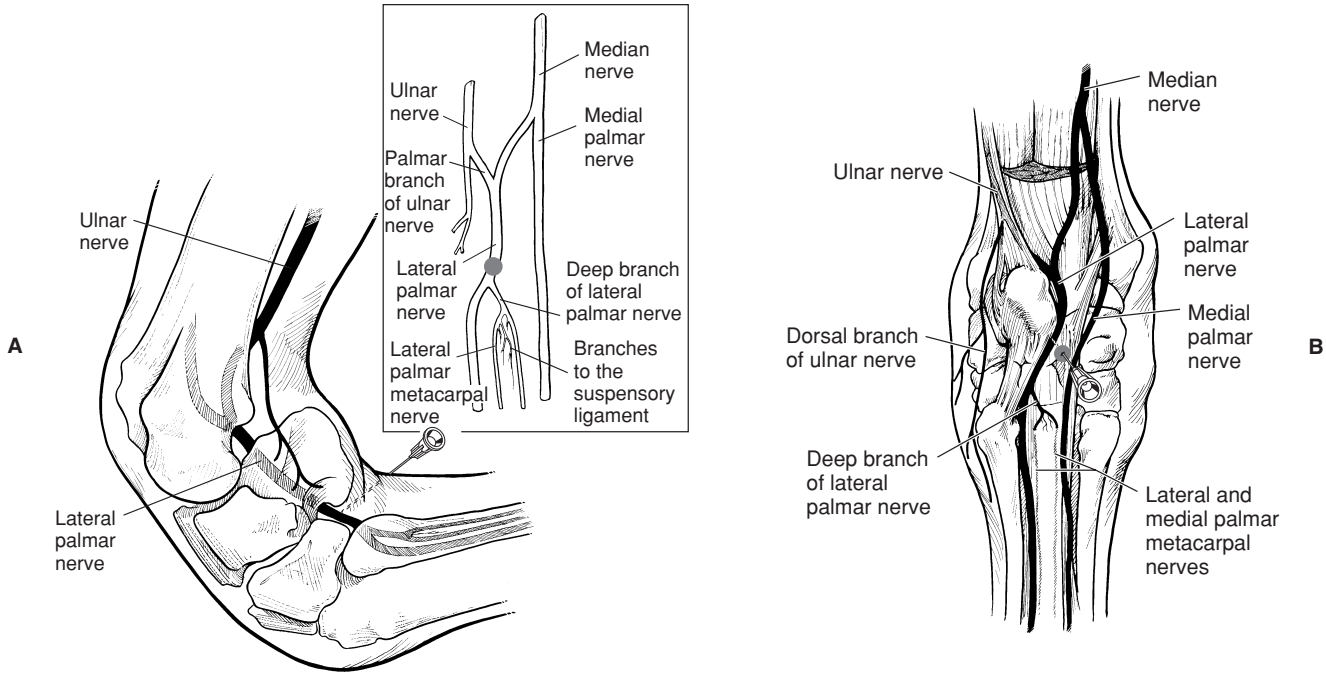

Fig. 10-12 **A,** This diagram of the left carpus in a flexed position shows the location of the lateral palmar nerve block and parent nerves (*inset*) contributing to the origin of the lateral palmar and other important nerves. **B,** Palmar view of the limb showing nerves in situ and the site for needle penetration for lateral palmar nerve block.

and the origin of the suspensory ligament. Pain associated with the carpal canal is abolished, however.

The lateral palmar block can be performed in the standing position or with the limb held off the ground, with the carpus in 90° of flexion. The nerve cannot be palpated because it courses in the accessorial-metacarpal ligament, dense connective tissue distal to the accessory carpal bone. A 25-gauge, 1.6-cm needle is inserted to the hub, perpendicular to the skin, just distal to the accessory carpal bone, and 5 ml of local anesthetic solution is deposited within this dense tissue. Injection can be difficult to perform, and breaking the seal between the needle and syringe is common, so a screw-type hub should be used. The medial palmar nerve is then blocked as described previously. If desired, a dorsal, circumferential subcutaneous ring block provides complete analgesia to the dorsum.

Median, Ulnar, and Medial Cutaneous Antebrachial Block

Although not frequently performed, analgesia of the distal antebrachium and carpus can be induced by blocking the median, ulnar, and medial cutaneous antebrachial (musculocutaneous) nerves.[19] Because the latter nerve supplies only skin sensation, for diagnostic purposes it does not need to be included in the technique. In our practices, this block is most commonly performed to facilitate lavage of the carpal joints or carpal canal or to perform regional limb perfusion of antibiotics in standing horses. We generally default to intrasynovial analgesia in these structures, however. The median, ulnar, and medial cutaneous antebrachial nerve block is occasionally useful in diagnosing subchondral carpal bone pain or lameness involving the carpal canal. Although the prevalence of lameness in the distal antebrachium is low, this block can be used to diagnose distal radial bone cysts or enthesitis at the origin of the accessory ligament of the superficial digital flexor tendon (SDFT) (superior check ligament). This block can be used to eliminate the entire distal limb as a potential source of pain. Alternatively, this block can be used alone to eliminate pain distal to the injection site, or the median and ulnar nerves can be blocked independently to improve specificity of the technique.

The ulnar nerve is blocked about 10 cm proximal to the accessory carpal bone on the caudal aspect of the antebrachium (Fig. 10-13). A 20- or 22-gauge, 4-cm needle is inserted to the hub, perpendicular to the skin, in the groove between the flexor carpi ulnaris and the ulnaris lateralis muscles. Needle contact with the ulnar nerve may cause the horse to strike forward.[5] Ten milliliters of local anesthetic solution is injected as the needle is slowly withdrawn. Skin sensitivity along the lateral aspect of the limb from the carpus to the metacarpophalangeal joint will be eliminated.[19]

The median nerve is blocked 5 cm distal to the cubital (elbow) joint on the medial aspect of the antebrachium. At this level, the nerve lies along the caudal aspect of the radius, just cranial to the flexor carpi radialis muscle. A 20- or 22-gauge, 4-cm needle is inserted to the hub, in a lateral direction, along the caudal aspect of the radius, just distal to the superficial pectoral muscle, and 10 ml of local anesthetic solution is used (see Fig. 10-13). Rarely in large horses, a 9-cm (3½-inch) spinal needle may be necessary to reach the median nerve. Often the needle hits the median nerve, a useful indicator that the tip is in the proper location.[5] In any event the needle should be kept close to or against the caudal cortex of the radius to avoid inadvertent puncture of the median artery or vein, which lies caudal to the nerve.[19,24] To facilitate these deep injections, the skin can be first desensitized by using a small volume of local anesthetic solution. A more distal injection site for the median nerve may eliminate the possibility of inadvertently eliminating elbow joint pain using the suggested approach.[5]

Finally (for therapeutic applications), to block the cranial and caudal branches of the medial cutaneous antebrachial (musculocutaneous) nerve, 3 ml of local anesthetic solution is injected, subcutaneously, on the cranial and caudal aspect of the accessory cephalic and cephalic veins, about halfway between the carpus and elbow (see Fig. 10-13).[19] Alterna-

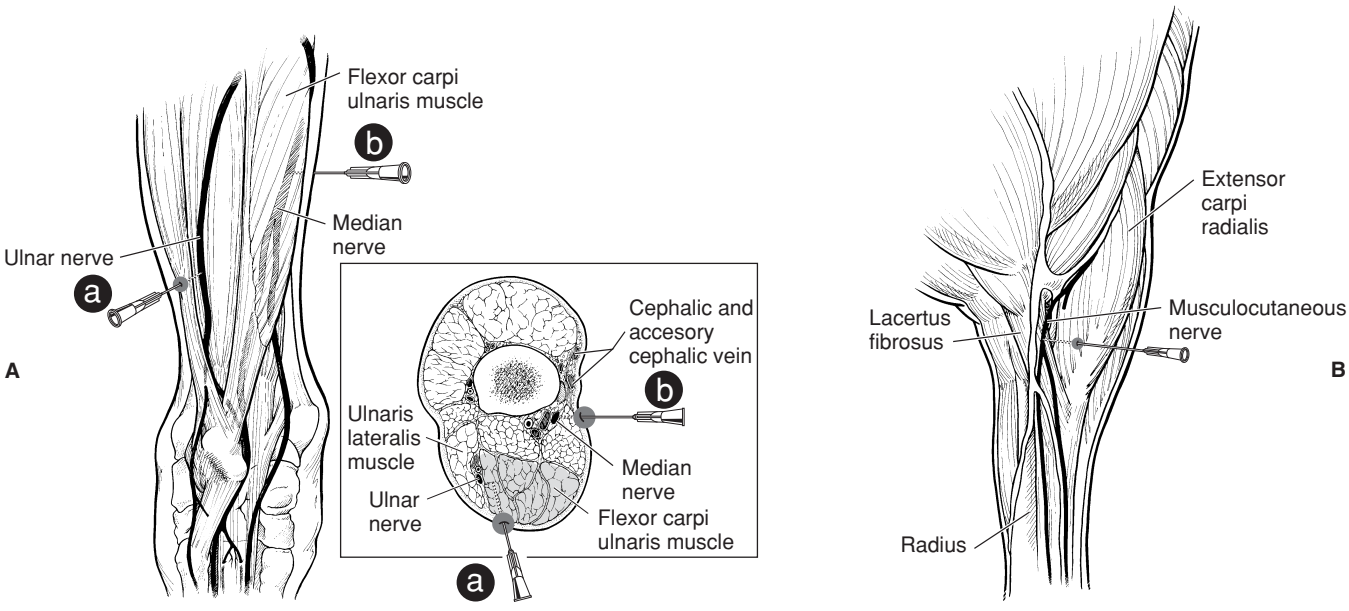

Fig. 10-13 **A,** This caudal view of the left antebrachium shows the sites of needle insertion for the median and ulnar nerve blocks. A needle placed between the ulnaris lateralis and flexor carpi ulnaris muscles (*a*), about 10 cm proximal to the accessory carpal bone, blocks the ulnar nerve. A needle inserted along the caudal aspect of the radius about 10 cm distal to the elbow joint (*b*) blocks the median nerve. The *inset* shows the orientation between the radius, median artery, vein, and nerve at the site of needle insertion (*b*) and shows the orientation of the needle for the ulnar nerve block (*a*), which is performed distally. **B**, This medial view of the proximal left antebrachium shows the technique for a musculocutaneous nerve block. The nerve is blocked as it crosses the lacertus fibrosus on the cranial aspect of the proximal antebrachium. This block abolishes skin sensation on the medial and dorsal aspects of the antebrachium.

tively, this nerve can be blocked before it branches, as it courses across the lacertus fibrosus. At this location, the nerve is easily palpable in most horses. A third method to completely abolish skin sensation is using a circumferential subcutaneous ring block, a technique that can effectively block all four cutaneous antebrachial nerves but requires a large volume of local anesthetic solution.

INTRA-ARTICULAR ANALGESIA IN THE FORELIMB

Distal Interphalangeal Joint

The assumption is that analgesia of the DIP joint is specific for intra-articular pain, but clinical experience and the results of recent clinical and anatomical investigations have convinced us otherwise (see Fig. 10-1). Of great clinical interest is the comparative accuracy of analgesia of the DIP joint and navicular (podotrochlear) bursa in the diagnosis of navicular syndrome. Overall, analgesia of the navicular bursa is likely the most specific technique to diagnose navicular syndrome. However, analgesia of the distal interphalangeal joint lacks specificity for intra-articular pain and in fact can eliminate pain associated with many conditions of the foot.[25,26] For instance, using high-performance liquid chromatography to study the effects of 8 ml of mepivacaine injected into the distal interphalangeal joint, there was local anesthetic solution in the synovium of the navicular bursa in all horses and in the medullary cavity of the navicular bones in 40% of horses.[27] Anatomical studies showed that nociceptive neurofibers are present in the dorsal and palmar aspects of the collateral sesamoidean ligaments, within the distal sesamoidean impar ligament, and directly innervating the navicular bone, in the periarticular connective tissues of the distal interphalangeal joint and proximal intramedullary portions of the distal phalanx.[28,29] The close anatomical relationship between these structures and the palmar digital neurovascular bundles to the distal interphalangeal joint capsule makes them susceptible to desensitization by local anesthetics injected into the DIP joint.[29]

In a recent study using a setscrew model to create solar pain at the toe, distal interphalangeal intra-articular analgesia abolished lameness, leading to the conclusion that pain in distant sites can be abolished using this technique.[20] Therefore a positive response to distal interphalangeal intra-articular analgesia could mean lameness is caused by an articular problem, navicular syndrome, or for that matter, solar pain. Close juxtaposition between the palmar synovial extensions of the distal interphalangeal joint and digital nerves at this level was theorized as the reason that these nerves were blocked, secondary to diffusion of local anesthetic solution from the joint.[20] Therefore a protocol to examine a lame horse no longer than 5 minutes after intra-articular analgesia of the distal interphalangeal joint may minimize diffusion and improve accuracy. Because diffusion of local anesthetic solution may be hastened by moving the horse, some clinicians prefer the horse to stand until the results of the block are evaluted.[5]

Traditionally, arthrocentesis of the distal interphalangeal joint has been performed in the dorsal pouch, either medial or lateral to the common digital extensor (CDE) tendon. A 20-gauge, 2.5- to 4-cm needle is inserted about 1.5 cm proximal to the coronary band, abaxial to the CDE tendon, and directed in a distal and axial direction (Fig. 10-14). An easier approach, however, is to insert the needle, angled just slightly distal from horizontal, on the dorsal midline, *through the CDE*. Synovial fluid is consistently obtained using this approach. To open up the dorsal aspect of the distal interphalangeal joint,

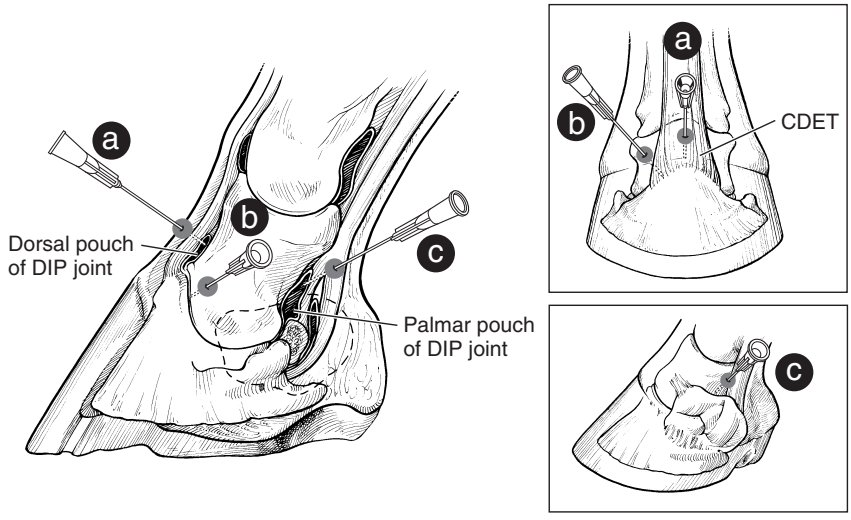

Fig. 10-14 A, Lateral view of the foot showing our preferred approach for arthrocentesis of the digital interphalangeal joint using a dorsal midline needle insertion site (*a*) and directing the needle slightly distally through the common (long) digital extensor tendon. Alternatively, the clinician approaches the digital interphalangeal joint using a site medial or lateral to the extensor tendon (*b*). The top inset shows the needle positions from the dorsal aspect. The clinician may use a palmar (plantar) approach by positioning the needle between the distal palmar (plantar) border of the middle phalanx and a palpable notch in the proximal border of the cartilage of the foot. The clinician directs the needle (*c*) in a palmaroproximolateral to dorsodistomedial direction. The lower inset shows the notch into which the needle is inserted. *DIP,* Distal interphalangeal; *CDET,* common (long) digital extensor tendon.

the limb should be positioned slightly ahead of the contralateral limb, and the horse should be in a standing position. Five to 10 ml of local anesthetic solution has been used traditionally, but a maximum of 6 ml may prevent leakage from the joint. The horse is examined after 5 minutes.

Alternatively, a lateral approach to the distal interphalangeal joint can be used (see Fig. 10-14). Landmarks include the distal palmar border of the middle phalanx dorsally and the palpable notch in the proximal border of the lateral cartilage of the foot distally. A 4-cm needle is inserted laterally and directed in a dorsodistomedial direction. This technique, however, is less reliable than the dorsal approach, because contrast material entered exclusively the distal interphalangeal joint in only 13 of 20 specimens and in 7 specimens inadvertently entered the navicular bursa or digital flexor tendon sheath.[30]

Proximal Interphalangeal Joint

Arthrocentesis of the proximal interphalangeal joint is most commonly performed in the dorsal pouch. Effusion is rarely present even in horses with severe lameness, a situation that makes arthrocentesis challenging. The injection site is just lateral (or medial) to the CDE tendon at a level of or just distal to the distal, palmar process of the proximal phalanx, located and easily palpable on the distopalmar aspect of this bone. With the horse in the standing position, a 20-gauge, 2.5-cm needle is directed slightly distally and medially (using the dorsolateral approach) and inserted until articular cartilage is encountered (Fig. 10-15). Although a desirable sign, synovial fluid appearing in the hub of the needle is an unusual occurrence. Five to 10 ml of local anesthetic solution is injected, and the horse is examined after 5 minutes.

Alternatively, the proximal interphalangeal joint can be approached using the proximal palmar pouch, from the lateral aspect. The injection location is a V-shaped notch, located dorsal to the neurovascular bundle and between the distal palmar process of the proximal phalanx the insertion of the lateral branch of the SDFT (see Fig. 10-15). The limb is held off the ground with the digit in flexion, and a 2.5- or 4-cm needle is directed distomedially (and slightly dorsally), at an angle of about 30° from the transverse plane, until fluid is collected (generally at a depth of 2 to 3 cm).[31] Advantages of this compared with the dorsal approach include less needle manipulation, a larger injection volume, and more frequent recovery of synovial fluid. Diffusion into palmar soft tissue structures could confound interpretation of results, however.[5]

Metacarpophalangeal Joint

Four sites commonly used for arthrocentesis of the metacarpophalangeal joint include the dorsal, proximopalmar, distopalmar, and approach through the collateral ligament of the proximal sesamoid bone. The two most commonly used, the dorsal and proximopalmar sites, have potential disadvantages compared with the less commonly used sites. The dorsal pouch can be prominent in horses with effusion, but inadvertently stabbing articular cartilage repeatedly is common using this approach. The proximopalmar pouch or recess is large and easily identified, but prominent synovial villi often occlude the needle end, complicating retrieval of synovial fluid, even in horses with severe effusion. Hemorrhage associated with large intra-capsular vessels is also a common complication with the proximopalmar approach. The palmar pouch is located dorsal to the suspensory branch, palmar to McIII, proximal to the collateral sesamoidean ligament, and distal to the bell of the splint bone (Fig. 10-16). Arthrocentesis using the proximopalmar approach can be performed with the limb in the standing position or being held. An 18- to 22-gauge, 2.5- to 4-cm needle is inserted in the center of the pouch and directed slightly distally in the frontal plane, until synovial fluid is recovered (Fig. 10-17). It may be necessary to aspirate synovial fluid if the joint capsule is not distended.

Dorsally, arthrocentesis is performed medial or lateral to the CDE tendon (see Fig. 10-17). With the limb in a standing or

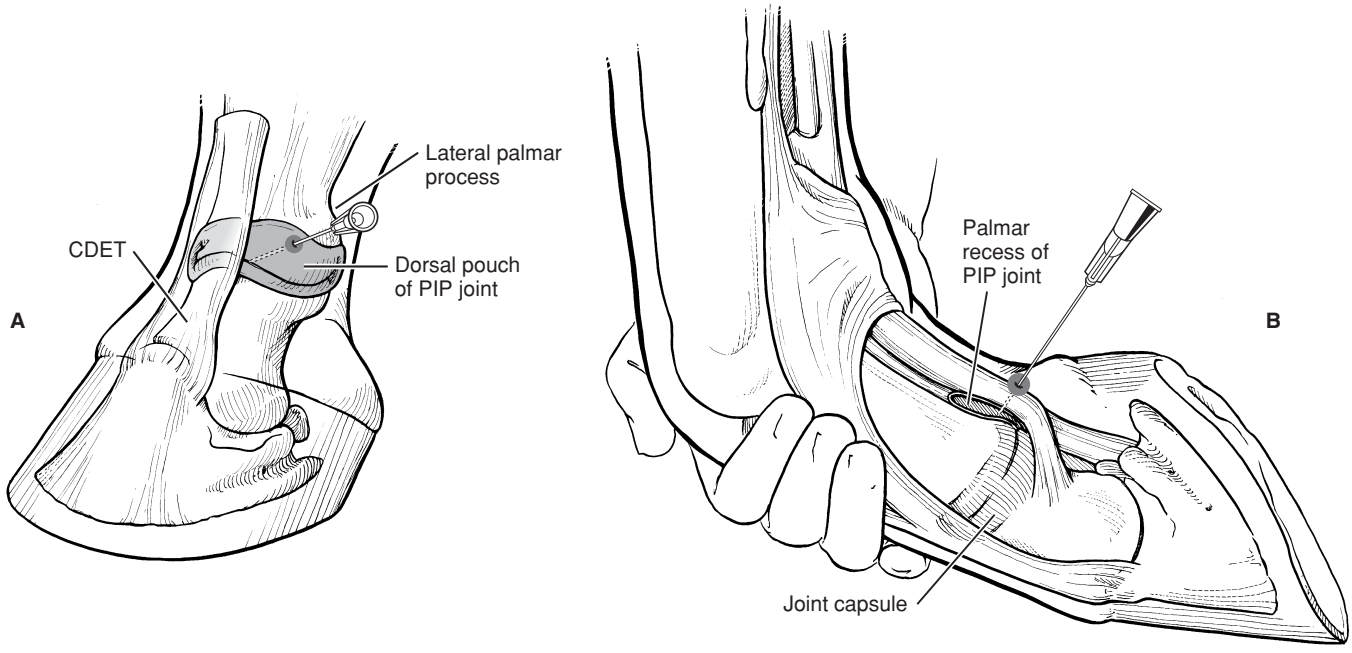

Fig. 10-15 **A,** Dorsolateral view of the digit showing the site for arthrocentesis of the dorsal pouch of the proximal interphalangeal joint. The clinician inserts the needle just abaxial to the digital extensor tendon at a site level with the palpable distal palmar (plantar) process of the proximal phalanx. **B,** Flexed lateral view of the digit indicating the site for arthrocentesis of the palmar (plantar) aspect of the proximal interphalangeal joint. The clinician inserts the needle into the V-shaped notch formed by the distal palmar (plantar) aspect of the proximal phalanx dorsally, the bony eminence associated with the attachment of the lateral collateral ligament to the distal aspect of the proximal phalanx and proximal aspect of the middle phalanx distally, and the insertion of the lateral branch of the superficial digital flexor tendon palmaro- (plantaro) distally. The clinician directs the needle distomedially (in a slightly dorsal direction) at an angle of about 30° from the transverse plane until fluid appears. *CDET,* Common (long) digital extensor tendon; *PIP,* proximal interphalangeal.

flexed position, the clinician can insert a needle in the distal aspect of the palmar pouch, through the collateral sesamoidean ligament, a less common but effective approach for arthrocentesis of the metacarpophalangeal joint. The technique is more easily performed with the joint held in flexion. This approach for arthrocentesis was shown to be associated with less subcutaneous and synovial inflammation than was the proximopalmar approach.[32]

Under most circumstances we prefer to perform arthrocentesis of the metacarpophalangeal joint using the distopalmar approach. The injection site is in a small but reliable recess bounded by a triad of structures. Just proximal to the readily palpable proximal, palmar process of the proximal phalanx is a distinct depression. The dorsal aspect of the proximal sesamoid bone and the palmar condyle of McIII complete the triad but are not readily palpable. The injection site is *dorsal* to the neurovascular bundle. Synovial fluid is consistently retrieved because the injection site is in the most distal aspect of the joint, and hemorrhage is rare. A large volume of fluid can be collected, if desired, because this area is devoid of the large synovial villi that complicate the proximopalmar approach. With the horse in a standing position, a 20-gauge, 2.5-cm needle is inserted, parallel to the ground, in a dorsomedial direction until fluid is obtained (see Fig. 10-17). The needle can be advanced to the hub, but the joint is quite superficial in this location. This technique can also readily be performed with the limb being held in a flexed position.

Ten milliliters of local anesthetic solution is injected, and the horse is reexamined in 5 to 10 minutes. In horses with subchondral bone pain, additional time may be necessary, but perineural analgesia may be necessary to abolish lameness in

Fig. 10-16 Positive contrast arthrogram of the metacarpophalangeal joint showing the extensive nature of the palmar pouch that extends proximally to the level of the distal end of the splint bones. The distopalmar outpouchings are reliable sites for retrieval of synovial fluid and injection.

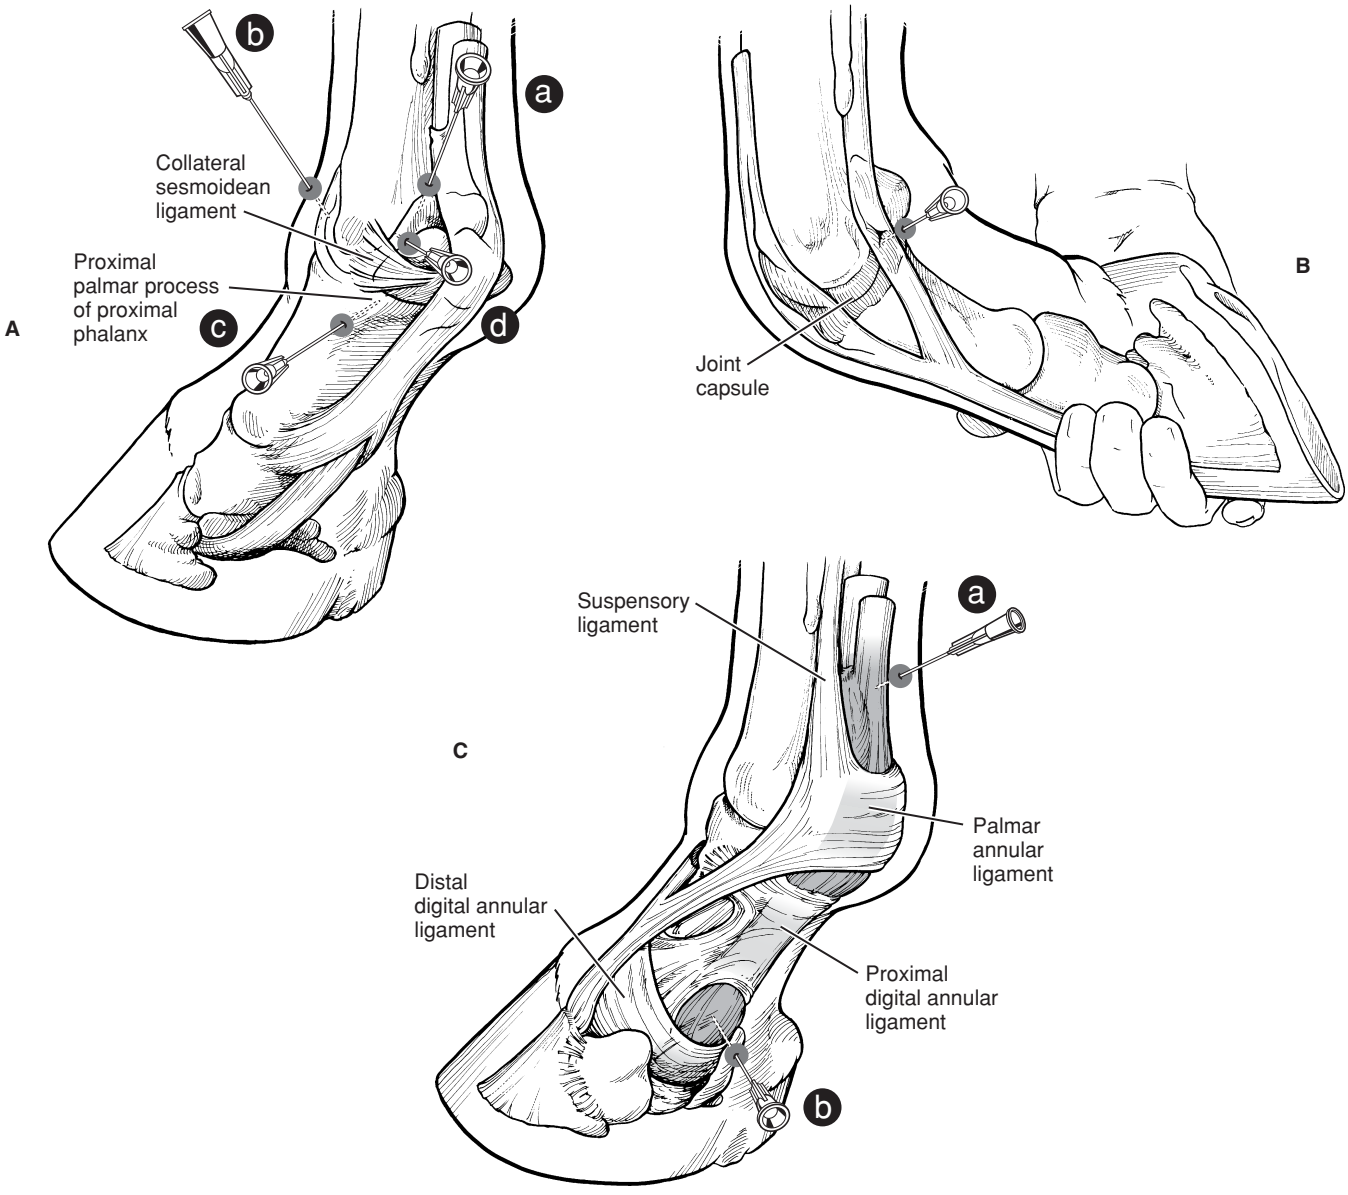

Fig. 10-17 **A,** Palmaro (plantaro) lateral view of the left metacarpophalangeal (metatarsophalangeal) joint and digit showing the sites for arthrocentesis of the proximal palmar (plantar) pouch (*a*), the dorsal pouch (*b*), the distal palmar (plantar) pouch (*c*), and the palmar (plantar) pouch through the collateral ligament of the proximal sesamoid bone *(d)*. **B,** Our preferred site for metacarpophalangeal (metatarsophalangeal) joint arthrocentesis, the distopalmar approach, using a site just proximal to the palmar (plantar) process of the proximal phalanx, is easily located in the standing or flexed position. **C,** Palmaro (plantaro) lateral view of the digit indicating sites for synoviocentesis of the proximal (*a*) and distal (*b*) aspects of the digital flexor tendon sheath. Proximally, the clinician inserts the needle proximal to the palmar (plantar) annular ligament, and distally inserts the needle on the palmar (plantar) midline into an outpouching of the digital flexor tendon sheath between the proximal and distal digital annular ligaments.

these horses. Diffusion of local anesthetic solution may account for partial improvement in lameness in horses with suspensory branch desmitis or sesamoiditis. Therefore timely evaluation of horses after metacarpophalangeal analgesia is necessary.

Carpal Joints

Arthrocentesis of the middle carpal or antebrachiocarpal joints is one of the easiest and most straightforward of all joint injection techniques. With the carpus in flexion, injection sites are easily identified, and large portals exist through which to access the joints. Portals can be found either medial to the extensor carpi radialis tendon or between the ECR and the CDE tendons (Fig. 10-18). The middle carpal and carpometacarpal joints always communicate, but a communication between the middle carpal and antebrachiocarpal joints rarely exists. A communication between the middle carpal joint and carpal sheath rarely is encountered clinically but

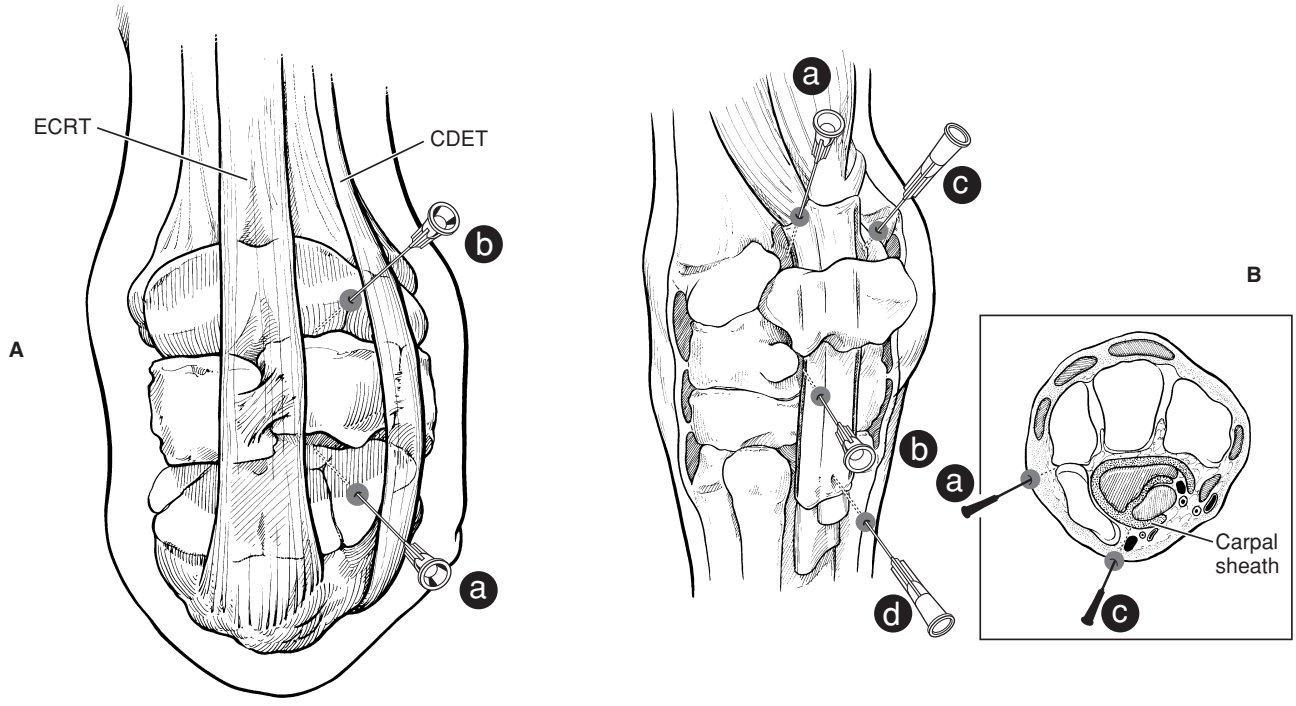

Fig. 10-18 **A,** Dorsal view of the left carpus in a flexed position showing the sites for arthrocentesis of the middle carpal (*a*) and antebrachiocarpal (*b*) joints. Needles are usually positioned between the extensor carpi radialis and common digital extensor tendons (as shown) but sites for injection of both joint cavities located medial to the extensor carpi radialis tendon can be used. **B,** Lateral view of the left carpus demonstrating sites for arthrocentesis of the proximal palmar pouch of the antebrachiocarpal joint (*a*), the palmarolateral pouch of the middle carpal joint (*b*), and the proximal (*c*) and distal (*d*) pouches of the distended carpal sheath. The inset shows the relative needle positions to enter the palmar pouch of the antebrachiocarpal joint and the carpal sheath. *CDET,* Common (long) digital extensor tendon; *ECRT,* extensor carpi radialis tendon.

was not seen in a study using cadaver limbs. Analgesia of the middle carpal and antebrachiocarpal joints should be performed separately to differentiate lameness between these independent cavities. Distopalmar outpouchings of the carpometacarpal joint complicate interpretation of analgesic techniques, because these extend a mean distance of 2.5 cm distal to the carpometacarpal articulation and are closely associated with the suspensory ligament origin and the palmar metacarpal nerves (see Figs. 10-8 to 10-10).[33] Careful differential analgesic techniques and comprehensive imaging are necessary for accurate diagnosis of lameness in the carpal and proximal metacarpal regions.

Typically, a 20-gauge, 2.5-cm needle is used to inject 5 to 10 ml of local anesthetic solution into the middle carpal and antebrachiocarpal joints. If the skin can be prepared aseptically on the dorsal aspect, the injections are most commonly performed with the joint in 90° to 120° of flexion. The clinician can maintain flexion, but having an assistant hold the limb securely is easier.

If the dorsal aspect of the carpus cannot be prepared aseptically, as occurs commonly in racehorses with chemically induced dermatitis (scurf), or if an additional site is needed for thorough lavage, the palmarolateral pouch of the middle carpal and antebrachiocarpal joints can be used. The palmar pouch of the antebrachiocarpal joint is bounded by the lateral digital extensor tendon dorsally and the ulnaris lateralis tendon palmarly. In horses with substantial effusion, this pouch is easily identified but must be differentiated from the lateral outpouching of the carpal sheath. Arthrocentesis can be performed either proximally or distally in the palmar pouch (see Fig. 10-18). The distal injection site is located in a shallow recess between the distal lateral radius (ulna) and the ulnar carpal bone, just distal to the V-shaped convergence of the lateral digital extensor and ulnaris lateralis tendons. With the horse in a standing position, a 20-gauge, 2.5-cm needle is inserted perpendicular to the skin and advanced until synovial fluid is recovered.

The palmar pouch of the middle carpal joint is similarly accessed in a shallow depression between the ulnar and fourth carpal bones, located 2 to 2.5 cm distal to the recess palpated to access the antebrachiocarpal in the palmar aspect (see Fig. 10-18). The shallow depression in the middle carpal joint is difficult to palpate, but in horses with severe effusion an outpouching of the joint is palpable. This approach is done with the limb in a standing position, decreases the potential for iatrogenic cartilage injury, and is less dangerous to the clinician because the procedure is performed on the side, rather than in front of the limb.[34] The injection is more difficult and less commonly used, however.

Cubital (Elbow) Joint

Two sites are used for arthrocentesis of the elbow joint. The cranial pouch is accessed at the level of the radiohumeral articulation, just cranial to the lateral collateral ligament. The lateral collateral ligament courses between the palpable lateral tuberosity of the radius and the lateral epicondyle of the humerus (Fig. 10-19). An 18- or 20-gauge, 6- to 9-cm needle is directed medially and slightly caudally to a depth of 5 to 6 cm, beginning in the adult horse, about 3.5 cm proximal to the lateral tuberosity of the radius and 2.5 cm cranial to the

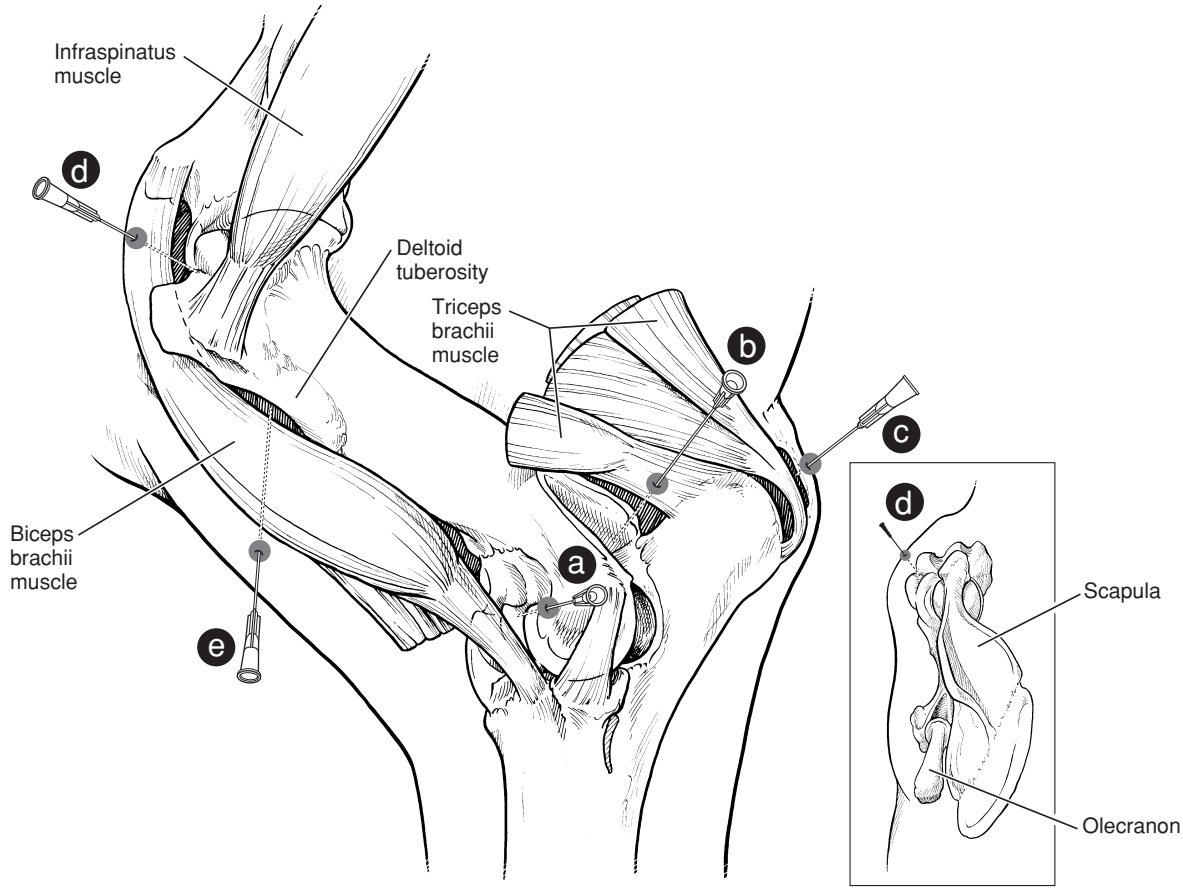

Fig. 10-19 Lateral view of the left elbow and shoulder regions. For arthrocentesis of the cranial pouch of the elbow (cubital) joint, the clinician directs the needle (*a*) medially and slightly caudally to a depth of about 5 to 6 cm at a point about 3.5 cm proximal to the lateral tuberosity of the radius and 2.5 cm cranial to the lateral collateral ligament. Arthrocentesis of the proximal, caudal pouch (*b*) is performed at a site in the palpable depression between the cranial aspect of the olecranon and the caudal aspect of the lateral epicondyle of the humerus. One injection site is for the rarely performed technique of synoviocentesis of the olecranon bursa (*c*). Proximally is the site for arthrocentesis of the scapulohumeral joint (*d*). A needle is inserted cranial to the infraspinatus tendon in the notch between the cranial and caudal eminences of the greater tubercle of the humerus and advanced in a caudomedial direction, roughly parallel to the ground and about 45° to the long axis of the body (*inset*). For the bicipital bursa (*e*), the clinician inserts the needle at a point about 4 cm proximal to the palpable distal aspect of the deltoid tuberosity of the humerus (or alternatively, a point about 3 to 4 cm distal and 6 to 7 cm caudal to the palpable aspect of the cranial process of the greater tubercle) and directs it proximally and medially, and in some patients slightly cranially.

lateral collateral ligament.[19] To account for differences in horse size, the injection site is generally located two thirds of the distance between the humeral epicondyle and the lateral tuberosity of the radius. This block may be more easily performed closer to the lateral collateral ligament, and at this site the joint is penetrated in a more superficial location.[5] Before injection, every effort should be made to verify the needle is actually in the joint. Peri-articular deposition of anesthetic solution in this location can induce temporary radial nerve dysfunction, and horses may lose the ability to extend the carpus and digit.[35] Twenty to 25 ml of local anesthetic solution is used. An older approach relied on injection of local anesthetic solution into the ulnaris lateralis bursa, once universally thought to communicate with the elbow joint. The frequency of communication between the elbow joint and ulnaris lateralis bursa was determined to be 37.5%, and therefore this approach is no longer recommended.[36]

We prefer to perform arthrocentesis in the proximolateral aspect of the caudal pouch in the palpable depression cranial to the olecranon process and caudal to the lateral epicondyle of the humerus. In most horses the site of needle penetration is 3 to 3.5 cm caudal to the lateral epicondyle (see Fig. 10-19). In small horses and ponies, an 18- or 20-gauge, 4-cm needle is sufficient, but in large horses a 9-cm spinal needle is often necessary. The needle is advanced for 5 to 7 cm in a distal, slightly cranial, and medial direction until synovial fluid is recovered.

Elimination of skin sensitivity at the site of needle insertion by depositing a small volume of local anesthetic solution may facilitate elbow arthrocentesis, because multiple attempts

may be necessary. Synovial fluid is consistently retrievable from the joint with proper needle positioning.

Scapulohumeral (Shoulder) Joint

The shoulder joint is frequently blamed for lameness in many horses but, based on the results of diagnostic analgesia, is an uncommon source of lameness. Arthrocentesis of this joint is most commonly performed at a site between the cranial and caudal prominences of the greater tubercle of the humerus, just cranial to the infraspinatus tendon. This tendon is easily palpated in most horses and serves as the primary landmark. Firm, careful palpation between the cranial and caudal prominences reveals a depression or notch, which is the point of needle insertion (see Fig. 10-19). Identification of landmarks is easier in horses with muscle atrophy resulting from chronic lameness.

In most horses an 18- to 20-gauge, 9-cm spinal needle is preferred, although using the entire length is not necessary. Elimination of skin sensitivity is usually not necessary. The needle is inserted in a caudomedial direction (about 45° from lateral), and directed slightly distal. Attaching a syringe to aspirate synovial fluid is sometimes necessary, because in joints with minimal effusion, confirming intra-articular position of the needle may be difficult. Twenty-five to 30 ml of local anesthetic solution is used and the horse is assessed 10 and 30 minutes after injection, because severe pain associated with osteochondrosis may resolve slowly. Analgesia of the suprascapular nerve and subsequent supraspinatus and infraspinatus muscle paralysis was reported following attempts at intra-articular shoulder analgesia.[35] This complication is rare, in our experience, and may result from anesthetic diffusion to nerves of the brachial plexus.[5] Trauma from multiple needle insertions or injection of large volumes of anesthetic solution (>30 ml) may increase the likelihood of this complication. In fact, some have recommended using only 8 to 10 ml, but false-negative results from the block would likely occur.[35] Our opinion is that the most likely cause of this rare complication is malposition of the needle or iatrogenic trauma. Rarely, a communication between the bicipital bursa and the shoulder joint occurs.[37] Thinking a horse has shoulder joint pain is possible then, but in reality the diagnosis is bicipital bursitis or tendonitis. Rather than a communication between the structures, the most likely explanation is inadvertent penetration of the bicipital bursa from a misdirected needle.

ANALGESIA OF FORELIMB BURSAE AND TENDON SHEATHS

In most instances, analgesia of bursae and tendon sheaths is achieved using perineural techniques, but in some horses, selective intrasynovial analgesia is indicated. Pain sensation from bursae and sheaths is likely complex, and lameness after intra-bursal or intrathecal (within a sheath) analgesia may improve but not completely resolve. In fact, horses with severe lameness resulting from bursitis or tenosynovitis often have other associated soft tissue damage, a fact that explains partial improvement after intrasynovial analgesia. Extra time is usually given, after blocking, to reassess the horse's clinical signs.

Podotrochlear (Navicular) Bursa

A palmar midline approach is most commonly used for analgesia of the navicular bursa. Because needle position is difficult to assess and fluid recovery varies, radiographs should be used to confirm proper needle position. Positioning the foot on a wooden block can minimize the problems of manipulation at the bulbs of the heel and helps to maintain aseptic technique. Subcutaneous deposition of a small volume (1 to 2 ml) of local anesthetic solution can improve patient compliance during this procedure. An 18- to 20-gauge, 9-cm spinal needle is inserted on the palmar midline, just proximal to the hairline, and directed parallel to the sole until the needle contacts bone (Fig. 10-20).[23,25,38] Others describe a similar approach, although they direct the needle parallel to the coronary band.[19,39,40] Because redirection of the needle proximally or distally often is necessary, these approaches differ little. Success depends most on personal experience, but radiographs can be critical in confirming successful entry into the navicular bursa. The direction in which the needle is inserted is often dictated by the shape of the horse's foot, and the projected position of the navicular bone.[5] Plotting and marking the navicular position on the hoof wall can be helpful in determining needle direction and depth of insertion. The navicular position is located at a site 1 cm distal to and halfway between the dorsal and palmar aspects of the coronary band.[41,42] However, with experience and after identifying the navicular position, the procedure can be done blindly. In most horses the flexor surface of the navicular bone will be contacted at a depth of 4 to 5 cm. The needle is likely improperly positioned if resistance is encountered at a depth of less than 3 to 4 cm or if the needle can be advanced more than 6 to 7 cm. Spontaneous retrieval of synovial fluid is rare and usually indicates that the needle is in the distal interphalangeal joint capsule or the digital flexor tendon sheath (DFTS). To avoid penetrating these structures, the needle should be placed in the middle of the flexor surface of the navicular bone.[5] Three to 5 ml of local anesthetic solution is used. If navicular syndrome is suspected, some clinicians combine injection of local anesthetic solution with a corticosteroid. Alternatively, navicular bursography can be performed in combination with diagnostic analgesia by adding 1 to 2 ml of sterile, iodinated contrast material (see Chapter 30). Because in the standing horse the navicular bursa is under compression by the DDFT, suspending the foot and having the foot in partial flexion during actual injection are useful. Without using radiographs, being confident of accurate needle placement is difficult.

A proximal, palmar injection technique has been described. A needle is inserted into the deepest part of the hollow between the heel bulbs and advanced dorsodistally, about 30° from horizontal, until contact with the bone is made.[38,43] A lateral (or medial) approach is also described. A needle is inserted just proximal to the cartilage of the foot, between the neurovascular bundle and the DFTS and directed axially, distally, and slightly dorsally until contact with bone is made (see Fig. 10-20).[38,40,44] Recently, these five techniques were compared in an in vitro study. The most reliable technique was determined to be the distal palmar approach, with the needle being directed to the navicular position and the limb in a non–weight-bearing position.[45]

Digital Flexor Tendon Sheath

Two sites for intrasynovial injection of the DFTS are just proximal to the palmar annular ligament (PAL) or in the palmar aspect of the pastern region in an outpouching of the sheath located between the proximal and distal digital annular ligaments (see Fig. 10-17). Effusion facilitates identification of these sites, and rarely would an intrathecal injection be contemplated without the presence of effusion. Proximal to the PAL, villous hypertrophy of synovial membrane can complicate the procedure, because even with severe distention of the sheath, synovial fluid may be difficult to retrieve. For this reason, we favor the palmar pastern approach. In some horses, the sheath appears to be compartmentalized and distended proximal to the PAL, but not below, and therefore injections are easier to perform

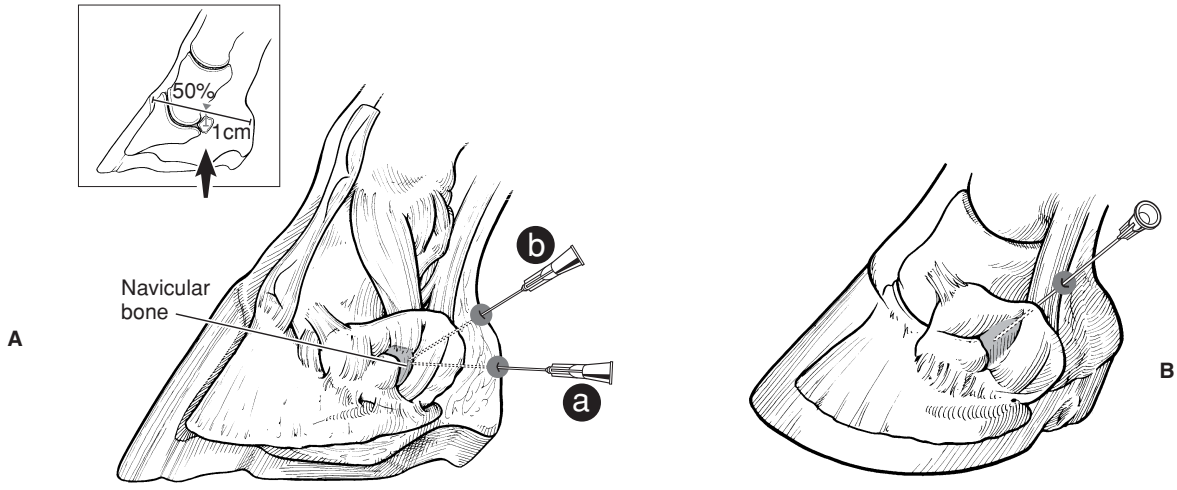

Fig. 10-20 **A,** Lateral view showing two techniques for synoviocentesis of the navicular bursa of the foot. In the palmar (plantar) approach (*a*) the needle is placed just proximal to the hairline between the bulbs of the heels and inserted to the navicular bursa using the navicular position as a guide. The navicular position (*arrow*) is located by determining the point on the outside of the hoof wall that is 50% of the distance from the dorsal to the palmar (plantar) extent of the coronary band and 1 cm below (*inset*). An approach slightly more proximal (*b*) requires placing the needle in the depression between the heel bulbs and advancing the needle in a dorsodistal direction, about 30° from horizontal toward the navicular position. **B,** Palmaro (plantaro) lateral view of the digit showing the lateral approach for synoviocentesis of the navicular bursa. The needle is inserted just proximal to the cartilage of the foot between the digital neurovascular bundle and the digital flexor tendon sheath and directed axially, distally, and slightly dorsally.

proximally. A 20-gauge, 2.5-cm needle and 10 to 15 ml of local anesthetic solution are used.

Alternatives to these approaches for intrasynovial injection of the DFTS are described. The procedure can be performed at a site just distal to the proximal sesamoid bones, between the distal aspect of the PAL and the proximal aspect of the proximal digital annular ligament (see Fig. 10-17). Recently the palmar axial sesamoidean approach was described. With the metacarpophalangeal joint held in flexion (225° angle between McIII and the proximal phalanx), a 20-gauge, 2.5-cm needle is inserted at an angle of 45°, 3 mm axial to the palmar border of the proximal sesamoid bone (mid-body) and just palmar to the neurovascular bundle. Putative advantages included more reliable access to the DFTS when effusion is absent and reduced time required for successful entry.[46]

Carpal Sheath

The carpal sheath (carpal flexor sheath) envelops the SDFT and DDFT in the carpal canal. Distention of the carpal sheath is most easily recognized laterally, just proximal to the accessory carpal bone, between the lateral digital extensor and ulnaris lateralis tendons (see Fig. 10-18). Effusion of the carpal sheath must be differentiated from that of the antebrachiocarpal joint. Concurrent distention of the dorsal aspect of the antebrachiocarpal joint or distention of the distal aspect of the carpal sheath (lateral or medial, distal to the flexor retinaculum on the palmar aspect of the metacarpal region) are signs that are helpful in determining this. Ultrasonographic evaluation or positive contrast radiography can be useful adjunct diagnostic techniques. Synoviocentesis can be performed either in the proximal or distal aspect of the sheath, using a 20-gauge, 2.5-cm needle and 10 to 15 ml of local anesthetic.

Olecranon Bursa

This technique is mentioned to be complete, but we have never found an indication to perform analgesia of this bursa (see Fig. 10-19). If distended, this bursa could be entered using the same techniques described for other bursae. Rarely, local analgesia over implants used to repair olecranon process fractures is necessary to investigate whether implant removal is indicated.

Bicipital Bursa

Bicipital bursitis and shoulder lameness are frequently diagnosed but in reality are uncommon causes of lameness, if the clinician religiously adheres to the principles of diagnostic analgesia. However, bicipital bursitis and tendonitis, and proximal humeral osteitis, fractures, or osseous cyst-like lesions can cause lameness, and are diagnosed using analgesia of the bicipital bursa. The bicipital bursa is located between the greater and lesser tubercles of the humerus and the overlying tendon of origin of the biceps brachii muscle. Synoviocentesis of the bicipital bursa is routinely performed from a lateral approach, but if severe effusion exists, the bursa can be accessed medially. The injection site is located just cranial to the humerus, 4 cm proximal to the distal aspect of the deltoid tuberosity.[38] Alternatively the site can be located by finding a point 3 to 4 cm distal and 6 to 7 cm caudal to the cranial process of the greater tubercle (see Fig. 10-19).[19] Subcutaneous infiltration of local anesthetic solution at the site can be used but is rarely needed. An 18-gauge, 9-cm needle is directed in a proximal, medial, and slightly cranial direction and can be "walked off" (shaft of the needle in contact with the bone) the cranial cortex of the humerus. A change in resistance is felt, and synovial fluid may be seen in the needle hub or can be aspirated. Ten to 20 ml of local anesthetic solution is used. If injection is difficult, synovial fluid cannot be retrieved, and retrieving

anesthetic solution already injected is not possible, the bursa likely has not been entered. An alternative is to use an ultrasound-guided technique.

PERINEURAL ANALGESIA IN THE HINDLIMB

Perineural analgesia in the distal hindlimb is similar to that described for the forelimb. Minor differences in innervation and anatomy must be taken into consideration, however. Technical differences in whether, or how, the limb is held and other intangible differences exist. Most clinicians are not as familiar, or frankly as comfortable, with performing hindlimb analgesic techniques, and this is particularly true with perineural analgesia. It takes a dedicated lameness detective to be enthusiastic about hindlimb analgesia, particularly in fractious or highly strung horses. Obviously, safety for the veterinarian and assistants is paramount, and physical and chemical restraint become important. Performing intra-articular analgesia is far easier, but the clinician must keep in mind that perineural techniques are much more effective in abolishing subchondral bone pain. Therefore false-negative results will likely be obtained if one is limited to only intra-articular procedures. We generally recommend that most perineural techniques distal to the tarsus be performed with the limb held off the ground by an experienced assistant, but personal preference can of course prevail. In some instances, such as when performing plantar digital analgesia, the anatomy is much easier to identify when the limb is bearing weight.

To limit the number of hindlimb injections in horses that lack clinical signs referable to the digit, starting with the low plantar block may be reasonable, in lieu of performing sequential blocks starting with palmar digital analgesia. Of course, performing blocks distal to this site at another time may be necessary if baseline lameness is discovered using this approach. The clinician should take care when testing the efficacy of hindlimb blocks, and using a pole or similar device may be safer than using forceps.[5] Complete abolition of skin sensation in the hindlimb is less likely than in the forelimb, because the distribution of cutaneous innervation varies.

Plantar Digital Analgesia

This analgesic technique is essentially the same as in the forelimb (see Fig. 10-5). The prevalence of lameness abolished by palmar digital analgesia in the hindlimb is considerably lower than in the forelimb but is not zero, and therefore this block should still represent a good starting point for a horse with undiagnosed lameness. Because of the reciprocal apparatus, the digit is constantly flexed when the limb is held off the ground, and this block can be slightly more difficult to perform in this position.

Dorsal Ring Block of the Pastern

The section on the dorsal ring block of the pastern in the forelimb describes this technique (see Fig. 10-5). This block requires several needle insertions and can be difficult to perform if the limb is held off the ground, because the dorsal aspect of the pastern is constantly flexed, making subcutaneous injection difficult.

Basisesamoid and Abaxial Sesamoid Blocks

Basisesamoid and abaxial sesamoid blocks present no essential differences between the forelimbs and hindlimbs (see Fig. 10-5). Our philosophical points about the basisesamoid block (see forelimb) hold true in the hindlimb as well. The abaxial sesamoid block is avoided, if possible, in racehorses, because of the high prevalence of lameness involving the metatarsophalangeal joint may lead to inadvertent misdiagnosis (a positive response to the block will be interpreted as lameness in the foot, when in reality lameness involves the metatarsophalangeal joint).

Low Plantar Block

Analgesia of the metatarsophalangeal joint region is achieved using the low plantar block, a procedure similar to the low palmar block (see Fig. 10-7). This block is one of the most overlooked but most useful of all perineural techniques. It is essential to block the medial and lateral plantar, the medial and lateral plantar metatarsal, and the dorsal metatarsal nerves. Anecdotal information suggests that some practitioners may not include the plantar metatarsal nerves when performing this block. The plantar metatarsal nerves supply innervation to the subchondral bone of the distal third metatarsal bone (MtIII), and to provide analgesia to this important area, these nerves need to be blocked. In fact a modification of this technique can be used in horses suspected of having subchondral, non-adaptive remodeling of MtIII, a common diagnosis in the Standardbred and Thoroughbred racehorse (see Chapters 108 and 109). A positive response to an independent block of the lateral plantar metatarsal nerve can help establish this syndrome as the cause of lameness.

The only difference between the low palmar and low plantar blocks involves the dorsal aspect of the limb (see Fig. 10-7). Skin sensation laterally and medially is retained after this block, unless a circumferential, subcutaneous ring block is used. In the forelimb, it is only necessary to use subcutaneous infiltration to the dorsal midline. Alternatively, the dorsal metatarsal nerves can be blocked individually.

High Plantar Nerve Block

The high plantar or sub-tarsal block is one of the most important but often overlooked perineural analgesic procedures in the horse. This block is used to diagnose suspensory desmitis, arguably one of the most important lameness conditions in the hindlimb. However, suspensory desmitis can be a catchall diagnosis in some horses with occult hindlimb lameness, and the high plantar block must be done to confirm the authentic location of pain. The tarsometatarsal joint has distoplantar outpouchings (similar to but less extensive than the distopalmar outpouchings of the carpometacarpal joint) that may complicate tarsometatarsal intra-articular or high plantar analgesic techniques (Fig. 10-21). However, this is certainly less of a problem in the hindlimb than in the forelimb. For example, inadvertent penetration of the tarsometatarsal joint occurred in only 5% of limbs in which high plantar analgesia was performed, at a level of 1.5 cm distal to the tarsometatarsal joint. However, contrast material was found in the tarsal sheath in 40% of limbs, adding yet another dimension to this already somewhat difficult blocking technique. False-negative results have been attributed to inadvertent injection into blood or lymphatic vessels.[47] The clinician should take care in preparing the limb for this procedure and interpreting the results. It is possible, although not likely, that when performing a high plantar block, local anesthetic solution could be inadvertently placed in the tarsometatarsal joint. A good chance also exists, however, of inducing analgesia of the tarsal sheath. Comprehensive evaluation using multiple imaging modalities is needed when attempting to differentiate causes of lameness in this important area.

The medial and lateral plantar and the medial and lateral plantar metatarsal nerves are blocked, and a circumferential dorsal ring block provides complete analgesia to the metatarsal region. Blocking only the plantar metatarsal nerves can abolish pain associated with the suspensory ligament. Most clinicians do not include the dorsal ring block, but it is necessary to do so to eliminate lameness resulting from injury of the dorsal cortex of MtIII or to suture lacerations in this

Fig. 10-21 Positive contrast arthrogram of the tarsometatarsal joint showing short, distoplantar outpouchings extending distally toward the origin of the suspensory ligament. Inadvertent penetration of these pouches occurs during subtarsal or high plantar analgesic techniques.

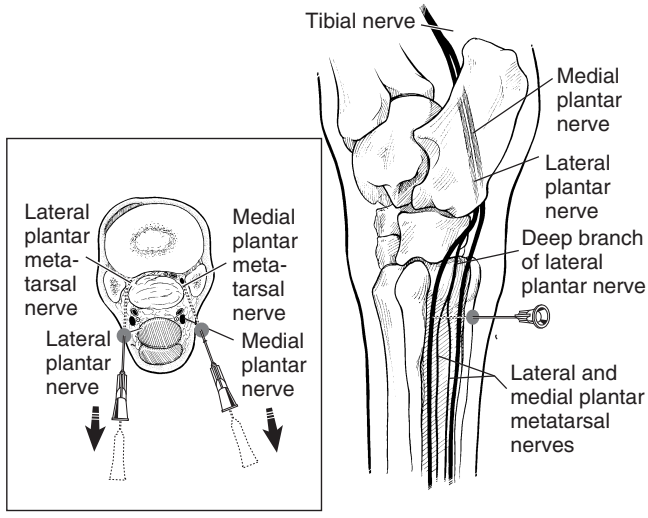

Fig. 10-22 The high plantar block is performed at a level 4 cm distal to the proximal aspect of fourth metatarsal bone and on the medial side 3 cm distal to the proximal aspect of second metatarsal bone. The needles are inserted axial to the respective splint bone and advanced deep to contact the plantar surface of the third metatarsal bone. Anesthetic solution is deposited in this location to block the lateral (medial) plantar metatarsal nerves and in a more superficial position as the needle is withdrawn blocks the lateral (medial) plantar nerves (*inset*).

area. This block is performed most commonly and safely with the limb held off the ground. Although uncommon to rare, needle breakage is a complication during high plantar analgesia, and for this reason we prefer to use needles no smaller than an 18- to 20-gauge and 4 cm long. At this level on the plantar aspect of the limb, it is impossible to palpate nerves, and unlike the high palmar block, only one injection site exists for each, on the medial and lateral aspects of the limb. The needle is placed just distal to the tarsometatarsal joint and axial to the fourth metatarsal bone and inserted until contact is made with MtIII (Fig. 10-22). A minimum of 5 ml of local anesthetic solution is deposited at this deep location, and an additional 5 ml is deposited as the needle is withdrawn, leaving a definite bleb in the subcutaneous tissues. Some clinicians prefer lower volumes of local anesthetic solution. Additional local anesthetic solution can be used without risk, and a common modification is flooding the origin of the suspensory ligament with an additional 5 to 10 ml of local anesthetic solution. The procedure is then repeated medially, and the needle is inserted axial to the second metatarsal bone. To complete the block, a circumferential subcutaneous ring block is performed. The clinician must take care not to lacerate the dorsal metatarsal artery or the saphenous vein during this procedure.

Fibular (Peroneal) and Tibial Nerve Block

Analgesia of the distal crus and tarsus or entire distal hindlimb is induced using the fibular and tibial nerve blocks. These blocks are used most commonly in horses with distal hock joint pain, in which intra-articular analgesia is difficult or impossible to perform. The fibular and tibial nerve blocks, when completed successfully, are more effective in eliminating pain from the complex hock joint than is intra-articular analgesia. The fibular and tibial nerve blocks also are useful in eliminating pain associated with subchondral trauma of the distal tibia and talus, distally located tibial stress fractures, the tarsal sheath, the distal aspect of the common calcaneal tendon, the calcaneal bursa, and the plantar aspect of the hock. The clinician should keep in mind that if the high plantar block has not already been performed, the fibular and tibial nerve blocks eliminate pain associated with proximal suspensory desmitis.

The deep fibular nerve is blocked at a site located laterally, 10 cm proximal to the point of the hock (tuber calcanei), in the groove between the long and lateral digital extensor muscles (Fig. 10-23). In this groove the superficial fibular nerve is easily palpated and can be rolled against the fascia of the crus. An 18- to 22-gauge, 4-cm needle is inserted to the hub or until it contacts the lateral tibial cortex, and 10 to 15 ml of local anesthetic solution is injected, beginning deep and continuing as the needle is withdrawn. The needle can be re-directed in a fan-shaped pattern if desired to ensure complete block of the deep branch of the fibular nerve. Seeing blood in the needle hub is common, a reliable sign of accurate needle placement, because the cranial tibial vein and artery are located close to the deep peroneal nerve.[48] Performing the tibial block first is therefore preferable, as is warning the client that blood may appear.[5] The superficial fibular nerve is blocked as the needle is withdrawn from deep within the injection site. Additional local anesthetic solution (5 to 10 ml) is placed in this subcutaneous location.

The tibial nerve is blocked at a site 10 cm proximal to the tuber calcanei, cranial to the common calcaneal tendon, and caudal to the deep digital flexor tendon (see Fig. 10-21). The nerve can be palpated as a firm cord-like structure with the limb in a flexed position. For this reason, performing this block is easier with the leg not bearing weight. Although the tibial nerve is slightly more superficial, medially, the injection can be performed either medially or laterally. A 20-gauge, 2.5-cm needle is inserted laterally, and 15 ml of local anes-

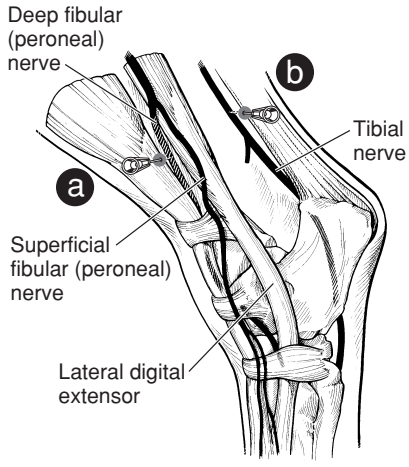

Fig. 10-23 Lateral view of the left crus and tarsus showing the fibular (peroneal) and tibial nerve block. The deep and superficial fibular nerves are blocked by finding the groove between the long and lateral digital extensor muscles, 10 cm proximal to the tarsus, in which the superficial fibular nerve is palpable. The needle (*a*) is advanced deep to block the deep branch and withdrawn to a more superficial position to deposit local anesthetic solution subcutaneously to block the superficial branch. The tibial nerve block (*b*) is performed by palpating the nerve just cranial to the common calcaneal tendon (from either a lateral or medial approach) in a location about 10 cm proximal to the tuber calcanei.

thetic solution is injected over the nerve. The needle tip should be palpated under the skin, medially, to ensure the proper depth of penetration. Local anesthetic solution can be placed using a fan-shaped injection technique, but the horse will object if the tibial nerve is penetrated. Although deep pain will be abolished if these nerves are successfully blocked, superficial sensation persists on the medial aspect and occasionally in the caudal (plantar) aspect of the limb. To use the fibular and tibial nerve blocks therapeutically, it is necessary to perform a circumferential subcutaneous ring block to completely abolish skin sensation. After the fibular and tibial nerve blocks, paradoxically, pre-existing toe drag may persist or increase, despite resolution of weight-bearing lameness.[5] Some horses stumble or knuckle, indicating loss of extensor muscle function, but this is not common and certainly not a necessary sign to suggest complete analgesia has been obtained. However, exercising a horse at speed or over fences should be avoided. Because of nerve size and depth, we suggest that additional time be given, as much as 20 to 30 minutes, to evaluate the effect of this block before reaching a final conclusion. Dyson has recognized improvement in horses up to 1 hour after blocking and warns that proceeding with a stifle block too soon leads to false-positive results.[5] The fibular and tibial nerve blocks are not commonly performed in practice, at least in the United States, and at best may result in only 50% to 80% improvement in lameness score, particularly in those horses with severe distal hock joint pain. Allowing more time for maximal response and taking a realistic approach to the percent improvement expected are warranted when using the fibular and tibial nerve blocks. Intrasynovial analgesic techniques are certainly more specific than are the fibular and tibial nerve blocks, and although the fibular and tibial nerve blocks have limitations, the lameness diagnostician should become familiar and comfortable with this procedure. Proficiency in performing these blocks is a must for accurate diagnosis of hindlimb lameness. Performing the fibular and tibial components can independently improve specificity of the fibular and tibial nerve blocks.

INTRA-ARTICULAR ANALGESIA IN THE HINDLIMB

Analgesia of the distal interphalangeal and proximal interphalangeal joints in the hindlimb is exactly the same as that described for the forelimb. Analgesia of the metatarsophalangeal (metatarsophalangeal) joint is the same as that described for the metacarpophalangeal joint. Perineural analgesic techniques should be used, whenever possible, because subchondral pain is more completely abolished using these techniques, and false-negative results are less likely.

Tarsus

Tarsometatarsal Joint

The most reliable site for arthrocentesis of the tarsometatarsal joint is a lateral approach, just proximal to the fourth metatarsal bone. At this site is a subtle but consistent depression that can reliably be palpated. A 20-gauge, 2.5-cm needle is inserted in a craniomedial and slightly distal direction (Fig. 10-24). The needle can usually be inserted to the hub, but occasionally it hits articular cartilage. Synovial fluid is consistently retrieved, but we find it interesting that even in horses without lameness of the tarsometatarsal joint, the fluid is generally watery, lacking what is thought to be normal viscosity. In most horses, 4 to 8 ml of local anesthetic solution can be injected without encountering elevated intra-articular pressures and patient discomfort. Anecdotal reports of a subtle pop or sudden decrease in pressure have been attributed to communication between the tarsometatarsal and centrodistal (distal intertarsal) joints. In reality, this most often results from rupture of the tarsometatarsal joint capsule and subsequent deposition of anesthetic solution (or medication) extra-articularly into the tarsal space and not the centrodistal joint. We recommend using no more than 4 to 8 ml of local anesthetic solution or injecting only that amount of local anesthetic solution necessary to develop moderate intra-articular resistance to avoid inadvertent deposition into the intertarsal space. An alternative site for tarsometatarsal arthrocentesis is a medial approach, similar to that described for the centrodistal joint.

The issue of communication between the distal tarsal joints is important from diagnostic and therapeutic standpoints. Studies have shown that the tarsometatarsal and centrodistal joints communicate in 8% to 35% of normal horses.[47,49,50] Communication between the tarsometatarsal joint (and presumably the centrodistal joint) and the talocalcaneal-centroquatral (proximal intertarsal) and tarsocrural joints was shown to be about 4% in an in vivo study, after injection of latex in the tarsometatarsal joint.[50] A common misconception is that a single injection into the tarsometatarsal joint also provides analgesia or treats the centrodistal joint. In addition, some clinicians preferentially inject a large volume of anesthetic solution, hoping to block or medicate the tarsometatarsal and centrodistal joints. However, based on the low communication rate, the clinician should consider *the tarsometatarsal and centrodistal joints to be separate synovial cavities*. Because the tarsometatarsal joint has distoplantar outpouchings, abolishing pain associated with the proximal suspensory attachment or lesions involving the proximal aspect of the third metatarsal bone is also possible when performing tarsometatarsal analgesia. Accurate differential diagnosis for pain involving the lower hock joints and proximal metatarsus depends on careful interpretation of response to diagnostic analgesia and evaluation of ancillary images.

Centrodistal Joint

Compared with the tarsometatarsal joint, arthrocentesis of the centrodistal joint is relatively difficult. The centrodistal joint is small, and in fact inserting a needle any larger than 22 to 25 gauge into this joint is difficult, even in horses with

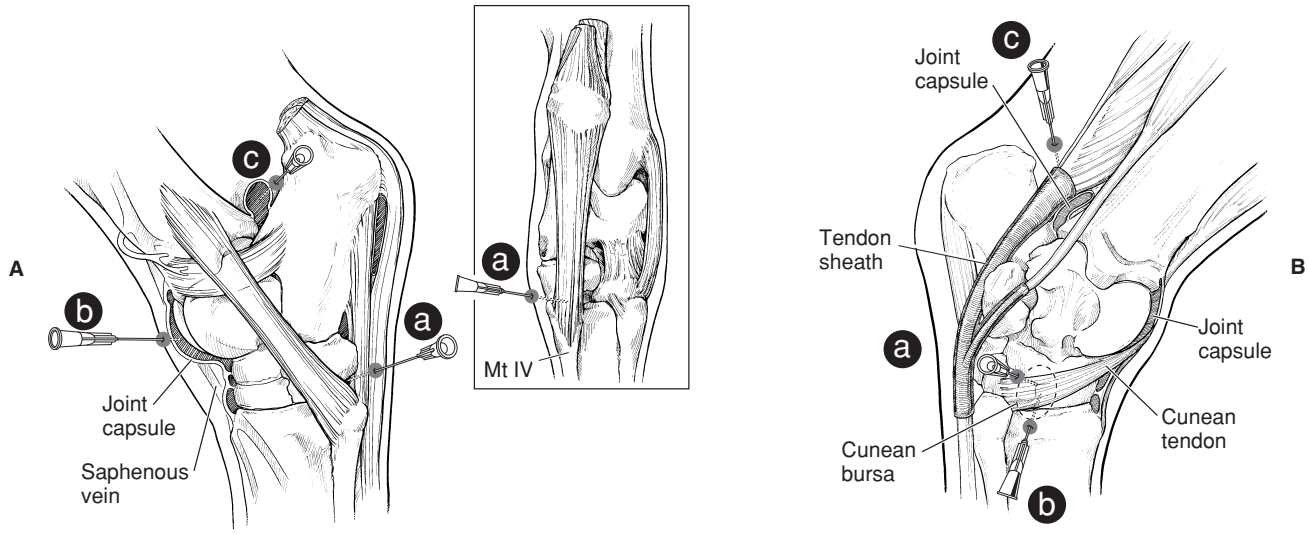

Fig. 10-24 **A,** Lateral and plantar (*inset*) views of the left tarsus showing sites for tarsal arthrocentesis. The tarsometatarsal joint is entered by locating the depression just proximal to the proximal aspect of the fourth metatarsal bone (*Mt IV*) and inserting a needle (*a*) in the plantar aspect of this depression, directing it dorsomedially. The dorsomedial pouch of the tarsocrural joint (*b*) is entered either just lateral or medial to the dorsal branch of the saphenous vein or, alternatively, using the plantarolateral pouch (*c*). **B,** Medial view of the left tarsus. The centrodistal joint is entered by placing the needle (*a*) in the depression formed between the fused first and second tarsal bones, the third tarsal bone, and the central tarsal bone, which is at the proximal edge or just slightly distal to the proximal edge of the cunean tendon. The cunean bursa (*dotted ellipse*) is entered by locating the distal border of the cunean tendon and inserting the needle (*b*) under the tendon from the distal aspect or placing it directly through the tendon. The distended tarsal sheath (*c*) can be entered proximal, just caudal to the tarsocrural joint capsule or distal (not shown) to the tarsus.

normal width of joint space. We have tried several alternative sites, including dorsomedial and dorsolateral approaches. Anecdotal reports suggest the dorsomedial approach, about 1 cm distal to the distal end of the medial trochlear ridge, is a consistent, reliable injection site, but we often enter the proximal intertarsal joint from this approach. An outpouching of the centrodistal joint exists dorsolaterally, but the perforating tarsal artery precludes use of this site in vivo. For these reasons, we use a medial approach at the distal aspect of, or through, the cunean tendon (medial tendon of insertion of the cranialis tibialis muscle), a structure that can be readily palpated. Using the fingertip, the distal edge of the cunean tendon is moved proximally to reveal an ill-defined concavity, the articulation of the fused first and second tarsal bones, with the third and central tarsal bones (see Fig. 10-24). This depression is sometimes located in a slightly more proximal location. This injection technique is one of the few commonly performed by standing on the opposite side of the horse. A skin bleb is useful because in most horses inserting a needle directly into the joint is difficult, and multiple attempts may be necessary. A 22- to 25-gauge, 2.5-cm needle is inserted directly in a lateral direction, horizontally, roughly parallel to the central and third tarsal articulation, perpendicular to the skin. Slight redirection of the needle may be necessary, and in many horses joint fluid is not obtained. If the needle can be inserted to a depth of 1 to 1.5 cm, it is likely properly positioned even if synovial fluid cannot be retrieved. Fluid retrieved in a more superficial location likely indicates penetration of the cunean bursa. In horses in which diagnostic information or therapeutic injection is critical and any question of needle placement exists, radiographs are warranted.

A maximum of 4 to 5 ml can be injected. If a larger volume can be comfortably injected, the needle tip is likely in the tarsal space or in the proximal intertarsal joint, or a communication with the tarsometatarsal joint exists. If the injection is difficult to perform, the needle is likely malpositioned in the subcutaneous tissues, or the needle tip is touching articular cartilage. Most clinicians attempt injection of the centrodistal joint *after* first injecting the tarsometatarsal joint, and in some instances, medication or local anesthetic solution readily flow from the needle. The typical response is, "There must be a communication between the tarsometatarsal and centrodistal joints." However, this clinical finding most often results from inadvertent penetration of the distended medial pouch of the tarsometatarsal joint. Fluid accumulation in the tarsal space from the tarsometatarsal joint injection can cause the same result, if the needle enters the tarsal space rather than the centrodistal joint space.

In horses with advanced osteoarthritis or even in horses with early distal hock joint pain, it may be difficult or impossible to be confident that intra-articular analgesia has been achieved. An alternative approach to provide tarsal analgesia is first to perform sequential, intra-articular analgesia of the tarsometatarsal and tarsocrural joints, and then to perform the fibular and tibial nerve blocks if lameness persists. If lameness abates after the fibular and tibial nerve blocks, a presumptive diagnosis of centrodistal joint pain can be made, assuming other sources of pain abolished by this block can be ruled out.

Tarsocrural Joint

Arthrocentesis of the tarsocrural joint is straightforward and easy compared to some joints, because of extensive and multiple dorsal and plantar outpouchings. In horses with moderate to severe effusion, identifying four distinct outpouchings—the dorsolateral, dorsomedial, plantarolateral, and plantaromedial pouches—is easy. The clinician must keep in mind that the tarsocrural and proximal intertarsal joints communicate through a large fenestration at the dorsal aspect of the joints in adult horses, although in weanlings and yearlings

the fenestration cannot be seen during arthroscopic examination. Any one of the tarsocrural joint pouches can be used, but the most common site of entry is on either side of the saphenous vein, in the dorsomedial pouch (see Fig. 10-24). This particular site is preferred in horses without obvious effusion. An alternative site is the plantarolateral pouch. The most consistent site to use is the distal aspect of the dorsomedial pouch, just distal to the medial malleolus of the tibia and medial to the saphenous vein. An 18- to 20-gauge, 2.5- or 4-cm needle is used to deposit 20 to 30 ml of local anesthetic solution into the tarsocrural joint. In horses with severe osteoarthritis of the tarsocrural joint or those with subchondral bone pain, as much as 30 to 50 ml of local anesthetic solution is necessary to abolish pain. In these horses, a false-negative result is common if only 10 to 20 ml of local anesthetic solution is used.

The plantar pouches can be useful alternative sites for arthrocentesis, if the dorsomedial pouch is unsuitable, as sometimes occurs with a wound, swelling associated with trauma of the fibularis (peroneus) tertius, or superficial dermatitis. The plantar pouches must be differentiated from distention of the tarsal sheath or other forms of thoroughpin. Although the dorsal and plantar pouches freely communicate, anatomically, flushing from one aspect of the tarsocrural to the other when the horse is in a weight-bearing position may be difficult. Fluid flow between articular surfaces and joint spaces under collateral ligaments is likely restricted when horses are in a weight-bearing position. This same phenomena occurs in other joint spaces.

Stifle Joint

The three compartments of the equine stifle joint are the medial femorotibial, lateral femorotibial, and femoropatellar joint compartments. Most consider that the femoropatellar and medial femorotibial joints communicate in almost all horses and that the lateral femorotibial compartment is solitary, but recent anatomical studies have shed new light on this time-honored concept. The frequency of communication between the medial femorotibial and femoropatellar compartments was found to be 60% to 74% in normal horses, when the injection was performed from the femoropatellar compartment.[51,52] The frequency of communication was higher (80%) when the injection was performed in the medial femorotibial compartment.[51] It is important to realize, however, *that the medial femorotibial and femoropatellar compartments did not communicate in all horses*. Inconsistency in communication depending on which compartment was injected was attributed to directionality in the normal foramen or slit between the two compartments (flow easier *from* the medial femorotibial *to* the femoropatellar compartment).

The time-honored assumption that the lateral femorotibial joint is a solitary compartment was also challenged. The lateral femorotibial joint communicated with the femoropatellar joint in 3% to 18% of horses but was indeed solitary in the majority of normal horses[51,52] Communication may be more frequent after trauma and certainly after arthroscopic surgical procedures.

We recommend that each compartment of the stifle joint be injected independently, either sequentially or simultaneously, to avoid confusing results during stifle analgesia. The variable degree of communication will obviously cause some degree of uncertainty in diagnosis. The same principle is recommended for therapy as well. Needle insertion in the stifle joints is complicated by a natural tendency of horses to react inappropriately to manipulation compared with other areas of the limbs. Horses seem to object to simple palpation of the stifle and may become fractious during arthrocentesis. To avoid excessive manipulation during injection, we have found it useful to attach an extension set to the needle, a procedure that obviates the need to touch the needle or skin when attaching the syringe. If necessary, the extension set may be useful for many diagnostic procedures, particularly in the hindlimbs. In general, 20 to 30 ml of local anesthetic solution is used in each of the medial femorotibial, lateral femorotibial, and femoropatellar compartments. A common misconception is that long needles are needed to perform arthrocentesis of the stifle joint compartments. In fact, some racehorse trainers will insist that "the long needles, Doc" are necessary to achieve success in medicating the femoropatellar joint. If arthrocentesis is performed with the limb in a weight-bearing position, the joint capsules can easily be penetrated with needles no longer than 4 cm. In the flexed position, using a spinal needle when performing femoropatellar arthrocentesis is necessary. We prefer to have the horse in a weight-bearing position, with the limb slightly ahead of the contralateral limb, a position that allows the clinician to palpate landmarks readily without undue tension on patellar and collateral ligaments.

Arthrocentesis of the medial femorotibial joint is performed at a site located just caudal to the medial patellar ligament, cranial to the medial collateral ligament, and 1 to 2 cm proximal to the medial tibial plateau (Fig. 10-25). In the normal horse a distinct depression occurs at this location, but in horses with effusion, a considerable bulge in the joint capsule can be present. An 18-gauge, 4-cm needle is inserted perpendicular to the skin and can be redirected or rotated if synovial fluid is not immediately retrieved. A common mistake is to insert the needle too far distally, and in this position the needle tip enters ligaments or the medial meniscus.

Arthrocentesis of the lateral femorotibial joint is more challenging than for the other two compartments, because the lateral joint pouch is small and located deep within tissue. The site is caudal to the long digital extensor tendon and cranial to the lateral collateral ligament, just proximal to the lateral tibial plateau (see Fig. 10-25). These landmarks are easily palpated, but distention of the joint capsule is not, in contrast to the medial femorotibial joint. An 18-gauge, 4-cm needle is inserted horizontally and directed in a slight caudomedial direction. Retrieval of synovial fluid varies, and redirecting or rotating the needle is often necessary. An alternate site can be used, located caudal to the lateral patellar ligament and cranial to the long digital extensor tendon, and just proximal to the tibial plateau.

Arthrocentesis of the femoropatellar joint is most commonly performed at a sub-patellar site and either lateral or medial to the middle patellar ligament. The joint capsule can be easily palpated even in most normal horses, if the horse is in a weight-bearing position. With the horse in a weight-bearing position, an 18-gauge, 4-cm needle is inserted perpendicular to the skin, or directed slightly proximally, until joint fluid is obtained or the needle tip contacts articular cartilage of the distal femur (see Fig. 10-25). The clinician does not need to angle the needle sharply proximally using this technique. What is sometimes frustrating is that even in horses with obvious femoropatellar effusion, a steady flow of synovial fluid cannot be obtained, and attempting aspiration of fluid with a syringe is seldom helpful, because synovial villi readily plug the needle, making aspiration impossible. Some clinicians perform femoropatellar arthrocentesis with the limb in a non–weight-bearing position, in which case a 9-cm spinal needle is used and the needle is directed severely proximally, between the patella and distal femur. An alternative lateral approach to the femoropatellar joint was described.[53] An 18-gauge, 4-cm needle is inserted into the lateral cul-de-sac of the femoropatellar compartment, located about 5 cm proximal to the lateral tibial plateau, caudal to the lateral patellar ligament and the lateral trochlear ridge of the femur. The needle is directed perpendicular to the long axis of the femur until bone is contacted (about 1.5 to 2 cm in most

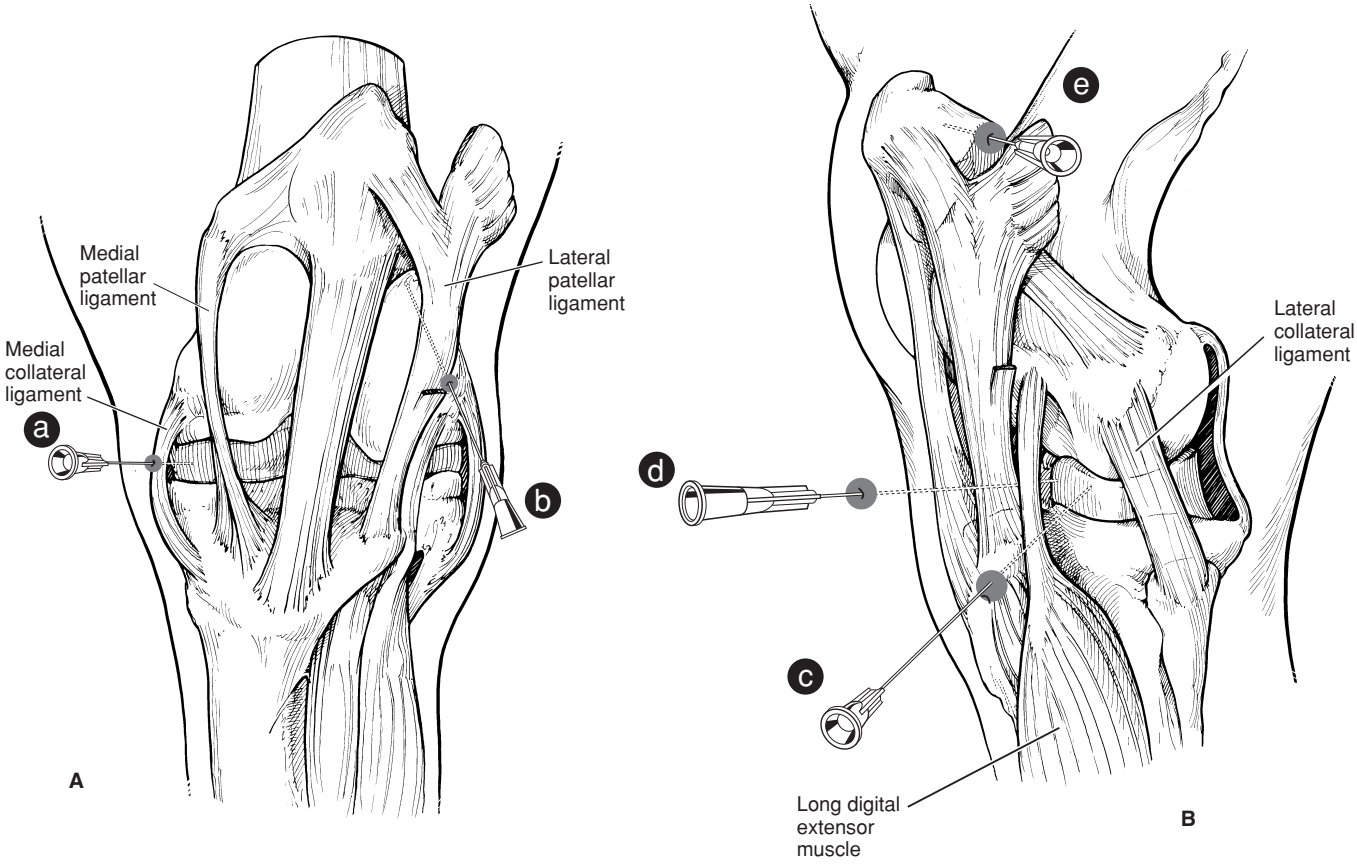

Fig. 10-25 **A,** Cranial view of the left stifle. The medial femorotibial joint (*a*) is approached from a site between the medial patellar and medial collateral ligaments, about 2 cm proximal to the proximal aspect of the tibia. The femoropatellar joint (*b*) most commonly is injected either between the lateral and middle patellar ligaments or between the middle and medial patellar ligaments (not shown). The needle is directed proximally in this subpatellar position. **B,** Lateral view of the left stifle. The lateral femorotibial joint can be approached by placing the needle caudal to the long digital extensor tendon and cranial to the lateral collateral ligament (*c*) or inserting it between the lateral patellar ligament and the cranial edge of the long digital extensor tendon (*d*). An alternative site for arthrocentesis of the femoropatellar joint (*e*) can be used by passing the needle through the lateral femoropatellar ligament.

horses) and then withdrawn slightly until synovial fluid is collected. Proposed advantages of this approach are a reduced potential for iatrogenic injury to the articular cartilage and more reliable recovery of synovial fluid compared to the subpatellar approach.[54]

Coxofemoral (Hip) Joint

Although the coxofemoral joint is relatively large and the landmarks for needle insertion are consistent, injection is considered to be a daunting task. Few of us perform this injection technique on a regular basis, and depth of penetration makes accurate needle placement difficult. An 18-gauge, 15-cm (6-inch) spinal needle is adequate for all but the largest of draft horses. A needle of this length should be inserted carefully, and if the horse is moving or fractious, it may be necessary to provide sedation. The site is in the angle formed between the long caudal and short cranial processes of the greater trochanter of the femur (Figs. 10-26 and 10-27). This site can be difficult to palpate in heavily muscled horses, and ultrasonographic evaluation can be useful to identify the injection site. The most difficult landmark to palpate consistently, but an important one nonetheless, is the cranial process. The site is *between* the two processes and not *caudal* to the trochanter.

Before the needle is inserted, blocking the injection site may be useful. Because the shaft of the needle is handled, sterile gloves are recommended. Needle direction is important. The needle is inserted in a slightly craniomedial direction and slightly distally and directed just dorsal to the femoral neck, until the joint capsule is penetrated. In most horses, a subtle pop can be felt as this occurs. "Walking" the needle off the femoral neck may be useful, using the bone as a guide to the coxofemoral joint. In most adult light breed horses, this occurs within 3 to 5 cm of the hub of the needle. Synovial fluid is reliably retrieved from the coxofemoral joint, spontaneously or by aspiration. A large volume of local anesthetic solution should not be injected if synovial fluid is not readily obtained, but injecting a small volume and attempting retrieval with a syringe is useful. It is possible inadvertently to inject local anesthetic solution around the sciatic nerve, causing temporary paresis, if the needle is caudally malpositioned, and therefore anesthetic solution should not be injected if any doubt exists that the needle is correctly positioned. Twenty-five to 30 ml of local anesthetic solution is used. Most patients are evaluated in 20 to 30 minutes, but in horses with fractures of the acetabulum the clinician should expect only 50% improvement in lameness score, and improvement may be short lasting (15 to 30 minutes).

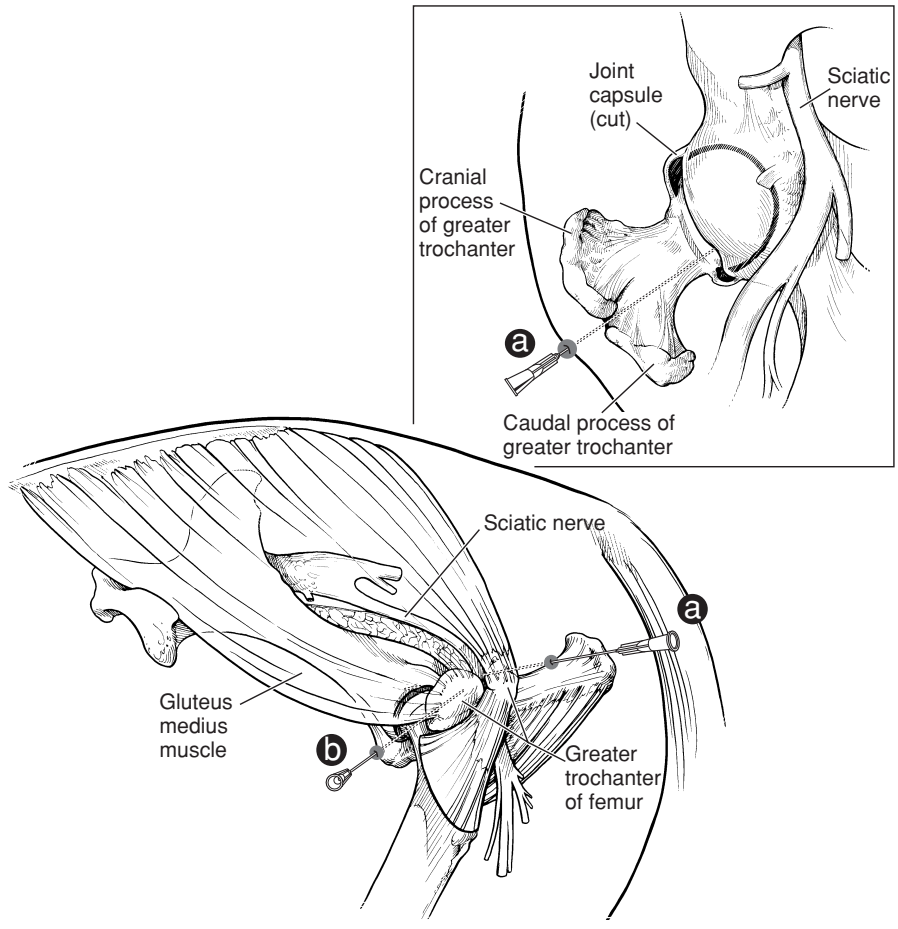

Fig. 10-26 Lateral and dorsal (*inset*) views of the left coxofemoral joint. Arthrocentesis of the coxofemoral joint is performed by inserting the needle (*a*) in the angle formed between the caudal and cranial processes of the greater trochanter of the femur. The needle is inserted slightly cranially, distally, and medially just dorsal to the shaft of the femoral neck (*inset*). This view (*b*) shows the seldom used diagnostic technique of synoviocentesis of the trochanteric bursa.

ANALGESIA OF HINDLIMB BURSAE AND TENDON SHEATHS

Analgesia of the navicular bursa and digital flexor sheath in the hindlimb is the same as in the forelimb.

Cunean Bursa

Occasionally, injecting the cunean bursa is necessary to assess the role of the cunean bursa and tendon in horses with distal hock joint pain, to perform cunean tenectomy, or to medicate the structure. The cunean bursa is seldom the sole source of distal hock joint pain, but can play a role, so analgesia or medication of this structure is sometimes combined with other injections.

The cunean bursa is between the distal tarsal bones and the medial branch of the cranialis tibialis tendon (called the *jack tendon* or *cord*) but is seldom palpable (see Fig. 10-24). The distal aspect of the cunean tendon is usually easily palpated, however, by starting at the distal aspect of the hock and sliding the fingertip in a proximal direction. Retrieving synovial fluid is unusual but possible, but during injection the clear outline of the bursa can be seen as it distends. A 20- to 22-gauge needle is inserted deep to the distal edge of the cunean tendon and directed in a proximal direction, and 3 to 5 ml of local anesthetic solution is injected. We prefer this approach, but alternatively the needle can be inserted perpendicular to

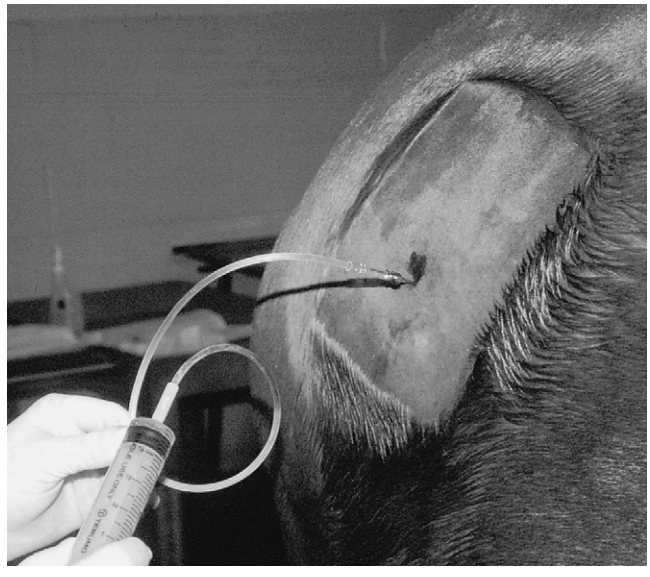

Fig. 10-27 Arthrocentesis of the right coxofemoral joint. Using an extension set between needle and syringe, a technique that reduces the amount of manipulation necessary during the procedure, facilitates arthrocentesis of this and other joints.

the skin and directly through the tendon itself until bone is contacted.

Tarsal Sheath

Analgesia of the tarsal sheath is performed to confirm the structure as a source of lameness associated with traumatic and infectious tenosynovitis (although the response may be limited in face of infection) and various osseous lesions, such as those involving the sustentaculum tali, or unusual exostoses (osteochondroma). The tarsal sheath surrounds the deep digital flexor tendon from a point approximately level with the tuber calcanei and extends to a point 2 to 3 cm distal to the tarsometatarsal joint. Distention of the tarsal sheath is commonly called thoroughpin, but occasionally, thoroughpin appears as fluid swelling proximal to the tarsus that does not involve the tarsal sheath. The deep digital flexor tendon is located medial to the calcaneus as it crosses the sustentaculum tali. The heavy tarsal retinaculum medially and the calcaneus laterally restrict outpouching of the tarsal sheath to the proximal and distal aspects. The clinician should take care to differentiate tarsal sheath effusion from distention of the plantar pouches of the tarsocrural joint. A 20-gauge, 2.5-cm needle is used to inject 10 to 15 ml of local anesthetic solution.

Calcaneal Bursa

Indications for analgesia of the calcaneal bursa include traumatic and infectious bursitis, tendonitis of the gastrocnemius or SDFT at this level, and osseous lesions of the tuber calcanei. The bursa is located between the SDFT and tuber calcanei. Proximal to the tuber calcanei, the bursa is interposed between the SDFT and the gastrocnemius tendon. When distended, an unusual clinical finding, the bursa is palpable as medial and lateral outpouchings just proximal to the tuber calcanei. Smaller outpouchings are often discernable just distal to the tuber calcanei but are inconsistent. The bursa can be accessed for injection at any of these outpouchings. A 20- to 22-gauge, 2.5- or 4-cm needle is used to inject 10 ml of local anesthetic solution, after retrieving fluid for analysis if indicated (see Fig. 10-24). Pain may take 20 to 30 minutes to abate in horses with osseous lesions or with severe lameness.

Trochanteric Bursa

Seldom does an indication exist to block the trochanteric bursa, although injections in this region are commonly performed to manage bursitis and muscle pain (see Chapter 48). The trochanteric bursa is located between the tendon of insertion of the gluteus accessorius muscle and the cranial process of the greater trochanter of the femur (see Fig. 10-26; see also Chapter 48). In normal horses, this bursa is small and likely has minimal synovial fluid. Synoviocentesis is performed using an 18- to 20-gauge, 4-cm needle, although in larger, more heavily muscled horses, a longer needle may be necessary. The needle is inserted perpendicular to the skin, directly over the cranial aspect of the greater trochanter until contact with bone is made. We have had difficulty retrieving fluid even in lame horses that have a positive response to analgesia. Generally, 5 to 10 ml of local anesthetic solution is injected until pressure is felt. If local anesthetic solution can be aspirated, the needle was likely in the bursa, but if not, the injection was likely performed in the surrounding tissues.

LOCAL INFILTRATION IN THE FORELIMB AND HINDLIMB

Local infiltration of local anesthetic solution in painful soft tissues or over painful bony swellings can be performed at any location, although some areas deserve special mention. Any localized area of pain, into which a needle can be inserted safely, is fair game for local analgesia.

The clinician must be aware, however, that local infiltration may not provide total analgesia to the region, mostly because the entire nerve supply to the region cannot be blocked. Incomplete analgesia is common in horses with bony lesions, such as bucked shins, because deep pain from the cortex of McIII is difficult if not impossible to eliminate using subcutaneous infiltration of local anesthetic solution. In most instances, perineural analgesia for this particular condition is preferred. Local infiltration is performed in many horses in lieu of perineural technique, or in horses in which perineural analgesia has localized pain to a general region, but conflicting or numerous clinical problems exist. An advantage of local infiltration is that proprioception is not lost, and horses can be moved at speed for re-evaluation after this form of analgesia. Efficacy can be assessed by deep, direct digital palpation, to confirm that the previously identified source of pain was eliminated by local analgesia.

Splints

A common suspected cause of lameness in many horses are exostoses associated most commonly with the second (McII) and fourth (McIV) metacarpal or metatarsal bones (MtII, MtIV) or in combination with the McIII or MtIII. A 20- to 22-gauge, 2.5- to 4-cm needle is used to deposit 5 ml of local anesthetic solution, subcutaneously, over the painful exostosis. The needle is slid directly alongside the proliferative lesion, between skin and bone. For splints involving McII/MtII and McIV/MtIV, it is important to deposit local anesthetic solution abaxial and axial (between the suspensory ligament and splint bones) to the lesion. In some horses proliferative changes involve only the axial aspect of McII/MtII or McIV/MtIV (blind splints), and it is critical to block in this location. In others with primary proliferation between McII/MtII, McIV/MtIV, and McIII/MtIII, subcutaneous injection will suffice. When local anesthetic solution is infiltrated on the axial aspect of the splint bones, the palmar/plantar metacarpal/metatarsal nerves are likely blocked, making it possible to abolish pain from a more distal site and leading to misinterpretation of results.

Suspensory Ligament Origin

Local infiltration or flooding the palmar/plantar metacarpus/metatarsus at the origin of the suspensory ligament is often done in lieu of perineural analgesia, as described previously. This is also referred to by some as sub-tarsal or sub-carpal blocks. An 18- to 22-gauge, 2.5- to 4-cm needle can be used to distribute 5 to 15 ml of local anesthetic solution in a fan-shaped pattern, usually from a lateral injection site just axial to McIV/MtIV. It is important to use adequate restraint and have the limb in a flexed position when performing this technique. In the hindlimb an 18- to 19-gauge needle should be used to minimize the potential for needle breakage, should the horse kick during the procedure.

False-positive results, attributed to inadvertent analgesia of palmar/plantar metacarpal/metatarsal nerves, penetration of the distal outpouchings of the carpometacarpal and tarsometatarsal joints, or penetration of the tarsal sheath can occur.[22,47] Compared with high palmar analgesia, the incidence of inadvertent injection of the distal palmar outpouchings of the carpometacarpal joint was highest when local infiltration of the suspensory origin was performed.[22]

Curb

Curb, the term used for swelling of the distal, plantar aspect of the tarsus, is a complex condition involving superficial digital flexor tendonitis, long plantar desmitis, subcutaneous swelling, or various combinations of these soft tissue injuries

(see Chapter 79). Local infiltration can partially abolish pain associated with curb and usually involves depositing local anesthetic solution subcutaneously. Completely blocking deep pain associated with the long plantar ligament or SDFT is not possible without using the fibular and tibial nerve blocks. A tibial nerve block may be more specific.[5] A 20-gauge, 2.5- to 4-cm needle is used to inject 15 to 20 ml of local anesthetic solution with the limb in a flexed position. Adequate restraint and the help of an assistant are mandatory. Local anesthetic solution is infiltrated subcutaneously along the plantar, medial, and lateral aspects of the swelling, but deep injection into or between the SDFT and long plantar ligament is avoided. The medial injection is most comfortably and safely performed by standing on the opposite side of the horse.

Dorsal Spinous Process Impingement

This local infiltration technique is performed when attempting to confirm or rule out lameness or poor performance associated with back pain caused by impingement or other pain originating from the dorsal spinous processes of the thoracolumbar vertebrae.[55] The horse is usually evaluated under saddle or in harness or on a lunge line, because lameness associated with this condition may be subtle and only manifested under these conditions. The hair along the dorsal midline is clipped, and the site or sites are prepared aseptically. We prefer to use 22-gauge, 9-cm spinal needles, although in most instances shorter needles can easily reach the tops of the dorsal spinous processes. Needles are inserted on the dorsal midline and directed ventrally to the dorsal spinous processes or the inter-spinous space. Markers placed after scintigraphic or radiographic examination are helpful to determine the precise location for blocking or to administer medication. The interspinous space can be located by redirecting the needle in a cranial or caudal direction. If impingement of the dorsal spinous processes exists, it may be impossible to infiltrate between them, but placing local anesthetic solution around the processes is satisfactory.[5] Seven to 10 ml (per site) of local anesthetic solution is deposited as the needle is slowly withdrawn, and the horse is reevaluated 10 to 15 minutes later.

Orthopedic Implants

Occasionally, pain associated with orthopedic implants is suspected to cause lameness. This is most commonly seen in horses after distal McIII/MtIII condylar fracture repair but can occur after repair of proximal phalanx or olecranon process fractures. Low-grade lameness is most common. Differentiating pain arising from negative interaction of implants with bone or surrounding soft tissue is nearly impossible based on the results of any diagnostic analgesia technique, because innervation to the joint or surrounding tissues is complex. Local anesthetic solution can be injected around screw heads, next to pins and wires or bone plates, and the horse is then re-evaluated. Because lameness is often subtle, improvement is often difficult to judge. A combination of clinical findings and those from ancillary diagnostic techniques is used to determine the role of implant pain.

Neurological Examination and Neurological Conditions Causing Gait Deficits

Jill Beech and William V. Bernard

Differentiating neurological gait deficits from lameness can sometimes be a dilemma for the clinician. Many repeated examinations and ancillary testing may be necessary, and even then experienced clinicians may give varied opinions about the same horse. Lack of definitive diagnostic tests to identify the origin of subtle gait changes, which in some horses may be perceived only by a rider or driver and not visible, promote diagnoses that are based purely on opinions and individual prejudices. This chapter discusses the examination of the horse with gait deficits caused by disease of either the spinal cord, the most frequently documented cause of neurological gait deficits, or peripheral nerves. The chapter does not consider neurological syndromes characterized by signs of brain dysfunction, such as vestibular, cerebral, and cerebellar disorders. We also refer readers to a recent review on the equine spinal cord.[1]

CHAPTER • 11

Neurological Examination and Neurological Conditions Causing Gait Deficits

Jill Beech and William V. Bernard

Differentiating neurological gait deficits from lameness can sometimes be a dilemma for the clinician. Many repeated examinations and ancillary testing may be necessary, and even then experienced clinicians may give varied opinions about the same horse. Lack of definitive diagnostic tests to identify the origin of subtle gait changes, which in some horses may be perceived only by a rider or driver and not visible, promote diagnoses that are based purely on opinions and individual prejudices. This chapter discusses the examination of the horse with gait deficits caused by disease of either the spinal cord, the most frequently documented cause of neurological gait deficits, or peripheral nerves. The chapter does not consider neurological syndromes characterized by signs of brain dysfunction, such as vestibular, cerebral, and cerebellar disorders. We also refer readers to a recent review on the equine spinal cord.[1]

DIAGNOSIS

History is important but depends not only on asking the appropriate questions but also on many uncontrollable factors, such as how closely, impartially, and astutely the horse has been observed. The time of onset of signs and rate of progression, whether the gait deficit waxes and wanes or is affected by exercise or rest, whether one or more limbs are affected, whether the affected limb varies, what the horse was doing before onset of signs occurred, whether exercise or management has changed, whether the horse has been moved geographically, whether signs occurred after transport, what medications may have been given and any observed effects, and whether other horses on the farm or in the stable have had any recent illnesses or fever should be determined. It is also important to know if other horses on the same farm have similar clinical signs. For instance, a history of fever, respiratory disease, or abortions in horses in contact with the patient would make one suspect equine herpes virus I (EHVI) infection.

Clinical Examination

The clinician should observe whether the horse displays cranial nerve dysfunction; muscle hypertrophy, atrophy, or asymmetry; muscle trembling; abnormal hoof wear; or abnormal posture. Muscle atrophy may be due to disease of the ventral horn cells of the gray matter of the spinal cord, peripheral nerve, or the muscle itself; it also can occur with disuse. Palpation can reveal abnormalities such as altered skin temperature, sweating, muscle fasciculations, abnormal sensitivity, or soreness. The horse should be observed on a flat surface, at a walk and trot, and in straight and curving lines. The horse should be evaluated on a surface that allows detection of abnormal hoof flight and placement, toe dragging, or excessive force when landing. The sound of the feet landing should be noted for consistency and loudness. Hard surfaces also may enhance abnormal hyperflexion in horses with stringhalt. Evaluation on a soft surface may be necessary if the horse is unstable or if the clinician is trying to determine whether the horse could have sore feet. Any abnormal head or neck movement associated with limb movement should be noted. It is important to permit normal neck and head movement when the horse is being led. The person leading the horse should hold the horse as loosely as is safely possible. Collapsing or sinking on a limb, knuckling, hyperflexion, spasticity, hesitance in any part of the stride, dragging of a toe, landing excessively hard, leaning to one side, or failing to track straight can indicate a neurological deficit. Various manipulations are used to diagnose whether proprioceptive or motor deficits exist and to localize the lesion. While being led, the horse should be evaluated while stopping and starting from a walk and trot, backing up, circling tightly in both directions, walking while sideway traction is applied and released on the tail, being pushed sideways from a standstill, and walking with its head elevated. Some clinicians also evaluate repositioning of the foot after placing the horse's hoof in an abnormal position. We do not find this particularly helpful because a horse's disposition, age, training, and distractions can affect its response. A horse with a normal gait may stand with its feet placed in an abnormal position for what seems an abnormally long time. Some clinicians also use wheelbarrowing and hopping reactions.[1] We do not use these tests in mature horses because we believe responses may be inconsistent and difficult to evaluate accurately and safely. Observation of the horse walking or trotting up and down inclines can be helpful in revealing whether the horse "knows where its limbs are" (proprioception) and can adjust limb movement appropriately. It may be helpful to observe the horse while it is being ridden or lunged, and in some horses while it is loose in an enclosure. Watching the horse stop and start, turn, back up, and maintain its balance during many postural maneuvers allows detection of neurological deficits that may not be obvious when the horse is being led. Are errors in range of movement of the limb (dysmetria) apparent? Is the horse extending its limbs to the full extent, or is the range decreased (hypometria)? Does the horse lift its limbs excessively high (hypermetria)? Is spasticity or stiffness of movement apparent? In some horses it is necessary to observe the horse performing its usual activity, providing it is capable. However, gait deficits may be much less apparent at speed than when the horse is walking or trotting slowly. Basically, the clinician is trying to determine whether the horse moves symmetrically and smoothly with normal stride length and height of foot flight appropriate to the breed and use, whether it appears strong and consistently places its feet in the appropriate positions, and whether it moves in balanced harmonious fashion. It is sometimes difficult to determine whether certain postural or gait changes are due to pain or weakness, or associated with motor or proprioceptive deficits. Is the horse flexing its hindlimbs excessively and holding its croup more ventrally and flexed because of pain or weakness? If the horse is shifting weight between the hind feet, is it because of weakness, as seen for example in lower motor neuron disease, or because of pain? When both limbs are affected, manipulation of a limb to try to localize pain may not be possible. Gaited horses can be extremely difficult to evaluate, especially if one is unfamiliar with the specific gaits. Conformation also can confound interpretation of clinical signs. It may be necessary to observe the horse on many occasions and compare its gait before and after exercise. Is the deficit consistent, or does it vary? If it worsens with exercise, is it because of pain or inability to compensate for a neurological deficit as the horse tires? Perineural analgesia may be helpful. Is there palpable evidence of muscle cramping with exercise or an increase in creatine kinase (CK) level, indicating rhabdomyolysis? A variable gait deficit and inconsistent alterations in foot flight or placement are more likely to represent a neurological deficit than lameness; single limb lameness may vary in intensity but usually remains similar in character. Painful and neurological conditions could coexist but may be difficult to differentiate even with use of commonly used analgesics such as phenylbutazone.

If the horse buckles in a limb, especially on turns, is easily pulled sideways by the tail when standing or walking, or trembles its limb, weakness of the extensor muscle groups should be suspected. When the flexor muscles are weak, the horse is unable to lift its limb normally, and the toe may be worn from dragging. Pushing the horse sideways or trying to pull on the halter and tail simultaneously can reveal weakness. If the horse is weak or has pain in one limb, it is not able to bear weight normally when the contralateral hoof is lifted from the ground. Neck flexion sideways and vertically should be evaluated for ease and range of movement. Skin sensation and the cutaneous trunci reflex and cervical reflexes should be evaluated. Tapping the trunk should elicit contraction of the cutaneous trunci muscle. Abnormalities can delineate a thoracic spinal cord lesion, because afferent input is through the dorsal thoracic nerves and cranially through the spinal cord white matter, and the efferent pathway involves the cranial thoracic motor neurons in the first thoracic and eighth cervical segments and the lateral thoracic nerve. Hypalgesia of the cutaneous trunci as assessed by response to a two-pinch test with a hemostat is rare and occurs only with severe thoracic spinal cord disease.[1] Lack of a cervicofacial reflex (failure of the facial muscles to twitch when the ipsilateral side of the proximal neck is tapped) can suggest a lesion in the cervical cord or a branch of cranial nerve VII. If tapping the side of the neck fails to elicit contraction of the cutaneous coli muscle, a cervical cord lesion could exist. If any abnormal response to skin stimulation is detected, the test should be repeated because

the horse's disposition can influence its responses. Limb reflexes usually are not used, although patellar reflexes can be elicited in horses. We do not consider the thoracolaryngeal reflex (slap test) to be helpful. Response is inconsistent in horses with cervical spinal cord lesions and may be absent in normal horses. Blindfolding the horse usually is not part of our routine neurological examination unless vestibular disease is suspected. A complete physical examination should always be conducted. In some horses with hindlimb gait deficits, palpation per rectum of the pelvic bones, lumbar region, distal aorta, and iliac vessels may be necessary. Simple observation may not differentiate hindlimb weakness caused by spinal cord disease from that caused by partial aortoiliac thrombosis. Horses that do not "feel right" to the rider yet show no obvious deficits to the observer whether observed saddled or in hand are problematic. It may be necessary to observe a horse from the jog cart or carriage if the gait deficit about which a driver complains is not visible to the bystander. In attempting to differentiate between a musculoskeletal and neurological condition causing a gait deficit in a limb, diagnostic analgesia may be necessary. Obviously, this does not help differentiate pain from lameness emanating from a lesion proximal to the coxofemoral or scapulohumeral joints. A course of non-steroidal anti-inflammatory drugs (such as moderate doses of phenylbutazone for days or even several weeks) may be helpful in determining whether a gait deficit is caused by pain.

Hematology and Serology

In most horses serum chemistry screens and hematological tests are not particularly helpful; however, in horses with a gait deficit caused by an underlying muscle disease, evaluation of aspartate aminotransferase (AST) and CK levels may be helpful. Stage of training, exercise pattern, and whether the blood specimen is obtained after exercise preceded by a day of rest must be considered in evaluation of enzyme levels. If a horse consistently has abnormally elevated enzyme levels, the horse has rhabdomyolysis, and the clinician must decide whether the condition is causing or contributing to the horse's abnormal gait. Plasma CK and AST levels do not increase simply because of muscle atrophy; rhabdomyolysis must occur to increase the enzyme levels in the blood (see Chapter 84). Elevated plasma concentrations of CK and AST in horses that are not being exercised suggest a primary muscle disorder, such as (but not limited to) polysaccharide storage myopathy (see Chapter 84). An elevation in white blood cell count and fibrinogen level indicates inflammation. In our experience, elevation in fibrinogen level is a more consistent indicator of inflammation in the adult horse than is elevation in white blood cell count.

If clinical signs suggest equine lower motor neuron disease, serum levels of vitamin E (α-tocopherol) should be measured because levels consistently have been low unless the horse has been given supplements.[2] Low vitamin E levels are not specific for equine lower motor neuron disease. Tocopherol concentrations can decrease during winter when horses lack access to green pasture.[3] Daily variations in plasma levels may occur.[4] Low levels also have been reported in clinically normal horses[5-7] and in one horse with chronic gastrointestinal disease.[8] The laboratory that performs the test should be contacted for any specific requirements for submission of samples and to ensure they have an established normal range for vitamin E levels.

Serological testing for antibodies to various infectious agents may be indicated. In EHVI infection, detection of an increase in antibody titer is considered diagnostic of the disease. A horse that shows signs of neurological disease secondary to EHVI should have an elevated serum antibody titer, and single high titers have been the basis for initial diagnosis in individual horses. Recent vaccination confounds interpretation. Rarely, high titers may be measured in horses with no history of recent vaccination and no obvious clinical signs of EHVI infection.

Antibody titers for *Borrelia burgdorferi*, the cause of Lyme disease, sometimes are measured in serum from horses with ill-defined gait deficits. High titers, or rising titers, have been used as a basis for treatment of the disease. A positive titer, however, does not mean the horse has active disease. Because of the geographical variation in exposure to *B. burgdorferi*, titers may vary greatly. Serological surveys in the United States have demonstrated positive test results in 1% of samples from non-endemic areas and up to 68% in endemic areas.[9-11] Reports of horses "responding" to treatment exist,[12,13] but to date we are unaware of any horses with Lyme disease in in which neurological deficits mimic primary lameness. Currently the importance of Lyme disease as a cause of equine gait deficits is unclear.

Serological testing for the presence of antibodies to *Sarcocytis neurona* can be used only to indicate exposure to the organism. Serological surveys in certain areas of the United States have shown that a high percentage of horses have positive antibody titers. A positive test result does not mean the horse has equine protozoal myelitis (EPM). A negative test result could theoretically occur in horses with peracute disease or perhaps in severely immunocompromised animals. However, a negative test result usually indicates that disease caused by *S. neurona* is highly unlikely. The test result also could be negative in a horse with signs of EPM if another protozoan, such as *Neospora*, causes the spinal cord lesions. In a U.S. study of several hundred horses with neurological disease, test sensitivity was 89%, but specificity was only 71%, because 30% of horses with other neurological diseases also had antibodies to *S. neurona*. Although the positive predictive value was only 72% in horses with neurological diseases, the negative predictive value was almost 90%, indicating that a negative test result is useful in this population.[14] In one study of 44 horses on a farm sampled for more than 1 year, all horses were seropositive for at least 50 weeks yet showed no neurological signs.[15]

Cerebrospinal Fluid Aspiration and Analysis

Cerebrospinal fluid (CSF) can be obtained from either the atlanto-occipital or the lumbosacral space. The advantage of lumbosacral centesis is that it can be performed in the standing sedated horse, whereas atlanto-occipital centesis requires general anesthesia. Fluid from the atlanto-occipital site is considered easier to obtain and not as likely to be contaminated with blood. The atlanto-occipital site is identified by palpating the cranial edge of the wings of the atlas. The hair is clipped and the site prepared aseptically. Atlanto-occipital centesis is performed at the intersection of the median plane and a line drawn across the cranial edge of the wings of the atlas. In the adult horse a 9-cm (3½-inch), 18- or 20-gauge spinal needle is directed toward the horse's lower lip with the head held in a flexed position. It is important that the needle remain on the midline as it is advanced, because otherwise it will be too far lateral to enter the sub-arachnoid space. The needle is initially inserted to a depth of approximately 2.5 cm (1 inch) and then gradually advanced. While the needle is gradually advanced to the sub-arachnoid space, it should be held carefully to prevent penetrating the spinal cord when advancing through the atlanto-occipital membrane and the dura mater. Usually a "pop" is felt as the needle advances through the dura; however, this finding is not consistent and the stylette should be frequently removed to observe for flow of CSF. CSF usually flows from the needle once the sub-arachnoid space is entered; however, once a substantial depth has been reached (about 5 to 8 cm [2 to 3 inches] in the average-size horse),

some clinicians advise gentle and frequent aspiration with a small syringe.

In preparation for aspiration from the lumbosacral space the type and degree of restraint is guided by the horse's behavior, the horse's stability, and the clinician's personal preference. A nose twitch, stocks, sedation, or a combination of physical and chemical restraint are options. We prefer to use light sedation with xylazine, sometimes combined with butorphanol. However, lumbosacral CSF pressure can be transiently decreased up to 15 minutes after administration of a high dose of xylazine (1.1 mg/kg intravenously).[16] The puncture site for lumbosacral centesis is identified by combining several landmarks, realizing that individual variation exists. A line drawn between the caudal edge of the tuber coxae and the intersection with the midline can be used to locate the lumbosacral space. The lumbosacral space is bordered cranially by the caudal edge of the sixth lumbar vertebra, caudally by the cranial edge of the sacrum, and laterally by the medial rim of the tubera sacrale. The dorsal spinous process of the last lumber vertebra is lower than the dorsal spinous process of the fifth lumbar vertebra. The V formed by the medial rim of the tubera sacrale is one of the more useful landmarks, and the appropriate site for puncture is within this V. The site should be prepared aseptically, and local anesthetic solution is placed subcutaneously. A small skin stab incision is usually made. The needle is inserted on the midline, at the depression palpated just caudal to the last lumbar vertebra, in the middle of the V formed by the tubera sacrale. A 15-cm, 18-gauge spinal needle is generally adequate for a horse that is 16 hands or less. A 20-cm needle may be necessary in a horse greater than 16 to 17 hands. While the clinician advances the needle, it is critical to remain on the midline. The needle can be advanced until a pop indicates it is advancing through the dura or until the patient responds as the needle stimulates nervous tissue. These responses can be unreliable and occasionally dangerous for the horse, handler, and the individual performing the tap. Because horses can react unpredictably (including rearing, bolting, collapsing, or kicking), it is safer to advance the needle gradually until it is near the spinal canal, approximately 12.5 cm (5 inches) in a 15- to 16-hand horse. Once the needle is near the canal, it should be advanced slowly with repeated frequent removal of the stylette and aspiration with a small syringe. The horse may move its tail when the dura is penetrated, but usually minimal reaction occurs. If fluid is obtained, but the amount is small, the needle can be rotated 180°. Jugular vein compression for at least 10 seconds (Queckenstedt's test) is thought to elevate intra-cranial CSF pressure and aid fluid collection, provided flow is not obstructed. If a hemorrhagic sample is thought to be from iatrogenic causes, the syringe can be changed frequently until subsequent aliquots are clear. If fluid is not obtained on the first attempt, the needle is withdrawn and the procedure is repeated slightly cranial or caudal to the original location. CSF samples should be placed in sterile tubes and rapidly processed after collection.

Normal CSF is clear and colorless, and red discoloration indicates hemorrhage. However, normal fluid can sometimes appear mildly hazy when grossly examined, especially in a tube with ethylenediamine tetraacetic acid. Hemorrhage can be iatrogenic or caused by underlying disease. Fluid may appear clear even with red blood cell contamination, and studies indicate that subjective evaluation of spinal fluid is sensitive in detecting blood only when the red blood cells number more than 1200/μl.[17,18] Centrifugation of a bloody sample should produce a clear fluid with a pellet of red blood cells on the bottom of the sample tube. If hemorrhage occurred before collection and lysis of cells has occurred, the supernatant may be slightly pink or xanthrochromic (orange/yellow or yellow). Lysis of red blood cells reportedly can occur within 1 to 4 hours.[19] Xanthochromic CSF results from red blood cell breakdown products (bilirubin) and suggests hemorrhage or vasculitis. A centrifuged xanthochromic sample does not become clear. Turbid CSF may appear with hypercellularity or epidural fat contamination. The latter is not uncommon with lumbosacral aspirates. Formulas used to differentiate between white cell or protein elevations caused by iatrogenic blood contamination of CSF versus pathological increases have been shown to be unreliable. Contamination with a few thousand red blood cells results in minimal increase in white blood cell count or protein content.[18]

The normal reported range for leukocyte counts has been variable; usually a range of 0 to 6/μl is cited,[20] but higher values have been reported.[21,22] Diversity in techniques can account for different values in normal CSF. Undiluted fluid can be assayed in a hemocytometer, or acidified crystal violet can be added to accentuate the cells.[20] It is important that equine reference values be determined in the laboratory the practitioner uses. As previously stated, the cell quality rapidly deteriorates in CSF, and samples for cytological testing should be processed rapidly or a portion fixed in 40% ethanol if processing must be delayed. For morphological and differential evaluation, cytocentrifugation or filtration through a glass fiber membrane filter is the preferred method of processing spinal fluid. In our experience, cell and differential counts are often normal in horses with spinal cord disease. Small lymphocytes and monocytes are normally seen. Neutrophils may be seen with blood contamination or inflammation. Eosinophilia is rarely seen in equine CSF but could occur secondary to parasite migration. Rarely, eosinophils have been seen in samples from horses with protozoal encephalomyelitis,[21] but frequently spinal fluid from horses with EPM is normal. A relative neutrophilia, with or without an increase in cell count, indicates inflammation, and intracellular bacteria may be seen in horses with bacterial meningitis.

Reported values for protein content of CSF vary considerably between laboratories, probably because of diversity in measurement techniques. A range of 10 to 120 mg/dl is generally acceptable, although some authors consider 100 to 105 mg/dl the high end of normal range.[20,23] Protein may increase because of vascular leakage (vasculitis), inflammatory lesions, trauma, iatrogenic blood contamination, or intrathecal globulin production. High-resolution protein electrophoresis of CSF has been reported in a small number of horses, but its value as a diagnostic test remains to be determined. Compared with normal horses (n = 18), horses with cervical cord compression (n = 14) often had a decreased β fraction and post-β peaks.[24] However, divergent findings have been reported. Because CK is abundant in neural tissue (and in skeletal tissue and cardiac muscle) and is a large macromolecule that does not cross the blood-brain barrier, measurement was suggested to be a sensitive index of central nervous system lesions. Horses with EPM were reported to frequently have increased CSF CK concentrations, unlike horses with cervical vertebral malformation.[25] However, another study showed the sensitivity and specificity of CSF CK activity are inadequate for diagnostic use. Also, CSF simultaneously collected from the atlanto-occipital and lumbosacral sites had disparate values for CK activity, which was not associated with site or other CSF parameters. Contamination of CSF with either epidural fat or dura, which is possible during collection, increases CK activity.[26]

Albumin is the predominant protein in normal CSF. Elevated albumin concentration can indicate hemorrhage or altered blood-brain barrier integrity. To eliminate serum albumin as a source of increased CSF protein and albumin, the following albumin quotient (AQ) has been suggested[27]:

$$AQ = \frac{\text{CSF albumin}}{\text{Serum albumin}} \times 100$$

The AQ cited for normal equine CSF 1.4 ± 0.04,[23,27] and it was suggested that an increase above reference range indicated blood contamination during sample collection or compromise of the blood-brain barrier. The immunoglobulin G (IgG) index

$$\frac{\text{CSF IgG concentration}}{\text{Serum IgG concentration}} \div \frac{\text{CSF albumin concentration}}{\text{Serum albumin concentration}}$$

was suggested to be useful for differentiating intrathecal IgG production from an increase secondary to blood contamination or increased blood-brain barrier permeability. Normal reference range has been reported to be 0.14 to 0.24.[27] However, we do not consider these to be specific, and a recent study has shown that blood contamination can increase the IgG index without a concomitant change in AQ.[18]

Although CSF cell count, cytological examination, and total protein often do not represent the extent or type of spinal cord or brain tissue disease, when abnormal, the values can be useful. For example, in CNS disease caused by EHVI infection the fluid may be xanthochromic with a high protein level but normal cell count. This disassociation between elevation in protein level and normal cell count may help differentiate EHVI infection from EPM. Also, xanthochromic CSF indicates an alteration in the blood-brain barrier and could explain false-positive CSF immunoblot findings for *S. neurona* in a horse with positive serological test results. Unfortunately, except for EHVI infections and meningitis, CSF analysis with currently available tests frequently is not helpful in diagnosing spinal cord disease in horses.

In the United States the frequency of performing CSF aspirates increased with the introduction of a Western immunoblot test for detecting *S. neurona* antibodies. Although limited data are available, the specificity and sensitivity of the immunoblot test on CSF from horses with clinical signs consistent with EPM were reported to be approximately 90%.[14] However, positive test results have been found in clinically normal horses and in horses with neuropathological lesions other than EPM. Even minute amounts of contamination of CSF with blood can cause the test result to be positive in a horse with high serum antibody levels.[19] When CSF was contaminated by even minute amounts of strongly immunoreactive blood (10^{-3} μL of blood/ml of CSF), the fluid was falsely positive even though the AQ was normal.[18] This small amount of blood contamination is grossly undetectable and can correlate with as little as eight red blood cells per microliter of CSF. Also, blood contamination, without increasing the AQ, can increase the IgG index. The IgG index is not specific for intrathecal IgG production. Although the red blood cell count may be a more sensitive indicator of blood contamination than the AQ, it does not correlate with the amount of antibody contamination. Minute amounts of highly immunoreactive blood may have a greater impact on CSF Western blot analysis than a greater amount of contamination with blood with low immunoreactivity.[18] Any compromise to the blood-brain barrier regardless of cause allows antibodies to leak into the CSF from the serum, causing a false-positive test result. Although the test for immunoblot *S. neurona* antibodies was reported to have 85% positive predictive value in a study of horses with neurological disease,[14] in the general equine population the test has poor positive predictive value. Many normal horses have positive antibody test results. In contrast the negative predictive value for the test is high. With what is currently known, interpretation of positive Western blot results must be made with caution. Negative Western blot tests are generally useful to rule out EPM.

Polymerase chain reaction (PCR) testing detects DNA of infectious organisms and has been applied to CSF. Its value in the diagnosis of EPM is controversial, especially when positive results have been reported on CSF samples that were negative for *S. neurona* antibodies and from horses that did not exhibit overt neurological deficits. We do not find PCR testing for the diagnosis of EPM useful. PCR technique on CSF has been useful in diagnosing neuroborreliosis in a horse. Similar to some human cases, the PCR test result was positive yet the CSF had a negative antibody titer.[12]

Radiography

The use of radiographs in evaluating traumatic or infectious injuries, congenital lesions, and developmental malformations of the spinal column is limited by the size of the patient. Radiographs are useful in diagnosing congenital abnormalities of vertebrae, narrowing of intervertebral disk spaces, stenosis of the cervical spinal canal, osteoarthritic changes, osteomyelitis or osseous cysts, vertebral neoplasia, malalignment, and fractures. However, in most mature horses, except for the cervical spine, anesthesia may be required for adequate radiographs of the spine. Computed tomography (CT) and magnetic resonance imaging have tremendous potential for evaluating the equine central nervous system but also are limited by the size of the horse. At present, except in foals, CT is available only for evaluating the head and cranial–mid-cervical regions. The primary use of radiography in evaluating horses with neurological disease is localization of cervical vertebral lesions or cervical vertebral malformation and diagnosis of cervical compressive myelopathy or stenotic myelopathy (see Chapter 62).

Survey radiography is useful in the diagnosis of cervical vertebral malformation and cord compression but can be misleading. Standing lateral radiographic views of the cervical vertebrae are routinely evaluated to detect vertebral malformation and to measure spinal canal diameter and can suggest the likelihood of cervical compressive myelopathy.[1,29,30] In horses with cervical compressive myelopathy, malformations that characteristically may be identified include flare of the caudal epiphysis of the vertebral body (vertebral endplate remodeling), caudal extension of the dorsal laminae, vertebral non-alignment, and osteoarthritis of articular facets. Remodeling of the articular processes of the caudal cervical vertebrae is a common malformation identified in horses with cervical compressive myelopathy and in horses not affected with cervical compressive myelopathy. Interpretation of changes is more difficult in older horses, because obvious changes may be seen radiographically, without impingement on the spinal canal. Subjective evaluation of articular facet abnormalities can result in a false-positive diagnosis of cervical compressive myelopathy. Identification of characteristic vertebral malformations supports, but does not confirm, the diagnosis of cervical compressive myelopathy, and subjective evaluation of radiographic malformation does not reliably differentiate between horses affected or not affected with cervical compressive myelopathy. Objective assessment of vertebral canal diameter is a more reliable indicator of cervical compressive myelopathy than the subjective evaluation of vertebral malformation. The minimum sagittal diameter (MSD) is the first described method of assessment of canal diameter based on lateral cervical radiographs.[29] Determination of canal diameter using the sagittal ratio improves on the original measurements by adjusting for magnification and providing a more accurate adjustment for body size.[30] The sagittal ratio measurements were developed using a population of affected (confirmed by myelogram or histopathological studies) versus non-affected horses.[30] The sagittal ratio is determined by dividing the MSD by the width of the corresponding vertebral body. Although a sagittal ratio percent at any cervical vertebra from the third to seventh cervical vertebrae less than 50% is a strong predictor of spinal cord compression, a few horses with no pathological evidence of spinal cord compression have had sagittal ratios of less than 50%. Recently intervertebral measurements of canal diameters were shown to improve diagnosis of cord compression, and addition of intervertebral sagittal ratio measurements was recommended to increase accuracy of plain radiographs.[1]

A semi-quantitative scoring system for evaluating cervical radiographs in horses younger than 1 year of age has been published. This scoring system used neurological examination alone to determine affected versus non-affected foals and combined subjective determination of radiographic vertebral malformation and objective determination of canal diameter.[29] Vertebral canal stenosis is determined by measurement of intervertebral and intravertebral MSD. Dividing the MSD by the length of the vertebral body corrects for magnification. Malformation is determined by the subjective assessment of five categories. The most discriminating factors in the semi-quantitative scoring system in differentiating affected from non-affected foals are canal stenosis and the angle between adjacent vertebrae. The disadvantage of the semi-quantitative scoring system is the inclusion of subjective determinations.

Myelographic examination is advised to obtain the best evidence of compression.[1,31-33] Myelograms also can demonstrate compression from soft tissue masses, which are not evident on radiographs, and suggest transverse compression. However, myelography may not be definitive and occasionally is misleading. A study to evaluate myelography critically and compare the results with necropsy findings in a large number of horses has not been done. A diagnosis of cord compression is assumed if a 50% reduction in the width of the dorsal dye column exists. However, the diagnostic criterion of 50% decrease in width of the dorsal dye column is not well documented[32] and has been found in horses with no histological evidence of cord compression at the site of dye column decrease. Iohexol is currently the preferred contrast medium for myelography. It is important that the owner understands the advantages and disadvantages (including risks) of a myelogram before the procedure is undertaken.

Electromyography and Nerve Conduction Studies

Recording electrical activity of muscles can indicate whether evidence of denervation or a myopathy exists, although the distinction is not always clear-cut. Electromyographic examination in the early stages of disease or injury may be normal. Certain abnormal patterns can indicate denervation. However, depending on the specific areas to be examined, electromyography may require anesthesia or heavy sedation. It may be helpful in identifying abnormal muscles and indirectly the affected nerves. In a standing, awake horse, spontaneous muscle movement can hinder interpretation.

Values for sensory and motor nerve conduction velocities in horses and ponies have been reported.[34-37] Differences in speed of conduction occur in different nerves and horses' sensory nerve conduction velocities are slower than those of ponies.[37] However, similar motor nerve conduction velocities have been reported for the median and radial nerves of ponies and horses.[35] Location of the segment being measured may be important, because distal tapering of nerves may be associated with slower velocity. Skin temperature significantly affects nerve conduction velocity,[37] and variability in technique can alter findings. Slower motor nerve conduction velocities were reported in horses older than 18 years of age.[34] The procedure usually requires the horse be anesthetized and, similar to electromyography, should be performed by a skilled person. The technique mainly has been used in research.

Nuclear Scintigraphy

Nuclear scintigraphy has been helpful in identifying lesions in the thoracic and lumbar spinal column and pelvic areas not readily evaluated by radiography. It also has been used to evaluate vertebral changes identified radiographically, to determine whether active bone change has occurred. It has revealed hairline fractures and other unsuspected bone lesions in the appendicular skeleton as the cause of gait deficits, which sometimes had been suspected to be caused by spinal cord disease. Scintigraphic imaging from both sides of the horse can differentiate which side may have a lesion. The role of nuclear scintigraphy in diagnosing equine spinal cord disease is limited.

Ultrasonography

Ultrasonography has been used to diagnose aortoiliac thrombosis and to identify soft tissue masses near the spine or deep within muscles. It has also revealed bony proliferation or fractures of the pelvis in horses with obscure gait deficits, which were originally suspected to be due to spinal cord disease.

Virus Isolation

If horses die or are euthanized with neurological signs thought to be caused by viral disease, the spinal cord, brain, or both should be sent for virus isolation. In horses with acute disease, nasal swabs and whole blood samples can be collected.

Immunohistochemistry and Polymerase Chain Reaction Testing

Immunohistochemistry and PCR testing can be used to detect the antigen of certain infectious organisms and are applied most commonly to tissues collected at necropsy but can also be used on affected tissues obtained by biopsy.

SPECIFIC DISEASES AND SYNDROMES

Equine Protozoal Myelitis

EPM was first reported in 1974[38-41] and appeared to be the same condition originally reported as segmental myelitis of unknown cause.[42] It is caused by infection with *S. neurona*. EPM currently appears to be limited to the Western hemisphere. It is particularly of concern in the United States, where in some regions a high percentage of horses are infected. The actual number of horses confirmed as having neurological disease from EPM is much lower than the actual number of horses infected, but the disease does have a substantial and serious impact. EPM has not been confirmed in horses younger than 6 months of age, although antibodies were detected in serum from a 2-month-old foal.[43] A recent comprehensive review of this disease should be consulted for details.[44] *Neospora* species have been identified as a cause of EPM in horses from the western United States.[45-48] CSF testing was positive for *S. neurona* antibodies by Western blot test, and no antemortem features distinguished *Neospora* infection from *Sarcocystis* infection.

The disease caused by *S. neurona* tends to occur in warm, temperate, non-arid areas with resident opossums. The horse is a "dead-end" host and the disease is not contagious. The life cycle is not completely understood, although opossums have been identified as the definitive host. The proportion of infected horses that show clinical signs is low. This disease can cause gait deficits affecting one or all limbs and may be difficult or impossible to differentiate from musculoskeletal or other neurological diseases. Signs ascribed to EPM by veterinarians in the United States have been seen in horses in the United Kingdom, where horses have no known exposure to the organism.[1] Infected horses and horses with confirmed EPM seen in Europe, Asia, or South Africa have been imported from the Western hemisphere.[44] Horses frequently show asymmetrical deficits and may have focal or multifocal muscle atrophy or cranial nerve deficits. Horses may have profound or mild motor or proprioceptive gait deficits, and onset of signs can be acute or chronic, with slow or rapid progression. It may be difficult or impossible to differentiate subtle neurological deficits from those caused by subtle lameness or musculoskeletal pain. Behavior may change. Focal sweating

may occur. Diagnosis is based on clinical signs and history, by eliminating other potential causes by radiography and other diagnostic tests, and by testing of serum or CSF for antibodies to *S. neurona*. No definitive antemortem test exists, although absence of serum antibodies to *S. neurona* makes it highly unlikely that a horse has EPM. If a horse demonstrates classic signs (e.g., asymmetrical motor deficits and muscle atrophy in the hindlimbs, asymmetrical motor deficits in one or more limbs, a limb deficit combined with cranial nerve deficits not deemed caused by peripheral nerve trauma) and has no other organ dysfunction, we would treat the horse for EPM if it has been in the United States and serological findings are positive. We would forgo CSF testing for reasons outlined earlier.

To date, drugs used to treat EPM have been a combination of trimethoprim sulfa (sulfadiazine or sulfamethoxazole) and pyrimethamine, or sulfas and pyrimethamine, diclazuril, toltrazuril, and nitazoxanide. Because no definitive antemortem test exists to confirm the disease, evaluation of response to therapy is problematic, especially because the clinical syndrome as treated is so variable and often poorly defined. To date, no treatment trials of experimental infections have been reported. Confounding assessment of drug response is the fact that experimentally infected horses develop clinical signs that decrease over time, despite receiving no treatment.[49] Numbers of organisms ingested, virulence factors, and the horse's own immune status (which depends on heredity, previous exposure to *S. neurona*, stresses such as transport and parturition, lack of adequate nutrition, and other factors) all presumably can affect development of and recovery from the disease. In the United States the most widely used drug combination is one of the sulfa drugs and pyrimethamine. Because pyrimethamine reaches higher concentrations in the CSF and neural tissue, it is considered superior to trimethoprim. The usual dosage regimen is 20 mg/kg of sulfadiazine once or twice daily and 1 mg/kg of pyrimethamine once daily, both by mouth for at least 2 to 3 months. Diarrhea occasionally occurs in horses treated with trimethoprim-sulfamethoxazole, and anemia and leukopenia have been observed in some horses receiving 1 mg/kg twice daily of pyrimethamine with sulfas. Whether horses require such a prolonged course of treatment or continued high levels of pyrimethamine is unknown. Earlier treatment regimens used a lower dose, but to our knowledge no observations comparing dosages have been reported. A syndrome of bone marrow aplasia and hypoplasia, renal nephrosis or hypoplasia, and epithelial dysplasia was reported in three foals born from mares given sulfonamides, trimethoprim, pyrimethamine, vitamin E, and folic acid during gestation. The authors of that report suggested that administration of the folic acid reduced absorption of active folic acid and combined with the folic acid inhibitors (trimethoprim and pyrimethamine) induced folic acid deficiency and lesions in the foals.[50] We do not routinely add supplements for horses being treated with trimethoprim or pyrimethamine, but if sequential blood tests indicate anemia or leukopenia, the horse should be given folinic acid, a form of bioactive tetrahydrofolate. Folic acid should not be used because it is poorly absorbed in the horse, conversion to its active form is prevented by the dihydrofolate reductase inhibitors pyrimethamine and trimethoprim, and it can competitively decrease absorption of the active form of folic acid.[44,50]

Diclazuril, a coccidiostat, has anti–*S. neurona* activity in cell cultures infected with *S. neurona*[51] and has been used to treat horses with suspected EPM.[52] It is absorbed quickly after feeding. Dosage and therapeutic efficacy is being evaluated. Toltrazuril, like diclazuril, is a triazine-based anti-coccidial drug. Because the drug has good lipid solubility and oral absorption and is absorbed into the CSF, it has potential for treating EPM.[53] Ponazuril, a metabolite of toltrazuril, has in vitro activity against *S. neurona*,[54] and the latter appeared to have favorable clinical results in a multicenter treatment study.[44]

Nitazoxanide kills *S. neurona* in cell cultures and has been tested in a field trial. Safety studies showed lethargy at twice the recommended dose and illness and death at four times the recommended dose. In seven horses with clinical signs compatible with EPM and positive immunoblot results for *S. neurona* antibodies in the CSF, clinical signs improved in six horses by the end of the trial (85 to 140 days).[55] Clinical signs recurred in two horses when treatment was stopped, but signs improved when treatment was re-initiated. Another report described two horses with a diagnosis of EPM that improved after 28 to 42 days of treatment with 50 mg/kg nitazoxanide once daily.[56] Anorexia and depression were reported as side effects.[56] The CSF remained positive for *S. neurona* antibodies. Until more information is available about this drug, we do not recommend its use.

To our knowledge, no evidence shows that concurrent use of immune stimulants, oral anti-oxidants, and anti-inflammatory drugs has any beneficial effect. The use of corticosteroids is controversial, because some clinicians claim corticosteroid administration can exacerbate infection. Severity of neurological signs in horses infected with *S. neurona* reportedly was increased by corticosteroids,[57] but in another study of induced disease, signs were less severe in horses given corticosteroids.[58]

Providing an accurate prognosis is difficult, given the inherent diagnostic problems. Some horses that recover or respond to treatment may not have EPM, and others may recover spontaneously. Economic factors influence duration of treatment and time allowed for convalescence. Even when a severely affected horse improves dramatically, if recovery of function is not complete, a return to previous performance levels is not possible. Signs also may recur in the same horse; whether this is caused by recrudescence of infection or re-infection is unknown. We usually give a guarded prognosis for full recovery of horses showing moderate gait deficits compatible with EPM.

Because the exact life cycle and natural intermediate hosts are unknown, definitive recommendations for control of the disease are difficult. Because the opossum is the definitive host and sheds sporocysts, which the horse ingests, fecal contamination of feedstuffs or water sources by this animal should be prevented. The role of other intermediate mammalian hosts is unclear. The efficacy of a recently introduced vaccine remains to be determined.

Cervical Spinal Cord Compression

Cervical vertebral malformations of various types have been described as the cause of cord compression and neurological signs.[1,59,60] Occasionally it may be difficult to decide if a horse is mildly affected with cervical cord compression or is bilaterally lame in the hindlimbs. Mildly affected horses may show only a slightly stiff, stabbing gait at a walk and trot, only mild circumduction of the outside hindlimb when turning, and equivocal hindlimb dysfunction at a canter. Horses with bilateral osteochondrosis dissecans of the hocks or stifles may show similar signs but usually also have joint capsule distention. Thorough lameness and neurological examinations and radiographs are needed. With more severe compression, the gait deficits increase. Circumduction may be severe, and the horse may strike the distal limb with the opposite hoof, causing hair loss or wounds from interference. A horse may lose balance or fall, especially when backing up or turning. If the caudal cervical spinal cord is compressed, thoracic limb motor deficits and hypometria, frequently asymmetrical, may occur. The horse may severely scuff or drag its toes and have abnormal hoof wear. Occasionally, substantial bony proliferation at the

synovial articular facets can result in neck stiffness and decreased ability to turn in one direction. Cervical muscle atrophy is rare but can occur if the nerves or lower motor neurons are affected. An affected horse usually lacks hindlimb impulsion and may have a somewhat stiff, bouncy canter. The horse frequently is imprecise when stopping, and the hindquarters may sway or bounce. When compression of the cranial cervical spinal cord occurs, the horse may hold its neck and head higher than normal, in an extended position, and in horses with severe clinical signs all limbs may be affected. Signs may occur suddenly or have a more gradual onset, and progression is variable.

Various vertebral abnormalities have been reported in young horses, but clinical signs can be delayed, even when radiographs reveal chronic lesions. We suspect that trauma may cause a pre-existing lesion to become clinically relevant. If a horse with vertebral malformation falls, acute spinal cord compression can occur. Acute cervical spinal cord compression caused by trauma can cause tetraparesis or recumbency, but signs may be delayed in the initial stages after injury and may become apparent only when muscle spasms subside, the unstable fracture displaces, or progressive hemorrhaging is present. In the neck the occipito-atlantoaxial and caudal cervical regions are predilection sites for spinal cord injury.[1] Synovial cysts may also cause severe sudden signs of spinal cord compression, often asymmetrical and sometimes intermittent.[1] The diagnosis of synovial cysts is usually made at necropsy.

Diagnosis of cervical cord compression is based on radiography and myelography. Numerous types of vertebral abnormalities have been described. Management depends on the nature of the lesion, severity of clinical signs, intended use of the horse, and financial considerations. Horses affected with cervical vertebral malformation and cord compression at less than a year of age may improve when exercise and energy intake are restricted.[61] Although no controlled studies of a paced diet and restricted exercise program have been conducted, clinical experience supports its use in young horses with radiographic evidence of cervical vertebral malformation.[1,61] This treatment is not helpful for young horses with very severe stenosis, for defects such as occipito-atlantoaxial or other cranial cervical malformations, or for older horses. Prognosis with conservative management is poor. Surgical fusion of vertebrae is indicated in some horses and has been used successfully.[60,62,63] This subject is discussed in Chapter 62.

Equine Degenerative Myeloencephalopathy and Neuroaxonal Dystrophy

Horses mildly affected with equine degenerative myeloencephalopathy and neuroaxonal dystrophy may be misdiagnosed as being lame. Clinical signs may be somewhat similar to those of cervical spinal cord compression. Because no definitive antemortem test exists, clinical diagnosis is based on clinical signs, sometimes supported by the presence of other affected horses on the same farm or in the same family.

Equine degenerative myelopathy is thought to be a vitamin E deficiency, with a likely genetic predisposition.[64,65] Neuroaxonal dystrophy appears to have a genetic basis in Morgan horses.[66] Various breeds and also Przewalski's horses and Zebras can be affected, and no geographical restriction is apparent. When horses are affected at a young age (i.e., < 6 to 12 months old), signs are more severe and progressive than when signs are first noted in horses 2 years old or older. However, because signs can be mild and only slowly progressive, owners may not be aware of the abnormality. When a severely affected horse is identified on an individual farm, other more mildly affected horses are often found on the same premises or among relatives. Signs tend to be most noticeable in the hindlimbs. Affected horses usually lift the hind feet too high and slap them down on the ground and frequently lift the hoof toward the midline and then place it more laterally. The gait is jerky and asynchronous and sometimes ataxic, with excessive sideways sway of the hindquarters. Interference may occur, with a hind hoof hitting the opposite hind fetlock or pastern region. The horse may have a jerky foot placement when stopping and may pivot on the hindlimbs when turning. Severely affected horses may show forelimb ataxia and weakness of all limbs. The gait lacks impulsion. Occasionally, middle-aged horses are examined because of inability to perform at collected gaits with impulsion and precision. No musculoskeletal cause is found, but the hindlimb gait is characteristic of mild equine degenerative myeloencephalopathy or neuroaxonal dystrophy. Mildly affected mature horses appear to function without substantial progression of signs. No ancillary diagnostic test confirms the disease. Vitamin E supplementation (5000 to 6000 units by mouth daily) has been used to treat affected horses, with some, but not total, improvement reported.[67] Horses at risk for the disease should be given vitamin E supplements. Supplementation on farms with a number of affected horses was associated with a subsequent decrease in the incidence of disease.[64] Mares and foals should have access to grass pasture, because lack of access to green pasture has been identified as a risk factor.

Equine Lower Motor Neuron Disease

Equine lower motor neuron disease has been diagnosed in many countries.[68] Older horses and those lacking access to green pasture appear to be at risk to develop equine lower motor neuron disease. The disease is thought to be caused by deficiency of antioxidant activity in the central nervous system, leading to degeneration and loss of lower motor neurons in the brainstem and spinal cord.[69] Affected horses lose muscle mass and have generalized muscle trembling, which may be more severe in the triceps and quadriceps and is exacerbated by transport. Other clinical signs include stiffness, shifting of weight between the hindlimbs, standing with all feet excessively under the body, excessive sweating, holding the tail elevated and trembling, long periods of recumbency, and sometimes excessively low head carriage. Trembling disappears when the horse lies down. Although the gait may be choppy, the horse has no lameness or ataxia. Horses move better than they stand, and therefore the condition is unlikely to be confused with lameness. Muscle atrophy may be profound. Ophthalmoscopic examination of horses with chronic equine lower motor neuron disease may reveal abnormal pigment deposition in the tapetum with a horizontal band of pigment at the tapetal-nontapetal junction.[70] Diagnosis is based on clinical signs and low serum vitamin E concentrations in unsupplemented horses or biopsy of the sacrocaudalis dorsalis medialis (dorsolateral coccygeal) muscle. Affected horses that have not been given vitamin E usually have serum vitamin E concentrations less than or equal to 1 μg/ml.[71] Biopsy of a branch of the spinal accessory nerve, which had a high specificity and sensitivity in diagnosis of equine lower motor neuron disease, has been replaced by the muscle biopsy, which is technically much easier, can be performed in the standing horse and has a similar diagnostic specificity and sensitivity.[72] However, false-positive test results can occur in horses that have had "tail blocks."[72] The dorsolateral coccygeal muscle is ideal for biopsy because it contains a high percent of type I oxidative fibers, which are the main muscle fibers affected in the disease. Other muscles with a high proportion of type I fibers are not accessible for biopsy. Most limb muscles have high percentages of type II fibers and are not suitable for diagnosis of the disease.

Oral vitamin E supplementation (6000 to 10,000 units by mouth daily) improves horses, and green pasture is also helpful. However, athletic ability may remain impaired.[69]

Equine Herpes Virus I Infection

Neurological disease caused by EHVI can occur in individual horses or as an outbreak. Ataxia is variable but usually symmetrical. The hindlimbs are more severely affected, and recumbency can occur. Signs occur acutely and usually stabilize within 24 to 48 hours. Because this condition is unlikely to be confused with lameness, it is not discussed further and readers are referred to a review.[1]

Miscellaneous Diseases of the Spinal Cord

Spinal cord disease from migrating parasites could manifest as an asymmetrical gait deficit. Incidence appears to vary geographically, and clinical signs reflect the path of migration. Antemortem diagnosis is usually not possible, although eosinophilia in the CSF supports the diagnosis. Various parasites including *Setaria* species, *Halicephalobus (Micronema) deletrix*, *Hypoderma*, and *Strongylus* species have been identified. Treatment includes anti-parasitic and anti-inflammatory drugs.

Vertebral osteomyelitis, neoplasia, and diskospondylitis are rare causes of spinal cord disease. Signs reflect location of the lesion, which may be confirmed by radiography or scintigraphy. CSF may reflect the disease condition if it extends through the dura. Traumatically induced diskospondylitis has been described and may be difficult to differentiate from bacterial diskospondylitis.[1,73] Spinal cord traumas may occur directly or from instability of intervertebral joints. External trauma can affect any horse, and clinical signs reflect the site of the lesions. Three predilection sites for injury are the occipito-atlantoaxial region, the caudal cervical region (the fifth cervical to the first thoracic vetebrae) and mid-thoracolumbar region.[1] Clinical signs may initially be mild or peracute, and some horses develop severe progressive signs. It is often not possible to perform an adequate or accurate neurological examination or form a prognosis on an acutely injured horse. Initial treatment includes first aid care, sedation if needed, and the administration of analgesics, anti-inflammatory drugs, and mannitol. Radiographs can be useful, depending on site of injury and size of the horse. Repeated neurological evaluations are used for prognosis.

Peripheral Nerve Injuries

Except for stringhalt and radial nerve injury, peripheral nerve diseases affecting the gait are rarely diagnosed. Suprascapular nerve injury *by itself* does not alter the gait but results in atrophy of the supraspinatus and infraspinatus muscles ("sweeney").[74-76] However, injury to the nerve usually occurs with more general trauma to the region such as a collision or fall. This type of injury frequently can lead to damage to other nerves of the limb and soft tissue structures. If other nerve roots of the brachial plexus are simultaneously damaged, the shoulder joint may be unstable and subluxate laterally. The horse may circumduct the limb during protraction. Rest and anti-inflammatory drugs are usually used. Several surgical procedures have been advocated for suprascapular nerve injury.[77]

Radial nerve paresis or paralysis is recognized, usually secondary to trauma. Horses with radial nerve paralysis cannot flex the shoulder joint or extend the elbow, knee, fetlock, or interphalangeal joints. The dorsum of the toe rests on the ground, and the elbow is dropped. Severely affected horses have difficulty rising and often collapse on the limb if it bears weight. More mildly affected horses may advance the leg by flinging or jerking it forward from the shoulder. Evaluation of skin sensation may not be helpful. Atrophy of the triceps and other limb extensor muscles occurs after 2 weeks, and denervation potentials can be found on electromyographic examination 3 to 4 weeks, or sooner, after radial nerve injury.[77,78] Because of the difficulty of knowing whether the gait deficits are due solely to radial nerve injury or muscle damage, an accurate prognosis can be difficult in horses with acute clinical signs. Signs of radial paralysis occurring after recumbency or general anesthesia are probably caused by ischemic myopathy, with possible ischemic neuropraxia, and these horses generally recover. Prognosis depends on the cause and extent of radial nerve injury, neither of which may be identified. Prognosis is obviously better in horses that are less severely affected and those that show early signs of improvement. However, some severely affected horses completely recover. Prognosis is worse if rapid severe atrophy of extensor muscle occurs. Signs of radial nerve dysfunction can also occur from lesions in the caudal cervical and cranial thoracic ventral gray matter, but other signs of spinal cord disease usually coexist, especially in EPM. Physical therapy, including splinting to avoid flexor deformity, is very important, and electrical stimulation of muscles may also help prevent atrophy. Irreversible fibrosis and contracture are likely without intervention.

Lesions in the nerves supplying the flexor muscles of the thoracic limb are extremely rare, although signs of dysfunction can accompany brachial plexus or spinal cord lesions.[75] If the ulnar nerve is sectioned, the horse may move its foot in a jerking fashion with decreased flexion of the fetlock and carpal joints. When the median nerve is cut, the horse drags the toe because of decreased flexion of the fetlock and carpus. Hypalgesia of the medial pastern occurs, whereas with ulnar neurectomy, hypalgesia of the lateral metacarpal region occurs.[75,77] After neurectomy of the proximal musculocutaneous nerve, the horse drags its toe because of decreased elbow flexion. Since natural disease syndromes affecting these nerves are not described, prognosis is difficult because gait deficits improve with time after neurectomy.[77]

If the femoral nerve is damaged, the horse cannot extend its stifle and rests the leg in a flexed position. The hip is lower than the opposite limb, and the horse cannot support weight normally or at all when walking. When both limbs are affected, the horse will appear crouched and have great difficulty rising. The patellar reflex is absent or depressed, and with time the quadriceps muscles atrophy. Damage to the nerve has occurred during anesthesia with horses positioned in dorsal or lateral recumbency (usually with the affected limb having been positioned uppermost) or after over-extension of the limb, pelvic or femoral fractures, or in association with space-occupying masses impinging on the nerve.[77,79,80] Lesions in the spinal cord ventral gray matter or nerve roots at L5 or L6 lumbar vertebrae can also cause signs of femoral paralysis. Complete neurological evaluation to detect other deficits may be difficult if signs of femoral nerve paralysis are severe. Because the condition is rare and rhabdomyolysis and postoperative myopathy can mimic the signs of femoral nerve damage, giving a prognosis is difficult. Anti-inflammatory drugs are usually used. Most horses with post-anesthetic femoral nerve paresis make a complete recovery.[80]

Signs of paresis or paralysis of the sciatic nerve can occur in horses with pelvic fractures, with deep muscle injections in foals, or with spinal cord lesions affecting the ventral gray matter or nerve roots of the fifth lumbar to third sacral nerves. Signs reflect flexor muscle weakness. The horse can support weight on the limb if the hoof is placed flat on the ground under the pelvis. Otherwise, the horse stands with the hock and stifle extended and the dorsum of the hoof on the ground behind it. When the horse walks, it drags or jerks the limb forward. With time all muscles distal to the stifle and those of the caudal thigh atrophy. The prognosis is very poor if the nerve is severed. If the fibular (peroneal) nerve is damaged (usually because of blunt trauma), the horse cannot extend the fetlock and interphalangeal joints or flex the tarsus normally. At rest it stands with the hoof behind it, resting on its dorsal surface. If the hoof is placed flat on the ground under

the horse, the horse can support weight. When the horse moves, it drags the foot cranially, then jerks it caudally, sliding it on the ground. Skin sensation is decreased over the front and lateral aspects of the tarsus and metatarsal region. With time muscle atrophy in the craniolateral crus can occur. Treatment involves support and protection of the distal limb. Electrical stimulation of muscles might help prevent muscle atrophy. Many horses recover with time. Gait had returned to virtually normal within 3 months of experimental transection of the fibular nerve.[77] Tibial nerve injury is uncommonly diagnosed, but a stringhalt-like gait has been described. When walking, the horse over-flexes the limb and drops the foot straight to the ground when it reaches the end of the cranial phase of the stride. The gastrocnemius muscle reportedly atrophies. The horse stands with the fetlock flexed or partly knuckled, the tarsus flexed, and the hip lower than that of the unaffected leg.[79] Obturator nerve damage, which can occur after foaling, results in signs varying from abduction or circumduction and stiffness of the affected limb when walking to paraplegia. Prognosis depends on severity of signs, whether both limbs are affected, and whether adequate supportive care can be provided.

Stringhalt is easily recognized with its exaggerated flexion of the hock, which can result in a bizarre hopping, jerking, and propulsive gait when both hindlimbs are affected (see Chapter 49). Horses may be so severely affected that they "freeze" in the abnormal position or are very reluctant or unable to move. They may strike the ventral abdomen with the hoof. The gait usually is worse when the horse is walking on a hard surface and when it is anxious or frightened. Horses with mild signs may show the exaggerated hock flexion only when backing, turning, or during the first few strides after walking from a standstill. Atrophy of the distal limb muscles may occur in horses with chronic stringhalt. Spasticity, toe scuffing, and stumbling of the thoracic limbs and left laryngeal hemiplegia have been described in some affected horses.[81,82] A distal axonopathy of peripheral nerves has been described.[83,84] The condition can be sporadic or occur in outbreaks. The cause frequently is unknown, especially when only one horse is affected. Outbreaks have been associated with particular pastures, and mycotoxins are a suspected cause.[81,82] Lathyrism can also be a cause. Phenytoin and baclofen have been used with some success to decrease clinical signs.[85,86] Tenectomy of the lateral digital tendon has also been used. The course is variable and some horses recover spontaneously. However, because it is difficult to predict which horses will recover, the prognosis is guarded, especially in horses with severe clinical signs or in those which are and not associated with a pasture outbreak.

Shivers is somewhat similar to stringhalt, and the origin and pathogenesis are unknown (see Chapter 49). Affected horses tremble one or both pelvic limbs, primarily when backing up or lifting a hoof, and they elevate the tail. Some affected horses cannot stand to have the hooves trimmed, even though the hindlimb gaits are relatively normal and otherwise functional. The clinical course seems variable, and the disease is thought to be progressive, at least in Draft breeds.[77] However, we have seen affected horses remain relatively static and functional, although hoof care can be difficult because of the inability to stand for the farrier. A group of horses exists with mild hindlimb deficits resembling a combination of stringhalt and shivers. Although they may continue to be functional for riding, the gait disability impairs the dressage performance. The cause usually is undiagnosed.

CHAPTER • 12

Unexplained Lameness

Sue J. Dyson

Lameness diagnosis is a never-ending challenge, even for an experienced clinician, since despite a logical and thorough investigation it still may prove difficult to reach a satisfactory conclusion. This chapter discusses some of the reasons that a definitive diagnosis may remain elusive. In some horses it may be possible to isolate the source of pain reasonably accurately, but it may not be possible to determine the cause of pain. In other horses the source of pain cannot be determined (see Chapter 100).

FALSE-NEGATIVE RESPONSES TO LOCAL ANALGESIC TECHNIQUES

A false-negative response to local analgesic techniques may occur for a variety of reasons, including the following:

- Inaccurate injection
- Inadequate time for the local anesthetic solution to be effective
- Failure to appreciate improvement in the lameness
- Very severe pain
- Failure to alleviate subchondral bone pain after intra-articular injection
- Extra-articular pain
- Aberrant nerve supply
- Failure, in an unshod horse, to appreciate the extent of foot soreness contributing to lameness
- Failure to appreciate the degree of lameness fluctuatation within an examination period

The following are common case examples:

1. It is misleading to conclude that pain does not arise from the centrodistal and tarsometatarsal joints and the central and third tarsal bones after a negative response to intra-articular analgesia of the centrodistal and tarsometatarsal joints. Intra-articular analgesia has only a limited ability to alleviate subchondral bone pain. In moderate to advanced osteoarthritis, subchondral bone pain is a significant contributor to pain. Hock pain may be missed if it is concluded that a negative response to intraarticular analgesia precludes the existence of hock pain and if there is a failure to desensitize the hock region using regional analgesia. It should also be recognized that perineural analgesia of the fibular and tibial nerves may only result in partial improvement in lameness associated with moderate to severe osteoarthritis of the centrodistal and or tarsometatarsal joints.
2. Laminitis, a fracture of either the distal phalanx or the navicular bone, and a subsolar abscess are all common causes of severe foot pain. Desensitization of the foot by perineural analgesia of the palmar (plantar) nerves at the level of the proximal sesamoid bones may have a negligible effect or result in only mild improvement in lameness. Foot pain in the hindlimb is often more difficult to alleviate than in a forelimb. If clinical signs point to foot pain, but apparent desensitisation of the foot fails to markedly alter the lameness, further investigation of the foot should be performed with other means (e.g., radiographic examination).

   The horse in Fig. 12-1 was admitted with suspected back pain, but showed obvious blateral forelimb lameness, with right forelimb lameness predominating. Digital pulse amplitudes were increased in the right forelimb, but there was no response to hoof testers. Nonetheless, the horse appeared clinically to have foot

The following are common case examples:

1. It is misleading to conclude that pain does not arise from the centrodistal and tarsometatarsal joints and the central and third tarsal bones after a negative response to intra-articular analgesia of the centrodistal and tarsometatarsal joints. Intra-articular analgesia has only a limited ability to alleviate subchondral bone pain. In moderate to advanced osteoarthritis, subchondral bone pain is a significant contributor to pain. Hock pain may be missed if it is concluded that a negative response to intraarticular analgesia precludes the existence of hock pain and if there is a failure to desensitize the hock region using regional analgesia. It should also be recognized that perineural analgesia of the fibular and tibial nerves may only result in partial improvement in lameness associated with moderate to severe osteoarthritis of the centrodistal and or tarsometatarsal joints.
2. Laminitis, a fracture of either the distal phalanx or the navicular bone, and a subsolar abscess are all common causes of severe foot pain. Desensitization of the foot by perineural analgesia of the palmar (plantar) nerves at the level of the proximal sesamoid bones may have a negligible effect or result in only mild improvement in lameness. Foot pain in the hindlimb is often more difficult to alleviate than in a forelimb. If clinical signs point to foot pain, but apparent desensitisation of the foot fails to markedly alter the lameness, further investigation of the foot should be performed with other means (e.g., radiographic examination).

   The horse in Fig. 12-1 was admitted with suspected back pain, but showed obvious blateral forelimb lameness, with right forelimb lameness predominating. Digital pulse amplitudes were increased in the right forelimb, but there was no response to hoof testers. Nonetheless, the horse appeared clinically to have foot

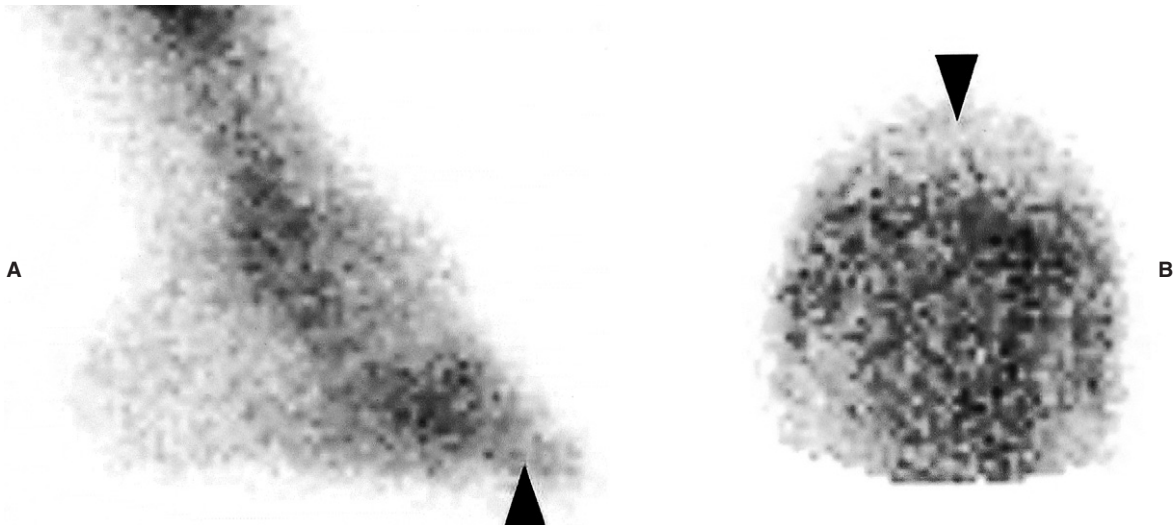

Fig. 12-1 **A,** Lateral and **B,** solar scintigraphic images of the front feet of a horse with suspected back pain but clinical signs of laminitis. There is reduced uptake of the radiopharmaceutical in the toe region *(arrows)*. The horse showed no improvement in lameness after apparent desensitization of the lamer right front foot by palmar (abaxial sesamoid) nerve blocks, despite the firm focal pressure applied with artery forceps around the coronary band. However, the horse responded well to symptomatic treatment for laminitis.

pain typical of laminitis. Apparent desensitization of the foot, performed to convince the owner that the horse had foot pain, produced absolutely no change in the lameness. The horse responded rapidly to treatment for laminitis.

3. Inadvertent intrasynovial injection may result in misleading results. For example, accidental injection into the tarsal sheath when attempting to deposit local anesthetic solution around the plantar metatarsal nerves distal to the hock may result in proximal suspensory lesions being missed.
4. Failure to allow sufficient time for local anesthetic solution to be effective may result in a false-negative response in some circumstances. Premature assessment of the response to intra-articular analgesia of the femorotibial joints may result in a false-negative result in association with a cruciate ligament injury. These ligaments have an extrasynovial location and it may take up to an hour after injection for cruciate ligament pain to be significantly improved.

Failure to allow sufficient time may in some circumstances result in a false-positive response and then confusion. The tibial and fibular nerves are relatively large, and it takes time for the local anesthetic solution to diffuse into them and take effect. This time requirement, combined with the deep location of the deep fibular nerve and thus difficulty in precisely locating the site for injection, may result in a response delayed for up to an hour after injection. Testing the efficacy of these blocks through evaluation of cutaneous sensation is unreliable. If the response is deemed to be negative after 30 minutes, and intra-articular analgesia of the compartments of the stifle is then performed and the lameness improves, it may be wrongly inferred that pain originated in the stifle. However, the improvement in lameness may reflect alleviation of pain arising from the hock region. Much wasted time and money may then be spent trying to establish a cause of stifle pain.

Blocking each compartment of the stifle joint separately (e.g., the medial femorotibial joint), may not result in substantial clinical improvement in the lameness, despite the presence of stifle pain. A considerably better response is frequently seen after blocking the medial and lateral femorotibial joints and the femoropatellar joint in combination.

The importance of the clinical examination and repeated observations of a horse cannot be overemphasised. Each clinician has to learn how much to trust nerve blocks. This depends on experience and the frequency of performing blocks. An inexperienced clinican is far more likely to encounter false-negative responses. The results of nerve blocks must be compared with the clinical signs, and if the interpretation is doubtful, the block should be repeated or the area desensitized with a different technique. The clinician must develop experience in the interpretation of improvement in lameness compared with complete alleviation of pain and lameness. This contrast depends to some extent on the degree of the baseline lameness and whether the forelimbs or hindlimbs are involved.

Failure to Perform the Appropriate Nerve Blocks

Failure to perform nerve blocks in a logical and complete sequence can lead to confusion. If the response to a low 6-point block in a hindlimb is negative and is followed by a positive response to tibial and fibular nerve blocks, the clinician may conclude that pain arose from the hock. Lesions of the proximal aspect of the suspensory ligament (SL) may be completely overlooked.

Blocking the Wrong Limb

Failure to appreciate that a head nod reflects hindlimb lameness and is not always a sign of forelimb lameness may result in a blocking a forelimb with negative results, when the primary source of pain is in the ipsilateral hindlimb.

Sources of Pain that Cannot Be Desensitized by Nerve Blocks

Many regions of the limbs proximal to the carpus and tarsus cannot be satisfactorily desensitized. In young horses, stress fractures are now well-recognized causes of lameness that in many circumstances cannot be blocked out. In young or older horses a fracture of the deltoid tuberosity of the humerus

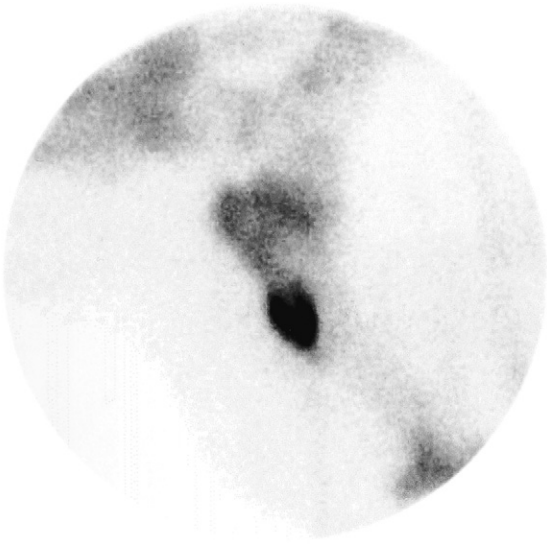

Fig. 12-2 Lateral scintigraphic image of the shoulder region of a 6-year-old Warmblood with acute onset of moderate right forelimb lameness. Note the marked focal increased uptake of the radiopharmaceutical in the region of the deltoid tuberosity of the humerus. There was a slightly displaced fracture of the deltoid tuberosity of the humerus, which healed satisfactorily with conservative management.

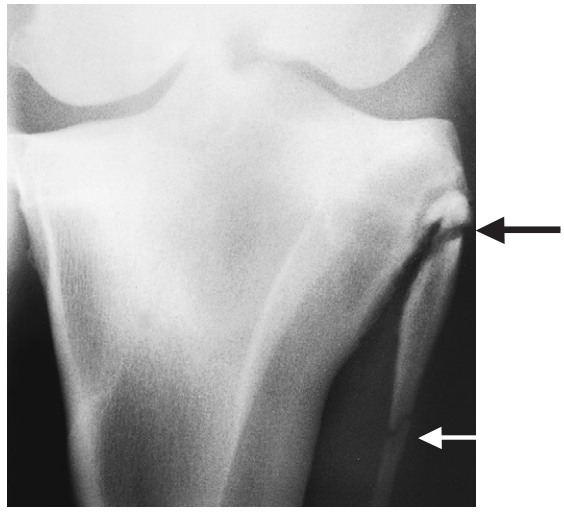

Fig. 12-3 Caudocranial view of the left stifle of a general purpose riding horse with recent-onset, episodic, and transient severe left hindlimb lameness. There is a fracture of the proximal aspect of the fibula *(large arrow)*. The lucent line separating the different centers of ossification further distally *(small arrow)* should not be confused as a fracture. There was little evidence of bony union after 6 weeks, but after 12 weeks the fracture healed satisfactorily.

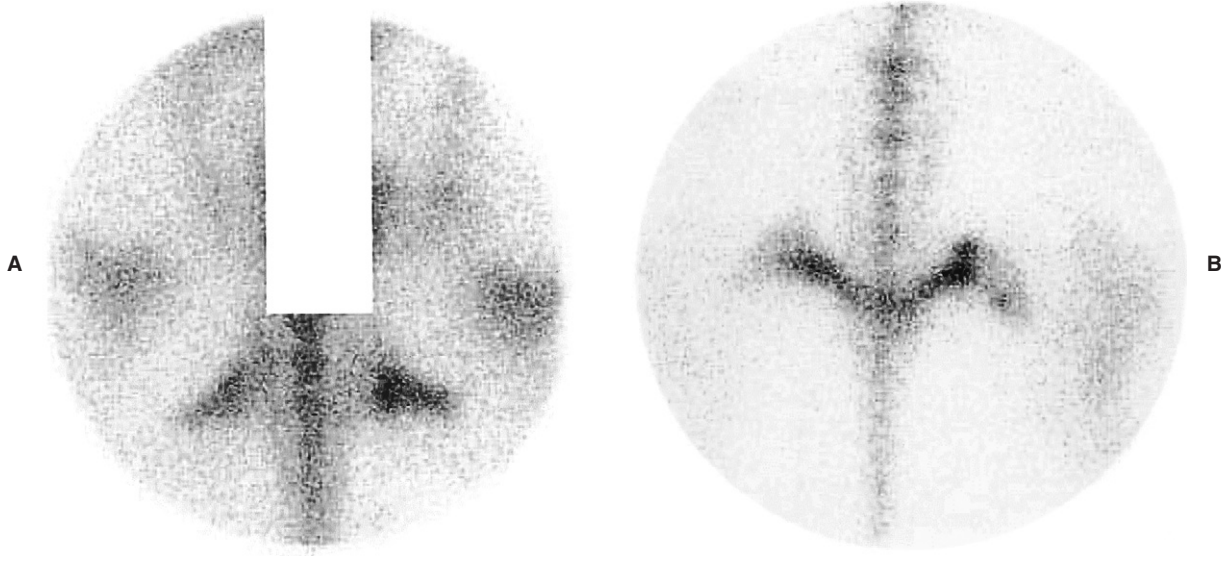

Fig. 12-4 **A,** Dorsal oblique and **B,** caudal scintigraphic image of the tubera ischii of an 8-year-old Grand prix show jumper with loss of hindlimb power and a tendency to jump to the right. There is increased uptake of the radiopharmaceutical in the right tuber ischium and a change of contour compatible with a fracture.

(Fig. 12-2), the proximal aspect of the fibula (Fig. 12-3), the third trochanter of the femur, and the tuber ischium (Fig. 12-4) are all causes of lameness that are unaffected by nerve blocks.

Muscle injuries, such as tearing or fibrosis of brachiocephalicus or the pectoral muscles, may have no localizing signs (see page 141). Associated lameness cannot be influenced by nerve blocks.

POTENTIALLY CONFUSING RESPONSES TO LOCAL ANALGESIC TECHNIQUES

Improvement without complete alleviation of lameness after perineural analgesia is not always easy to interpret. It may reflect failure to completely alleviate pain from a single source, or it may be due to additional sources of pain. Sometimes lameness improves with each successive block

(e.g., palmar digital, palmar [abaxial sesamoid], low 4-point, and subcarpal nerve blocks). However, the lameness is not associated with any detectable radiographic, ultrasonographic, or scintigraphic abnormalities. Sometimes further useful information can be obtained by performing intra-articular analgesia of the interphalangeal and metacarpophalangeal joints, but if the response is negative the diagnosis remains inconclusive.

Isolation of pain to a region but failure to define the cause is particularly frustrating. For example, intra-articular analgesia of the femorotibial joints may be positive, but no radiographic or ultrasonographic abnormalities may be detectable. Nuclear scintigraphy may reveal a generalized increased uptake of the radiopharmaceutical in the distal femur and proximal tibia compared with the contralateral limb. Medication of the joints may result in no improvement. Exploratory arthroscopy may reveal minor findings (e.g., mild fibrillation of the cranial meniscal ligaments) of questionable significance, but evaluation of all the joint surfaces and meniscal cartilages is impossible. The definitive diagnosis for the cause of pain remains elusive.

The importance of subchondral bone pain as a cause of lameness must not be overlooked. Such pain frequently is present without associated radiological change. A comparison of the responses to intra-articular analgesia and perineural analgesia (and the response to intra-articular medication) may be helpful. With subchondral pain, intra-articular analgesia may have a limited effect. Nuclear scintigraphy is a sensitive indicator of increased remodeling in the subchondral bone. Magnetic resonance imaging (MRI) has the potential to show subtle structural changes in the subchondral bone.

Until recently, soft tissue lesions within the hoof capsule have proved elusive to definitive diagnosis. Diagnostic ultrasonography, although possible, has marked limitations. Pool-phase scintigraphic images sometimes are helpful. Examination of the navicular bursa may yield useful information about the bursa, the deep digital flexor tendon, and the distal sesamoidean impar ligament. Advanced imaging techniques such as computed tomography and MRI have the best potential to demonstrate soft tissue pathological conditions, although determining the clinical significance of lesions is not necessarily easy.

False-positive results may be obtained if the horse is only mildly lame at investigation but has a history of a more obvious lameness. The detectable mild lameness may not necessarily reflect the original cause. Lameness that is induced when a horse is lunged in small circles on a concrete surface may not reflect the primary cause of lameness. Thus eliminating this lameness by nerve blocks may be misleading. Lameness induced by flexion also may not reflect the principal cause of lameness. Blocking the flexion response does not necessarily identify the primary cause of lameness.

A pony had moderate forelimb lameness that was markedly accentuated by lower limb flexion. The response to flexion was eliminated by either regional or intra-articular analgesia of the fetlock joint. However, the baseline lameness was unchanged and did not respond to any of the nerve blocks that were repeated on several occasions. Surgical removal of a large osseous fragment from the fetlock joint did not improve the lameness.

Multiple Sources of Pain in a Limb and More than One Lame Limb

Problems can arise in interpretation of nerve blocks in a horse that is lame in more than one limb, especially if there is more than one source of pain in a limb. Perineural nerve blocks usually last for up to 2 to 3 hours unless a long-acting local anesthetic agent, such as bupivacaine, is used. If a horse is lame in several limbs it is usually easiest to start with the lamest limb and block it first. Interpretation becomes difficult if there is a failure to desensitize all the lame limbs simultaneously. If the blocks in one limb are wearing off, then lameness in the least lame limb becomes less apparent. The horse's tolerance for nerve blocks may also compromise how much can be done. It may be necessary to start again on another occasion using bupivacaine. If simultaneous lameness of the ipsilateral forelimb and hindlimb is suspected, blocking should begin in the hindlimb. In this situation a substantial amount of the head nod probably originates from the hindlimb component. Because elimination of head nod is vital to improvement after blocking, forelimb diagnostic procedures cannot be fairly evaluated.

Very Low-Grade Lameness

Nerve blocks, especially in hindlimbs, often result in improvement rather than complete alleviation in lameness. Assessing improvement in subtle lameness is nearly impossible. If the horse has a history of more severe lameness previously, delaying further investigation often is worthwhile. The horse should be worked to accentuate the lameness and simplify interpretation of the response to local analgesic techniques.

Improvement of Lameness in Some Situations, but Unrelieved Lameness under All Situations: Which Is the Baseline Lameness?

Sometimes a horse has lameness that appears different in nature under different circumstances. Such findings may be related to more than one cause of lameness, and it is important to recognize this fact. For example, a dressage horse was admitted with left forelimb lameness that was only apparent to the rider when the horse was ridden on the right rein (to the right). Clinical examination revealed left forelimb lameness on the right rein on the lunge on a hard surface. This was alleviated by desensitization of the foot. However, desensitization did not alter the lameness that was apparent when the horse was ridden. The cause of the lameness could not be identified. It is vitally important to relate the results of the investigation to the history.

CHALLENGES TO LAMENESS DIAGNOSIS

Very Intermittent or Sporadic Lameness

Sometimes lameness is intermittent, and the horse may be perfectly normal between episodes. Lameness may be provoked only by maximal exercise in competition. It is very important to carefully assess the history and get the owner to pay great attention to any clinical features of the lameness when present. For example, mild, transient diffuse swelling in the midmetacarpal region medially may reflect axial impingement of a splint on the SL (Fig. 12-5) (see Chapter 73). Spontaneous resolution of hindlimb lameness after standing still is suggestive of aorto-iliaco-femoral thrombosis (see Chapter 52). Ask the owner to assess the reaction to manipulation of specific joints when the horse is lame. Pain on manipulation may suggest a joint problem such as hemarthrosis.

If it is not possible to examine the horse when it is lame, nuclear scintigraphic examination can be helpful but also has the potential to mislead (see page 141). For example, an Arab endurance horse had episodic right forelimb lameness that was present only immediately after rides longer than 30 miles. Comprehensive clinical evaluation revealed no evidence of lameness and no suggestions of the cause of previous lameness. Scintigraphic examination revealed increased uptake of the radiopharmaceutical in the third carpal bone of the lame limb (Fig. 12-6). Radiographic examination revealed marked sclerosis of the third carpal bone in the lame limb only, an unusual finding in an endurance horse and thought likely to be of clinical significance. Another Arab endurance horse had an acute-onset, severe right hindlimb lameness that resolved within

48 hours, but mild, extremely transient, and episodic lameness persisted over the next 3 weeks. Clinical evaluation revealed no suggestion of the cause and no current lameness. Nuclear scintigraphic examination revealed focal increased uptake of the radiopharmaceutical in the medial wing of the distal phalanx, and radiographic examination confirmed a recent fracture (Fig. 12-7).

If nuclear scintigraphic findings are negative, it is necessary to try to recreate the circumstances under which the horse exhibits lameness. For example, hemarthrosis can cause a very severe but extremely transient lameness. The horse may be completely normal between episodes. Diagnosis can be reached only by arthrocentesis at the time of acute episode, when there is usually some degree of joint capsule distention and pain on manipulation of the affected joint. Working the horse on a treadmill sometimes is helpful (see Chapter 101).

Lameness that Varies within and between Examinations

Sometimes lameness varies considerably in degree both within an examination period and between examinations. This variation makes interpretation of the response to nerve blocks potentially difficult, unless the veterinarian is aware of the fluctuation. It is important to watch a horse move for a sufficient length of time to appreciate any spontaneous changes in the degree of lameness. Horses with a subchondral bone cyst in either the distal scapula or the medial femoral condyle may behave in this way. Within a single examination period the horse may appear sound or lame. In such circumstances it is vital to compare the response to nerve blocks with the clinical signs exhibited. For example, if the characteristics of the lameness are suggestive of shoulder pain, but the lameness is apparently improved after desensitization of the foot, consider the possibility of spontaneous improvement in the lameness that is unrelated to the nerve block. This is, however, an unusual clinical situation, and generally it is best to rely on the results of the diagnostic blocks. A combination of nerve blocks, scintigraphic examination, and radiographic examination may enable a conclusive diagnosis to be reached.

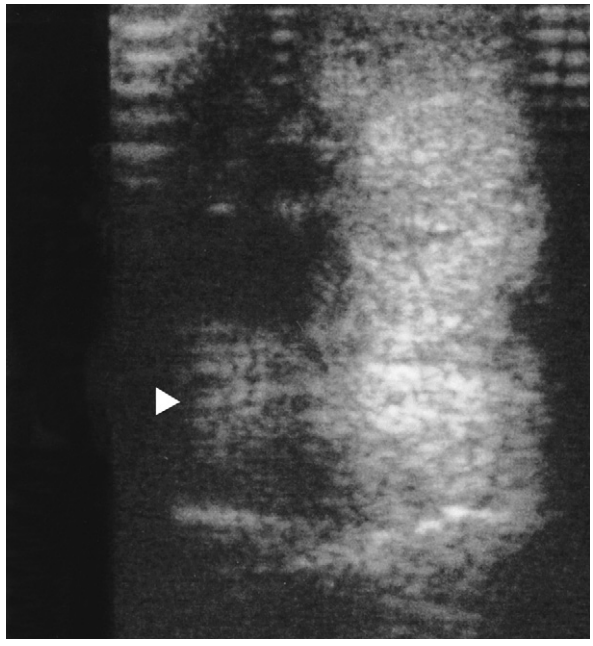

Fig. 12-5 Transverse ultrasonographic image of the palmar metacarpal soft tissues of the right forelimb of an endurance horse at 10 cm distal to the accessory carpal bone. Medial is to the left. The horse had low-grade lameness at the end of endurance rides that resolved completely within 24 hours. Note the echogenic tissue *(arrowhead)* next to the suspensory ligament (SL). This was a granulomatous reaction between an exostosis on the second metacarpal bone (McII) and the SL. The distal half of the McII was excised and the granulomatous tissue removed. The horse made a complete recovery.

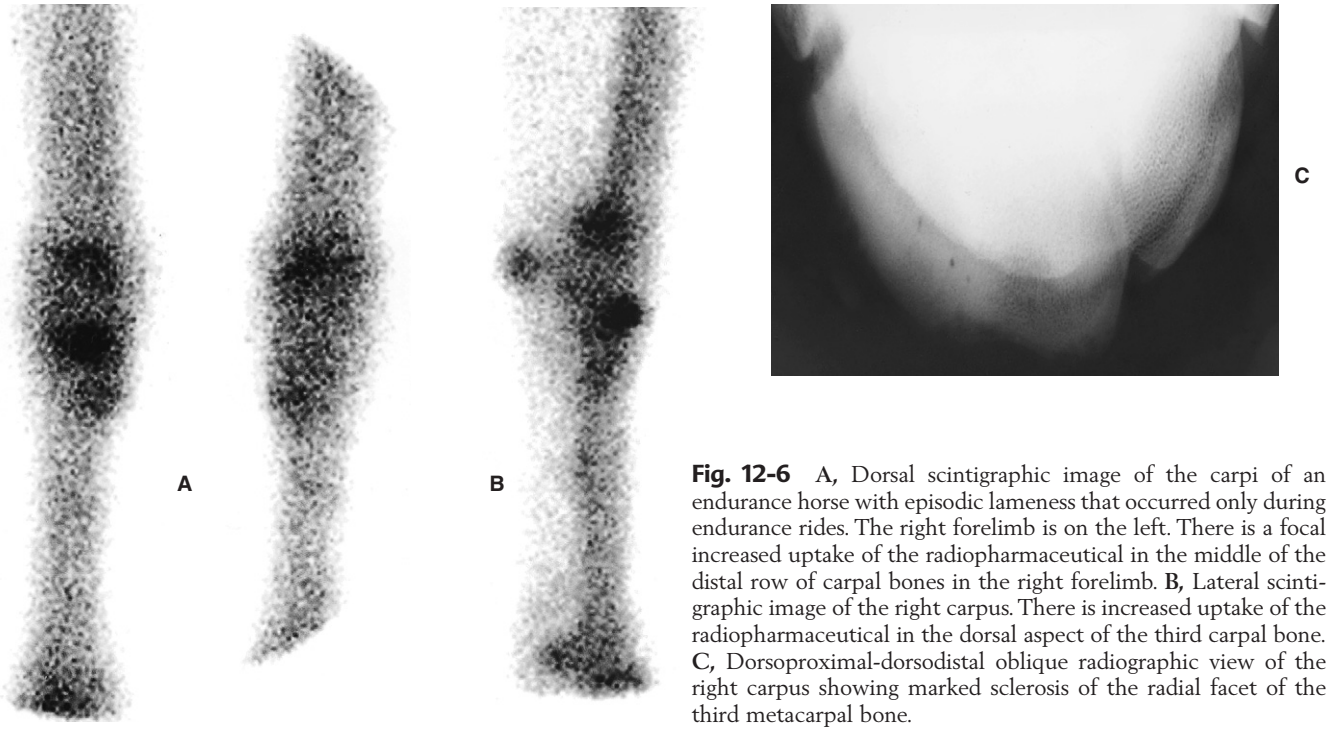

Fig. 12-6 **A,** Dorsal scintigraphic image of the carpi of an endurance horse with episodic lameness that occurred only during endurance rides. The right forelimb is on the left. There is a focal increased uptake of the radiopharmaceutical in the middle of the distal row of carpal bones in the right forelimb. **B,** Lateral scintigraphic image of the right carpus. There is increased uptake of the radiopharmaceutical in the dorsal aspect of the third carpal bone. **C,** Dorsoproximal-dorsodistal oblique radiographic view of the right carpus showing marked sclerosis of the radial facet of the third metacarpal bone.

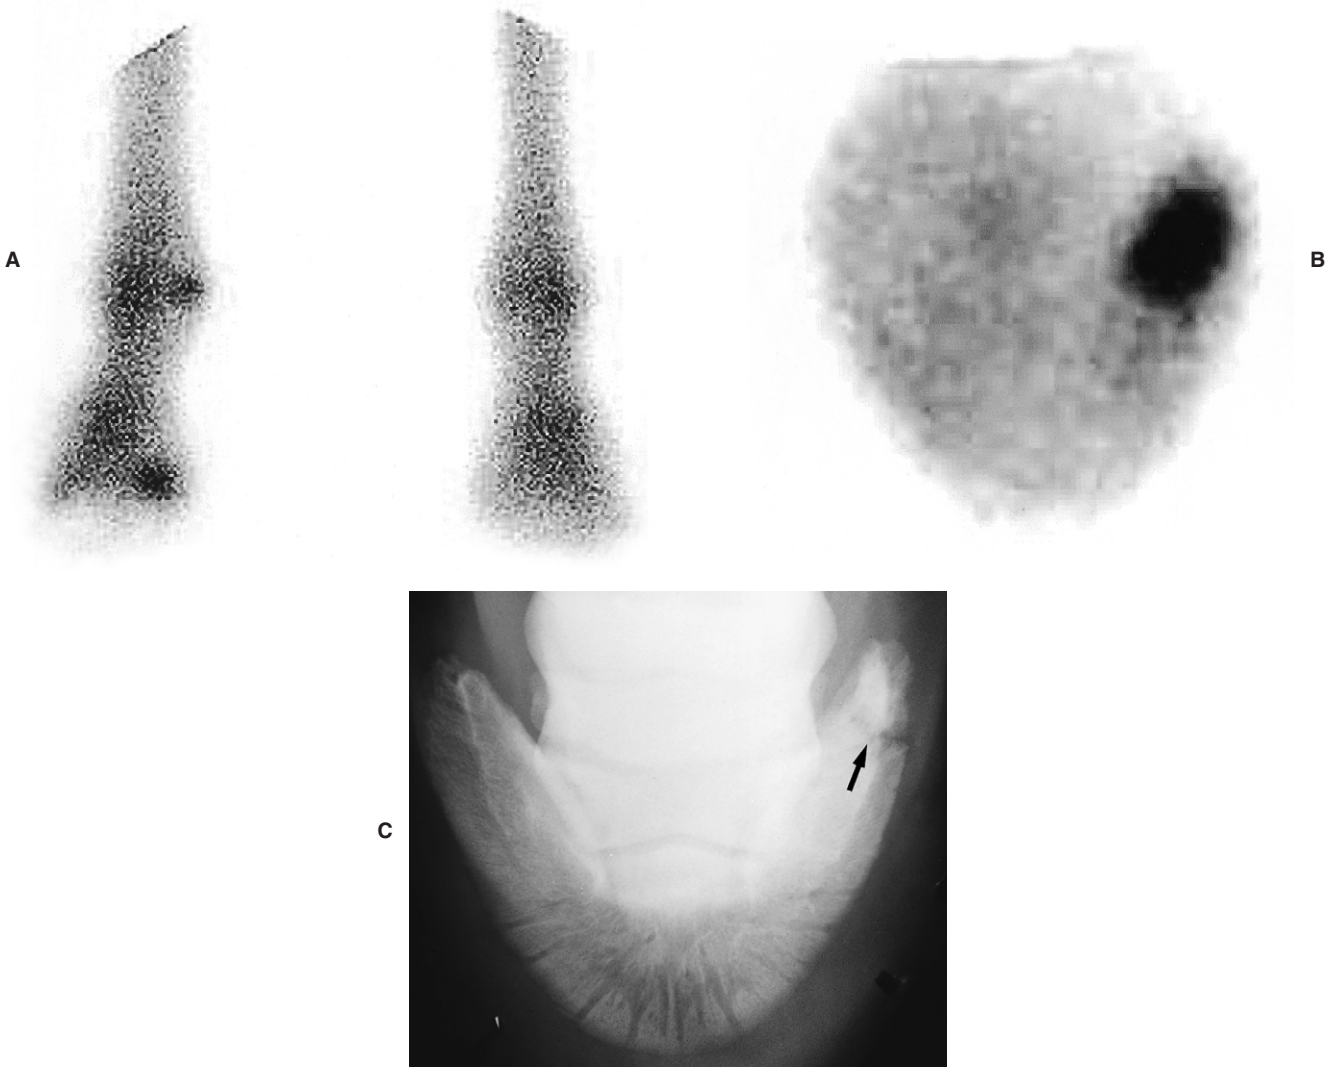

Fig. 12-7 **A,** Plantar scintigraphic image of the hind feet of an endurance horse with recent onset of left hindlimb lameness that was only apparent after an endurance ride. The horse appeared clinically normal at the time of the examination. There is moderate focal increased uptake of the radiopharmaceutical in the medial aspect of the left hind foot *(left)*. **B,** Solar scintigraphic image of the left hind foot. Medial is to the right. There is marked increased uptake of the radiopharmaceutical in the medial plantar process of the distal phalanx. **C,** Plantarodorsal radiographic view of the left hind foot. There is a fracture of the medial plantar process *(arrow)*. The horse was treated conservatively and made a complete recovery.

The Dangerous Horse and Nerve Blocks

Some horses do not tolerate needle placement and cannot be restrained safely. Nuclear scintigraphic examination sometimes indicates a diagnosis, but the results may be negative. Under such circumstances the horse can be sedated for each block. This approach obviously is time consuming and may be of low specificity, because time must be allowed for the sedative to wear off adequately before the response to the block can be assessed. During this time the local anesthetic solution has the potential to diffuse away from the site of injection and influence more remote pain. Sedation may result in a rather sloppy gait, which can hinder interpretation, especially with mild hindlimb lameness characterized only by a toe drag. Therefore patient selection is important. However, bearing in mind these limitations, it may be the only way to proceed. Xylazine is the shortest-acting α_2-agonist available and is the drug of choice, but with a difficult horse, combination with an opioid such as butorphanol may be necessary.

NEGATIVE RESPONSES

Negative Response to All Nerve Blocks: Where Next?

Occasionally a horse is evaluated for forelimb or hindlimb lameness that is not influenced by any local analgesic technique. Clinical signs may be suggestive of a source of pain (e.g., the foot). The reason for nerve blocks that result in apparent desensitization of a region but fail to eliminate or improve pain is not understood, but it does occur occasionally.[1] Alternatively, there may be no clinical clues for the source of pain. Nuclear scintigraphic examination may be helpful in either situation if the pain is bony in origin but is likely to be less helpful for soft tissue injuries.

Negative Responses to Nerve Blocks, No Clinical Clues, and Negative Scintigraphic Findings

Consideration may be given to systematic radiographic examination, bearing in mind that not all bony lesions are sufficiently active to yield positive scintigraphic findings. However, com-

prehensive radiographic examination is time consuming, expensive, and frequently unrewarding, and potentially results in unnecessary exposure to radiation. Thus it is usually discouraged. In the forelimb, unusual causes of lameness such as neurological disease (usually lower motor neuron diseases, such as equine protozoal myelitis), cervical nerve root pain (radiculitis), spondylosis of the cranial thoracic vertebrae, and pectoral, sternal, or rib pain may be considered. In the hindlimb, neurological disease and thoracolumbar or pelvic soft tissue injuries visible neither on pool nor bone phase scintigraphic images should be considered. Keep in mind that horses with forelimb or hindlimb lameness could potentially have a distant source of pain and comprehensive imaging (whole body bone scan, for instance) may be necessary.

NECK LESIONS AND FORELIMB LAMENESS

Forelimb lameness that is unassociated with primary limb pain has been recognized in association with bony lesions of the mid-cervical and caudal cervical vertebrae and the cranial thoracic vertebrae (see Chapter 55).[2] There are not necessarily any detectable clinical signs that can be related to the neck. In horses with confusing forelimb lameness, evaluation of the neck with radiography, scintigraphy, or both modalities is certainly indicated.

REFERRED PAIN

The concept of referred pain is well recognized in people but is more difficult in the horse. We must accept that referred pain originating from a lesion far removed from the lame limb may contribute to pain and thus cause lameness.

PREVIOUSLY UNRECOGNIZED CAUSES OF LAMENESS PROXIMAL TO THE CARPUS AND TARSUS

I think it is naive to consider that all potential causes of lameness proximal to the tarsus and carpus have been recognized. Injuries that primarily involve bone usually can be identified with nuclear scintigraphic examination. However, scintigraphy is rather insensitive in the identification of soft tissue injuries, although it may help identify some muscle injuries (Fig. 12-8). Muscles can be examined ultrasonographically, but we need to know where to look for damage. Acupuncture trigger point sensitivity may provide information. Use of muscle stimulators may help to identify superficial muscles that are damaged. We know that the horse can tear fibularis tertius, resulting in pathognomonic clinical signs. We do not know if minor injuries to this modified muscle could cause lameness. Tendonous and ligamentous pain without palpable abnormalities and therefore without a specific indication for ultrasonographic examination must always be considered. We must remain open-minded and search for other means of diagnosis.

MISINTERPRETED IMAGING FINDINGS THAT RESULT IN MISDIAGNOSIS

In horses in which the results of local analgesic techniques are equivocal or negative, it may be tempting to rely on the results of other diagnostic techniques, such as radiography, ultrasonography, and nuclear scintigraphy, without necessarily relating them to the initial clinical signs. Although these imaging modalities may help to confirm a clinical diagnosis, they also have the potential to mislead, especially if interpreted in isolation.

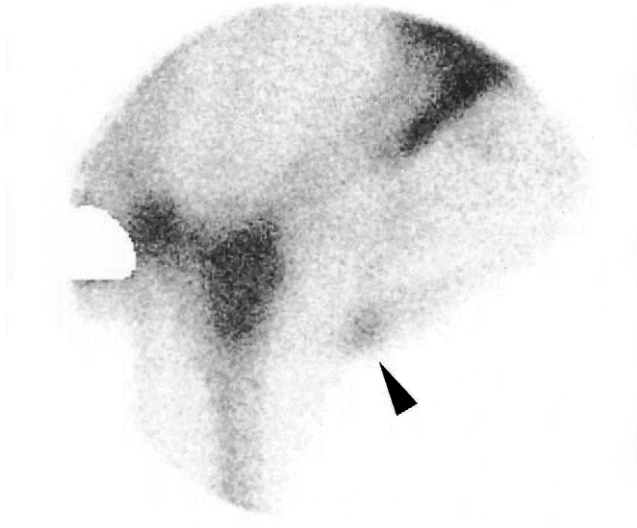

Fig. 12-8 Lateral scintigraphic image of the right elbow region of a 4-year-old Warmblood stallion with right forelimb lameness evident only at the walk, which was unaltered by any local analgesic technique. Uptake of the radiopharmaceutical was increased in the biceps brachii muscle *(arrow)*, which corresponded to an area of increased echogenicity compatible with fibrosis.

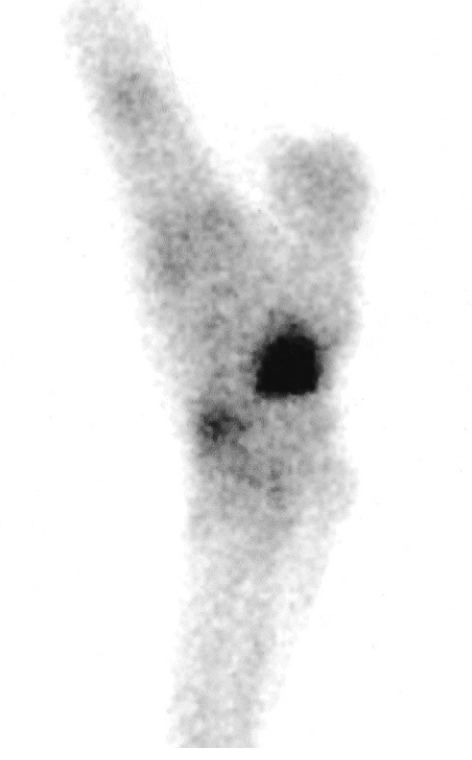

Fig. 12-9 Lateral scintigraphic image of the tarsus of a 7-year-old riding horse. Note the marked focal increased uptake of the radiopharmaceutical in the hock. Lameness was completely alleviated by desensitization of the fetlock region. There was no radiographic abnormality of the hock.

The horse illustrated in Fig. 12-9, with focal increased uptake of the radiopharmaceutical in the hock, was admitted with left hindlimb lameness that was alleviated by desensitization of the fetlock region. The horse illustrated in Fig. 12-10, which has increased uptake of the radiopharmaceutical in the distal tibia, was admitted with forelimb lameness. No hindlimb lameness

Fig. 12-10 Lateral radiographic view of the tarsus and tibia of a 12-year-old advanced event horse with bilateral forelimb lameness associated with distal interphalangeal joint synovitis. The horse had no history or evidence of hindlimb lameness and competed successfully thereafter. Note the intense increased uptake of the radiopharmaceutical in the tibia. The horse was reexamined approximately 8 months later with similar results. The horse had been competing successfully but had recurrent forelimb lameness.

was observed at any time, even after alleviation of the forelimb lameness. The horse in Fig. 12-11, with increased uptake of radiopharmaceutical in the region of insertion of the deep digital flexor tendon, had lameness associated with a fracture of the deltoid tuberosity of the humerus.

ODD LAMENESS APPARENT ONLY DURING RIDING

Some causes of lameness are apparent only when the horse is ridden. Some of these are easy to block, but a minority fail to respond to local analgesic techniques. Consideration must always be given to rider-induced lameness (see page 144 and Chapter 100), discomfort caused by tack, and gait abnormalities arising through thoracolumbar (see Chapter 54), sacral, and sacroiliac pain (see Chapters 52 and 53). The possibility of the rider's weight compressing muscles in the saddle and caudal neck region and nerve compression should be considered as potential causes of forelimb pain.

IDENTIFIABLE LESIONS: WHICH CONTRIBUTE TO THE CURRENT LAMENESS?

The presence of radiographic lesions is not necessarily synonymous with pain, or the pain may be low grade and not compromise the horse's gait sufficiently to be recognized by the rider. For example, a horse may have an acute lameness referable to the stifle. Several lesions may be identified radiographically (e.g., smooth flattening of the middle of the lateral trochlear ridge of the femur, modeling of the medial

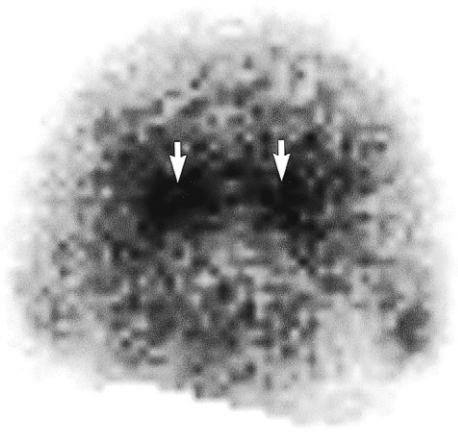

Fig. 12-11 Solar view of the right front foot of a 6-year-old Warmblood. There is increased uptake of the radiopharmaceutical in the region of insertion of the deep digital flexor tendon on the distal phalanx. The gait characteristics were typical of proximal limb lameness and lameness was unaltered by desensitization of the foot. The horse had a fracture of the deltoid tuberosity of the humerus.

articular margin of the tibial plateau, and a complete fracture of the proximal aspect of the fibula [Fig. 12-3]). It is likely that acute lameness is related to the fibular fracture. The horse in Fig. 12-3 had been coping despite radiographic evidence of both ostechondrosis of the femoropatellar joint and osteoarthritis of the medial femorotibial joint.

OTHER CAUSES OF LAMENESS

Lacerations and Occult Spiral Fractures

Acute-onset, moderate to severe lameness sometimes develops within 2 to 3 weeks of trauma to, or laceration over, a long bone (see Figs. 3-3 and 3-4). Sometimes lameness is first observed when the horse is still restricted to box rest and controlled exercise while the wound heals. There may or may not be any detectable focus of pain. Consideration must always be given to the possibility of an occult spiral fracture of, for instance, the radius, which was obviously sustained at the time of the initial injury. Occult spiral fractures are most common in the radius but can involve the third metacarpal or metatarsal bones and tibia. Radiographic examination should be performed to eliminate this possibility.

Rib Lesions

A fracture of one or more cranial ribs is a rather unusual cause of forelimb lameness that usually is a sequel to direct trauma, such as a collision with another horse or a gate post, or a fall. There are usually no localizing clinical signs, although secondary neurogenic muscle atrophy may develop within the next 10 to 14 days. The lameness may suggest an upper limb problem. Diagnosis is dependent on radiographic or scintigraphic identification of the fracture.

Sternal Injury

Sternal injury usually causes a change in behavior, such as a tendency to buck when first tacked up and mounted (i.e., extreme cold back behavior) rather than lameness. Frequently it is not possible to elicit pain by deep palpation.

Fracture of the Summits of the Dorsal Spinous Processes in the Withers Region

Acute fractures of the withers usually result in a very shortened forelimb stride and a tendency to move very closely in front ("the mini-skirt walk"). There is usually obvious palpa-

ble deformity of the withers region. Diagnosis is confirmed radiographically.

Temporomandibular Joint Pain

Pain associated with one or both temporomandibular joints may cause reluctance for the horse to take the bit properly, crookedness in the head and neck carriage, and secondary gait irregularities. The joints can be assessed by applying firm pressure over each joint, which may cause pain, and by opening the mouth and moving the upper and lower jaws relative to one another and assessing mobility. Thermography may be a sensitive indicator of local inflammation. If temporomandibular pain is suspected, further investigation can be performed using nuclear scintigraphic examination and diagnostic ultrasonography.[3] Radiography is relatively insensitive unless major bony changes are present.[4]

Neurological Problems and Lameness or Stiffness

Early compressive lesions of the cervical spinal cord can cause an apparent low-grade hindlimb lameness that is characterized by slight toe drag and asymmetrical movement of the hindquarters. Signs of weakness or ataxia may not be evident unless a comprehensive neurological examination is performed, especially if the horse is quite fit and fresh. Neurological signs may only be seen when the horse is tired and not compensating for its gait deficits.

Equine protozoal myelitis can cause rather bizarre forelimb or hindlimb gait abnormalities, either unilaterally or bilaterally. It should be considered in the differential diagnosis of odd gait abnormalities in horses that reside or have spent time in America.

Damage to the branch of the radial nerve, which results in an innervation of the extensor muscles of the carpus and digits, may cause a subtle gait abnormality that is characterized by a tendency to stumble and associated with slight knuckling of the carpus and distal limb joints.

Stiff horse syndrome[5-7] and equine motor neuron disease[8] are unusual neurological conditions in which the horse moves better in the trot and canter than at a walk and may stand abnormally.

Shivering behavior often is seen in one or both hindlimbs in association with hindlimb lameness. The two conditions generally are unrelated. Shivering behavior may be more apparent when the horse is stressed. The behavior can make it difficult to assess whether any manipulation of the limb causes pain, or whether the horse is uncomfortable with one hindlimb picked up.

Stringhalt, or exaggerated flexion of a limb, usually a hindlimb, results in a gait abnormality most obvious at the slower speeds of walk and trot. It is not usually directly associated with any other form of lameness. It may be sudden or insidious in onset.

Congenital abnormalities of the first ribs in association with abnormalities of the adjacent brachial plexus have been seen as a cause of persistent forelimb lameness (Fig. 12-12).

Acute-onset, severe, and persistent forelimb lameness has been seen in association with a mediastinal abscess that encroached on the nerve roots of the seventh cervical and first thoracic vertebrae, the stellate ganglion, and the first rib (Fig. 12-13). Measurement of fibrinogen may help to identify the presence of an infective or inflammatory process.

Lyme Disease

Lyme disease has frequently been incriminated as a cause of shifting lameness that involves several limbs, but confirmed cases are extremely rare.[9] Many horses that are in areas where there are many ticks have relatively high antibody titers to *Borrelia burgdorferi*,[9,10] but this is not consistent with clinical disease. Lyme disease may be suspected in adult horses in endemic areas when unusual synovitis develops in absence of any known injection history or presence of a wound (see Chapter 67).

Fig. 12-12 Post-mortem specimen showing an anomalous first rib from a 3-year-old Thoroughbred with right forelimb lameness that was not altered by any local analgesic technique. There was an abnormal web of fibrous tissue that extended from this anomalous rib to incorporate part of the brachial plexus on the right side.

Fig. 12-13 A 7-year-old pony with severe right forelimb lameness that progressively deteriorated. The pony had an increased fibrinogen level and intermittent pyrexia. There was a mediastinal abscess that encroached on the roots of the seventh cervical and first thoracic nerves, the stellate ganglion, and the first rib.

Immune-Mediated Polysynovitis

Immune-mediated polysynovitis is relatively uncommon but may result in generalized stiffness associated with transient synovial distention of several joint capsules. It is frequently not

possible to identify the underlying cause, but this condition usually responds to corticosteroid medication (see chapter 67).

Tack-Induced Pain

An ill-fitting saddle can induce back pain and restricted action or poor performance. The bit can induce pain through poor fit (too narrow or too wide), being too low in the horse's mouth, banging on the canine teeth, pinching the corners of the horse's mouth, or being too severe. Any oral pain related to the bit, sharp teeth, or lacerations of the tongue, cheeks, or corners of the horse's mouth may cause reluctance to accept the bit properly and gait irregularities.

Rider-Induced Problems

The rider has a potentially huge influence on the gait of the horse. If a horse is not going forward properly, either because the rider is restricting it or because the rider is not asking it to go forward properly, the forelimb and hindlimb gaits may appear irregular, mimicking pain-induced lameness. An overweight rider who is too heavy for the horse may induce hindlimb lameness. A rider who constantly sits crookedly may induce back pain and hindlimb lameness. (Rider-related problems are discussed further in Chapter 100.)

Physical Limitations of the Horse, Temperament, and Confidence

With appropriate handling and training, most horses are cooperative. However, a previously compliant horse can very rapidly change if regularly handled and ridden by someone who lacks confidence, technique, or strength. Such a horse can quickly develop evasions, such as not going forward properly, rearing, bucking, or taking off. These problems may be pain related, but not necessarily. A horse that has never been trained properly may be very difficult and even potentially dangerous to the rider. Horses homebred by amateur enthusiasts are high-risk candidates. Some horses are innately lazy and unwilling to go forward. Others are very exuberant and excessively forward going and "fizzy." The veterinarian may be asked to investigate any of these behavioral features as a potentially pain-related problem.

It is important to establish how the horse was previously. It may be useful to see a video. Determine if there has been a change in rider or management. Establish what the horse is being fed and how much work it is getting: there is a tendency for people to overfeed and underwork horses. A comprehensive clinical evaluation may need to be repeated on several occasions before you can determine if it is a pain-related problem. Nuclear scintigraphic examination of selected areas may be useful to eliminate the presence of any underlying problems and to convince the owner that there is not a physical problem. A change of rider or work pattern may be necessary. The use of high doses of non-steroidal, anti-inflammatory drugs (e.g., 2 to 3 g twice daily for at least 7 to 10 days) can be helpful to determine if the problem is pain related, but be aware that there may be a placebo effect. Not all pain responds to phenylbutazone, so a negative response does not preclude a pain-induced problem (see Chapter 100.)

Reproductive Problems

Some mares become more difficult to handle and ride when in season and the judicious use of a synthetic progestagen such as altrenogest (Regumate, Intervet, Millsboro, DE) to stop the mare's cycling can sometimes be helpful. While some stallions can be used successfully for both competition and breeding, especially if the management is good and a very clear distinction is made with handling routines, others cannot focus adequately and thus perform athletically below expectations. Performance may be enhanced by castration. However, although malorientation of testicles is frequently blamed for lameness or poor performance, in the Editors' experience this is highly unusual.

A schirrhous cord in a gelding or mastitis in a mare can cause loss of hindlimb action and hindlimb stiffness. Chronic episodic, transient hindlimb lameness associated with strenuous work (jumping) has been seen in a stallion with large internal inguinal rings.[11] The lameness resolved after herniorrhaphy.

CHAPTER • 13

Assessment of Acute-Onset, Severe Lameness

Sue J. Dyson

FIELD DIAGNOSIS OF THE INJURED HORSE

The assessment of an acutely lame horse presents a challenge in diagnosis and in dealing with the people associated with the animal, particularly if lameness occurs at a competition. The horse may have fallen and been lame immediately or may have pulled up lame, and the veterinary surgeon may be called to examine the horse on course in full view of the public.

Ideally the horse should be transported to an examination area for comprehensive evaluation, but the veterinary surgeon must establish whether the injured limb requires support, before moving the horse. Although the horse may be very lame, establishing a definitive diagnosis for the cause of the lameness at this stage may be difficult.

This may surprise riders, trainers, and owners, and maintaining their confidence in what is an emotionally charged situation can be quite difficult. If a fracture is suspected, pressure to destroy the horse humanely without delay may be felt. Although some fractures are catastrophic and horses merit immediate destruction on humane grounds (e.g., a spiral fracture of the humerus), other serious fractures can be repaired. Therefore as much information as possible about the site of the fracture and its configuration should be obtained before a decision is made. The limb should be supported appropriately before the horse is moved for radiographic examination. If a horse must be destroyed on humane grounds at a competition, this should be done off the course.

Although a diagnosis may be obvious in some horses immediately after the onset of lameness, the veterinarian must recognize that severe lameness may occur without an evident cause. Serial re-examinations over the following hours or days may be required before a diagnosis can be reached. Sometimes the lameness resolves spontaneously within 12 to 18 hours and its cause is never established.

The clinician must be aware of the most common causes of acute-onset, severe lameness, which include the following:

- Sub-solar abscess
- Fracture
- Laminitis
- Intra-synovial sepsis
- Periarticular cellulitis

When lameness occurs during training or competition, a spectrum of other injuries must be considered. However, a history of acute-onset, severe lameness during exercise must not mislead the clinician into thinking that lameness must be caused by internal or external trauma associated with exercise. Lameness may still be caused by pain from a sub-solar abscess.

This chapter describes a systematic approach to management of a horse with sudden-onset, severe lameness and focuses particularly on injuries that occur during work.

ASSESSMENT

Medical History

While performing an initial visual appraisal of the horse, establishing a history is useful. The examiner must determine the following:

- Any previous lameness, tendon or ligament injury, or history of tying up
- Date of last shoeing
- Circumstances of lameness: whether the horse was performing normally, fell, hit a fixed fence, or collided with a fixed object such as a guide rail or a tree. The horse may have reared in the starting stalls or reared and fallen over backward. Another horse may have kicked it.

The clinician should also be aware of common injuries in the discipline in which the horse is competing.

The horse may be distressed because of the severity of pain and excited because of the atmosphere of a competition and thus difficult to restrain and examine adequately. Sedation with romifidine or detomidine, with or without butorphanol, may be necessary to facilitate examination of the horse.

The horse's posture should be observed while it stands still and walks a few steps. If the horse bears weight only on the toe, it may be inapparent that a horse has lost some support of the fetlock because of rupture of the superficial digital flexor tendon (SDFT) in the metacarpal region or at the musculotendonous junction in the antebrachium, unless it walks a few steps.

Limb Examination

The veterinarian should establish whether the horse is able and willing to bear weight on the limb, bearing in mind that after a fall, a neurological component may contribute to the lameness, in addition to the pain. The horse's demeanor should be assessed; the degree of pain and distress usually but not invariably reflects the severity of the injury. The horse may be greatly distressed, shifting weight constantly between limbs, and may be reluctant to move. Reluctance to move may be due to a bilateral problem (e.g., bilateral severe superficial digital flexor [SDF] tendonitis) or a more generalized problem such as equine rhabdomyolysis (tying up).

The horse should be carefully appraised visually to identify areas of swelling or a laceration. If the horse's limbs are covered in mud or grease (commonly applied to the limbs during the speed and endurance phase of a Three-Day Event), this should be washed off before proceeding with the evaluation. Boots, bandages, and the saddle and martingale should also be removed. Temporary studs in the shoes should be removed, because they may be more difficult to remove later if the injury is severe.

The horse may be obviously lame on a hindlimb or forelimb, but this may mask a similar, less severe injury in a contralateral limb or a different injury; therefore all limbs should be assessed carefully. For example, a racehorse may develop a lateral condylar fracture of the third metacarpal bone in one limb and SDF tendonitis in the contralateral limb. Although the former injury results in a more severe lameness, the latter may be more important to the horse's long-term prognosis.

Occasionally, forelimb and hindlimb lameness are concurrent. Each limb should be palpated systemically with the horse bearing weight and not bearing weight. The examiner should pay careful attention to heat, swelling, abnormal muscle texture, pain on firm pressure, pain induced by manipulation of a joint, restriction of flexibility of a joint, an abnormal range

of motion of the joint, audible or palpable crepitus, and the intensity of the digital pulse amplitudes.

The position of the shoe should be assessed carefully. A shoe that has moved slightly may result in nail bind. Hoof testers should be systemically applied across the wall and sole, gently at first and then firmly. Percussion should also be applied to the sole of the foot with the limb picked up and to the wall with the limb bearing weight. The clinician should not forget that if the sole is very hard, eliciting pain with hoof testers may not be possible, despite the presence of a sub-solar abscess.

The limbs should be carefully assessed for lacerations. Serious damage may occur to underlying structures if the laceration was sustained while the horse was moving at speed, and the position of the laceration and the site of damage to underlying structures may not coincide.

Shoulder and Chest

Injuries to the shoulder region usually result from a fall or collision, which may result in severe bruising only or a fracture. A fracture of the supraglenoid tubercle of the scapula results in severe lameness (Fig. 13-1). Slight soft tissue swelling may develop, usually without audible or palpable crepitus, and pain on palpation may be difficult to differentiate from that caused by severe bruising alone. Articular fractures of the scapula may be associated with audible crepitus on manipulation of the limb. Fractures of the body of the scapula or the humerus are usually associated with severe lameness, soft tissue swelling, and pain in that area.

After collision with a fixed object, or occasionally a fall, the scapulohumeral joint may become luxated or subluxated, with or without a fracture of the glenoid cavity of the scapula. The horse bears weight on the limb reluctantly, soft tissue swelling develops rapidly, and the distal aspect of the scapular spine may become more difficult to palpate. The limb may appear straighter than usual. A collision also may result in collateral instability of the shoulder, so-called shoulder slip, usually caused by trauma to nerves of the brachial plexus. The horse may have pain-related lameness because of bruising, together with mechanical lameness caused by neurological dysfunction (Fig. 13-2).

Although major fractures of the scapula and humerus are usually readily evident by clinical signs, most other shoulder injuries require radiographic and sometimes ultrasonographic examination to reach a diagnosis.

Pectoral muscle tears may result in similar clinical signs, with severe lameness and distress. Repeated clinical examinations may reveal the site of muscle rupture, with increasing evidence of hemorrhage, inflammatory effusion, and edema.

Rib fractures can also result from direct trauma or from falls and occur most commonly in steeplechasers and polo ponies. Fractures in the region of the scapula and triceps result in acute, severe forelimb lameness. More caudal fractures may result in extreme stiffness and may cause severe respiratory embarrassment.

Lameness associated with the upper forelimb may also be caused by strain of the biceps brachii or brachiocephalicus muscles or hematoma formation. Careful, deep palpation of these muscles is required to identify focal pain and possibly swelling or abnormal muscle texture.

Elbow and Carpus

Acute-onset lameness associated with pain arising from the elbow region is rare, except as the result of a fall or kick. Fracture of the olecranon process of the ulna is the most common injury (Fig. 13-3). If the fracture is non-displaced, the horse may stand normally, but with severe pain or if the fracture is complete with loss of triceps function, the horse stands with a dropped elbow.

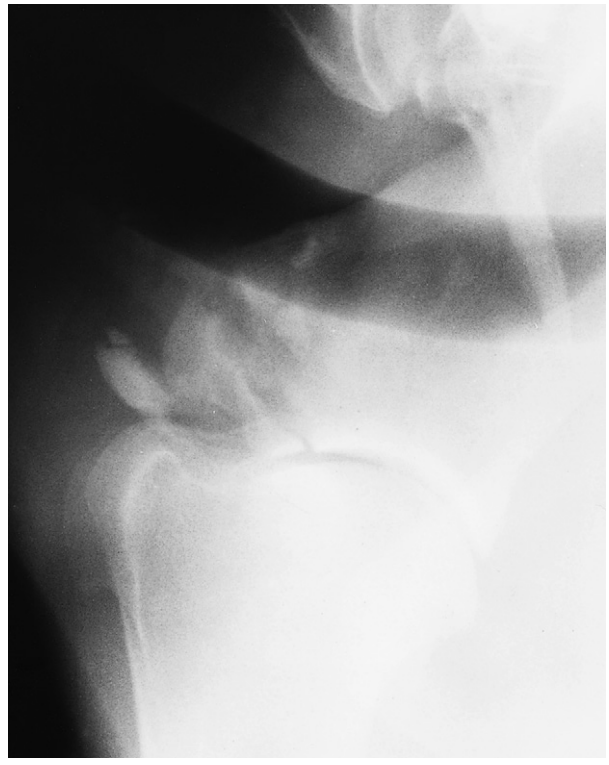

Fig. 13-1 Mediolateral radiographic view of the left shoulder of an advanced event horse that fell during competition 3 days previously and developed severe left forelimb lameness from a displaced comminuted fracture of the supraglenoid tubercle of the scapula.

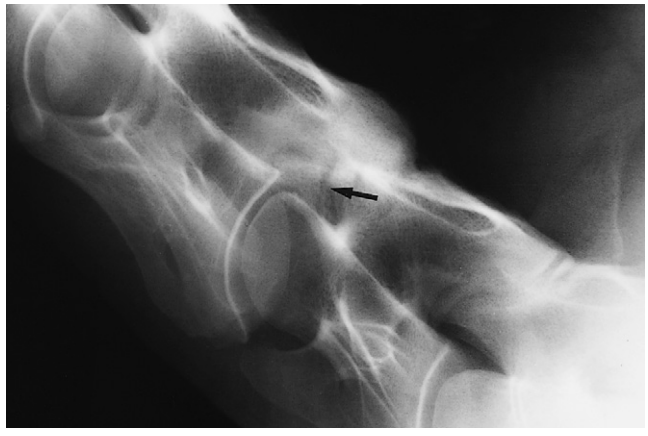

Fig. 13-2 Lateral radiographic view of the mid-cervical region of a 6-year-old event horse that fell on a cross-country course. The horse was not bearing weight on the left forelimb and showed moderate hindlimb ataxia. The synovial facet joints were fractured between the sixth and seventh cervical vertebrae (*arrow*). A cause of the forelimb lameness was not identified and the lameness resolved within 24 hours. The horse had a complete functional recovery but had some residual neck stiffness.

Acute-onset lameness associated with the carpus occurs most commonly, in racehorses, both flat racehorses and steeplechasers, and usually is associated with a chip or slab fracture or, less commonly with hemarthrosis. Synovial effusion within the antebrachiocarpal or middle carpal joint usually develops rapidly. The horse may resent maximal flexion of the carpus,

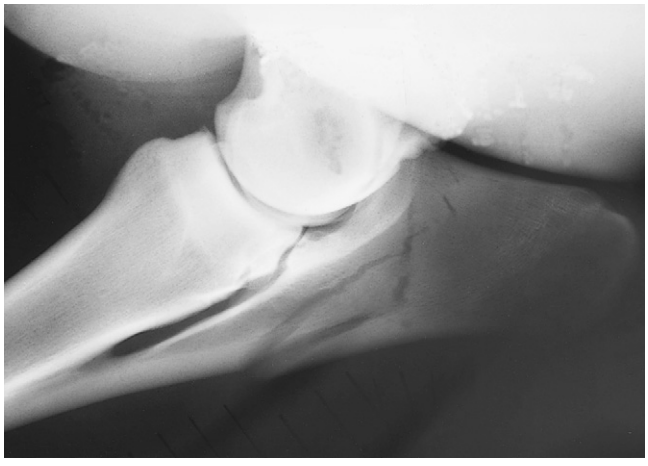

Fig. 13-3 Mediolateral radiographic view of left elbow of an event horse that was very lame after a fall and stood with the elbow dropped. The olecranon of the ulna sustained a displaced, comminuted fracture.

and direct palpation of the carpal bones may elicit pain. Fracture of the accessory carpal bone usually results from a fall and occurs most commonly in steeplechasers; such fractures may be associated with effusion within the carpal sheath. Acute tears of the accessory ligament of the SDFT sometimes occur in polo ponies, with associated distention of the carpal sheath.

Forelimb Soft Tissue Injuries

Injuries of the forelimb suspensory ligament (SL) (proximal, mid-body, and branch lesions), and of the forelimb SDFT occur most commonly in racehorses and event horses, whereas desmitis of the accessory ligament of the deep digital flexor tendon (ALDDFT) occurs more commonly in show jumpers, older steeplechasers, and polo ponies.

Severe, apparently acute onset lesions of the SDFT occasionally occur in show jumpers, especially those of international standard. Evaluation of the posture of the limb and the presence of heat, pain, and swelling are important for accurate diagnosis. Clinical signs associated with these injures can vary markedly. Substantial lesions of the SDFT can develop without detectable lameness, whereas a large tear can result in acute, severe, non–weight-bearing lameness. Bilateral tears may result in extreme distress, a reluctance to move, and a laminitic-like stance. In event horses, lameness can develop after the speed and endurance phase of a Three-Day Event, associated with SDF tendonitis, but no clinical signs may suggest the injury. Swelling or localized heat and pain may take several days to develop despite improvement or resolution of the lameness. Therefore careful re-appraisal of the horse over the next few days is strongly recommended if an event horse develops an acute-onset, forelimb lameness for which no diagnosis can be identified.

Rupture of the SDFT results in hyperextension of the fetlock with normal foot placement. Elevation of the toe with normal angulation of the fetlock indicates disruption of the deep digital flexor tendon (DDFT). Hyperextension of the fetlock and elevation of the toe reflect laceration or rupture of the SDFT and the DDFT. Sinking of the fetlock to the ground indicates disruption of the suspensory apparatus, with or without the flexor tendons.

Severe lameness and distress, with hyperextension of the fetlock, without obvious swelling in the metacarpal region suggests rupture of the SDFT at the musculotendonous junction. This injury occurs most commonly in steeplechasers. Rupture of the SDF tendon usually is a sequel to a previous injury; therefore the tendon is generally chronically enlarged. Detection of the rupture is easiest at the peracute stage, before exudate and hemorrhage fill the deficit. The site of rupture is usually in the mid-metacarpal region.

Desmitis of the ALDDFT usually causes acute-onset, moderate to severe lameness with rapid development of soft tissue swelling in the region of the ligament. However, recurrent injuries can develop with no detectable alteration of a chronically enlarged ligament. The degree of lameness associated with a SL injury varies from mild to moderate but may be worse if a concurrent fracture of the second or fourth metacarpal bone or of the apex of a proximal sesamoid bone exists, and these structures should be evaluated carefully. Some severely lame horses with proximal suspensory desmitis have no palpable abnormalities.

Each of the tendons and ligaments in the metacarpal region should be palpated carefully, from proximally to distally with the limb bearing weight and picked up. The size, shape, and consistency of the tendons and ligaments and any pain on palpation should be carefully assessed. With severe SDF tendonitis the horse may be distressed, and peritendonous edema rapidly develops, which makes accurate palpation of the tendon difficult. Bilateral SDF tendonitis sometimes occurs, with the only detectable palpable abnormality being slight enlargement of each tendon and rounding of its margins. The clinician must be aware of this, because these lesions may be missed if one assumes that because the limbs feel symmetrical, the tendons are normal.

Fractures of the Distal Aspect of the Limbs

A fracture of the lateral, or more rarely the medial, condyle of the third metacarpal or metatarsal bone results in acute-onset, severe lameness. If the fracture is incomplete and non-displaced, no palpable abnormality may be detectable, although some effusion in the metacarpophalangeal joint usually develops within 12 to 24 hours. The horse may resent fetlock flexion; however, some horses become so distressed that in the acute phase, determining whether pressure or joint manipulation causes pain is impossible. The same can apply for a fracture of the proximal phalanx.

Subluxation of the metacarpophalangeal joint occasionally occurs, with disruption of a collateral ligament, with or without an associated fracture. The horse may be very lame, but during normal load bearing the joint may appear to be aligned normally. Instability of the joint may only be detectable with the joint stressed with the limb not bearing weight.

Feet

Trauma to the palmar aspect of the pastern may result in an innocuous skin wound but severe damage to the underlying soft tissue structures. The branches of the SDFT, the DDFT, and the digital flexor tendon sheath are particularly vulnerable. Posture of the limb should be carefully assessed to determine which structure or structures may be involved.

An over-reach on the bulb of the heel can result in severe, deep-seated bruising and lameness, especially on hard ground. Injuries of the foot are common, especially in event horses. The differential diagnosis should include sub-solar hemorrhage (especially corns), nail bind, a sub-solar abscess, and a fracture of the distal phalanx.

If the horse shows any reaction to percussion of the foot or pressure applied with hoof testers, the shoe should be removed for further exploration of the foot. If the horse is very lame, removal of each nail individually using nail pullers may be preferable to levering off the shoe.

Hindlimb Injuries

When presented with a horse with acute hindlimb lameness that developed during exercise, consideration should always

be given to tying up, even if the hindlimb musculature feels soft and local pain cannot be elicited and the horse is not unduly distressed. The clinical manifestations of tying up vary considerably from acute, severe bilateral or unilateral hindlimb lameness with obvious firmness of the muscles of the hind quarter, with or without swelling, to a moderate unilateral hindlimb lameness that developed after the horse was not moving as freely as normal, with no detectable palpable abnormality. This lameness may persist for several hours but usually resolves within 12 to 18 hours. Occasionally, tying up can affect forelimbs, alone or together with the hindlimbs.

Measurement of substantially raised serum creatine kinase concentration 3 to 24 hours after the onset of lameness may be the only way to reach a definitive diagnosis. Alternatively, a horse may not be moving as freely as normal during the competition and subsequently may be withdrawn; further clinical signs may not develop.

Major hindlimb muscle rupture of quadriceps, semimembranosus, gastrocnemius, adductor, or belly muscles results in severe lameness and distress, but diagnosis may be difficult. Careful palpation may reveal a site of rupture. Detection of acute muscle strains may be possible when superficial muscles are involved. Pain on palpation and sometimes swelling may be present; however, this is not always the case, and evaluation of deep muscles is limited.

Stifle trauma is common in horses that jump fixed fences at speed, even if the rider cannot recollect the horse hitting a fence. Lameness caused by a fracture may be sudden and severe in onset, and the horse may pull up, but in some horses it does not become apparent until the horse has finished.

Because the cranial aspect of the stifle is relatively poorly covered with soft tissues, the bones are particularly susceptible to bruising or fracture (Fig. 13-4). The degree of pain on palpation does not necessarily reflect accurately the severity of the injury. Development of femoropatellar or femorotibial effusion or marked periarticular soft tissue swelling suggests a fracture. Sometimes a displaced fragment of bone can be palpated. The superficial location of the femoropatellar joint capsule also makes it vulnerable to puncture and the introduction of infection, and effusion and severe lameness may develop rapidly.

Fig. 13-4 Cranioproximal-craniodistal oblique radiographic view of right stifle of an event horse that hit the penultimate fence at the World Equestrian games. The horse completed the course, pulled up slightly lame, and was very lame within a few hours. The *arrows* show an articular fracture of the medial pole of the patella (*arrows*).

Most horses with stifle injuries require radiographic examination to establish or confirm the presence of a fracture. Although lameness associated with bruising may initially be severe, the horse generally rapidly improves within 24 to 48 hours, whereas with most fractures the lameness usually persists unchanged. The horse may be reluctant to extend the stifle and tends to stand with the limb semi-flexed and the weight on the toe, a posture also typical of severe foot pain. Occasionally severe ligamentous injury occurs in the stifle, which cannot be detected radiographically.

Rupture of fibularis tertius usually results from a traumatic episode, with the limb getting trapped in an extended position, and results in a severe lameness with the horse unwilling to load the limb fully. Passive extension of the hock is pathognomonic.

Acute injuries to the hock are uncommon, unless the horse has a severe fall resulting in damage to the hock joint capsules and the collateral ligaments or a lateral malleolar fracture of the distal tibia. The horse usually is severely lame and rapidly develops distention of the tarsocrural joint capsule and periarticular soft tissue swelling. Radiographic examination is indicated to determine the extent of the damage. Less commonly, slab fractures of the central or third tarsal bone cause acute, severe lameness. Kick injuries may result in a fracture.

Displacement of the SDFT from the tuber calcanei may occur suddenly, resulting in marked distress, especially if the tendon continues to move on and off the tuber calcanei. The tendon may slip laterally, or less commonly medially, and occasionally splits. Peritendonous soft tissue swelling develops rapidly. The horse is reluctant to bear weight on the limb and characteristically shows extreme distress, caused by pain or instability. Careful palpation usually confirms the diagnosis, although acute soft tissue swelling may make this difficult in the initial period after injury.

Periarticular cellulitis of the tarsal region results in an extreme lameness associated with the rapid development of extensive soft tissue swelling, which is exquisitely sensitive to touch. The horse is often lamer than with a fracture, and swelling is more extensive than with synovial infection.

Injuries to the soft tissue structures of the metatarsal and pastern regions are less common than those of the metacarpal and forelimb pastern regions. Suspensory branch injuries are the most common injuries resulting from direct blunt trauma. Acute tears of the DDFT may occur within the digital flexor tendon sheath, with rapid development of effusion. Fractures of the third metatarsal bone and phalanges are also less common than in the forelimbs, except in barrel racing or cutting horses or polo ponies. Plantar process fractures of the proximal phalanx are rare but do occur in racehorses and result in moderate to severe lameness, with pain on manipulation of the fetlock, effusion, and in some horses periarticular soft tissue swelling especially on the plantar aspect. Stability of the fetlock should be assessed carefully.

Stress Fractures

In young Thoroughbred racehorses the possibility of a fatigue or stress fracture must always be considered. The most common sites are the humerus, radius, ilial wing, tibia, third metacarpal bone, and tarsus. With the exception of ilial wing fractures, in which asymmetry of the tubera sacrale and pain on palpation in this area may be obvious, localizing clinical signs may otherwise be absent. A definitive diagnosis can rarely be made by clinical examination alone.

Hemarthrosis

Hemarthrosis may occur in any joint and results in acute onset, non–weight-bearing lameness associated with distention of the joint capsule. Lameness often improves rapidly

within the following 48 hours. Diagnosis is based on ultrasonography and synoviocentesis. Draining blood from the joint produces rapid relief of clinical signs.

TRANSPORTATION

In any horse with severe lameness in which making a tentative diagnosis based on a preliminary but thorough clinical examination is not possible, a decision has to be made about whether the horse is fit to travel, whether any risks are involved in travel, and whether the horse should be stabled as close as possible and be reassessed later or the following day (if this is practical). Whether the horse is insured should be established, together with the terms of the insurance policy.

The majority of horses can be taken safely to the nearest adequate diagnostic facility, which ideally should have a loading ramp, a veterinarian experienced in orthopedics, facilities for hospitalization, and high-standard radiographic, ultrasonographic, and possibly nuclear scintigraphic, equipment.

Facilities for orthopedic surgery are not necessarily essential, although desirable, because the first step must be to reach an accurate diagnosis. Having reached a diagnosis, the limb may then be appropriately supported to minimize risks of exacerbating the injury, if the horse is to be treated conservatively, or during induction of general anesthesia or for transfer to a suitable surgical facility. If a hindlimb fracture is suspected, the horse should be tied up (cross tied). For transport for further diagnostic investigation or surgical treatment the injured limb should usually be supported using a Robert Jones bandage,[1] with or without splints, or an appropriate commercial splint, bearing in mind the proposed site of injury[2] (see Chapter 87). For forelimb injuries the horse should ideally travel facing backward, although some low-loading ambulances are not designed for loading from the front.[3] When possible a low-loading trailer should be used, but if this is not available, the ramp of the vehicle should be placed on a slope to minimize the gradient for loading and unloading. If a diagnosis has been made for a horse with an injury that requires rapid surgical treatment, the limb should be supported in the most appropriate way and the horse referred to the nearest surgical facility, or to the best surgical facility in close proximity to the horse's place of origin, or to the person with the most expertise and experience dealing with that kind of injury. Provided that the limb is adequately immobilized and adequate pain relief is possible, the horse should be fit to travel several hours safely and humanely.

GUIDELINES FOR HUMANE DESTRUCTION OF AN INJURED HORSE

If the horse is insured for all risks of mortality, owners, trainers, and other interested people may request humane destruction. The American Association of Equine Practitioners (AAEP) and the British Equine Veterinary Association (BEVA) have issued guidelines indicating the requirements that should be fulfilled to satisfy a claim under a mortality insurance policy. Nonetheless, the decision to advise an owner to destroy a horse on humane grounds must be the responsibility of the attending veterinary surgeon, based on the assessment of clinical signs at the time of the examination or examinations, regardless of whether the horse is insured. The veterinary surgeon's primary responsibility is always to ensure the welfare of the horse. On occasion the attending veterinary surgeon will advise euthanasia, but such a decision may not necessarily lead to a successful insurance claim. It is important that all parties are aware of these potential conflicts of interests before a horse is destroyed. The owner's responsibility is to ensure compliance with any policy contract with an insurer.

The AAEP has issued the following guidelines for recommending euthanasia:

> The AAEP recommends that the following criteria should be considered in evaluating the immediate necessity for intentional destruction of a horse. It should be pointed out that each case should be addressed on its individual merits and that the following are guidelines only. Not all criteria must be met in each case.
>
> 1. Is the condition chronic, incurable and resulting in unnecessary pain and suffering?
> 2. Does the immediate condition present a hopeless prognosis for life?
> 3. Is the horse a hazard to itself or its handlers?
> 4. Will the horse require continuous medication for the relief of pain for the remainder of its life?
>
> Justification for euthanization of a horse for humane reasons should be based on medical grounds, not economic considerations; and further the same criteria should be applied to all horses regardless of age, sex or potential value.

The BEVA guidelines for compliance for a mortality insurance policy are as follows:

> That the insured horses sustains an injury, or manifests an illness or disease, that is so severe as to warrant immediate destruction to relieve incurable and excessive pain, and that no other options of treatment are available to that horse, at that time.
>
> If immediate destruction cannot be justified, then the attending veterinary surgeon should provide immediate first aid treatment before:
>
> 1. Requesting that the insurance company be contacted, or, failing that
> 2. Arranging for a second opinion from another veterinary surgeon.

It is essential that the attending veterinary surgeon keep a written record of the injuries sustained by the horse, its identification, and the date, time, and place. The owner or agent should whenever possible sign a form consenting to euthanasia. Insurance companies frequently require some form of examination after death and may request an independent postmortem examination, and this must be borne in mind when arranging for disposal of the carcass.

CHAPTER • 14

The Swollen Limb

Sue J. Dyson

The development of diffuse or more localized swelling in one or more limbs can present a diagnostic challenge, requiring a systematic approach to identify the cause. Although the metacarpal, metatarsal, and pastern regions are most commonly affected, an entire limb may be swollen, or swelling may initially be restricted to the antebrachium or crus or the carpus or tarsus, with swelling subsequently spreading distally. This chapter discusses an approach to diagnosis and management but does not provide exhaustive differential diagnoses and treatments. Some conditions are discussed in more detail in other chapters.

DIAGNOSIS

Many stabled horses develop some degree of enlargement of the distal limbs, especially the hindlimbs, that dissipates with work. Termed *filled legs* or *cold edema* (stocked-up, stoved-up), this swelling may be controlled by applying stable bandages and is of no consequence.

History

Accurate diagnosis of the cause of limb swelling requires knowledge of the history.

- Was the problem sudden or gradual in onset?
- What is the duration of the swelling?

It may be pertinent to establish when the owner last thought that the horse was normal, especially in horses that are not inspected reguarly while kept at pasture. The actual duration of swelling may be longer than the owner recognized. The veterinarian also should bear in mind that some owners are remarkably unobservant, despite maintaining that they veterinarian and groom the horse thoroughly daily.

- Were any swellings pre-existing?
- What was the initial distribution of the swelling and has this changed?
- Has similar swelling appeared previously (lymphangitis may be a recurrent problem)?
- Does any history of trauma exist?
- Has the limb been bandaged, or have boots or bandages been used for exercise? Overly tight bandages can rapidly result in severe cellulitis, skin excoriation, and hair loss. Sand or grit inside a boot can provoke severe skin inflammation and diffuse soft tissue swelling.
- Has the horse had tendonitis or desmitis? Recurrent injury may be much more severe and result in diffuse swelling, prohibiting accurate palpation of the injured structure.
- Has the horse had any other recent clinical problems (strangles may predispose to purpura hemorrhagica)?
- Does the horse show any other clinical signs, and could the limb swellings reflect systemic disease?
- Is the horse lame, and when did lameness develop relative to the recognition of swelling? If swelling preceded the lameness, more than one problem may exist.
- Has the horse received any treatment, and what was the response? Has anything topical been applied to the limb that may be irritant?

Swelling in a single limb usually reflects a local problem, whereas swelling in several limbs may be due to systemic disease or a primary skin problem. The differential diagnosis should include the following: sub-solar abscess (see Chapter 28); mud fever or scratches; scabby skin lesions on the palmar aspect of the fetlock; other bacterial pyodermas; hemorrhage or thrombosis (see Chapter 38); desmitis or tendonitis (see Chapters 70, 72, and 73); cellulitis associated with superficial digital flexor tendonitis (see Chapter 70); skin necrosis and cellulitis after topical application of proprietary products; infected tendon or tendon sheath; cold edema; cellulitis caused by trauma or infection; fracture; or hypertrophic osteopathy (see Chapter 38); muscle rupture (see Chapter 13); muscle trauma resulting in compartment syndrome (see Chapter 84); lymphangitis; photosensitization; equine viral arteritis; heart failure; and hypoproteinemia.

Clinical Examination

A systematic clinical examination should be performed by careful observation and palpation. The veterinarian should assess the horse's posture, demeanor, and attitude. Depression may reflect pain or infection.

- Is the horse febrile? The clinician should determine whether one or more limbs are involved.
- What is the distribution of the swelling? Is it localized or more diffuse? Swelling associated with a sub-solar abscess is usually diffuse and involves the pastern and metacarpal or metatarsal region, extending a variable degree proximally, and is symmetrically distributed around the limb. In contrast, swelling associated with direct trauma may be restricted to the metacarpal region in the acute phase and only later spread distally.
- Does the swelling relate to a joint or to a long bone and the surrounding soft tissues?
- Where is swelling maximal? Is swelling predominantly on one side of the limb, which may reflect trauma, because of the horse becoming cast?
- Does the metacarpal (metatarsal) region have a straight palmar (plantar) contour? Diffuse swelling in the metacarpal region is unlikely to reflect superficial digital flexor tendonitis if the palmar aspect of the limb is straight.
- Is the swelling cool, warm, or hot? Hot swelling is most likely to be associated with infection.
- Is the swelling tense, often reflecting infection, or soft?
- Is evidence of pitting edema present?
- Does light digital pressure or firm pressure elicit pain? Pain caused by only light pressure is often associated with cellulitis caused by infection or less commonly by intra-tendonous infection.
- How does the location of pain relate to the site of maximal swelling?
- How easily can underlying anatomical structures be palpated, and does palpation cause pain? The

veterinarian should note that scabby skin lesions overlying soft tissue swelling can in themselves be remarkably painful.
- Does a draining tract suggest an abscess, cellulitis, or infectious osteitis or osteomyelitis?
- Does joint manipulation cause pain?
- Do any skin lesions exist through which infection may have entered? This may not be readily apparent in a horse with a long hair coat, and clipping may be necessary. In a horse kept at pasture the limb may be caked in mud, and thorough cleaning may be necessary before an accurate clinical examination can be made.
- Do any other skin lesions reflect a primary dermatological problem? The clinician should try to categorize any lesions identified.

The digital pulse amplitudes should be assessed: any increase highly suggests a primary foot problem. The response to pressure and percussion applied with hoof testers should be evaluated. Pulse rate, the quality of the peripheral pulses, capillary refill time, and careful auscultation of the heart and lungs should reveal whether a primary cardiac problem exists.

The mucous membranes should be examined for evidence of petechial hemorrhages, which can be seen with purpura hemorrhagica. The veterinarian should relate the swelling to the color of the limbs; swelling confined to white limbs may result from photosensitization.

The clinician should establish the degree of lameness and bear in mind that mild stiffness may result from extensive limb swelling and mechanical restriction. Extremely severe lameness often reflects infection, either periarticular (e.g., peritarsal cellulitis; see Chapter 45), intra-articular, intra-thecal, intra-tendonous, or sub-solar. A horse with a fracture may be less lame.

The results of this clinical examination should suggest the likely causes of the swelling, but definitive diagnosis might not be possible without further investigation. This may include radiography, ultrasonography, routine hematological testing, measurement of total protein and fibrinogen, and liver enzyme levels if indicated. Paired serum samples may be required to confirm equine viral arteritis. Treating the horse symptomatically to reduce the soft tissue swelling may be helpful to facilitate more accurate palpation. This may include the use of non-steroidal anti-inflammatory drugs (NSAIDs), hydrotherapy, poulticing or leg sweats, bandaging, and walking, with or without antimicrobial medication. Without evidence of a primary infectious process the response to corticosteroids may be helpful diagnostically, because limb filling may be an immune-mediated response. The clinician should be prepared to make repeated examinations if a primary diagnosis is not readily apparent.

Early periosteal new bone associated with hypertrophic osteopathy is readily overexposed, and greatly reduced exposure factors are required for its radiographic detection. On the first day of examination the results of radiographic and ultrasonographic examinations may be misleading, and repeated examinations may be necessary. Following trauma, laceration, or both injuries, to the antebrachium, crus, and metacarpal or metatarsal regions, delayed-onset lameness caused by an occult spiral fracture of the radius, tibia, or third metacarpal or metatarsal bones is possible. Many oblique radiographic views or follow-up examination be may be necessary to identify the fracture. If extensive cellulitis occurs around a joint or tendon sheath, but intra-articular or intra-thecal infection are suspected, the examiner should be cautious about performing synoviocentesis through infected tissues, because iatrogenic intra-articular or intra-thecal infection may ensue. If skin lesions are identified as a possible primary cause of limb swelling, but these fail to respond to topical or systemic treatment, obtaining skin biopsies for culture and histological examination or seeking specialist advice from a dermatologist may be necessary.

MANAGEMENT

Mud Fever

Mud fever (scratches or pastern dermatitis) is associated with bacterial or fungal skin infection and usually is restricted to the palmar or plantar aspect of the pastern but sometimes extends farther proximally if severe. Mud fever is associated with many excoriated skin lesions, which may develop severe crusting. Deep fissures may develop in the skin, especially if the condition goes unrecognized or in horses with many skin folds in the pastern region. Extensive edematous swelling often extends up the metacarpal and metatarsal regions. If the condition is mild, no associated lameness may occur, but severe lesions are associated with marked stiffness. The condition can occur in horses kept out in wet, muddy conditions or in horses that are stabled but work in a muddy environment. Certain soil types seem to be associated with a higher occurrence. Some horses seem prone to recurrent episodes, although this may in part reflect management practices. The condition is difficult to manage if the horse is left in wet, muddy pasture and it must be stabled. The affected areas should be clipped and thoroughly cleaned with chlorhexidine solution. The scabs should be softened to facilitate removal. If the condition is mild, no further treatment may be required, but if the condition is more severe, daily topical application of lanolin-based emollient cream with trimethoprim and sulfadiazine and dexamethasone is indicated, sometimes combined with systemic antimicrobial treatment. Alternatively, a proprietary topical preparation can be used. The limbs should be carefully cleaned and dried after exercise.

Scabs on the Palmar Aspect of the Fetlock

Some horses seem prone to develop many small skin scabs on the palmar or plantar aspects of the fetlock. The scabs appear to be related to work on specific surfaces, which presumably cause skin irritation and subsequent bacterial infection. These skin lesions are often associated with diffuse swelling and can be exquisitely painful. The lesions rarely resolve spontaneously but usually resolve with penicillin therapy.

Cellulitis Caused by Trauma

Direct trauma to a limb may result in extensive edematous soft tissue swelling unassociated with infection. If skin abrasion is concurrent, the site of the wound relative to synovial structures susceptible to infection must be evaluated carefully. Lameness may vary in degree, but if severe, the possibility of fracture must be considered. If little soft tissue covers the underlying bones, radiographic examination is prudent to eliminate the possibility of a fracture. With primary cellulitis, treatment with NSAIDs and rest and controlled exercise is usually all that is required.

Cellulitis Caused by Infection

Cellulitis associated with infection from a penetrating wound usually results in fairly extensive soft tissue swelling, which tends to be warmer and more painful than noninfectious cellulitis (see Fig. 5-8). Associated lameness may also be severe, depending in part on the location of infection. If untreated, abscessation may develop in muscular areas and may require surgical drainage. Cellulitis may also be concurrent with infectious osteitis or osteomyelitis (see Chapter 38). Horse with acute infectious cellulitis usually respond well to systemic broad-spectrum antimicrobial treatment, unless clostridial organisms are involved (see Chapter 84).

Lymphangitis

So-called lymphangitis occurs more commonly in hindlimbs than forelimbs and is often unilateral but may be bilateral. Diffuse soft tissue swelling occurs throughout the limb, often

extending distad from immediately below the stifle. The superficial lymphatic vessels may appear more prominent than usual. Serum may ooze through taut skin. The degree of swelling usually results in mechanical stiffness that improves with progressive walking. Careful inspection may reveal some small skin lacerations, often in the more distal part of the limb. Once a horse has had a severe attack of lymphangitis, it seems prone to recurrence, often after seemingly innocuous skin abrasions. Although the condition appears to be triggered by infection, antimicrobial treatment alone is inadequate and usually must be combined with long-term corticosteroid treatment (dexamethasone 0.05 to 0.2 mg/kg once daily intravenously or intramuscularly, using the lowest dose necessary to control edema, and replacing with prednisolone 0.5 to 1 mg/kg intramuscularly or by mouth twice daily, when the dexamethasone dose is <0.04 mg/kg), together with aggressive hydrotherapy and walking exercise, with or without bandaging and topical application of leg sweats. Bandaging the metatarsal region in the face of more proximal limb swelling tends to result in persistent proximal limb swelling that cannot move distally. Although prompt aggressive treatment may resolve clinical signs, persistence of marked filling for more than a week may result in chronic enlargement of the limb. Ulcerative lymphangitis occurs much less frequently and is caused by bacterial or fungal infection.

Purpura Hemorrhagica

Purpura hemorrhagica usually occurs as a sequel to previous streptococcal respiratory infection but occasionally follows other antigenic stimuli. Purpura hemorrhagica results in extensive submucosal petechial hemorrhages, evident clinically in the mucous membranes but actually more widespread, including muscle and viscera. Facial swellings and limb edema may be extensive. The horse is usually depressed, inappetant, and pyrexic. Purpura hemorrhagica is an acute, probably immune-mediated, necrotizing vasculitis. Aggressive treatment with penicillin and corticosteroids (see the previous discussion) is required.

SECTION • 2
Diagnostic Imaging

CHAPTER • 15

Radiography and Radiology

Sue J. Dyson

Radiography is an important part of the diagnostic armamentarium in the evaluation of lameness. Its most important role is to give information about bones and joints. However, it also can provide information about soft tissues, most particularly tendon, ligament, and joint capsule insertions. If radiography is to be used properly, then the area under investigation must be evaluated comprehensively and appropriately. A sufficient number of views, all which have been appropriately centered and exposed, should be obtained.

Obtaining high-quality radiographs requires attention to detail. The horse must be correctly positioned and adequately restrained or sedated. For most weight-bearing examinations the horse should stand with the cannon bone of the limb to be examined in a vertical position. The horse should be standing on all four limbs, not resting a limb. The area under investigation should be cleaned to remove any surface dirt. For examinations of the foot, the shoe should be removed (if possible) to facilitate proper paring of the sole and frog, to ensure it is adequately clean, and to avoid superimposition of a radiodense shoe over the distal phalanx and navicular bone. The tail should be tied to facilitate correct positioning of the cassette when examining the stifle and hock regions.

RADIOGRAPHIC DETAIL

The aim is to obtain as highly detailed radiographic images as possible. The detail that can be obtained is influenced by a number of factors, including the following:

- Film screen combination. High-definition screens for use with single-emulsion and relatively slow film provide the best definition in the distal limbs. When higher exposure factors are required to gain adequate penetration of the more proximal parts of the limb, rare earth screens are required to minimize exposure times and thus reduce the risk of movement blur.
- Proper contact between the film and the screen. Old screens become warped and result in loss of image quality.
- Cleanliness of the screens. Dust and hair accumulate easily within cassettes, resulting in radiopaque artifacts and lines on the films. Screens must be cleaned regularly. Careful darkroom technique is essential to reduce the risk of dust build-up.
- Power of the x-ray machine. The use of high-definition screens is possible only with x-ray machines capable of an output of 100 kV and 100 mAs. Otherwise, exposure times are too long, resulting in movement blur.
- Choice of appropriate exposure factors. This step is less critical with digital radiography when post-processing can be used.
- Use of the correct focus film distance (FFD). X-rays obey the inverse square law, so that an alteration in the FFD potentially has a big effect. Single-emulsion film is particularly sensitive to a slight change in the FFD.
- Exposure time. The exposure time should be as short as possible to reduce movement blur.
- Use of grids. Grids are required in areas with a large amount of soft tissue, which results in scattered radiation. The use of a grid requires a higher exposure factor. If a focused grid is used, the x-ray beam must be perpendicular to the grid and centered on it, and the correct FFD should be used. Parallel grids have slightly more latitude when a FFD of more than 120 cm is used. The higher the grid ratio and lines per centimeter, the more effective the grid is in reducing scattered radiation, but the higher the grid factor. The grid factor denotes how much an exposure must be increased from non-grid values for comparable opacity. For example, if the grid factor is 2, then the milliamperes seconds (mAs) should be doubled.
- Lead. Lead is placed behind the cassette when large exposures are used to reduce the amount of backscatter.
- Collimation of the x-ray beam.
- Use of stationary cassette holders when possible and practical to reduce movement of the cassette.
- Size and shape of the horse. These factors become particularly important when examining the thoracolumbar region. The amount of muscle mass and fat influence the exposure factors; with very large horses the risk of the radiographic images becoming flat as the exposure is increased. The shape of the horse's barrel also influences how closely the cassette can be placed to the back and thus influences magnification. The use of an aluminum wedge filter allows the intensity of the beam to be reduced in specific areas and is of particular value when examining areas with a marked change in soft tissue thickness from one side of the film to the other (e.g., the dorsal spinous processes in the thoracolumbar region, the shoulder, and the stifle).
- Amount of soft tissue swelling. If marked periarticular soft tissue swelling is present, higher exposures are required to achieve adequate penetration. The use of a grid in these circumstances helps to reduce scattered radiation.
- Cooperation of the patient.

Image Resolution

Image resolution is the objective measurement of how much detail can be provided by a film screen combination and is measured in line pairs per millimeter. Resolution indicates the size of the smallest object that the system will record (i.e., the smallest distance that must exist between two objects before they can be distinguished as two separate entities). *Image definition* cannot be quantified but is the subjective impression of the amount of detail that can be seen on a radiograph.

Image Contrast

Contrast is the degree of definition on a radiograph between adjacent structures of differing radiopacities. *Opacity* or *radiopacity* is the degree of whiteness of the object being radiographed. The denser the physical structure, the greater the degree to which the tissue absorbs x-rays, and the more opaque it appears on a radiograph.

Exposure Factors

Exposure factors affect the opacity and contrast of the radiographic image. The kilovoltage governs the quality and intensity of x-rays and affects both contrast and opacity. The quantity of x-rays reaching the x-ray film is the product of milliamperage and time, and is also influenced by the FFD, according to the inverse square law. The following equation is used to calculate the exposure of a change in distance:

$$\text{Old mAs} \times \frac{(\text{New FFD})^2}{(\text{Old FFD})^2} = \text{New mAs}$$

The milliamperes seconds and FFD affect the opacity of the image, not the contrast.

Exposure Latitude

Exposure latitude is the degree of over-exposure or under-exposure that can be tolerated in a correctly developed film and still produce an image of acceptable radiographic quality. A low kilovoltage yields high contrast with low latitude, whereas a high kilovoltage results in low contrast but has wide latitude. For good bone detail the kilovoltage should be less than 70 kV. Attenuation of the x-ray beam depends heavily on the atomic number of the tissues, and it is desirable that photoelectric absorption predominates. Increasing the kilovoltage also results in more forward-scatter.

To obtain a radiograph with the same opacity as the original, but with decreased contrast, the milliamperes seconds are halved and the kilovoltage is increased by 15% (approximately 10 kV). To increase the contrast but maintain the opacity, the milliamperes seconds are doubled and the kilovoltage is reduced by approximately 15%.

Image Sharpness and Resolution

Lack of image sharpness can be caused by a number of factors, including movement of the patient. Short exposure times help to reduce the risk of movement blur. Reducing the FFD can increase the amount of x-rays reaching the patient and therefore the exposure time could be reduced. However, reduction of FFD results in an increase in geometric indistinctness or *penumbra*. Image blur also may be the result of poor screen film contact. Contact can be tested by placing a wire mesh on top of the cassette and making an exposure using a large FFD. Any loss of image sharpness is due to poor film screen contact.

Image resolution also can be influenced by the focal spot size of the x-ray machine. High-output x-ray machines usually have different size focal spots. A small focal spot (e.g., 0.6 mm) usually results in better image resolution, but an increased exposure time is required to achieve the same milliamperes. When movement is likely to be a problem (e.g., proximal limb examinations), a larger focal spot (1.5 to 2.0 mm) is preferable to reduce exposure times.

Film and Screen Factors

Relative speed ratings of screens and distance factors must be considered when selecting exposure factors. Speed classification of film screen combinations allows comparison of systems between manufacturers. Some manufacturers use 100, 200, 400, and so on, and others use 2, 4, 8, and so forth, but the interrelationship is the same. Speed 8 screens require half the exposure (milliamperes seconds) needed for speed 4 screens; speed 200 requires twice the exposure (milliamperes seconds) of speed 400. Although the same exposures are required to provide the same image opacity using similar film screen speeds, the detail and resolution may vary. Generally when only one screen from a pair is used (when using single-emulsion film), the speed of the system will halve. Thus if one screen from a pair rated 400 is used, the speed will be 200.

RADIATION SAFETY

Radiation safety (i.e., ensuring that personnel around the horse do not receive doses of radiation) is essential. Different codes of practice apply in various countries, but the basic principles can be summarized as follows:

- The number of people present during radiography should be kept to the absolute minimum required to restrain the horse, position the limb and the x-ray cassette, and obtain the radiograph.
- Appropriate restraint or sedation of the horse is essential to ensure it remains still during exposures. This practice will limit the number of repeat exposures needed.
- Collimation of the x-ray beam. Use of a light beam diaphragm permits maximum collimation. No part of any attending person, even if covered with protective clothing, should be placed in the primary x-ray beam. Protective lead clothing protects from scattered radiation only, not the primary beam. The primary beam continues beyond the patient and cassette, and personnel standing on the opposite side also are at risk.
- All personnel who must remain present for the exposure must wear protective lead gowns. If near the primary beam, they should also wear protective lead gloves, hand and arm protection, and a thyroid protector.
- All protective clothing should be checked annually and replaced when necessary.
- All personnel working with and around the x-ray machine must be monitored using a film badge system.

RESPONSE OF BONE TO STIMULI: WOLFF'S LAW

Correct interpretation of radiographic images requires knowledge of the ways in which bone responds to various stimuli. Bone models according to Wolff's law: it models according to the stresses placed on it so that it can be functionally competent with the minimum amount of bone tissue. The use of the terms *modeling* and *remodeling* creates considerable confusion because usage differs in histology and radiology. *Histologically, bone remodeling* refers to resorption and formation of bone that is coupled and occurs in basic multicellular units. This regulates the microstructure of bone without altering its shape and is a continuous process, replacing damaged bone with new bone. Thus remodeling cannot be appreciated radiographically. *Radiographically,* the term has been used to describe reshaping of bone to match form and function (e.g., after fracture repair). Strictly speaking, the term *modeling* should be used to describe the change in the shape of a bone as it adapts to the stresses applied to it.

Bone is a dynamic tissue, constantly reacting to the stimuli that it receives both internally and externally. However, it takes time to respond, and a 40% change in bone density must occur before changes are evident radiographically. Therefore radiographs, although anatomically accurate, are relatively insensitive in the early stages of a disease process. This is known as the radiographic *latent period*. It is critical to appreciate these limitations when interpreting radiographs. Bone can be undergoing abnormal modeling without identifiable

structural change. Once radiographic abnormalities have developed, some will persist over the long term without necessarily being associated with ongoing pain. Thus in effect these changes remain as scars reflecting previous injury. Aging of such lesions is impossible, and assessing clinical significance must be evaluated in the light of the clinical signs.

Bone can react to stimuli in only a limited number of ways. Bone can produce new bone, such as periosteal new bone, endosteal new bone, cortical thickening, increased thickness of trabeculae, callus formation, osteophyte and entheseophyte formation, and the pallisading periosteal new bone typical of hypertrophic osteopathy. New bone often results in what is described radiographically as *sclerosis*: increased opacity of the bone, caused by either new bone being laid down within the bone or superimposition of new bone on the surface of the bone. More than one radiographic view usually is required to determine why a structure appears sclerotic. Strictly speaking, however, sclerosis is a localized increase of opacity of the bone caused by increased bone mass within the bone.

O*steolysis* is resorption of bone resulting in a radiolucency. Again, a lag period, usually of at least 10 days, occurs between the onset of lysis and its radiographic detection. Osteolysis occurs for a variety of reasons, including pressure, infection, as part of early fracture repair, and as part of the disease process in osteoarthritis, osteochondrosis, osseous cyst-like lesions, and subchondral bone cysts. Bone destruction and resorption usually are seen more easily in cortical bone, rather than cancellous bone, because of the greater contrast.

Generalized demineralization, or *osteopenia*, of bone throughout the body rarely occurs in the horse. Localized demineralization in a single limb usually is the result of disuse and is characterized by thinning of the cortices and more obvious trabecular pattern. The proximal sesamoid bones are particularly sensitive indicators of disuse osteopenia in the horse.

Focal demineralization and loss of bone may be due to pressure, for example, as seen in chronic proliferative synovitis in the fetlock, resulting in erosion of the dorsoproximal aspect of the sagittal ridge of the third metacarpal bone (McIII). It may be the result of infection, invasion by fibrous tissue, or a neoplasm.

Cortical thickness changes (models) according to Wolff's law as an immature athlete develops into a mature, trained athlete. The dorsal cortex of the third metacarpal and third metatarsal bone becomes thicker. If a horse has marked conformational abnormalities, such as "offset or bench knees," the bones model accordingly with the lateral cortex of the distal limb bones becoming thicker.

Periosteal New Bone

Blunt trauma to bone can lead to subperiosteal hemorrhage, resulting in lifting of the periosteum away from the bone. This process may stimulate the production of periosteal new bone (Fig. 15-1). Some bones, such as the second and fourth metacarpal and metatarsal bones, seem particularly prone to such reactions. The variation in susceptibility to such reactions between horses appears to be individual. Usually a lag period of at least 14 days occurs between trauma and the radiographic detection of periosteal new bone. Such bone usually is much less dense than the parent bone; therefore soft exposures (or low kilovoltage) are essential for detection of this bone, which initially has a rather irregular outline. As the bone gradually consolidates and then models, it becomes more opaque and more smoothly outlined. Curiously, although a well-established splint would be expected to become inactive, many appear slightly hotter than the parent bone if examined scintigraphically.

Periosteal new bone can also develop as a result of fracture, infection, inflammation, and neoplasia. Inflammation of the interosseous ligamentous attachment between the second and third metacarpal or fourth and third metacarpal bones caused by movement and loading can result in periosteal new bone formation and a splint. It is curious that some of these formations develop rapidly without associated pain, whereas others can cause persistent pain and lameness for many weeks, despite a similar radiographic appearance. The bony protuberances that develop on the proximolateral aspect of the metatarsal regions, often bilaterally, are even more enigmatic. They are rarely associated with clinical signs, although they often appear hot scintigraphically despite having been present for several years.

Fig. 15-1 Dorsomedial-palmarolateral oblique view of the metacarpal region. Soft tissue swelling overlies periosteal new bone on the mid-diaphyseal region of the second metacarpal bone.

Endosteal New Bone

Endosteal new bone may develop as a result of trauma (e.g., a cortical or subcortical fracture) or inflammation, infection, or less commonly, a tumor (Fig. 15-2). Stress fractures of the dorsal cortex of the third metacarpal bone are accompanied by the development of endosteal new bone, which may be more readily detected than the fracture itself.

Sclerosis

Sclerosis is the localized formation of new bone within bone and results in increased bone mass. It is most easily identified in trabecular bone (Fig. 15-3) and occurs in response to several stimuli, including the following:

- Stress (e.g., subchondral sclerosis in osteoarthritis and sclerosis of the medulla of the navicular bone in navicular disease)
- Protection of a weakened area (e.g., sclerosis surrounding an osseous cyst-like lesion or a subchondral bone cyst)
- Walling off infection (e.g., adjacent to a sequestrum or in the medullary cavity adjacent to an area of osteomyelitis)

Fig. 15-2 Lateromedial view of the proximal tibia. There is increased opacity of the subcortical bone of the proximocaudal aspect of the tibia. Endosteal new bone *(arrows)* is associated with a fatigue fracture.

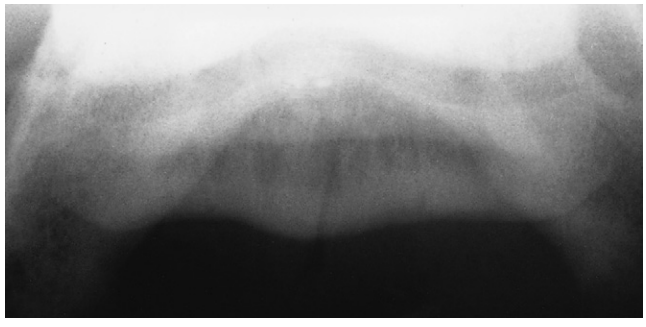

Fig. 15-3 Palmaroproximal-palmarodistal oblique view of a navicular bone. There is increased thickness of the trabeculae of the medulla of the navicular bone, resulting in sclerosis. Several large, oval-shaped lucent zones are present within the medulla. The flexor cortex is thickened and corticomedullary demarcation is poor.

Enostosis-like lesions are the development of bone within the medullary cavity or on the endosteum, resulting in a relatively sclerotic area of variable size. They frequently occur adjacent to the nutrient foramen, and the origin is unclear. They may develop as a focal or multifocal lesion. They vary in size and generally are seen in the diaphyseal regions of long bones in the horse. These lesions have been seen most frequently in the humerus, radius, and tibia and the third metacarpal and third metatarsal bones. When these lesions develop, they are very hot scintigraphically and may be associated with pain and lameness. However, they also are seen as incidental findings.

Small focal opacities in the proximal metaphyseal region of the tibia have been seen. The origin and significance are not known. Care must be taken in the fetlock region not to misinterpret the radiopacity caused by the ergot as an opaque lesion within the proximal phalanx.

Osteophyte Formation

An *osteophyte* is a spur of bone on a joint margin that develops as a result of a variety of stimuli, including joint instability, or in association with intra-articular disease, particularly osteoarthritis. Not all periarticular modeling changes at the junction of the articular cartilage and periarticular bone are associated with ongoing joint disease, but radiological differentiation between a subclinical osteophyte and a clinically significant one is difficult. Small spurs frequently are seen on the dorsoproximal aspect of the third metatarsal bone close to the tarsometatarsal joint. Some are quiescent, unassociated with articular pathological findings, whereas others are progressive. Small spurs on the dorsoproximal aspect of the middle phalanx are frequent incidental findings in Warmblood breeds. Mature horses with offset or bench-knee conformation frequently have spurs on the lateral aspect of the antebrachiocarpal joint without associated clinical signs.

The time of development of an osteophyte after stimulus varies depending on the inciting cause and individual variation. Two weeks to several months may pass before an osteophyte may be identified radiographically. A smoothly marginated osteophyte of uniform opacity is more likely to be long-standing, whereas a poorly marginated osteophyte with a lucent tip is likely to be active.

Some joints seem to have a greater propensity than others for the development of periarticular osteophyte formation. The reason for this tendency is unknown and may in part reflect the ease with which osteophytes can be detected radiographically. Even within what is currently considered a single disease process, osteoarthritis of the distal hock joints (bone spavin), some horses develop predominantly periarticular osteophytes (Fig. 15-4), whereas others have narrowing of the joint space and subchondral sclerosis. A third group develops extensive radiolucent areas (Fig. 15-5).

Entheseophyte Formation

Entheseophyte formation is new bone at the site of attachment of a tendon, ligament, or joint capsule to bone. Entheseous new bone reflects the bone's response to stress applied through these structures, such as ligamentous tearing or capsular traction (Fig. 15-6). Like osteophytes, entheseophyte formations take several weeks to months to develop and may or may not be associated with clinical signs. Knowledge of ligament, tendon, and capsular insertions is essential to determine which soft tissue structure may have been damaged. In some locations, such as the hock, differentiation between entheseophyte and osteophyte formation is not easy. The attachments of cranialis tibialis and fibularis tertius are close to the joint margins of the tarsometatarsal joint, and differentiation between entheseous new bone at these attachments and periarticular osteophyte formation may be difficult. Entheseous new bone may take the form of spur formation, such as at the site of attachment of the common digital extensor tendon on the distal phalanx or the site of attachment of the middle distal sesamoidean ligament on the palmar aspect of the middle phalanx. At other sites, such as the origin of the suspensory ligament (SL) on the plantar aspect of the third metatarsal bone, new bone formation may be more diffuse. Diffuse new bone formation on the caudal aspect of the occiput reflects tearing of the attachment of the nuchal ligament. New bone on the dorsal aspect of the radial, intermediate, ulnar, or third carpal bones may reflect entheseous new bone at the site of attachment of intercarpal ligaments or joint capsule. Such new bone does not necessarily reflect osteoarthritis, but it may reflect slight joint instability, which itself may predispose to the development of osteoarthritis. Similarly, joint trauma resulting in sprain of periarticular ligaments and subsequent entheseous new bone may ultimately also result in osteoarthritis.

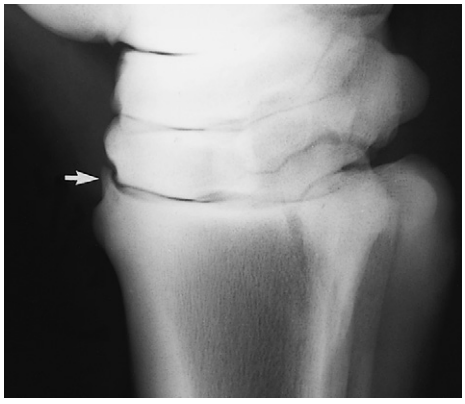

Fig. 15-4 Lateromedial radiographic view of a hock. There is a large periarticular osteophyte on the dorsoproximal aspect of the third metatarsal bone, close to and traversing the tarsometatarsal joint *(arrow)*.

Fig. 15-5 Dorsolateral-plantaromedial oblique radiographic view of a hock. There is narrowing of the centrodistal joint space. Lytic regions are seen in the subchondral bone of the central and third tarsal bones dorsomedially. There is loss of trabecular architecture due to medullary sclerosis in the central and third tarsal bones.

Fracture of an entheseophyte and mineralization within the tendon or ligament attachment also may occur. A relatively common site is the radial tuberosity at the attachment of biceps brachii. Small linear opacities may be seen dorsal to the summits of the spinous processes in the thoracic region, which is associated with tearing of the attachment of the supraspinous ligament.

Spondylosis

Ossifying spondylosis occurs in the caudal half of the thoracic region in the horse. Spondyles (osteophytes) arise from the ventral aspect of the vertebral bodies near the intercentral articulations. The osteophytes extend across the intercentral articulation toward similar osteophytes on adjacent vertebrae. Usually a lucent line persists between the two spondyles, although sometimes complete bridging does occur. Spondylosis may be progressive in cranial and caudal directions, although in some horses it remains static.

New Bone of Unknown Origin

New bone sometimes develops on the dorsal aspect of the diaphysis and distal metaphyseal region of the middle phalanx. The cause of this is unknown. It may be asymptomatic.

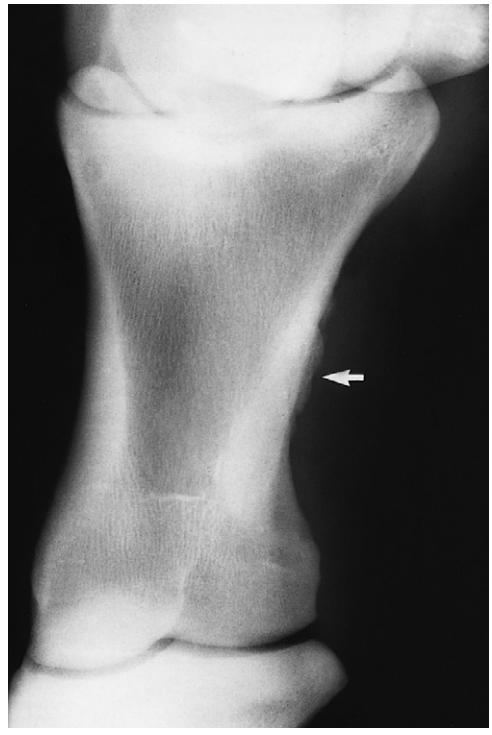

Fig. 15-6 Dorsolateral-palmaromedial oblique radiographic view of a pastern. There is entheseous new bone *(arrow)* on the mid-diaphyseal region of the proximal phalanx at the site of attachment of the middle (oblique) distal sesamoidean ligament.

Hypertrophic Osteopathy

Hypertrophic osteopathy (Marie's disease) is typified by palisading periosteal new bone, which appears to be perpendicular to the cortices and irregular in outline in the acute stage. It affects principally the diaphyseal and metaphyseal regions of long bones and spares the joints. In the early stages, very soft exposures must be used to avoid overexposing this relatively radiolucent bone. Later the margins of the new bone become more opaque and smoother and the distinction between the original cortex and the new bone becomes less obvious. These bony lesions develop secondary to a tumor, abscess, or other lesion in the thorax or abdomen, or in association with diffuse granulomatous disease. The bony lesions may regress and model if the primary lesion can be identified and successfully treated.

Osteitis

Osteitis is inflammation of bone. It may be non-infectious or infectious. Non-infectious osteitis usually is the result of trauma or inflammation of the adjacent soft tissues. It is characterized by new bone formation and, less commonly, bone resorption.

Infectious Osteitis and Osteomyelitis

Infectious osteitis is inflammation of bone as a result of infection. In bones with a myeloid cavity the term *osteomyelitis* is used if the myeloid cavity is affected. Infection results in soft tissue swelling, new bone formation, and bone resorption. In the distal phalanx and the distal sesamoid (navicular) bone, bone lysis predominates with little new bone formation. In other bones a combination of loss of bone and new bone formation usually occurs. A piece of dead radiopaque bone, or a *sequestrum*, may develop, surrounded by an area of lucent granulation tissue, the *involucrum* (Fig. 15-7). An area of more radiopaque bone may be laid down surrounding the infected area to wall off infection. A radiolucent tract, a *sinus,* may

Fig. 15-7 Dorsolateral-plantaromedial oblique view of the tuber calcanei. There is a small radiolucent region on the plantarolateral aspect with a radiopaque center *(arrow)*. These are an involucrum and sequestrum caused by infectious osteitis.

develop between the infected tissues and the skin. In the early stages, diagnostic ultrasonography may be more sensitive than radiography for detecting infection.

Osseous Cyst-Like Lesions and Subchondral Bone Cysts

Osseous cyst-like lesions are solitary, circular, or semicircular lucent areas in a bone; they usually develop in the subchondral bone. Sometimes a neck can be identified connecting the cyst to the joint cavity. Cyst-like lesions may be unicameral (single chambered) or, less commonly, multicameral. A sclerotic rim frequently surrounds osseous cyst-like lesions. Those that develop before skeletal maturity often appear to migrate away from the joint surface as normal endochondral ossification occurs. These single osseous cyst-like lesions, which are not associated with any pathological changes in the articular cartilage, should be differentiated from the more poorly defined lucent zones that develop in the subchondral bone in osteochondrosis.

The cause of osseous cyst-like lesions is probably multifactorial. Some are true subchondral bone cysts and have a fibrous cystic lining. There is increasing evidence that some of these lesions develop as a response to trauma to the articular cartilage and subchondral bone. They tend to occur most commonly in the medial femoral condyle of the femur and in the center of the glenoid cavity of the scapula. Other osseous cyst-like lesions may have a different histological appearance, despite similar radiographic appearance. Osseous cyst-like lesions in the proximal medial aspect of the radius tend to be associated with periosteal new bone in the region of insertion of the medial collateral ligament. Other common locations include the distal aspect of the third metatarpal bone and the proximal, distal, and middle phalanges.

Care should be taken when evaluating some bones, especially the phalanges, not to confuse the myeloid cavity with an osseous cyst-like lesion.

The development of some osseous cyst-like lesions can be followed radiographically. Some start as a small, elliptical depression in the articular surface that progressively enlarges into the subchondral bone. A sclerotic margin develops.

Osseous cyst-like lesions may be associated with lameness. Lesions deep in the bone, such as those seen in the first, second, and ulnar carpal bones, are rarely associated with lameness. Cyst-like lesions that are close to an articular surface are more likely to be associated with lameness. However, the lameness may be remarkable in its variable nature and severity. Lameness may resolve spontaneously, or after surgical intervention, despite persistence of a radiographic lesion.

The incidence of the development of osseous cyst-like lesions is higher in young horses than older horses. Some horses develop a subchondral bone cyst early in life that remains clinically quiescent, only to cause clinical signs later in life. However, subchondral bone cysts and osseous cyst-like lesions can develop in skeletally mature horses.

It can be difficult to determine the likely clinical significance of a subchondral bone cyst or an osseous cyst-like lesion based purely on radiographic appearance. Scintigraphic evaluation may be helpful, since many are hot, but it can also be confusing because a long-established cyst-like lesion that has been clinically quiescent can suddenly become a source of pain without evidence of active bone modeling. It is always important to evaluate radiographically the joint in its entirety, since evidence of secondary osteoarthritis warrants a more guarded prognosis.

Osteochondrosis

Osteochondrosis is considered a disorder of endochondral ossification, although there is increasing evidence that primary subchondral bone lesions also may occur. Osteochondrosis can cause osseous cyst-like lesions and osteochondritis dissecans. Osteochondritis dissecans may be generalized although it is only evident clinically and radiographically in certain joints. The femoropatellar, tarsocrural, fetlock, and scapulohumeral joints are most commonly affected. Radiographic abnormalities vary depending on the joint involved and include the following:

- Discrete osteochondral fragments
- Flattening or depression in the articular surface
- Subchondral lucent zones
- Sclerosis in the subchondral bone, surrounding lucent zones, or parallel with the joint surface
- Secondary osteoarthritis

Radiographic changes are not always clinically significant but must be interpreted in the light of clinical signs. Flattening of contour of the lateral trochlear ridge of the femur, with sclerosis of the subchondral bone, may be seen in the absence of lameness in mature horses. However, identical changes may be present in horses with poor hindlimb action referable to pain associated with the femoropatellar joints (Fig. 15-8). Flattening of contour or elliptical depressions in the trochleas of the talus with normal subchondral bone opacity are rarely associated with clinical signs. The more change in the subchondral bone, the more likely that clinical signs will be present. Small osteochondral fragments may become lodged in the synovial membrane and become progressively larger. Trauma may result in such lesions becoming dislodged and mobile and result in clinical signs.

FRACTURE

A *fracture* is a discontinuity of bone that may be seen radiographically as one or more lucent lines. Mach lines or bands should not be confused with a fracture. A *Mach line*, or band, is a radiolucent line created by edge enhancement when one bone edge is superimposed over another bone. Superimposition of the second and fourth metacarpal bones on the third metacarpal bone commonly results in Mach lines. In a caudocranial view of the proximal tibia, a Mach line is created by superimposition of the tibial crest on the tibia.

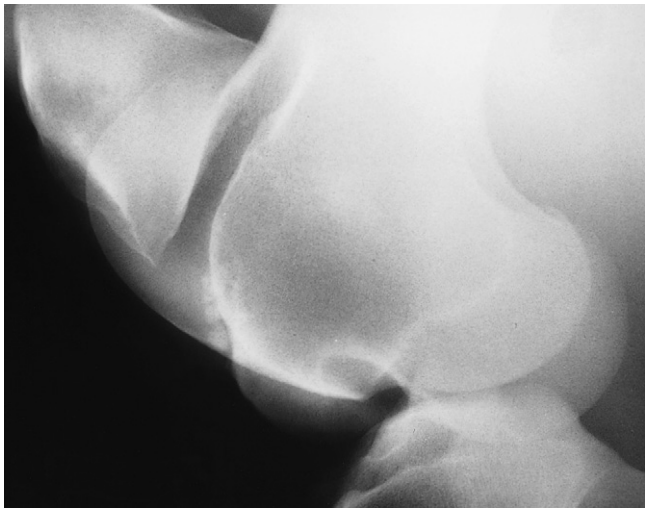

Fig. 15-8 Caudolateral-craniomedial oblique view of a stifle of a 5-year-old Thoroughbred with mild lameness associated with an effusion of the femoropatellar joint. A concave depression is seen in the middle of the lateral trochlea of the femur, with subchondral sclerosis and ill-defined lucent areas. In addition, several radiopaque bodies are visible in the concave depression. This is osteochondrosis.

Large exostoses involving the second or fourth metacarpal bone or fourth metacarpal or fourth metatarsal bone often result in confusing lucent lines, apparently within the bone, which must not be interpreted as fractures. Likewise, some bony exostoses in these locations incorporate some fibrous tissue, resulting in a persistent lucent line that should not confused with a fracture. A nutrient foramen that traverses a bone should also not be interpreted as fracture. Most nutrient foramina are broader than a recent fracture would be expected to be. A notable exception is the vertically orientated nutrient foramen in the third metacarpal or second metatarsal bone and the fourth metacarpal or fourth metatarsal bone. It is important not to misinterpret lucent lines in the foot created by the frog clefts as fracture lines. Despite careful packing of the frog clefts and sulcus (with, for example, Play-Doh; Hasbro, Inc., Pawtucket, RI), complete packing is impossible if these are very deep and will result in narrow lucent lines. Care should be taken to see if such a lucent line (e.g., apparently in the navicular bone) extends beyond the bone margins. If the angle of projection is altered slightly, does the position of the line change relative to the medial and lateral borders of the bone? Can the same lucent line be seen in a dorsopalmar projection? Care must also be taken not to confuse the lucent bands between separate centers of ossification with fracture lines. The cartilages of the foot and the fibula frequently develop as separate centers of ossification and bony union may never develop between the different ossification centers, which results in lucent gaps within each bone that persist over the long term. A long, thick hair coat that is wet sometimes can result in the appearance of a lucent line or lines superimposed over bone, which must not be interpreted as a fracture.

Some stress or fatigue fractures are never detectable radiographically. Some can be seen as one or more lucent lines, or if chronic, there may be endosteal new bone or medullary sclerosis. If a chronic stress fracture traverses a cortex, there may be periosteal callus, although the fracture line itself may not be detectable.

Ideally, the postulated radiolucent fracture line should be detectable on more than one radiographic projection to confirm the presence of a fracture. However, this is not always possible, especially if the fracture is incomplete and non-displaced. This is particularly true for fractures of the distal phalanx and incomplete dorsal cortical fractures of the proximal phalanx. For best results, the x-ray beam must be perpendicular to the plane of the fracture line. Many different views that differ by only 5° in angle of projection may be required to detect a fissure fracture. With a complete fracture, many different views may be required to determine the precise configuration of the fracture.

Some fractures are not detectable in the standard radiographic projections of the area under examination. A fracture of the lateral palmar process of the distal phalanx may not be detectable in lateromedial, dorsopalmar, and dorsoproximal-palmarodistal oblique views. Dorsolateral-palmaromedial oblique or sometimes a palmaroproximal-palmarodistal oblique or palmaroproximal-palmarodistal oblique views, or a dorsal 60° proximal 45° lateral-palmarodistal medial oblique view, are required. Sagittal and some slab fractures of the third carpal bone are only visible in dorsoproximal-dorsodistal oblique views of the flexed carpus (the skyline projection). Similarly, fractures of the medial pole of the patella are only detectable in cranioproximal-craniodistal oblique views of the flexed stifle.

The normal healing process of a fracture involves osteoclasis along the fracture line within 5 to 10 days, resulting in initial broadening of the fracture line. Therefore if a fracture is suspected but cannot be seen in the acute stage, radiography should be repeated after 5 to 10 days. Care should be taken not to underexpose the radiograph, since a faint lucent line may be missed. Paradoxically, early callus formation, which develops within 14 to 21 days, will be missed if the radiograph is overexposed or not viewed over high-intensity illumination.

A fracture should be evaluated to determine whether it is complete or incomplete, simple or comminuted, whether fracture fragments are displaced, presence of articular involvement, and whether any other concurrent pathological condition is present that may influence the prognosis. An apical sesamoid fracture may be accompanied by severe desmitis of the branch of the SL, which prognostically is the more severe injury. Biaxial transverse fractures of the proximal sesamoid bones result in disruption of the suspensory apparatus and severe risk of compromising the blood supply to the distal part of the limb. An avulsion fracture of the lateral collateral ligament of the metacarpophalangeal joint from the proximal phalanx will result in loss of joint stability.

It is important to be aware that with a single, complete fracture, two lucent lines representing the fracture traversing, for example, the dorsal and palmar cortices, may be seen. These lines should not be confused with two fractures. However, care must always be taken to make sure that there is not more than a single fracture line. For example, a common fracture in steeplechasers that fall is a vertical fracture through the body of the accessory carpal bone. These horses have a good prognosis with conservative management. Rarely, one or more chip fractures involving the articular margins of the bone occur; such injuries warrant a much more guarded prognosis. An event horse that hits a fixed fence during cross-country jumping may fracture the medial trochlear ridge of the femur. Fracture fragments may readily be seen in a lateromedial projection of the stifle. Such fractures also can be accompanied by a fracture of the medial pole of the patella, which can be seen only in a skyline projection. Therefore it is essential to obtain a complete radiographic series and interpret each radiograph in its entirety.

Intra-articular fractures occur when a break in the articular surface occurs. Unless some degree of displacement is present, damage to the articular cartilage may not be seen but is assumed to exist. A small degree of displacement is indicated

by the presence of a slight step in the two sides of the articular portion of the fracture line. Comminution at the joint surface sometimes occurs. This may not be evident in standard radiographic projections. For example, lateral condylar fractures of the third metacarpal bone may be accompanied by a Y fragment at the articular margin that is detectable only in dorsodistal-palmaroproximal oblique projections.

Fractures on an articular margin are called *chip fractures*. In some locations, such as the antebrachiocarpal and middle carpal joints, it is important to assess the radiographs carefully for evidence of pre-existing osteoarthritis, which predisposed to the fracture and may influence the prognosis. The veterinarian should bear in mind that more than one chip may exist.

Chip fractures of the articular margins should be differentiated where possible from separate centers of ossification, avulsion fractures that occurred in the neonatal period, and ectopic mineralization. The position of the mineralized body relative to the articular margin, the size and shape of the body, and the contour of the articular margin should all be assessed carefully. A recent chip fracture may have a sharp edge and a detectable fracture bed from which it originated may be seen. Separate centers of ossification usually are well rounded and uniformly opaque with no discernible fracture bed. It is important to recognize that such pieces may be clinically silent, but some are associated with lameness. The significance must be interpreted in the light of clinical signs and the response to local analgesic techniques. Ectopic mineralization may be present within the joint capsule.

Osteochondral fragments, the result of osteochondritis dissecans, should not be confused with a fracture. Osseous fragments may be seen, for instance, distal to the trochleas of the talus at the entrance to the talocalcaneal-centroquatral (proximal intertarsal) joint. These fragments may have originated from the distal intermediate ridge of the tibia and usually are of no clinical significance. Well-rounded, smoothly marginated osseous opacities may be seen on the proximoplantar aspect of the proximal phalanx. These may be the result of avulsion fractures of the short, deep cruciate sesamoidean ligaments that were sustained early in life; they are not always clinically significant but may compromise performance at maximum levels. The variably present first and fifth carpal bones should not be confused as fractures.

In some joints, it may not be possible to determine radiographically the origin of a fracture fragment. For example, fragments in the femorotibial joint frequently are not associated with any detectable disruption in bone outlines and only arthroscopic evaluation of the joint allows determination of the origin. It also may not be possible to determine whether an accompanying soft tissue pathological condition exists. A fracture of the medial intercondylar eminence of the tibia may occur alone. The prognosis is good with surgical removal. Sometimes, however, concurrent cranial cruciate ligament damage exists at its insertion cranial to the eminence, resulting in a much more guarded prognosis.

A *slab fracture* is a fracture that extends from one joint surface to another (e.g., from the proximal to distal aspect of the third carpal or tarsal bones). These fractures can be extremely difficult to detect in the acute stage if not displaced.

In some locations the origin of a fracture fragment is facilitated by ultrasonographic examination. For example, a fragment on the palmar aspect of the fetlock may be an avulsion fracture of the insertion of the palmar annular ligament on the proximal sesamoid bone, and this is readily confirmed ultrasonographically.

Fracture healing depends on many factors, including the age of the horse, its nutritional and metabolic status, the site and stability of the fracture, the presence or absence of periosteum or infection, and the blood supply to the bone. After initial mineral resorption along the fracture line and formation of fibrous callus, calcified periosteal and endosteal callus develop. The amount and quality of callus that develops depends on the degree of stability at the fracture site and the presence or absence of infection. If a fracture is stable, either because it is incomplete or because it has been stabilized by internal fixation, healing is predominantly by primary union and endosteal reaction with minimal periosteal callus. Instability results in the development of periosteal callus.

The fracture may become stable long before the fracture line disappears radiographically. Healing may be complete within 6 to 12 weeks, with progressive narrowing and ultimate disappearance of the fracture line. However, healing of some fractures takes considerably longer. A horse may be sound and able to withstand full work despite the persistence of a radiolucent fracture line. In some locations (e.g., lateral condylar fractures of the third metacarpal bone) a persistent lucent line may be associated with recurrent and persistent pain.

Some bones tend to heal by fibrous union, resulting in a persistent lucent line. These include the accessory carpal bone, the proximal and distal sesamoid bones, and the distal phalanx. Unless a fracture of the navicular bone is stabilized by internal fixation, lucent areas tend to develop in the adjacent bone along the fracture line. These indicate a chronic fracture of the navicular bone of at least 6 to 8 weeks' duration.

If a fracture line persists beyond 6 months, it can be considered to be a delayed union. Sclerosis of the bone adjacent to the fracture line may be present, and the ends of the bone may be slightly flared. Delayed union is not uncommon, but non-union is unusual in the horse except in those bones that tend to heal by fibrous union.

Aging of a fracture is not easy to determine radiographically with any accuracy. The presence of periosteal callus (Fig. 15-9) indicates a fracture of at least 14 days' duration and often substantially longer. An acute fracture has very clearly defined margins, which become less distinct as resorption occurs along the fracture line during early healing.

Fig. 15-9 Craniolateral-caudomedial oblique view of the proximal tibia of a 3-year-old Thoroughbred filly. Periosteal callus formation *(arrows)* on the caudoproximal aspect of the tibia is associated with a stress fracture. The oblique lucent line in the proximal tibia is a nutrient foramen.

DEGENERATIVE JOINT DISEASE: OSTEOARTHROSIS OR OSTEOARTHRITIS

Arthritis means inflammation of a joint. *Osteoarthritis* or *osteoarthrosis* indicates that bone has become involved and that a soft tissue component may (-itis) or may not (-osis) be present. The term *secondary joint disease* sometimes is used to denote that the degenerative changes are secondary to a known condition, such as infection or osteochondrosis. Any condition that damages cartilage, causes joint instability, or places abnormal forces on the joint may result in osteoarthritis. It may develop as a result of abnormal conformation or be the result of wear and tear on an athletic horse. However, advanced osteoarthritis sometimes is seen in relatively young horses with no identifiable predisposing cause.

Radiographic abnormalities associated with osteoarthritis include the following:

- Periarticular osteophyte formation
- Narrowing of the joint space
- Subchondral lucent zones, either well or poorly defined
- Subchondral bone sclerosis; loss of trabecular pattern
- Thickening of the subchondral bone plate
- Joint capsule distention

However, it is important to recognize that in some joints advanced osteoarthritis may be present without any detectable radiographic change. Periarticular osteophytes are not necessarily synonymous with clinically significant osteoarthritis. It is relatively unusual to see subchondral lucent zones in high-motion joints. These occur more commonly in the low-motion joints, such as the distal hock and proximal interphalangeal joints.

A relatively poor correlation exists between the degree of radiological change associated with osteoarthritis and the degree of pain and thus lameness. Advanced radiological change may be present when lameness is first recognized, which clearly must have pre-dated the onset of recognizable clinical signs. In contrast, obvious lameness associated with joint pain may be present without detectable radiological change. Widespread wear lines may be present on the articular cartilage without associated radiological change.

Therefore dating the likely onset of clinical signs based on the radiological appearance of a joint can be difficult. It also can be difficult to predict the likely progression of minor radiological changes, such as small periarticular osteophytes, which may be present without clinical signs at, for example, a prepurchase examination.

LUXATION AND SUBLUXATION

Luxation is the complete loss of contact between articular surfaces. *Subluxation* is partial loss of contact between joint surfaces and may be intermittent. Both are usually the result of trauma, although congenital luxation of the patella occurs occasionally. Subluxation of the proximal interphalangeal joint may occur without any obvious cause, especially in hindlimbs. Subluxation is easy to identify radiographically, but the radiographs must be evaluated carefully to identify any concurrent fracture that will adversely influence prognosis.

Subluxation may not be obvious radiographically and stress radiographs obtained with the limb not bearing weight, with pressure applied in a mediolateral or dorsopalmar direction, may be necessary to determine if the bones can be moved relative to each other.

DYSTROPHIC AND METASTATIC MINERALIZATION

Soft tissue mineralization is classified as metastatic or dystrophic. *Metastatic mineralization* is the deposition of mineral in normal tissues and is associated with hypercalcemia, hyperphosphatemia, or hypercalciuria and is unusual in the horse. *Dystrophic mineralization* is the deposition of mineral in injured, degenerating, or necrotic tissue and occurs quite commonly in the horse in, for example, a damaged SL. It can occur secondary to any injury to soft tissue subsequent to infarction, hemorrhage, or inflammation. Dystrophic mineralization may ultimately become ossified.

RADIOGRAPHIC EXAMINATION

For each joint or region to be examined there is a standard radiographic technique that includes a basic minimum number of views for routine evaluation of the region. This usually includes a minimum of four views for joints distal to the elbow and stifle. However, radiographic technique must be flexible. For example, if a fracture is suspected, various views differing only slightly in angle of projection may be required. Some fractures are visible only on special projections. For example, a fracture of the medial pole of the patella may be detected only in a cranioproximal-craniodistal oblique view. Exposure factors need to be altered depending on the size of the horse and the area being evaluated. Exposure factors ideal for assessing trabecular structure within medullary bone result in overexposure of immature periosteal new bone. Underexposure may result in a fracture line or alterations in corticomedullary demarcation and trabecular structure being missed.

It is also important to realize how position-sensitive some radiographic abnormalities are and how easily artifacts can be created. For example, the accurate evaluation of corticomedullary demarcation and trabecular structure within the navicular bone in a palmaroproximal-palmarodistal oblique view depends highly on the position of the limb and the angle of the x-ray beam. The optimum angle of the x-ray beam depends on the shape of the foot. Inappropriate positioning of the foot or using an x-ray beam that is not tangential to the flexor surface of the navicular bone will result in artifacts.

The x-ray beam should be coned down on the area of interest as much as possible and centered on the area of interest. Lesions will be missed if an attempt is made to evaluate too much in a single view (e.g., the fetlock, pastern, and foot). It frequently is helpful to obtain comparative views of the contralateral limb. These should be obtained with identical exposure factors and similar positioning of the limb and angulation of the x-ray beam for accurate evaluation. Comparison of radiographs with a known normal example of similar age can also be helpful. It is thus useful to compile an image library of normal examples.

INTERPRETING RADIOGRAPHS

Radiographs should be evaluated in a systematic way. First, the quality of the radiographs should be assessed. Is the horse positioned appropriately? Are the radiographs of adequate quality? Are there any artifacts? The films should be viewed on a proper viewing box, both close to and from far away. The veterinarian should view the films under both normal and high-intensity illuminations and interpret the entire film, and should follow all the bone margins and then evaluate the internal architecture. The veterinarian should avoid lesion or disease spotting but aim to describe the radiological abnormalities and then deduce potential causes of the abnormality.

If a lesion is suspected but further information is required, the clinician should consider coning down, altering the exposure factors, slightly changing the angle of projection, or using special views. The radiographs should be compared with normal bone specimens, with an awareness that not all radiographic abnormalities are necessarily of clinical significance.

Knowledge of normal anatomy and normal variations is essential, together with knowledge of the sites of ligament, tendon, and joint capsule insertions.[1] Recognition of breed differences also is important. Radiographic abnormalities must be interpreted in the light of clinical signs. It is also important to recognize that there are discipline differences in the potential significance of some lesions. For example, mild osteoarthritis in the antebrachiocarpal or middle carpal joint may compromise the performance and career of a flat racehorse but be of little significance for a show horse or low-level show jumper. It must also be recognized that it is often not possible to predict the future development of lesions. A horse with a small osteophyte on the dorsoproximal aspect of the third metatarsal bone may look identical in a later year, but a different horse may have developed extensive periarticular osteophytes involving both the centrodistal and tarsometatarsal joints.

Determining the Age of a Lesion

It is often not possible to accurately determine the age of a lesion that is identified radiographically. Periosteal new bone usually takes at least 14 days to be visible radiographically following trauma. Once new bone is well consolidated and smoothly marginated, it is impossible to determine how long it might have been present. A non-displaced fracture may take up to 10 days before it is evident radiographically; loss of clarity of the fracture margins may indicate that it has been present longer. Radiological changes compatible with osteoarthritis can precede the onset of clinical signs and may be relatively advanced when lameness is first recognized. It is not possible to determine when the changes first developed.

RADIOGRAPHIC TECHNIQUE

Standard radiographic projections are outlined in Table 15-1. For detailed descriptions of radiographic technique for all regions of the musculoskeletal system, readers are referred to *Clinical Radiology of the Horse*.[2] Throughout this text, radiographic views are described using the technique advocated by the American College of Veterinary Radiologists.[3]

All radiographs should be permanently labeled photographically on the film, either by use of special tape attached to the cassette when the film is exposed or by a labeling light box system in the darkroom. Labels should include at least the identity of the horse, the date, the limb examined, and medial or lateral when appropriate. The following facts also are preferable on the label: the name of the owner or agent of the horse, the name of the veterinary practice, and the identity of the view (e.g., PaL-DMO). For ease of identification, it can be helpful if the horse's label is always positioned on the lateral aspect of the cassette; if a medial marker was omitted, it is then still possible to differentiate between the medial and lateral sides.

Radiographs are part of the horse's permanent medical and legal record and should always be retained by the veterinary practice for future reference unless the owner of the horse gives permission for the radiographs to be transferred to another veterinary practice. Copy radiographs are easily produced if a client wishes to have his or her own copy.

Digital radiography generally uses imaging plates with a larger exposure latitude compared with traditional film screen combinations. Therefore it is potentially easier to obtain good-quality images with a single exposure. With a computerized system the images can be manipulated to enhance contrast and magnify areas of interest; therefore lesions that might previously have been missed may be more readily identified. With an appropriate archiving system, all images can be stored digitally rather than printed. Digital radiography is not a substitute for good radiographic technique but offers the advantage of providing images that may be of superior quality and can be stored and transmitted electronically.

Table • **15-1**

Standard Radiographic Projections and Suggested Extra Views

REGION	NOTES ON RADIOGRAPHY	NOTES ON RADIOLOGY
Front Feet		
LM	• Center on position of navicular bone • Angle the x-ray beam at a tangent to the bulbs of the heels • Position the foot on a block so that the cassette can be placed lower than the solar surface of the foot • Place a radiodense marker on the dorsal hoof wall with the proximal aspect at the coronary band to determine any possible deviation of the distal phalanx • Soft exposures needed to see remodeling of distal phalanx	• Variable shape of extensor process • Small osseous opacities on the proximodorsal aspect of the distal phalanx may be insignificant • Smoothly outlined depression in sagittal ridge of navicular bone is normal
DPa	• Place foot on a block • Horizontal x-ray beam centered midway between the coronary band and the ground and aligned perpendicular to a tangent to the bulbs of the heels	• Useful for assessing mediolateral balance and joint space width • Mineralization of the cartilages of the foot (sidebone) rarely significant • Mineralization of cartilages may be from separate centeres, resulting in permanent lucent lines that are not fractures

L, Lateral; *M*, medial; *D*, dorsal; *Pa*, palmar.

Table • **15-1**

Standard Radiographic Projections and Suggested Extra Views—cont'd

REGION	NOTES ON RADIOGRAPHY	NOTES ON RADIOLOGY
Front Feet—cont'd		
DPr-PaDiO	• Remove shoe and clean thoroughly • Pack the frog clefts • Different exposures needed for distal phalanx and navicular bone • Avoid excessive flexion of the fetlock • Dorsal hoof wall should be just in front of the vertical	• Variable shape and size of crena of distal phalanx • Variable smoothness of solar margins of distal phalanx • Entheseophyte formation on proximolateral aspect of navicular bone a common finding in normal horses • Seven or less small radiolucent zones along the distal border of navicular bone often normal
Pa 45° Pr-PaDiO	• Remove shoe and clean foot • Angle the x-ray beam according to heel height: if the heels are low, reduce the angle to 35°-40° • Position the foot to be examined behind the contralateral limb • Center the beam between the bulbs of the heel	• Artifacts (e.g., reduced corticomedullary demarcation) easily created by poor technique
Extra views		
Flexed oblique views of interphalangeal joints (D 60° L-PaMO) or of palmar processes of distal phalanx (D 45° L-PaDiO)	• Remove shoe and clean foot • Pack frog clefts	• Useful for detection of modeling changes of articular margins of DIP joint • Essential for diagnosis of some distal phalanx fractures
Hind Feet		
As for front feet, but easier to obtain PlPr-DDiO views of distal phalanx and navicular bone		
Pasterns		
LM		• Entheseous new bone on the palmar aspect of the proximal phalanx is often seen without associated clinical signs • A small spur on the dorsoproximal aspect of the middle phalanx is commonly seen in Warmblood breeds
DPa	• Angle the x-ray beam downward, perpendicular to the pastern	• Best view for evaluation of joint space narrowing
Flexed DL-PaMO and DM-PaLO	• Flexed oblique views open up the proximal interphalangeal joint, allowing much better appreciation of the joint margins than in weight-bearing views	
Fetlocks		
LM or flexed LM	• Flexed LM gives more information about the distal aspect of the sagittal ridge of the third metacarpal bone, supracondylar region, and articular margins of the proximal sesamoid bones • For LM of hindlimb fetlock, angle the x-ray beam from 10° plantar to a tangent to the bulbs of the heel	• Well-rounded osseous fragments may be seen distal to the proximal sesamoid bones, which may be previous avulsions from either the palmar/plantar aspect of the proximal phalanx or from the sesamoid bones

D, Dorsal; *Pr,* proximal; *Pa,* palmar; *Di,* distal; O, oblique; *L,* lateral; *M,* medial; *Pl,* Plantar.

Ultrasonographic Evaluation of the Equine Limb: Technique

Norman W. Rantanen, Joan S. Jorgensen, and Ronald L. Genovese

Diagnostic ultrasonography was introduced in the early 1980s as a practical imaging modality to evaluate soft tissue injuries of the equine limb.[1] It continues to be used extensively for evaluation of tendonous and ligamentous structures to identify, confirm, and monitor soft tissue injury (Box 16-1).[2-8] Ultrasonography is now the imaging modality of choice for soft tissue evaluation. However, it is user specific, and diagnostic information relies heavily on adequate equipment, limb preparation, and the scanning skills of the ultrasonographer. This chapter describes terminology and techniques and provides advice about interpretation based on our collective experiences. We describe our systematic approach that includes both qualitative and quantitative ultrasonographic analysis of distal limb injuries. The resulting data can be used to categorize the severity of the injury and compare with subsequent examinations. The state of the art

Ultrasonographic Evaluation of the Equine Limb: Technique

Norman W. Rantanen, Joan S. Jorgensen, and Ronald L. Genovese

Diagnostic ultrasonography was introduced in the early 1980s as a practical imaging modality to evaluate soft tissue injuries of the equine limb.[1] It continues to be used extensively for evaluation of tendonous and ligamentous structures to identify, confirm, and monitor soft tissue injury (Box 16-1).[2-8] Ultrasonography is now the imaging modality of choice for soft tissue evaluation. However, it is user specific, and diagnostic information relies heavily on adequate equipment, limb preparation, and the scanning skills of the ultrasonographer. This chapter describes terminology and techniques and provides advice about interpretation based on our collective experiences. We describe our systematic approach that includes both qualitative and quantitative ultrasonographic analysis of distal limb injuries. The resulting data can be used to categorize the severity of the injury and compare with subsequent examinations. The state of the art

Box • 16-1

Indications for Ultrasonographic Evaluation of Limbs

- Diagnosis of soft tissue injuries, including muscular, vascular, tendon, tendon sheath, ligament, joint capsule, or bursal defects
- Assessment of fluid accumulation
- Evaluation of bony surfaces
- Monitoring of the healing progress
- Monitoring of the effect of training on soft tissue structures, especially tendons and ligaments

is still developing, and changes will evolve to improve the clinician's ability to identify and substantiate clinical findings leading to improved management of soft tissue injury in the horse.

EQUIPMENT

Ultrasound machines used for musculoskeletal imaging require a range of transducer frequencies to examine superficial and deep structures. Soft tissues within 5 to 7 cm of the skin surface should be examined using a transducer with a frequency of at least 7.5 MHz or higher. Tissues within 7 to 15 cm of the skin surface are best evaluated with a 5.0-MHz transducer, whereas deeper tissues require a transducer in the 2.5- to 3.5-MHz range.

Sound is attenuated at 1 dB/cm depth per megahertz. Higher frequencies are attenuated at higher rates, thus limiting penetration. Conversely, lower frequencies, attenuated at lower rates, have greater penetration. The highest frequency possible should be used to obtain maximum resolution.

Claiming that one instrument is the only one to perform musculoskeletal examination is naive at best and totally inaccurate. All state-of-the-art machines have similar focusing capabilities and resolving power. Image appearances made by different machines at the same frequencies have subtle differences; however, resolution is about the same. Images may appear more crisp from transducers with a greater number of elements. Operator proficiency (or lack of it) largely determines image quality.

Large muscle masses or bone surfaces, such as the pelvis, are more effectively scanned with convex, annular array, or sector transducers. The small skin surface imprints and divergent beam are advantageous when imaging tissues at greater depths. However, annular array and sector transducers have focal zones that usually favor the central portion of the beam and have beam divergence, which causes far-field, lateral beam width artifact. Convex array transducers have electronic focusing, and the examiner can control focal zone placement. It is common for sector and annular array transducers to penetrate up to 30 cm, but most convex array transducers are limited to 24 cm.

Linear array transducers are the most popular for tendon and ligament scanning because they facilitate anatomical recognition of structures and evaluation of longitudinal tendon and ligament fiber alignment parallel to the skin surface. Convex array and sector transducers, if used properly, work equally well. However, they are more difficult to use because it is easier to change the beam direction because of the smaller contact area. It is necessary to keep the beam at 90° to the tendon or ligament fibers. Anatomical features may be more difficult to recognize. Standoff pads are essential with any transducer to image the most superficial structures.

Sector and convex array transducers are preferable for use on contoured skin surfaces. For instance, scanning between the heel bulbs is difficult with a flat-face, linear array transducer but simple with convex or sector transducers. It is easier to steer a divergent beam and look around from a smaller contact area compared with the flat-face, linear array transducer's broad contact area and rectangular sound beam.

Dual-frequency scanheads are available from most manufacturers; these scanheads allow operators to change frequencies relative to tissue depths without changing transducers. Newer broadband scanhead technology ensures quality, and there are no disadvantages in using these scanheads for musculoskeletal scanning provided basic ultrasound principles are practiced.

PATIENT PREPARATION

The horse should be adequately restrained, because an anxious, fidgety patient may cause a hurried or inadequate examination, resulting in poor-quality images and interpretive errors. One author (R.L.G.) prefers to sedate most horses that are not entered in drug-tested competition to ensure that the horse stands quietly during the examination. The horse should be held by a person who has responsibility for the safety of the ultrasonographer and the equipment. A calm, well-positioned patient allows a thorough, tension-free evaluation.

Hair, air, scurf, scabs, and dirt induce artifacts and reduce image quality. The hair should be clipped with a No. 40 or No. 50 blade, then cleaned with an antiseptic scrub, followed by a generous rinse with water, taking care to follow the growth pattern of the hair. In some horses an additional close shave with a disposable razor may improve image quality. Acoustic coupling gel is applied to improve transducer contact. Excessive application of gel causes a lateral image artifact that may impair assessment of the structures being examined, especially if peritendonous or peri-ligamentous neural, vascular, and connective tissue structures are being evaluated. Removal of the excess gel from the transducer head or the limb corrects the artifact.

If the hair coat is fine and clipping or shaving is not possible or desired, then the limb can be washed. The examiner should spend some time wetting and soaking the hair to improve transducer contact. Topical application of alcohol while stroking the hair along its growth path may improve transducer contact,[5] but *alcohol can be harmful to some transducers*. The operator should contact the manufacturer of the equipment to ensure that it is safe to use the transducer with alcohol.

MEDICAL RECORDS

Ultrasonographic images should be recorded using thermal prints, video recording, or digital recording. Thermal images are used most commonly.

Thermal Print Storage Envelope

Practical hints and suggestions for medical record documentation that can simplify case records, enhance clinical information for serial studies, and improve documentation are provided in the following text. We recommend a simple form stamped on the outside of a storage envelope. The information on the envelopes can be quickly filled in using symbols or checkmarks and should include the following data: horse identification, date, owner, trainer, limb or limbs examined, and structure or structures evaluated (superficial digital flexor tendon [SDFT], deep digital flexor tendon [DDFT], accessory ligament of the DDFT [ALDDFT], main body of the suspensory ligament [SL], SL branch, pastern, hock, antebrachium,

crus, and other). It is also useful to record exercise level, the reason the examination was performed, and a brief summary of clinical findings. This checklist indicates which structures have been targeted and assists in interpretation of an actual lesion versus an off-incidence angle artifact. This is especially helpful if the images are reassessed at a later time.

We have developed an alphanumerical system for ranking exercise levels (Box 16-2). The current exercise level may have an important impact on diagnosis, treatment, future exercise control, and prognosis. For instance, if a horse at pasture injured a SDFT, advising pasture rest would be contraindicated. A chart for ranking exercise levels can be duplicated easily, laminated, and taped to equipment for easy reference.

Clinical findings may be recorded concisely as follows:

Leg	Which limb.
S	Subcutaneous swelling on a scale of 0 to 5. This does not refer to tendonous or ligamentous enlargement.
L	Lameness on a scale of 0 to 5.
T	Thickening of a tendon or ligament on a scale of 0 to 5. This is independent of subcutaneous swelling.
Sen	Response to digital palpation of a tendon or ligament on a scale of 0 to 5.
H	Heat or skin temperature on a scale of 0 to 5.
TS	Distention of the digital flexor tendon sheath (tenosynovitis) on a scale of 0 to 5.
AS	Ankle sinking or hyperextension of the metacarpophalangeal joint, either at rest or during movement, on a scale of 0 to 5.
Qualitative diagnosis	Comments on preliminary qualitative ultrasonographic interpretation.
New	Whether this is the first time this horse has been examined ultrasonographically for this complaint.
Re-Ck	A recheck of a previous injury.
Normal leg	This indicates which is the clinically normal limb, which may not be normal ultrasonographically. It is strongly recommended that both limbs be examined routinely.
Both abn	Both limbs are clinically abnormal.

Image Labeling

All ultrasonographic images should be labeled with the date of examination, the horse's name, the owner's or trainer's name, the limb being examined, and the location of the image. In addition, it is helpful to include the age, breed, use of the horse, and the current exercise level. Most machines automatically record the frequency of the transducer and the focal zone.

Box • 16-2

Exercise Level Grading Scale

Exercise Level	*Type of Exercise Allowed*
0	Complete stall rest.
1A	Hand walk for 15 to 30 minutes once a day.
1B:	Hand walk ≥30 minutes a day or walk on a mechanical walker. We believe horses usually are more active walking on a mechanical walker than in hand.
2A	Thoroughbred (TB) and Standardbred (STB) racehorse, event horse (EV), and sport horse (SH): exercise level- 1A/B plus trotting *in hand* for 5 to 10 minutes a day.
2B	TB racehorse, SH, and EV: trot under saddle 10 to 15 minutes once a day or swim. STB racehorses: walk *only* in the bike or swim. This level also includes 10 to 15 minutes of trotting on a treadmill.
3A	Small paddock turnout for all horses. Small paddock implies small enough not to be able to work up to a sustained canter or gallop.
3B	Large paddock turnout for all horses.
4A	TB and SH: 15 to 20 minutes a day of walk, trot, and canter under saddle, 3 days per week, plus any of the above levels. This level does not apply to most STBs.
4B	TB: 20 to 30 minutes a day of walk, trot and canter under saddle, 3 to 4 days a week. TB racehorse: "ponying" (being led from another horse) on the racetrack. This level does not apply to most STBs.
5	TB racehorse and EV: all of the above plus normal galloping. STB racehorse: all of the above plus jogging. SH: all of the above plus normal arena flat work with limited low fence jumping where applicable. Dressage horses: normal work minus lateral movements and special gaits.
6	TB racehorse: all of the above plus faster gallops. EV: all of the above plus jumping. STB racehorse: all of the above plus training miles ≥2:10. SH: all of the above plus unlimited low fence jumping where applicable. Dressage: all of the above plus lateral movements and special gaits. Contest horses (reiners, cutters, and so on): all of the above plus practicing specific turns and movements.
7	In essence, this is the maximal work level for any type of athletic horse. TB and EV: racing, fast works, and competing. STB racehorse: training miles <2:10 and racing. SH: showing, jumping, hunting, and so on. Dressage and contest horses: competing.

EXERCISE LEVELS

One of the basic concepts in the management of tendon and ligament injuries is to relate increasing levels of exercise to increases in tendon and ligament loading. For instance, walking a Thoroughbred (TB) racehorse in hand results in far less SDFT loading (stretching) than racing at 35 mph. Understanding the current exercise level is important in interpretation of ultrasonographic information and advising management programs for controlled exercise during rehabilitation from an injury (see Box 16-2).

For example, if a TB racehorse with a SDFT injury of 4 months' duration was re-examined and the SDFT showed little improvement, despite box or stall rest, the veterinarian would conclude that the repair was of poor quality with a poor prognosis for a return to racing. However, if the horse had been turned out for 6 hours a day with other horses that ran around, the delayed healing would be interpreted as being caused by too much tendon loading and the lack of improvement was due to low-level ongoing injury. The client would be advised to reduce the exercise level and would be given a little more positive outlook for future racing soundness.

In the rehabilitation of a tendon or ligament injury, the odd exercise level numbers result in the most salient changes in tendon or ligament loading. Exercise level 1 is limited to walking, resulting in little structure loading, whereas exercise level 3 is a major step up in exercise and structure loading because it allows free movement of the horse. Exercise level 5 signals the return to active training. Finally, exercise level 7 is the ultimate goal of rehabilitation and is the return to maximal athletic use. During rehabilitation the ultrasonographer assesses the current morphological status of a structure and advises changes in exercise levels consistent with those findings. Readily available and definable exercise levels make exercise decisions more efficient and consistent.

SCANNING TECHNIQUE

The basic objective of an ultrasonographic evaluation is to characterize the morphological characteristics of the soft tissue structures and bony surfaces of each designated anatomical area. Although physical examination findings may direct the clinician's attention to a specific structure, a thorough examination of all soft tissue and bone surface structures is imperative. In many instances, lesions in more than one anatomical region may be identified and often result in a completely different recuperation regimen. To avoid off-incidence artifacts, the ultrasound beam must be perpendicular to the target structure. Although more than one structure may be perpendicular to the ultrasound beam simultaneously in either transverse or longitudinal images, often it is necessary to redirect the ultrasound beam to adequately examine all structures at each level. Initially the limb should be systematically examined from proximal to distal to assess the morphological features of the vasculature, peri-ligamentous and peri-tendonous tissue, tendons, and ligaments. Once specific abnormal or normal structures are identified, each tendon or ligament is analyzed systematically by ultrasonographically targeting the transducer to the structure at each zone and simultaneously documenting the scan on tape or print record.

ARTIFACTS

Artifacts cause major problems with any method of imaging, but especially with ultrasonography, because the operator steers the ultrasound beam and sets the instrument parameters. Three primary artifact sources are common with diagnostic ultrasonography: operator error, ultrasound-tissue interaction, and inherent instrument design artifacts. Nothing can be done about the limitations of the imaging system except to recognize the artifacts in special scanning situations. Sound-tissue interaction creates a myriad of artifacts, some of which are useful and help with diagnosis. Others are annoying and cannot be overcome. Readers are referred to several publications that address the majority of artifacts peculiar to ultrasonography.[9-14] Operator error and ultrasound-tissue interactions are discussed further.

Operator Errors

Inadequate Skin Preparation

Excessively long or dirty hair and unclean skin attenuate the ultrasound beam and produce image artifacts. Improper scanhead coupling to the skin caused by a lack of gel or the presence of scabs or scurf is common (Fig. 16-1). Artifacts created by improper skin preparation result from poor contact. Images may be dark even though gain settings may be set at the highest limits. The tendons do not have a fine texture and are more grainy or mottled than normal. Tendon margins may not be seen, and reverberation artifacts caused by trapped air within the hair may appear within images, especially if standoff pads are used. Hypoechoic streaks may be present in the images.

Ultrasound Beam Angle

Reflection of the ultrasound beam is dependent on the sound-interface and tissue-interface geometry. Ideally the ultrasound beam should strike tissue interfaces at 90° to produce the best echo reflection back to the transducer crystals, which also act as receivers. If the beam strikes a tissue interface at a smaller angle, a portion of the ultrasound is reflected away from the primary beam direction, and the interface is not seen as well or at all. This is especially important in the evaluation of tendons and ligaments in the metacarpal and metatarsal regions because the fibers usually are parallel to the skin. If the ultrasound sound beam is not perpendicular to a tendon in a transverse image, information is lost and hypoechogenic areas, which mimic lesions, are created (Fig. 16-2). The problem is not seen in longitudinal images of the metacarpal or metatarsal region obtained using a linear array transducer because its surface is parallel to the fibers. However, with convex array and sector transducers that have divergent ultrasound beams, there are only small areas within longitudinal tendon fiber images in which valid information is found (Fig. 16-3). In the divergent area of the beam, sound is reflected away from the beam path and is lost to the image. It is important not to confuse these

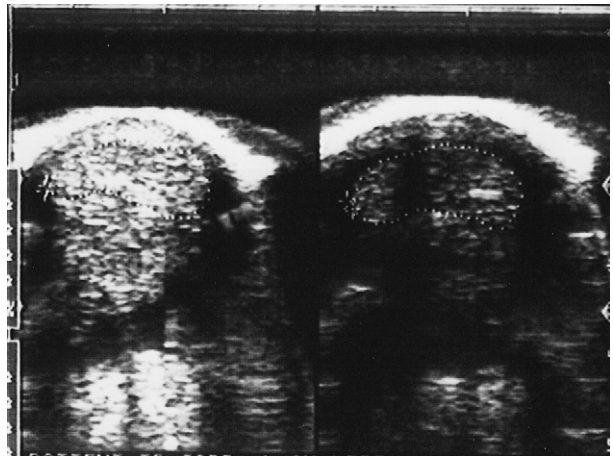

Fig. 16-1 Transverse ultrasonographic images of the palmar metacarpal region. Improper skin preparation causes artifacts within the image on the right.

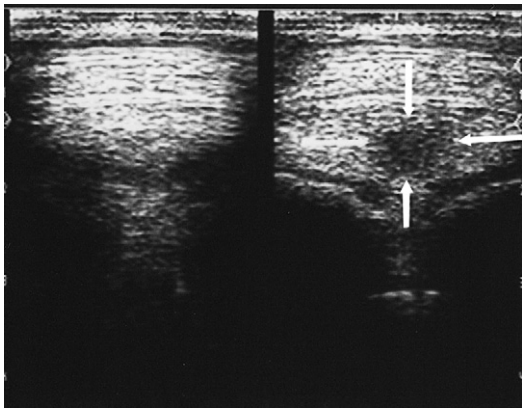

Fig. 16-2 Transverse ultrasonographic images of the distal palmar aspects of the metacarpal region. The left deep digital flexor tendon image has a normal tendon fiber pattern. The right image has an apparent central core artifact *(arrows)* that was produced by slightly changing the angle of the ultrasound beam.

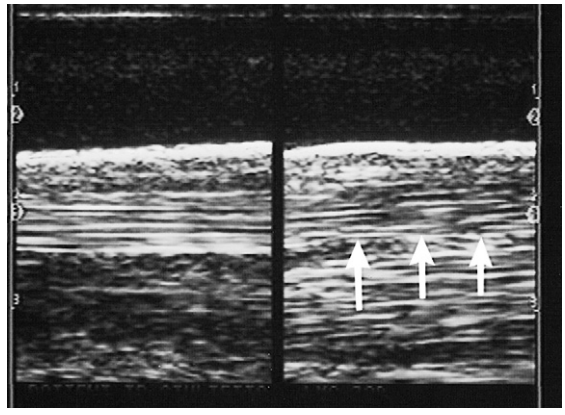

Fig. 16-4 Longitudinal ultrasonographic images of the palmar metacarpal region. The left image was obtained with a linear array transducer parallel to the tendon fibers. The right image was obtained with the transducer slightly oblique to the tendon fibers, causing them to appear as short segments instead of continuous fiber strands *(arrows)*.

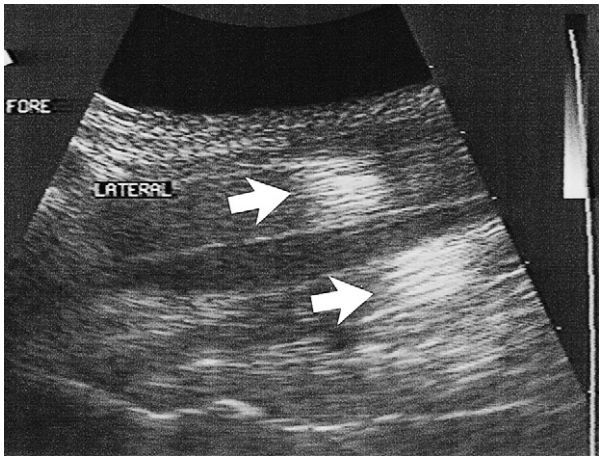

Fig. 16-3 Longitudinal image of the proximal metacarpal region. The *arrows* point to tendon and ligament sections where the ultrasound beam is at 90°, which allows the fibers to be seen. The remaining parts of the image provide no diagnostic information.

areas with pathological conditions of the tendon. The ultrasound beam must be positioned parallel to the tendon fibers. Normal tendon or ligament fibers should be seen as continuous linear echogenic structures across the image (Fig. 16-4). If the transducer is turned slightly, the fibers appear as short linear segments as the beam cuts obliquely across the longitudinal axis. Because fiber alignment is an important criterion to assess in diagnosis and rehabilitation of tendon injury, care must be taken to not create this artifact.

Improper Gain Settings

Ultrasound machines have gain settings referred to as *overall*, *near,* and *far gain*. As ultrasound penetrates normal soft tissues, it is attenuated at the rate of 1 dB/cm of tissue thickness per MHz. Obesity and dehydration cause greater attenuation and can limit penetration. Because energy is lost from the ultrasound beam as it passes into the tissues, the instrument gain must be increased to allow echo detection from the deeper tissue depths. Overall gain changes the brightness and darkness over the entire image. The near-gain adjustment affects the echoes closest to the transducer. Increasing the near gain brightens the echoes and decreasing it darkens them. The far gain affects the deeper image. Some machines display a time gain compensation curve at the side of the screen. Adjustment of the gain settings should produce an image in which the gray scale is similar over the entire image. Bright whites in the near field should prompt decreasing the near gain; conversely, if echoes are difficult to see, increase in the gain is necessary (Fig. 16-5). Improper near-gain settings are the most common error in settings. Visibility of far-field echoes is enhanced by far-gain increases.

Improper Focal Zone Use

Before the advent of moveable and multiple focal zones, transducers had fixed focal points and well-defined focal zones. The ultrasound beam was narrowest in the focal zone in which the lateral resolution produced the best image quality. If the tissues of interest were outside the focal zone, image quality was not ideal. Use of transducers with appropriate focal zones became necessary. If a sector transducer is used to image the SDFT, a standoff pad is necessary to place the tendon in the focal zone. Variable focal zones have eliminated this problem and allow focal zone placement throughout the image depth. Modern linear array and convex array transducers have multiple and moveable focal zones. However, they need to be set in the proper locations to investigate the areas of suspected abnormality. If the focal zones are not placed properly, significant tendon and ligament fiber damage can be overlooked (Fig. 16-6).

Incorrect Frequency Transducer

Tissue depth dictates the optimal transducer frequency. Tissues within 5 to 7 cm of the skin surface should be examined with a 7.5-MHz or higher-frequency transducer. A 5.0-MHz transducer is required to examine tissues from 7 to 12 and up to 15 cm (depending on the instrument), and a 3.0-MHz or lower-frequency transducer is necessary for tissues 15 to 30 cm deep.

Imaging the flexor tendons or SL with a transducer of 5.0 MHz or less results in major compromise of image quality because of lateral beam width artifact. Two types of resolution are peculiar to ultrasound. Resolution along the beam axis, or axial resolution, is frequency dependent; the higher the frequency, the better the axial resolution. Resolution in the transverse plane, or lateral resolution, is dependent on the width of the ultrasound beam; the better the focusing or sound beam narrowing, the better the lateral resolution. Smaller crystals produce narrower sound beams, hence increased lateral resolution. A transducer with a minimum frequency of 7.5 MHz should be used for superficial tendons and ligaments for best axial and lateral resolution.

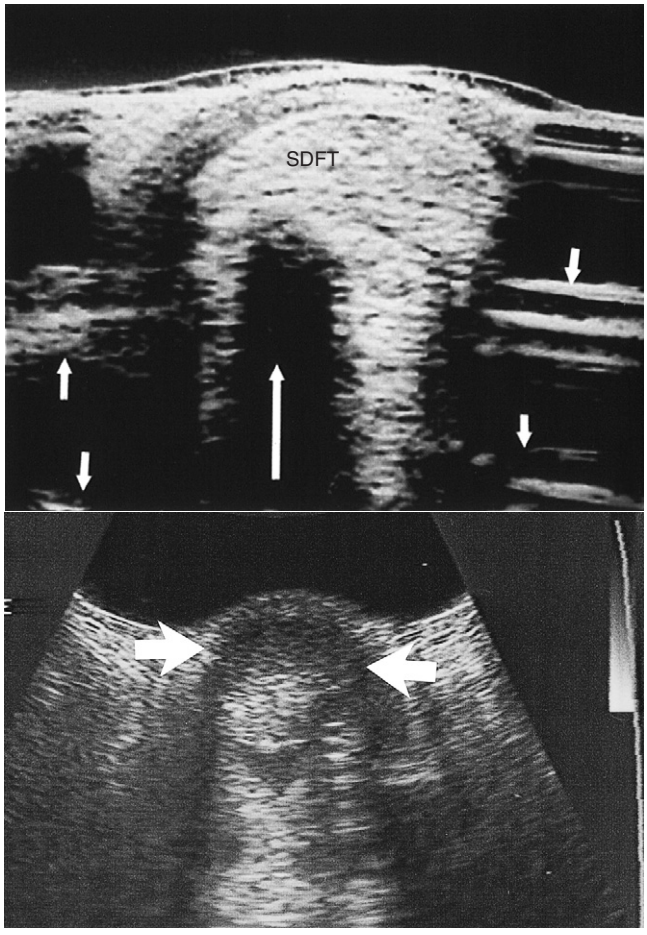

Fig. 16-5 **A,** Transverse sector scan image of the palmar metacarpal region with the near gain set too high. The superficial digital flexor tendon (SDFT) echoes are too bright and cannot be differentiated. Acoustic shadowing *(large arrow)* is caused by flexor tendon and reverberation artifacts caused by the standoff pad *(small arrow)*. **B,** The near gain set too low, so the SDFT cannot be seen *(arrows)*.

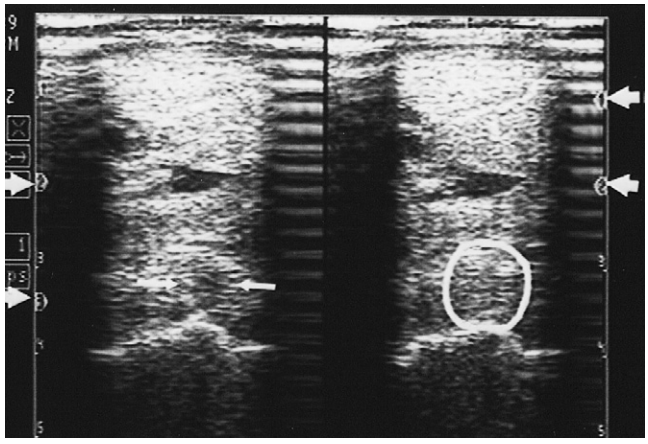

Fig. 16-6 Transverse images of the proximal metacarpal region. A focal lesion in the suspensory ligament *(arrows)* is visible on the left image. The lesion disappears *(circle)* in the right image because the focal zones are improperly placed. *Arrows* in the left and right margins point out the focal zone levels.

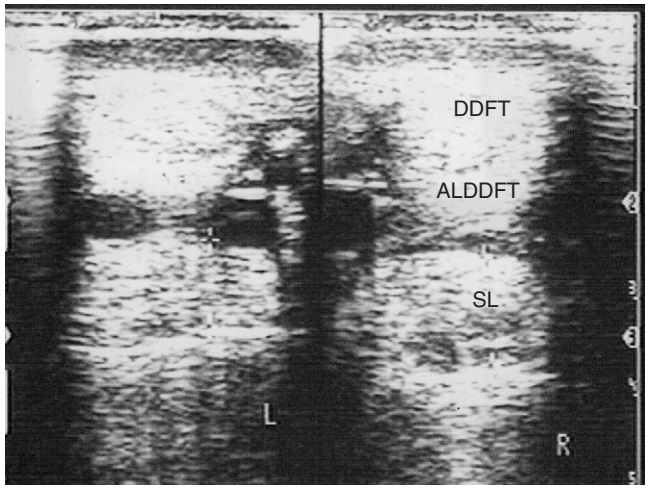

Fig. 16-7 Transverse images of the metacarpal region obtained without a standoff pad showing the deep digital flexor tendon (DDFT), accessory ligament of the accessory ligament of the DDFT, and the suspensory ligament. The brightness is set too high, causing tendon fiber detail loss.

Recording Images

A thermal printer is the most popular method for recording ultrasonographic images, but excellent images can be misrepresented. Brightness may be set too high, causing echoes to have no differentiating characteristics (Fig. 16-7), or set too low, causing the image to be too dark (Fig. 16-8). The same problem occurs with contrast settings; too high causes excessive contrast, and too low causes the image to be washed out and too dark.

A series of dual inline package switches in the back of the printer can change the image and produce a myriad of artifacts. It is important to consult the instruction manual or company representative to ensure that the switches are set properly. Proper settings also are necessary for the paper type. Interpreting improperly recorded (sub-optimal) images causes substantial diagnostic error. Images must be assessed for photographic quality to preclude overlooking lesions or over-interpretation. Sub-optimal images should be repeated to preclude inaccurate interpretation and misdiagnosis. Images should always be frozen before capture.

Recording digital images on floppy disks is an effective way to capture all of the information. Depending on the system, images may be recorded in bitmap (bmp) or Joint Photographic Experts Group (JPEG) formats. These may be archived on a hard drive and may be sent by e-mail if desired. External image capture devices function well, and some instruments have internal floppy drives. Hard copy from the disk can be obtained by using a thermal or other type of printer at a later time if necessary. It must be remembered that the image is an accurate copy of the image created by the operator and contains any artifacts that are due to operator error.

Various video formats, including video home system (VHS), 8 mm, S-Video, cineloop, and videodisk, are used to record motion. Recording static tissue (e.g., tendon) studies while moving the scanhead during recording can produce errors if the transducer is moved too rapidly for the frame rate to keep pace. Tendon examinations should be performed at relatively slow frame rates, as low as 7 per second, if multiple focal zones are activated. Moving the scanhead too fast causes ghosting of the image that blurs the anatomy. Activating multiple focal zones and the resultant slow frame rate can cause a similar problem with minimal scanhead movement.

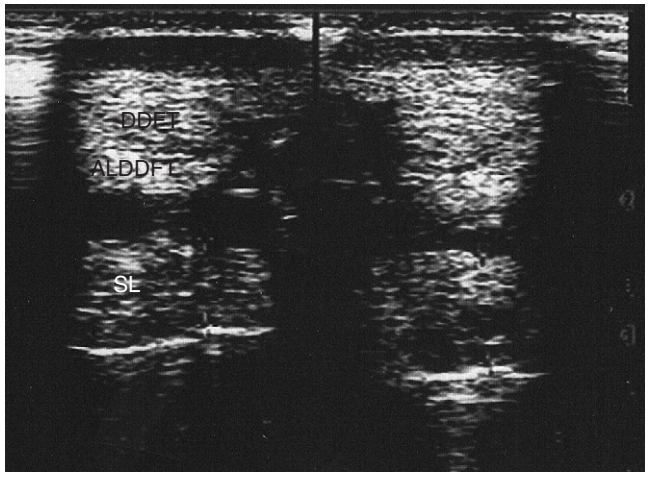

Fig. 16-8 Transverse images of the metacarpal region obtained without a standoff pad showing the deep digital flexor tendon *(DDFT)*, accessory ligament of the accessory ligament of the DDFT *(ALDDFT)*, and the suspensory ligament *(SL)*. The brightness is set too low, causing the image to be too dark.

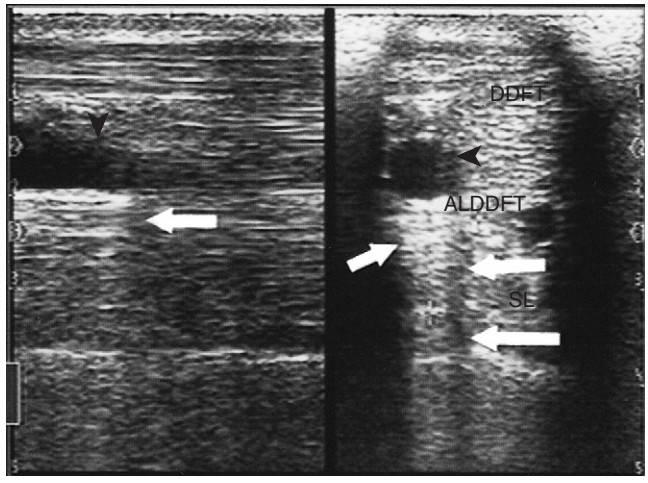

Fig. 16-9 Longitudinal image *(left)* and transverse image *(right)* of the metacarpal region obtained without a standoff pad showing the deep digital flexor tendon *(DDFT)*, accessory ligament of the accessory ligament of the DDFT *(ALDDFT)*, and the suspensory ligament *(SL)*. The tissue brightness *(short arrows)* increases deep to the blood vessels. An anechoic line *(arrow)* extends deep to the blood vessels *(arrowheads)*.

Standoff Pads

Standoff pads are necessary when scanning structures near the skin, such as the SDFT and SL branches. Artifacts are produced each time they are used and can compromise image quality. It is important to recognize them. Transducers with built-in fluid standoff devices are no different. The artifacts are caused by reverberation within the standoff material and occur at a depth equaling the pad thickness (see Fig. 16-5), which may obscure detail. For instance, examination of SL branches with a standoff pad can place artifacts in or near the axial border of the SL. This technique can obscure small axial border tears that are fairly common in sports horses. If the standoff pad thickness produces interfering artifacts, the SL branch should be examined with and without a standoff pad.

Ultrasound Tissue Interaction Artifacts (Patient-Produced)

Ultrasonographic images are composed of returning echoes from many tissue interfaces, regardless of whether they are real or artifact. Some artifacts are useful in diagnosis and provide clues to tissue composition. Others are annoying and do not contribute to the diagnosis. Echoes are generated at tissue interfaces because of differences in acoustic impedance. Acoustic impedance is the product of tissue density (grams per cubic centimeter) and sound propagation velocity (meters per second). Substantial changes in either parameter produce acoustic barriers proportional to the magnitude difference, which causes sound reflection at the interface. Higher (brighter) amplitude echoes are created by greater acoustic impedance differences at tissue interfaces.

Skin Surface Contact

Debris and air trapped in the hair create large acoustic impedance differences and do not allow adequate sound penetration (see Fig. 16-1).

Acoustic Enhancement

Whenever ultrasound passes through non-attenuating tissues, such as fluid with few or no interfaces, a slight increase in ultrasound intensity occurs in addition to less attenuation. The adjacent tissues attenuate the ultrasound normally. This causes brighter (enhanced) echoes deep to the less attenuating tissues. A good example is the enhancement seen deep to the metacarpal and metatarsal blood vessels. The SL has brighter echoes deep to the blood vessels, whereas between the blood vessels it is less echogenic (darker); it is tempting to interpret such results as abnormal (Fig. 16-9). This is an inherent, tissue-produced artifact that can lead to interpretation errors but may help identify less attenuating areas within tissues such as muscle.

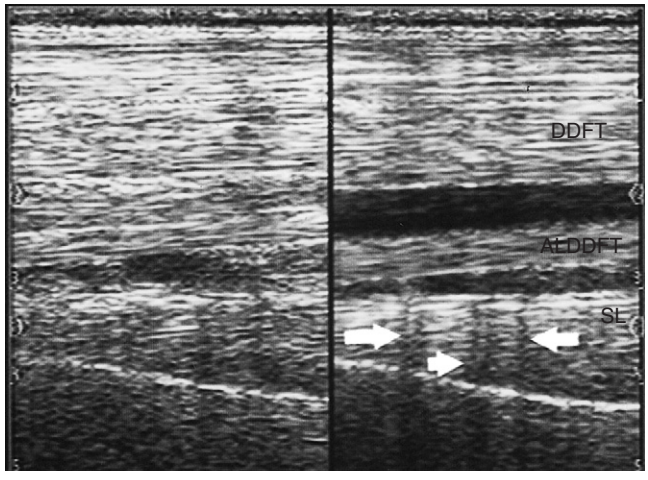

Fig. 16-10 Longitudinal images of the proximal palmar metacarpal region. Proximal is to the left. Refractive scattering *(arrows)* caused by the veins between the origin of the suspensory ligament *(SL)* and the accessory ligament of the deep digital flexor tendon *(ALDDFT)*. *DDFT*, Deep digital flexor tendon.

Refractive Scattering

If the ultrasound beam is not perpendicular to a tissue interface, hypoechoic artifacts are caused by refraction. These artifacts can be a major problem in assessing the origin of the SL because of the anastomotic veins between it and the ALDDFT (Fig. 16-10). The curved blood vessel walls create hypoechoic lines that extend deep to the vessel walls in transverse images (see Fig. 16-9). This is called *refractive scattering* and should not be misinterpreted as a lesion.

Acoustic Shadowing

A high acoustic impedance difference blocks the ultrasound beam and causes an anechogenic shadow deep to the reflecting interface. Bone and other mineralized tissue are much denser than soft tissues, and the sound propagation velocity is much faster. This creates an impenetrable acoustic barrier and, characteristically, the reflector surface has bright echoes and the

deeper tissues cannot be seen. These artifacts are useful because they identify soft tissue mineralization (see Fig. 16-5). Bone surfaces are easily recognized because of shadowing. Dense scar tissue may create incomplete shadowing.

Reverberation

Reflection of ultrasound back and forth to the transducer from high acoustic impedance interfaces produces reverberation artifacts. The classic example is an air-filled lung surface that produces characteristic concentric reverberation echoes. Reverberation artifacts are not a major problem in tendon and ligament scanning; however, they can be important in certain circumstances. Gas production by anaerobic bacteria and air accidentally injected during diagnostic analgesia are two examples in which reverberation can be found in soft tissues. Standoff pads also create reverberation artifacts (see Fig. 16-5).

Mirror Image Artifacts

Mirror image artifacts are not common problems in musculoskeletal ultrasonography and are more common in thoracic and abdominal scanning. They usually are found deep to interfaces that are highly reflective, such as air-filled lung.

TERMINOLOGY AND QUANTITATIVE MEASUREMENTS

The basis of diagnosis is to determine the morphological variation from normal, which is not always easy. The goal is to determine the size, shape, echogenicity, fiber pattern, and surrounding inflammatory reaction of any structure. These findings should be considered carefully in conjunction with clinical impressions and the current athletic use of the horse. Box 16-3 lists parameters used for characterizing tendon and ligament lesions.[15]

Echogenicity

Echogenicity refers to the whiteness or brightness of a structure. Each tendon and ligament has a characteristic echogenic pattern at specific anatomical sites. Lesions vary in echogenicity depending on morphological consistency at the time of the examination. A scoring system can be used to improve objectivity when assessing the severity of an injury or the response to therapy (Box 16-4). Such a system may improve case management and illustrate to the client the changes in echogenicity that correlate with repair of an injury.

The following terms are used to describe ultrasound images:

Isoechoic	The echogenicity of the structure is normal and is scored as 0.
Hypoechoic	The lesion is less than isoechogenic. There are two categories of reduced echogenicity defined under the term hypoechoic. The first is gray or slightly off-white. This is a type 1 hypoechogenic lesion (Fig. 16-11). If the lesion is of mixed black and white tones, it is scored as a type 2 hypoechogenic lesion (Fig. 16-12).
Anechoic	The lesion is mostly black, a type 3 lesion.
Hyperechoic	Denoix[8] grades hyperechogenic lesions as hyperechoic 1, which indicates that the lesion is brighter than isoechoic and represents dense scar tissue without an acoustic shadow. Hyperechoic 2 lesions (see Fig. 16-5) represent soft tissue mineral deposition, which is characterized by casting an acoustic shadow. These echo patterns are uncommon and generally seen in long-standing and repetitively injured tendons and ligaments.

Box • 16-3

Parameters Used for Characterizing Tendon and Ligament Lesions

- Region or location of the lesion
- Length of the lesion
- Alteration in echogenicity
- Pattern of altered echogenicity (i.e., homogeneous, heterogeneous, focal, and diffuse)
- Alteration of fiber pattern in longitudinal images
- Percent of cross-sectional area of tendon injury
- Changes in the character of the lesion over time

Box • 16-4

Type Scores

Score	*Description*
0	Isoechoic
1	Slightly hypoechoic; mostly echoic
2	Mixed echogenicity (50% echoic and 50% anechoic)
3	Mostly anechoic or anechoic

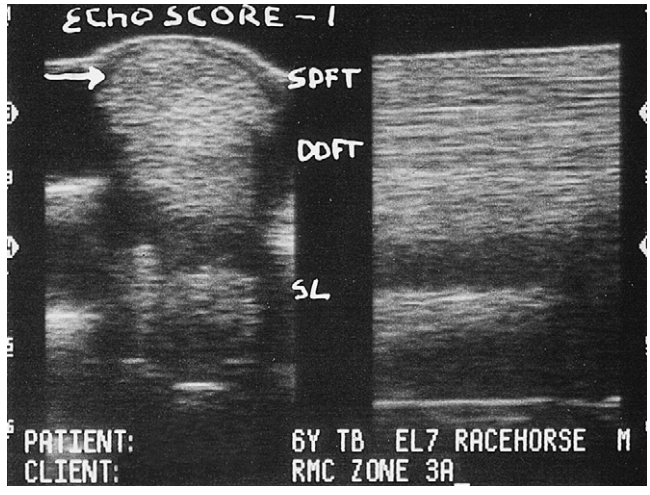

Fig. 16-11 Transverse *(left)* and longitudinal *(right)* images of zone 3A of the metacarpal region obtained using a standoff pad. A type 1 hypoechogenic lesion is present in the superficial digital flexor tendon (SDFT) *(arrow)*. (See text for zone descriptions.) *DDFT,* Deep digital flexor tendon; *SL,* suspensory ligament.

Fiber Alignment Pattern Assessment

Assessment of fiber bundle alignment in longitudinal images determines the nature of a tendon's or ligament's fiber arrangement. Normally the fibers are aligned in parallel except in some anatomical areas, such as the origin of the hindlimb SL. When injury occurs, the expected parallel fiber pattern is disrupted. During healing of an injury, random orientation and cross-linking of new collagen fibers may create scar tissue that results in a substantial improvement in echogenicity but constitutes a poor scaffold for parallel alignment of fibers. Parallel alignment is more physiologically advantageous than random orientation

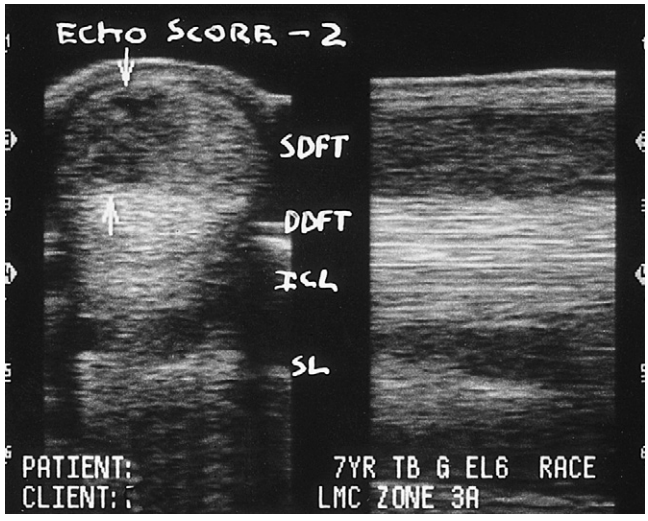

Fig. 16-12 Transverse *(left)* and longitudinal *(right)* images of zone 3A of the metacarpal region. A type 2 hypoechoic lesion is present in the superficial digital flexor tendon *(SDFT; arrows)*. *DDFT*, Deep digital flexor tendon; *ICL*, inferior check ligament (accessory ligament of the deep digital flexor tendon); *SL*, suspensory ligament.

of a scar, because randomly oriented scar tissue is susceptible to re-injury, especially during increased exercise. In a new injury or re-injury, longitudinal images are used to confirm the presence of a lesion identified in transverse images. When monitoring repair, fiber alignment can be assessed.

The longitudinal image must be obtained through the area of fiber bundle compromise to accurately assess the lesion. This is easy if a large proportion of the cross-sectional area is involved. If a lesion is small or located on the margins of a tendon or ligament, it is more difficult. It is important to remember that fiber alignment, *not* echogenicity, is being assessed. In some instances, such as new injuries or re-injuries in the SDFT, the echogenic and fiber alignment scores may be the same. This is rarely true for SL injuries.

An arbitrary scoring system for fiber alignment has been reported (Box 16-5).[6,8] In this system, a score is assigned to semi-quantitate fiber alignment of the target path. The veterinarian should bear in mind that the target path is wide with large lesions, but in small lesions it is quite narrow.

During repair the echogenicity score usually improves at a more rapid rate than the scar remodeling and fiber alignment score. The difference in these scores may be important for tailoring an appropriate controlled exercise program. A delay in fiber alignment improvement suggests that scar remodeling must continue and prompts conservative progression in exercise management.

It is more difficult to identify the target path of fiber bundles during healing once echogenicity has improved. Printed images of the initial examination can be reviewed to identify the exact location of the lesion. If the original scans are not available, one author (R.L.G.) prefers to scan each zone from medial to lateral (or vice versa) and document the longitudinal image with the most abnormal fiber alignment. Fiber alignment score (FAS) (see Box 16-5) has been useful in predicting the prognosis for return to racing.[16] A horse with mean FAS of less than or equal to 0.5 at 4 months after treatment of SDFT was more likely to return to racing than a horse with a mean FAS greater than 0.5. An improvement in total FAS of greater than 75% was associated with a greater chance of returning to racing.[17]

Box • 16-5

Fiber Alignment Scoring

Score	*Definition*
0	Target path ≥75% parallel
1	Target path 50% to 75% parallel
2	Target path 25% to 50% parallel
3	Target path ≤25% parallel

Cross-Sectional Area

Cross-sectional area (CSA) measurements of transverse images of a ligament or tendon are useful, especially in assessing a subtle injury or determining the significance of a localized, focal hypoechogenic fiber bundle path. When assessing the proximal SL, it is useful to determine whether a focal hypoechogenic fiber bundle is likely to be a lesion or the remains of muscle fibers. An injured tendon or ligament usually is enlarged, and although this finding may not be obvious subjectively, measurements of CSA confirm structural thickening.

CSA is also a useful parameter to evaluate the quality of repair, because decreasing size during rehabilitation indicates resolution of the inflammatory component of healing or may indicate favorable scar remodeling. Randomly oriented scars usually form in a rounded fashion and occupy more space. As the scar remodels into a more parallel alignment, less space is necessary, resulting in a reduction in CSA.

The transducer must be perpendicular to the structure to obtain accurate CSA data; otherwise the CSA may be falsely enlarged. The most common technique is to trace the structure on the monitor and the computer software automatically calculates the size. This technique also can be used to calculate lesion size and the proportion of the CSA involved (Fig. 16-13). Initially this method of quantifying CSA may be time consuming, especially when assessing several structures. Eventually the veterinarian can become extremely proficient at producing accurate measurements.

One author (R.L.G.) uses a computer-assisted method that is not commercially available. Transverse images are traced with a microfine-point felt pen after the ultrasonographic study. Using a digitizing pad and software program, surface area data are produced from the tracings of structures and lesions. This method is equally accurate but saves time because scans can be traced more quickly and at a more convenient time. The disadvantage is that the final quantitative information is not immediately available, but it does allow the clinician time to review the images before giving a conclusion to the owner. An alternative method is to save images on a computer disk using commercially available software (Metron-V, EponaTech, Creston, Calif.)

Another simple and inexpensive method to determine structure and lesion CSA is creation of thermal images at all zones, and then at a convenient time, use of handheld calipers to make structures and lesions into two-dimensional squares or rectangles. This is done by measuring the palmar/plantar to dorsal length and the medial to lateral length. These measurements are multiplied to determine the CSA. CSA obtained with handheld calipers is likely larger than the actual size. However, absolute values are less important than the relative difference between normal and suspected abnormal values. Thus if measurements are performed in a consistent manner, handheld calipers provide valid relative CSA data.

Relative sizes are best obtained by comparing the injured limb with the normal contralateral limb, but this is not possible if the injury is bilateral. The veterinarian must rely on the

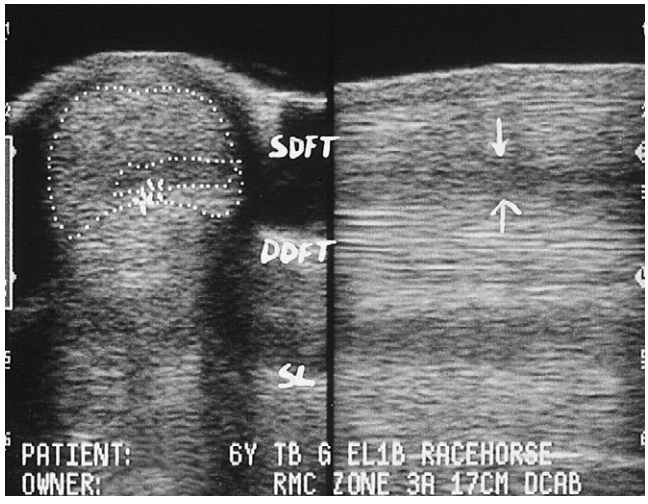

Fig. 16-13 Transverse *(left)* and longitudinal *(right)* images of zone 3A of the metacarpal region. The cross-sectional area (CSA) of the superficial digital flexor tendon *(SDFT)* is 3.05 cm^2. A dorsolateral type 1 hypoechoic lesion is present; the lesion is 43 mm^2 and represents 14.1% of the CSA of the tendon. The fiber alignment score of the targeted fiber path is 3 *(between arrows)*. *DDFT*, Deep digital flexor tendon; *SL*, suspensory ligament.

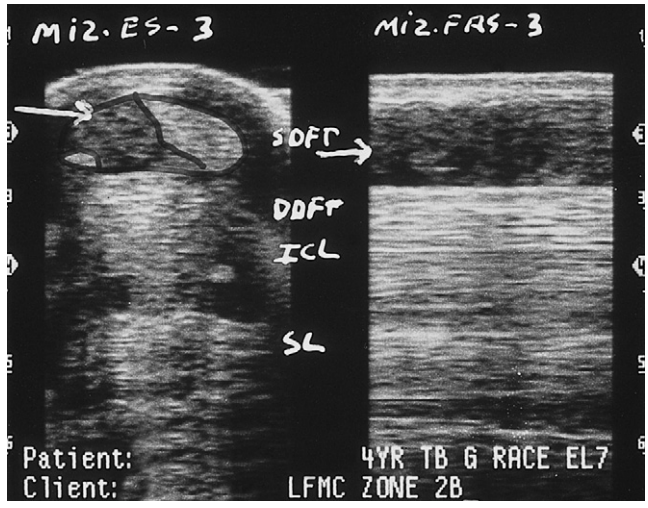

Fig. 16-14 Transverse *(left)* and longitudinal *(right)* images of zone 2B, obtained using a standoff pad. There is a large lateral border type 3 lesion of the superficial digital flexor tendon (SDFT; *horizontal arrow)* confirmed on longitudinal scan *(horizontal arrow)*. *DDFT*, Deep digital flexor tendon; *MIZ-ES*, maximal injury zone echo score; *MIZ-FAS*, maximal injury zone fiber alignment score; *SL* suspensory ligament.

expected values for the age, size, and breed of the horse and level or zone of the image based on personal experience and previous images if availabe. Normal values for various structures are difficult to determine and few studies have been published. Normal values for tendon and ligament sizes for TB and SB horses have been reported.[18] It is essential to measure both limbs at the same depth setting on the ultrasound machine.

In summary, quantifying the ultrasonographic image using echogenicity and fiber alignment scores, along with CSA of the lesion, provide powerful resources to aid in interpreting lesions (Fig. 16-14). When assessing an injury from proximal to distal, these scores can be summed to estimate the volume of the injury. These values can be used to categorize the injury and to monitor repair objectively.

ZONE DESIGNATIONS

The anatomical location of an ultrasonographic image can be designated by measuring the distance from a fixed landmark, such as the accessory carpal bone, or dividing the limb into zones.

Distal Forelimb

The palmar metacarpal and metacarpophalangeal regions may be separated into seven zones, or eight zones if the medial aspect of the carpus is included (Fig. 16-15). The pastern also may be divided into zones (see page 180). Many of these zones have unique anatomical features. The measurements outlined in the following text refer to a 16.1-hand TB horse.

Zone Definitions

Zone 0 Zone 0 (~5 cm in length) is located along the medial aspect of the carpus adjacent to the accessory carpal bone (Fig. 16-16). Off-incidence angle artifacts may be present on the dorsal border of the DDFT, and rarely, hypoechogenic muscle bundles are seen (Fig. 16-17). At this level the SDFT is uniform in echogenicity, but further proximally are hypoechogenic muscle bundles that should not be confused as lesions. The carpal sheath, common digital artery, and palmar carpal fascia are visible.

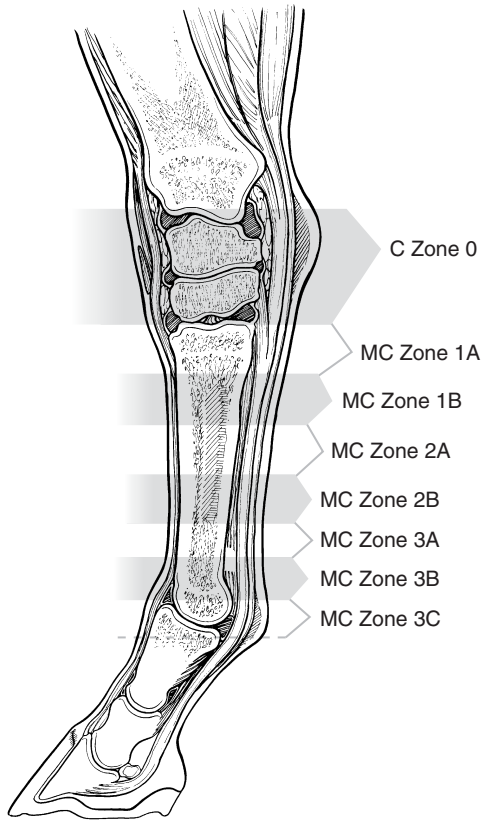

Fig. 16-15 Ultrasonographic zone designations for the carpal *(C)* and metacarpal *(MC)* regions.

Zone 1A Zone 1A extends from approximately 0.5 to 4 cm distal to the base of the accessory carpal bone. The SDFT is slightly medially placed, oval shaped, and readily visible on the midline. The carpal retinaculum covers its palmar border proximally. The common digital artery lies close to the medial

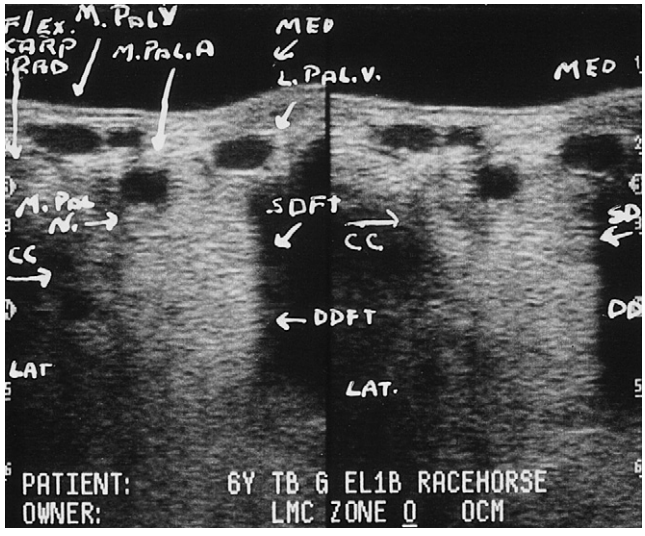

Fig. 16-16 Transverse images of a forelimb zone 0 obtained along the medial aspect of the accessory carpal bone with a standoff pad. The left image is focused on the superficial digital flexor tendon *(SDFT)* and the right image is focused on the deep digital flexor tendon *(DDFT)*. CC, Carpal canal; *Flex Carp Rad*, flexor carpi radialis; *Lat*, lateral; *L Pal V*, lateral palmar vein; *M Pal A*, medial palmar artery; *M Pal N*, medial palmar nerve; *M Pal V*, medial palmar vein; *Med*, medial.

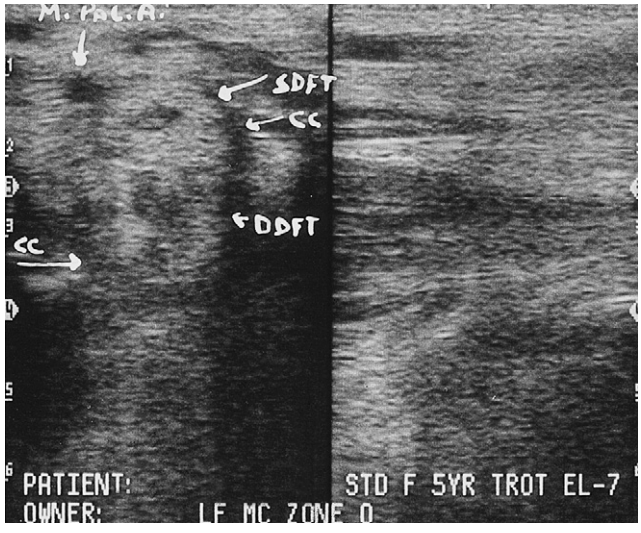

Fig. 16-17 Transverse *(left)* and longitudinal *(right)* images of the forelimb zone 0 obtained from the medial aspect of the carpus, immediately proximal to the accessory carpal bone, without a standoff pad. Note the centrally located muscle bundles of the superficial digital flexor tendon *(SDFT)* and the deep digital flexor tendon *(DDFT)*. This is normal and should not be confused with a lesion. CC, Carpal canal; *M Pal A*, medial palmar artery.

border of the SDFT. The DDFT is triangular, and the lateral border is more rounded (Fig. 16-18). The ALDDFT and SL are rectangular in shape. The medial and lateral borders of the ALDDFT and SL may not be visible from the palmar midline; therefore the transducer should be moved medially and laterally. However, to measure CSA of these structures, the veterinarian should use what can be seen from the palmar aspect. In most horses, anechoic fluid in the carpal sheath is seen between the dorsal border of the DDFT and the palmar

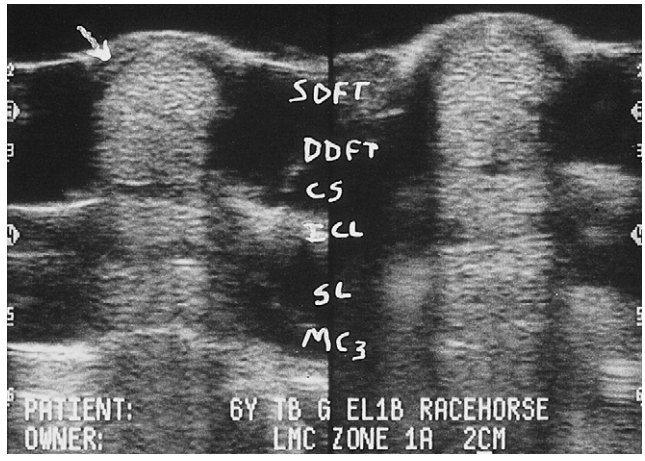

Fig. 16-18 Transverse images of the forelimb zone 1A. Carpal retinaculum *(arrow)*. *CS*, Carpal sheath; *DDFT*, deep digital flexor tendon; *ICL*, accessory ligament of the DDFT; MC_3, palmar border of the third metacarpal bone; *SL*, suspensory ligament; *SDFT*, Superficial digital flexor tendon.

border of its accessory ligament. The medial aspect of the rectangular carpal sheath is wider than the lateral border.

The origin or enthesis of the SL is approximately 3 to 4 cm long. The SL rapidly increases in palmar to dorsal thickness as it descends distally. In contrast, the ALDDFT rapidly decreases in palmar to dorsal thickness. Comparative CSA measurements in each forelimb should be done at precisely the same distance distal to the accessory carpal bone in zone 1A.

In the proximal metacarpal region a ligamentous band often extends proximally from the origin of the SL to insert on the palmar carpal fascia of the distal row of carpal bones (Fig. 16-19). It is located between the dorsal border of the ALDDFT and the palmar recess of the carpometacarpal joint, which lies between the fibrous band and the third metacarpal bone (McIII). Anechoic fluid in the carpometacarpal joint should not be confused with a lesion of the SL. The proximal aspect of zone 1A is proximal to the enthesis of the SL on the McIII.

At 2.5 cm distal to the accessory carpal bone the origin of the SL is firmly attached to the McIII (Fig. 16-20). Entheseal fiber tearing usually occurs 1 to 3 cm distal to the accessory carpal bone. The oblique orientation of the McIII at the origin of the SL attachment can be seen on a longitudinal view (see Fig. 16-20). Fig. 16-21 is at the distal extent of zone 1A and the distal extent of the enthesis of the SL. Note the palmar to dorsal width at this point in zone 1A and the firm bony attachment of the entire dorsal surface of the SL. In this example, there is complete dorsal attachment of the SL. However, in many normal horses the origin of the SL has a bilobed appearance (medial and lateral attachments), with a rounded or triangular-shaped hypoechoic area dorsally in the midline. Clinicians must be cautious not to interpret this as a focal tear. Rarely the origin of the SL can be injured in this central location, but generally size and shape of the hypoechoic region are changed.

Zone 1B Zone 1B extends from approximately 4 to 7 cm distal to the accessory carpal bone. At this level the slightly crescent-shaped SDFT is on the midline over the oval-shaped DDFT. There are no unique anatomical features of this zone that identify it, and its location is determined by measurement. In all mid-metacarpal zones, as in zone 1A, the medial and lateral borders of the SL and ALDDFT may not be visible from the palmar midline. The transducer must be moved medially or laterally to identify a focal peripheral lesion of one of these structures. At times, the dorsal border of the SL can be difficult

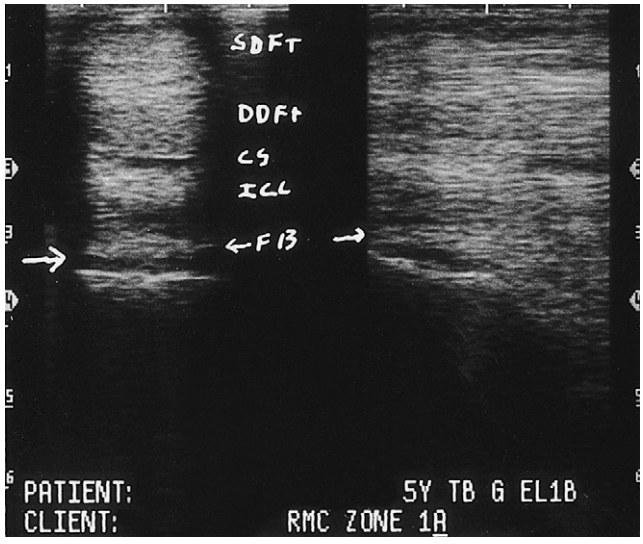

Fig. 16-19 Transverse *(left)* and longitudinal *(right)* (proximal is to the left) images from zone 1A of a forelimb obtained without a standoff pad. There is a ligamentous band (ligamentous segment of origin of suspensory ligament that originates from the palmar carpal fascia *[FB]* and *small arrows)* extending from the palmar aspect of the suspensory ligament, passing palmarly over the anechoic joint recess of the carpometacarpal joint *(large horizontal arrow)* and inserting proximally on the dorsal surface of the accessory ligament of the superficial digital flexor tendon. *CS,* Carpal sheath; *DDFT,* deep digital flexor tendon; *ICL,* accessory ligament of the DDFT; *SDFT,* superficial digital flexor tendon.

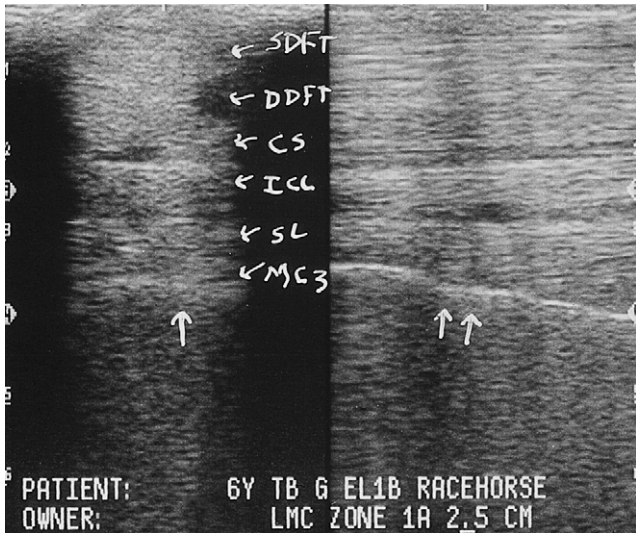

Fig. 16-20 Transverse *(left)* and longitudinal *(right)* (proximal is to the left) images from zone 1A, 2.5 cm distal to the base of the accessory carpal bone, without a standoff pad. There is a firm attachment of the suspensory ligament *(SL)* to the third metacarpal bone *(MC_3)* on the transverse *(single vertical arrow)* and the longitudinal *(double vertical arrows)* views. *CS,* Carpal sheath; *DDFT,* deep digital flexor tendon; *ICL,* accessory ligament of the DDFT; *SDFT,* superficial digital flexor tendon.

to identify because of the density of the periligamentous, fibrous connective tissue. To assist in defining that border, it can be helpful to split the screen and place the longitudinal image adjacent to the transverse image. This technique clearly demarcates the dorsal and palmar borders (Fig. 16-22).

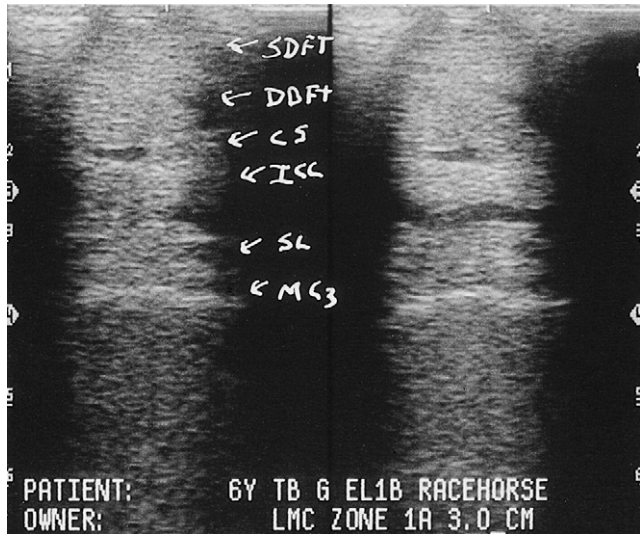

Fig. 16-21 Transverse images at the distal extent of zone 1A (3.0 cm distal to the base of the accessory carpal bone), without a standoff pad. The palmar to dorsal dimension of the suspensory ligament *(SL)* is the greatest for this zone in a normal horse. *CS,* Carpal sheath; *DDFT,* deep digital flexor tendon; *ICL,* accessory ligament of the DDFT, *MC_3,* third metacarpal bone; *SDFT,* superficial digital flexor tendon.

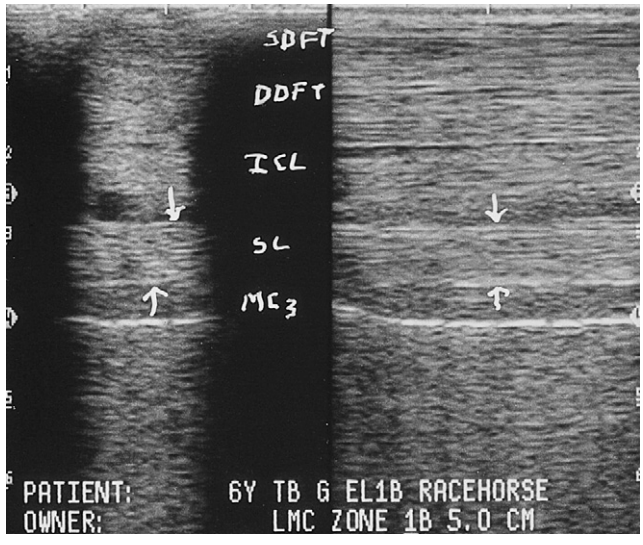

Fig. 16-22 Transverse *(left)* and longitudinal *(right)* (proximal is to the left) images of zone 1B (5 cm distal to the base of the accessory carpal bone) obtained without a standoff pad. The *down arrows* mark the palmar border of the suspensory ligament *(SL)*, and the *up arrows* mark the dorsal border. *DDFT,* Deep digital flexor tendon; *ICL,* accessory ligament of the DDFT, *MC_3,* third metacarpal bone; *SDFT,* superficial digital flexor tendon.

Zone 2A Zone 2A extends from approximately 7 to 10 cm distal to the accessory carpal bone. The same comments apply for this zone as zone 1B.

Zone 2B Zone 2B extends from approximately 10 to 14 cm distal to the accessory carpal bone. One unique feature of this zone is an obliquely coursing nerve located subcutaneously on the palmar surface of the SDFT. This nerve (the communicating branch of the medial palmar nerve) and associated small vessels are a common site for a bandage pinch or "cording" swelling that suggests a primary tendon injury. Overall the

anatomical relationships of tendons and ligaments are similar to zones 1B and 2A. The SDFT and ALDDFT are more crescent shaped and smaller from palmar to dorsal. At this level the carpal sheath still can be identified ultrasonographically.

Zone 3A Zone 3A extends from approximately 14 to 18 cm distal to the accessory carpal bone. Several anatomical features characterize this zone. The first is that in many horses with tenosynovitis, this is the initial zone that incorporates the origin of the digital flexor tendon sheath (DFTS).

The SDFT is crescent shaped and smaller from palmar to dorsal but wider from medial to lateral. The ALDDFT inserts into the DDFT. In transverse images normal crescent-shaped hypoechogenic fiber bundles are seen between the dorsal surface of the DDFT and the palmar surface of its AL. The carpal sheath generally is not appreciated in this zone.

At the region of ALDDFT insertion onto the DDFT, the two structures can clearly be separated ultrasonographically, although grossly they are conjoined. When measuring the CSA of the DDFT, the ALDDFT can be separated from the DDFT, which results in a reduced DDFT CSA, or included with it, which is a more correct CSA determination of the DDFT. The method used is personal preference and results in valid information provided it is consistent.

Zone 3A is just proximal to the bifurcation of the SL. In zone 3A the SL is still a single structure, but the medial and lateral borders become more rounded and the central region may be less echogenic. This is a common site of injury, especially in STB racehorses. At times it can be quite difficult to establish structural borders in acute injury. A longitudinal image viewed adjacent to a transverse may be helpful (Fig. 16-23).

Zone 3B Zone 3B is larger (~5 cm in the average adult horse) than more proximal zones and is the region in which the SL bifurcates into medial and lateral branches. The zone extends from 18 to 23 cm distal to the accessory carpal bone. Anatomical structures include the DFTS; the manica flexoria, a fibrous band extending from the medial and lateral borders of the SDFT and encompassing the DDFT that is associated with a thecal space; and the intersesamoidean space and ligament with associated connective tissue and vasculature. The SDFT decreases in size from palmar to dorsal and widens from medial to lateral. The DDFT becomes ovoid. CSA measurements should be made at identical sites distal to the accessory carpal bone for accurate comparisons between limbs.

The SL branches must be examined individually from palmaromedial and palmarolateral aspects of the limb with a standoff pad. If the ligament is enlarged, no standoff pad is required. The length of a metacarpal SL branch is about 6 cm. To increase data points for CSA comparison, each branch is divided into three, 2-cm sub-zones within zone 3B. For the medial branch, the zone designations are 3B-MP (medial proximal), 3B-MM (medial middle), and 3B-MD (medial distal) (Fig. 16-24). For the lateral branch the zone designations are 3B-LP (lateral proximal), 3B-LM (lateral middle), and 3B-LD (lateral distal). The proximal and middle segments of each branch are oval shaped and the distal segment is more triangular.

Zone 3C Zone 3C extends from 23 to 28 cm distal to the accessory carpal bone and basically includes tissues on the palmar aspect of the metacarpophalangeal joint. The characteristic features of this zone are the presence of the bony shadows of apices of the proximal sesamoid bones (PSBs), the presence of the palmar annular ligament (PAL), and the intersesamoidean ligament (Fig. 16-25).

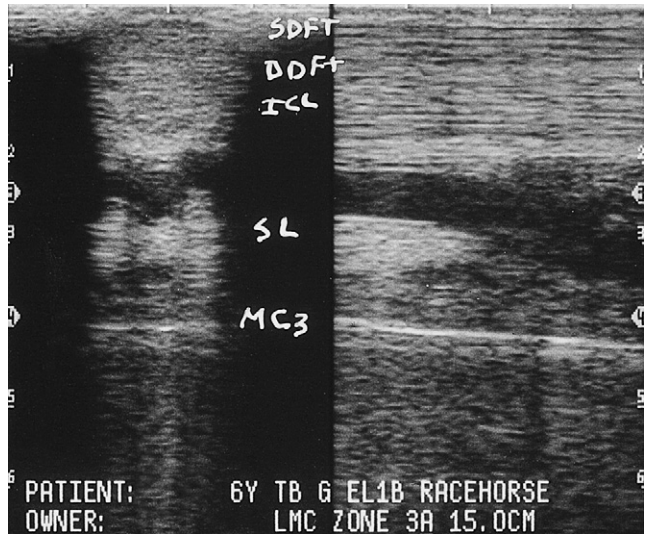

Fig. 16-23 Transverse *(left)* and longitudinal *(right)* (proximal is to the left) images from zone 3A (15 cm distal to the base of the accessory carpal bone), in which the suspensory ligament *(SL)* bifurcates. *DDFT,* Deep digital flexor tendon; *ICL,* accessory ligament of the DDFT, MC_3, third metacarpal bone; *SDFT,* superficial digital flexor tendon.

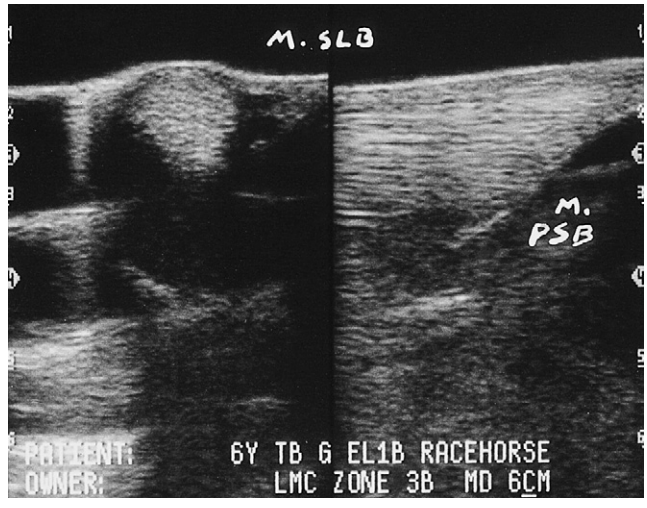

Fig. 16-24 Transverse *(left)* and longitudinal *(right)* (proximal is to the left) images of zone 3B-MD (medial placement of the transducer at the distal extent of the insertion of the medial branch of the suspensory ligament onto the medial proximal sesamoid bone). *M SLB,* Medial suspensory ligament branch; *M PSB,* bone border of the abaxial medial proximal sesamoid bone.

Distal Hindlimb

The anatomical location of an ultrasonographic image can be designated by measuring the distance from a fixed landmark, such as the tuber calcanei or tarsometatarsal joint, or reference to a numbered zone. Most distal limb anatomical features are the same as in the forelimb. However, because of the added length of the SDFT/DDFT and the plantar ligament (long plantar tarsal ligament), the metatarsal zones move up one number.

In the hindlimb, zone 1 includes the plantar aspect of the tarsus. In the adult horse, this is approximately 16 cm in length. Zone 1 is subdivided into two, 8-cm zones, 1A and 1B. The most proximal zone of the metatarsal region is zone 2, which is subdivided into 2A and 2B; the middle one third is zone 3, which is subdivided into zones 3A and 3B; and the distal aspect is zone 4, which is subdivided into zones 4A, 4B, and 4C (Fig. 16-26).

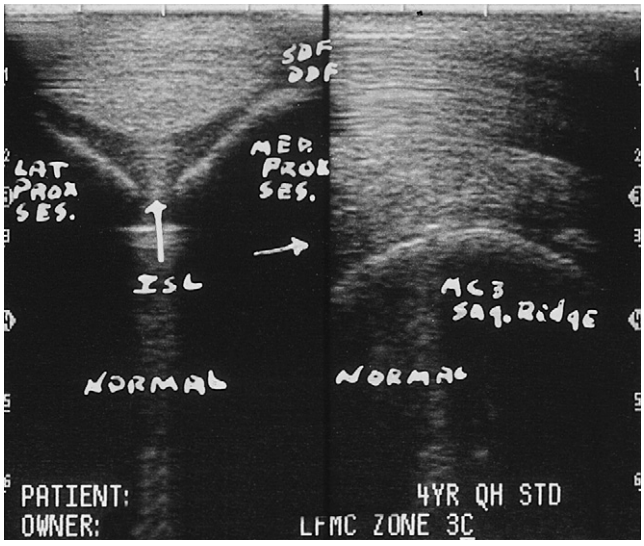

Fig. 16-25 Transverse *(left)* and longitudinal *(right)* images of zone 3C obtained without a standoff pad. Vertical and horizontal *arrows* indicate a normal intersesamoidean ligament. Fig. 16-26 Ultrasonographic zone designations for tarsus/metatarsus.

Hindlimb Zones

Zone 1A This zone extends to 8 cm distal to the tuber calcanei (Fig. 16-27). The SDFT is slightly crescent shaped and located subcutaneously. Deep to the SDFT is the origin of the plantar ligament. Occasionally the subcutaneous bursa or the subtendonous calcanean bursa or both bursae may be seen. The entire width of the SDFT may not be observed on a single midline view, but useful CSA data can be obtained. The extreme medial and lateral borders of the SDFT and the retinacular attachment to the calcaneus may be more visible with slight medial and lateral placement of the transducer. The plantar ligament is located on the midline, firmly attached to the calcaneus, with its origin approximately 3 cm distal to the tuber calcanei. The DDFT and tarsal sheath must be viewed individually by medial positioning of the transducer. The origin of the plantar ligament widens in a plantar to dorsal plane rapidly in this zone. Accurate comparative CSA data require precise anatomical positioning on both hindlimbs. Usually at this level, no visible muscle bundles of the DDFT are seen, but clinicians must be aware of this possibility and not interpret them as a core lesion. At 5 cm distal (zone 1B) to the tuber calcanei, the plantar ligament is roughly triangular shaped and has multiple septated bundles that are all included to measure the CSA (Fig. 16-28).

Zone 1B Hindlimb zone 1B includes the distal half of the tarsus, extending from 8 to 16 cm distal to the tuber calcanei. Multiple images must be obtained from the plantar midline to assess the SDFT, from plantaromedial to assess the DDFT, and from slightly lateral to the midline to assess the plantar ligament. A wedge-shaped fibrous band emanates from the medial border of the SDFT and the fascia of the fibrous tarsal sheath and surrounds the DDFT (see Fig. 16-28). There is a narrow anechoic space representing fluid in the tarsal sheath separating the DDFT and the plantar ligament. The plantar ligament decreases in plantar to dorsal size as it courses distally; it has a firm enthesis to the plantar aspect of the fourth tarsal bone and inserts onto the head of the fourth metatarsal bone (MtIV).

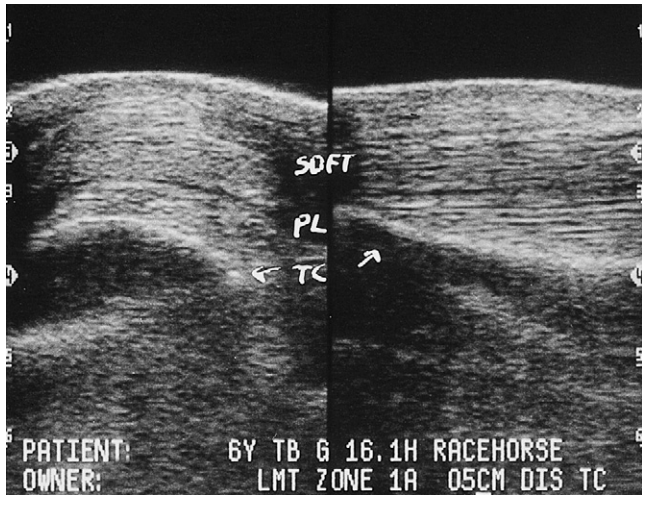

Fig. 16-27 Transverse *(left)* and longitudinal *(right)* (proximal is to the left) images of the plantar tarsus (zone 1A, 5 cm distal to the tuber calcanei) obtained using a standoff pad. *PL*, Plantar ligament or long plantar tarsal ligament; *SDFT*, superficial digital flexor tendon; *TC*, plantar border of the calcaneus.

Zone 2A This is the first metatarsal zone and includes the origin of the SL (~16 to 21 cm distal to the tuber calcanei) and the ALDDFT, which is a rudimentary structure in many horses. The transducer must be slightly medial to midline for complete examination of the DDFT. The SDFT can be assessed from the plantar midline. The origin of the SL can be somewhat confusing on ultrasound images, and this may create

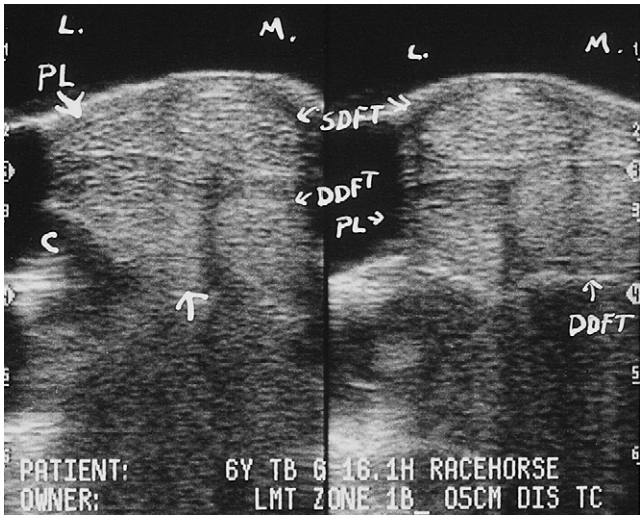

Fig. 16-28 Transverse images from zone 1B, 5 cm distal to the tuber calcanei, obtained using a standoff pad. Medial is to the right. The left image is slightly lateral of midline to highlight the plantar ligament *(PL; between arrows)*, and the right image is slightly medial of midline to highlight the superficial digital flexor tendon *(SDFT)* and the deep digital flexor tendon *(DDFT)*. *C*, Osseous border of the calcaneus. *L*, Lateral; *M*, medial; *PL*, plantar ligament or long plantar tarsal ligament.

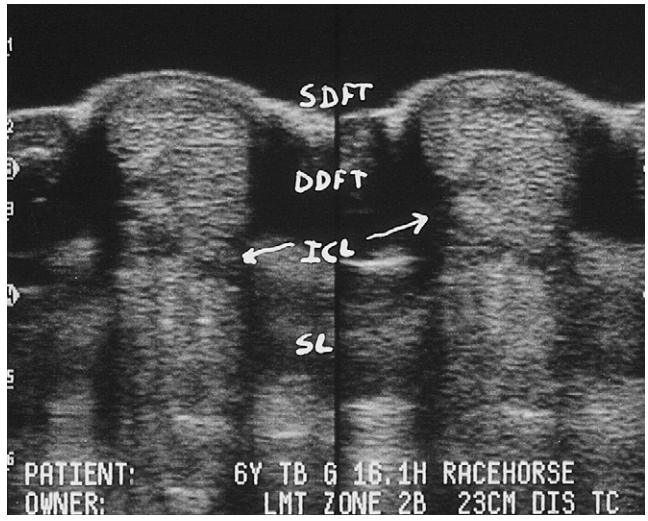

Fig. 16-29 Transverse images of zone 2B, 23 cm distal to the tuber calcanei, obtained using a standoff pad. *DDFT*, Deep digital flexor tendon; *ICL*, accessory ligament of the DDFT; *SDFT*, superficial digital flexor tendon; *SL*, suspensory ligament.

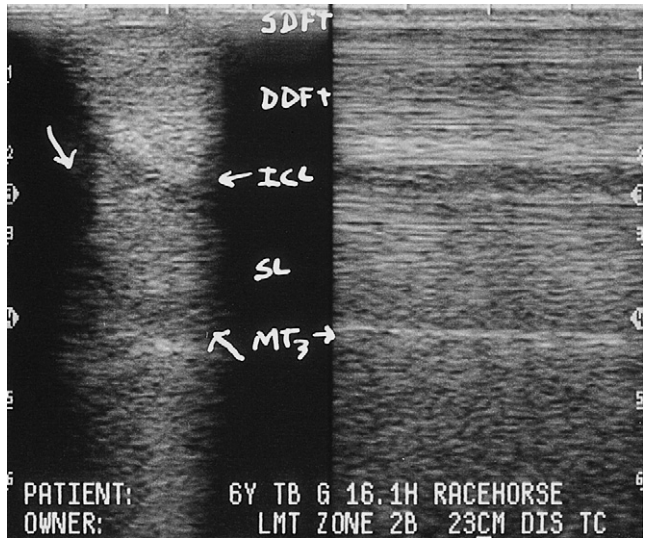

Fig. 16-30 Transverse *(left)* and longitudinal *(right)* images of zone 2B obtained without a standoff pad. The suspensory ligament *(SL)* is located between the large oblique arrows. *DDFT*, Deep digital flexor tendon; MT_3, plantar border of third metatarsal bone; *SDFT*, superficial digital flexor tendon.

a dilemma in detecting subtle injury. The SL is firmly attached to the third metatarsal bone (MtIII) (~4 to 5 cm enthesis) and rapidly increases in plantar to dorsal size within zone 2A. Therefore care must be taken when measuring comparative CSAs to do so at exactly the same level within zone 2A. In longitudinal images the origin of the SL often does not have a tight parallel fiber pattern, which results in a FAS of 1. The large bony surfaces of the second metatarsal bone (MtII) and MtIV obstruct a clear view, and often a linear anechogenic artifact is created by more superficial blood vessels. The origin of the SL begins slightly lateral to midline and thus is not parallel to the plantar surface of MtIII. The SL appears rhomboid from the plantar midline, but if viewed from slightly medial of midline, it appears more rectangular. CSA measurements should be obtained from one view or the other, but not mixed. Comparison of the longitudinal and transverse views of the SL may help in identifying the plantar and dorsal borders.

Zone 2B Hindlimb zone 2B extends approximately 21 to 24 cm distal to the tuber calcanei. The SDFT, DDFT, ALDDFT, and SL can be viewed adequately from a midline and slightly medial positioning of the transducer (Fig. 16-29). At this level the SDFT is slightly crescent shaped, and the DDFT is ovoid and slightly medially placed. The ALDDFT is seen on the dorsal border of the DDFT. The SL is roughly rectangular with an apex toward the plantar lateral aspect (Fig. 16-30). No unique anatomical features identify this zone; it is identified only by measurement.

Zone 3A This zone ranges from 24 to 32 cm distal to the tuber calcanei. The SDFT is slightly crescent shaped and is positioned directly over the DDFT. The SL at this level is roughly rectangular with an apex on the plantar lateral border. Zone 3A has no unique anatomical features.

Zone 3B Hindlimb zone 3B extends from 28 to 32 cm distal to the tuber calcanei. The SDFT is crescent shaped and narrower in the plantar to dorsal plane and wider in a medial to lateral plane, whereas the DDFT is ovoid. This zone has no unique anatomical features.

Zone 4A The hindlimb zone 4A extends from 32 to 36 cm distal to the tuber calcanei. In this zone the ALDDFT inserts into the DDFT, and a normal hypoechogenic artifact may be seen on the dorsal border of the DDFT (Fig. 16-31). This is the most distal zone in which the SL is a single unit. The proximal aspect of the DFTS may be seen.

Zone 4B Hindlimb zone 4B extends from 36 to 43 cm distal to the tuber calcanei and has the same anatomical features as forelimb zone 3B. The hindlimb branches of the SL tend to be longer (~10 cm) and a little larger than the forelimb branches.

Zone 4C This zone extends from 43 to 47 cm distal to the tuber calcanei and has the same anatomical features as forelimb zone 3C.

Palmar/Plantar Pastern Zones and Descriptions

Qualitative assessments are more critical in pastern ultrasonography because some lesions are not accompanied by

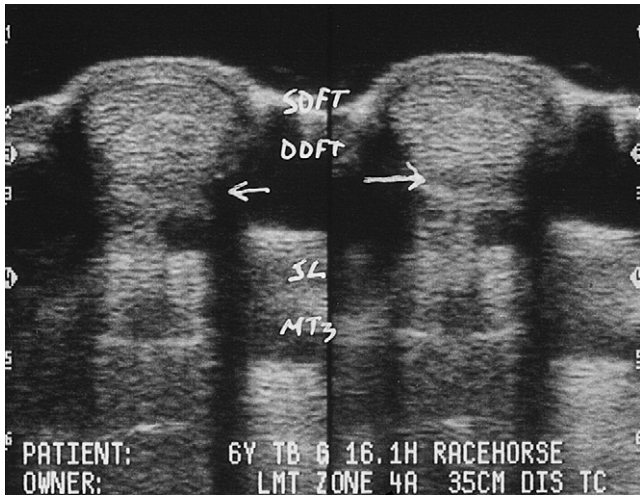

Fig. 16-31 Transverse images from zone 4A, 35 cm distal to the tuber calcanei. There is an artifactual hypoechogenic zone between the dorsal aspect of the deep digital flexor tendon *(DDFT)* and the plantar border of the accessory ligament of the DDFT insertion *(horizontal arrows)*. MT_3, Plantar border of third metatarsal bone; *SDFT;* superficial digital flexor tendon; *SL*, suspensory ligament.

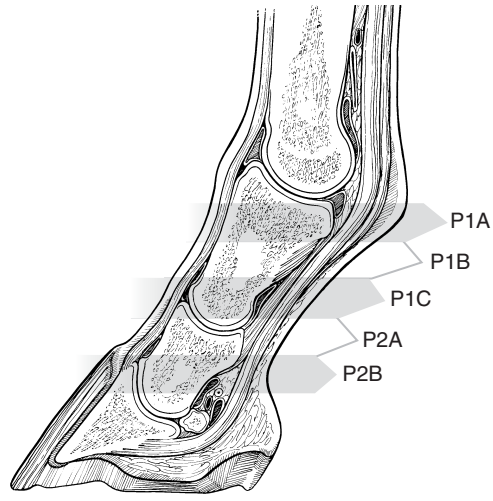

Fig. 16-32 Zone designations for the pastern. See text for zone descriptions.

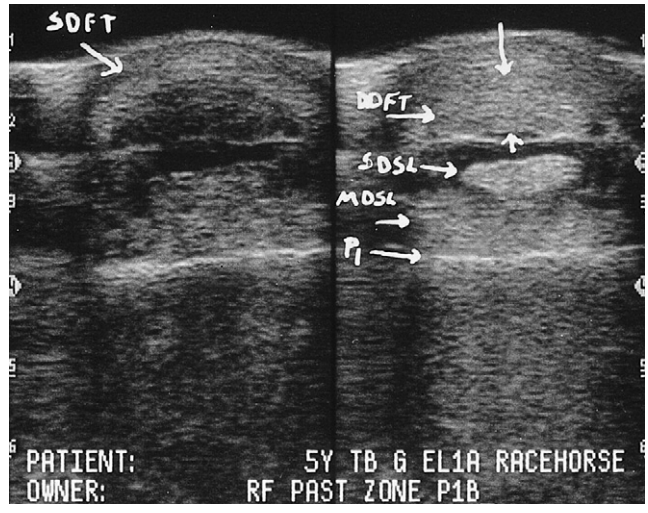

Fig. 16-33 Transverse images of zone P1B obtained using a standoff pad. The left image targets the superficial digital flexor tendon *(SDFT)*. The right image targets the deep digital flexor tendon *(DDFT)*, straight distal sesamoidean ligament *(SDSL)*, and the middle distal sesamoidean ligament or oblique sesamoidean ligament *(MDSL)*. P_1, Palmar border of the proximal phalanx.

significant changes in CSA. If DFTS tenosynovitis is coupled with a subtle primary tendon injury, the tendon may be mildly enlarged. Marginal longitudinal tears of the DDFT require precise qualitative inspection of the lateral and medial borders of the DDFT and the vinculae. Fibrous adhesions of the sheath may be identified but may not be accompanied by an increase in DDFT CSA.[19] It also is more difficult to obtain accurate FAS for the branches of the SDFT and oblique sesamoidean ligament (or middle distal sesamoidean ligament). The distal metacarpal or metatarsal regions should also be examined when assessing the DFTS in the pastern.

The pastern is a complex anatomical structure including many ligaments, joint recesses, vasculature, fibrocartilaginous insertional attachments, entheses, joint surfaces, and two major tendons.[20] The major structures of practical and common clinical concern are the DFTS, SDFT and branches, DDFT, oblique sesamoidean ligament (middle distal sesamoidean ligament), and straight sesamoidean ligament (or superficial distal sesamoidean ligament). The pastern can be arbitrarily divided into four zones, each with unique anatomical features. The pastern is divided into three palmar/plantar zones along the proximal phalanx (P1) and one zone at the proximal interphalangeal joint (Fig. 16-32).

Pastern Zone Designations and Descriptions

Zone P1A Zone P1A extends approximately 1 to 3 cm from the base of the ergot. Anatomical landmarks, such as the ergot, can be used to identify this zone. The SDFT is viewed from the midline and is a crescent-shaped, single-unit structure with very slight enlargement and rounding of the medial and lateral borders. The entire SDFT is included for CSA data. The palmar/plantar surface of the SDFT is covered by the thin proximal digital annular ligament. Dorsal to the SDFT on the midline view lies the ovoid-shaped DDFT. Anechoic fluid in the DFTS is interposed between the DDFT and the triangular-shaped straight distal sesamoidean ligament. Occasionally a fibrous bridge of the middle distal sesamoidean ligament or a small portion of the cruciate sesamoidean ligament (or deep distal sesamoidean ligament) may be identified dorsal to the straight distal sesamoidean ligament. Dorsal to the SDFT on the midline view is a hypoechogenic/anechogenic rounded joint recess of the metacarpophalangeal/metatarsophalangeal joint. The medial and lateral origins of the middle distal sesamoidean ligament are seen as two distinctly separate structures and are more adequately viewed by medial and lateral parasagittal placement of the transducer.

Zone P1B Zone P1B extends from 3 to 5 cm distal to the base of the ergot (Fig. 16-33). The SDFT is still a single unit starting to form rounded medial and lateral branches, which are evaluated by moving the transducer medially and laterally. The DDFT has a bilobed appearance and unless the transducer is perpendicular to the DDFT, central hypoechoic areas are seen in each lobe. The DFTS is seen on the dorsal surface of the DDFT, dorsal to which is the square- or rectangular-shaped superficial distal sesamoidean ligament. The oblique distal sesamoidean ligament is seen as a single structure in close proximity to the palmar/plantar surface of P1, dorsal to the straight distal sesamoidean ligament.

Zone P1C This zone extends approximately 5 to 7 cm distal to the base of the ergot (Fig. 16-34). The bilobed-shaped DDFT lies subcutaneously. The square-shaped or

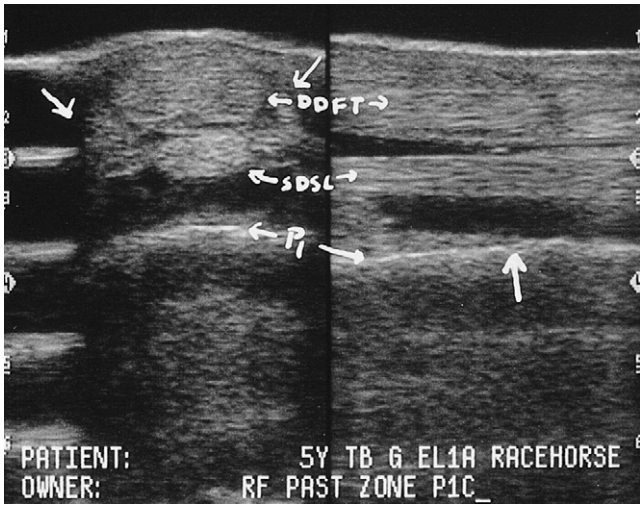

Fig. 16-34 Transverse *(left)* and longitudinal *(right)* images of zone P1C obtained using a standoff pad. The *oblique arrows* indicate the untargeted medial and lateral branches of the superficial digital flexor tendon. The *vertical arrow* indicates the insertion of the middle distal sesamoidean ligament *(MDSL)*. *DDFT*, Deep digital flexor tendon; P_1, palmar border of the proximal phalanx.

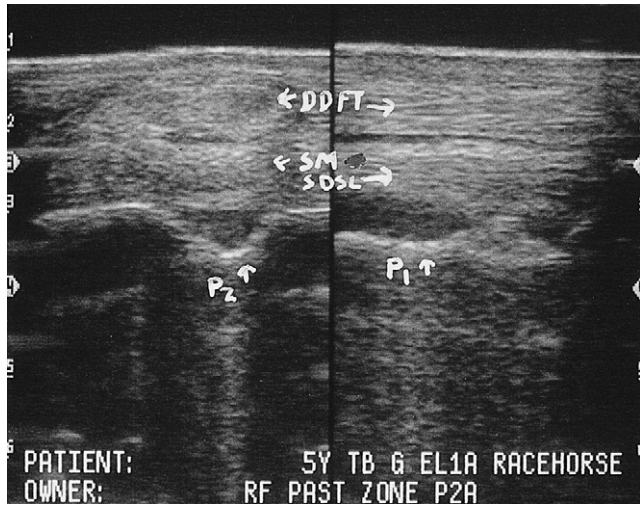

Fig. 16-35 Transverse *(left)* and longitudinal *(right)* images of zone P2A obtained using a standoff pad. *DDFT*, Deep digital flexor tendon; P_1, palmar border of the proximal phalanx; P_2, the palmar border of the middle phalanx; *SDSL*, superficial distal sesamoidean ligament or straight sesamoidean ligament; *SM*, scutum medium.

slightly rectangular-shaped straight distal sesamoidean ligament is on the dorsal surface of the DDFT. The oblique distal sesamoidean ligament is not seen because zone P1C is distal to its insertion. The teardrop-shaped medial and lateral branches of the SDFT are viewed by moving the transducer medially and laterally.

Zone P2A Zone P2A extends approximately 6 to 9 cm distal to the base of the ergot. A thin distal digital annular ligament is closely associated with the palmar/plantar border of the DDFT. The DDFT has a bilobed appearance but is narrower from palmar/plantar to dorsal and wider from medial to lateral. Deep to the DDFT is the middle scutum, the fibrocartilaginous insertion of the straight distal sesamoidean ligament, which may have a heterogeneous echogenicity (Fig. 16-35). Deep to the middle scutum is the proximal interphalangeal joint recess. The medial and lateral branches of the SDFT insert onto the distal aspect of the proximal phalanx and the proximal eminence of the middle phalanx.

Ultrasonography of Proximal Parts of the Limbs

Quantitative ultrasonographic evaluation can be applied to other anatomical areas and the lower limb areas described. These areas do not have zonal designations, and all are identified by measurement from a bony eminence. Many structures contain some muscle fiber bundles that are hypoechogenic, which makes detection of lesions more difficult. Whenever possible, we compare echogenicity, fiber alignment, and CSA between the limbs to determine some quantitative data to support a qualitative diagnosis.

CLINICAL ULTRASONOGRAPHY

With these suggested fundamental principles in terminology and a systematic concept of data collection, the clinician is prepared to examine the patient. A 7-year-old TB gelding racehorse that had raced for 5 years with 80 lifetime starts, 14 wins, and $74,568 in earnings, raced poorly 4 days previously. The next day, the trainer noted peritendonous swelling but no lameness. The horse had never had swelling in this area previously. The horse had received 2 g of phenylbutazone intravenously 24 hours before the race and 2 g immediately after the race. There was heat, slight subcutaneous swelling, and sensitivity and slight enlargement of the SDFT. A core lesion of the SDFT was detected ultrasonographically (Fig. 16-36). This scenario raises several questions. How serious is the injury? Can the horse be treated symptomatically and continue to race? If the horse is rested, will it be able to race again? If the horse is rested, which therapy should be used? How will the degree of healing be determined? Each horse is assessed by subjective evaluation of the ultrasonographic images and quantitative analysis.

Quantitative Analysis

The weakest link, or maximal injured zone, is the level at which the biggest proportion of tendon CSA is reduced in echogenicity, or the zone with the largest increase in CSA when compared with a normal contralateral limb. Total structural size is obtained by summing the CSA from each zone. To obtain the percentage of total extent of injury, add the lesion CSA from all levels with a lesion. The total lesion CSA is divided by the total structure CSA and multiplied by 100. The resulting number provides an estimate of structural compromise. It is this percent of total lesion (%T-lesion) that is used to categorize injury and relates the severity of structure injury to the client.

Quantitative Terms

The following terms are used in reference to injuries:

1. Maximal injury zone (MIZ)
2. Maximal zone cross-sectional area (MIZ-CSA)
3. Maximal injury zone lesion cross-sectional area (MIZ-LCA)
4. Maximal injury zone type or echo score (MIZ-TS) (MIZ-ES)
5. Maximal injury zone fiber alignment score (MIZ-FAS)
6. Total cross-sectional area (sum of included levels; T-CSA)
7. Total lesion cross-sectional area (sum of all levels with a lesion; TL-CSA)
8. Total type or echo score (sum of all levels with a score; T-TS or (T- ES)

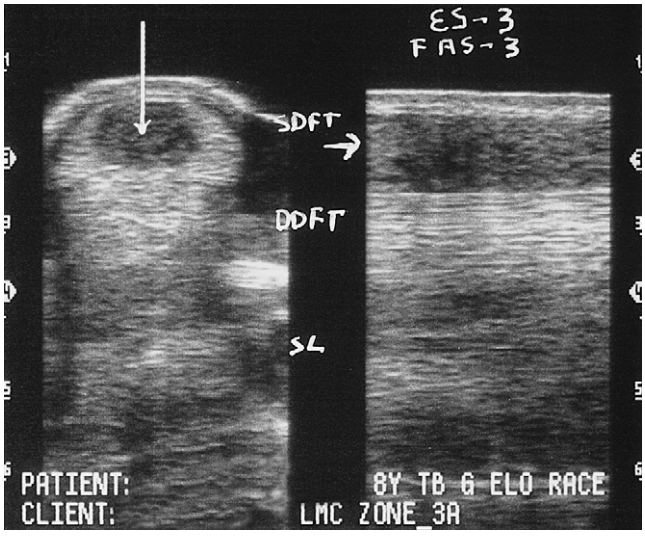

Fig. 16-36 Transverse *(left)* and longitudinal *(right)* images from zone 3A obtained using a standoff pad. The *vertical arrow* indicates a type 3 core lesion of the superficial digital flexor tendon *(SDFT)*. The *horizontal arrow* indicates the target path on the longitudinal image, with a fiber alignment score of 3 *(FAS-3)*. *DDFT,* Deep digital flexor tendon; *ES-3*, echo score 3; *SL*, suspensory ligament.

9. Total fiber alignment score (sum of all level scores; T-FAS)
10. Average fiber alignment score: (total divided by number of levels included; A-FAS)
11. Percent total lesion: ([TL-CSA ÷ T-CSA] × 100 = % T-lesion)

In a normal horse, typical measurements of T-CSA in the forelimb include the following:

- 8 zones of the SDFT = 886 mm^2
- 8 zones of the DDFT = 1001 mm^2
- 5 zones of the ALDDFT = 449 mm^2
- 11 zones of the SL = 1156 mm^2
  - Main body of the SL (5 zones) = 614 mm^2
  - Lateral branch (3 zones) = 258 mm^2
  - Medial branch (3 zones) = 284 mm^2

We find that this quantitative assessment provides practical, useful information that can be used routinely and that lesions can be placed in one of six categories.

Lesion Categories

Category I Category I implies no substantial qualitative or quantitative abnormality. No tendon or ligament fiber bundle lesions are detected, and all zones have lesion and fiber alignment scores of zero. No single zone has a CSA measurement greater than 39% compared with the contralateral limb. This percentage of tolerance more than adequately allows for method error, especially in zones 1A and 3A. However, with precise technique, a variation greater than 25% indicates substantial structural enlargement. Assessment of T-CSA depends on the number of zones included. The larger the number of zones included, the less difference there should be between limbs:

6/7 zones: <15%
11 zones: <12%
5 zones: <17%
3 zones: <20%
2 zones: <25%.

A 9-year-old TB mare competing as a hunter developed new swelling in the right proximal metacarpal region and slight, intermittent lameness. The client was concerned that the tendon was injured, and if so, did not want to continue athletic use of the horse, which would risk further injury. Palpation revealed swelling (2/5), increased skin temperature (2/5), and a painful response to direct digital pressure of the proximal right fore SDFT. Both forelimbs were examined ultrasonographically. No qualitative abnormalities were detected in the normal limb. Subcutaneous fluid was accumulated in the affected limb, indicating edema with or without hemorrhage, but echogenicity of the SDFT was normal. CSA was measured for 7 zones of each limb. Zone 1B was determined the maximal injured zone, and the CSA of the SDFT was 25% larger than the normal limb (i.e., category I) but suggestive of tendon enlargement. The T-CSA difference was only 3%. The SDFT was considered normal, although 2 zones had slightly enlarged CSA (1B was +25% and 2A was +23%). It was recommended that exercise should be restricted to walk and trot for 7 days with daily icing, daily bandaging with alcohol and thick standing bandages, and treatment with phenylbutazone (2 g once daily for 5 days). If the swelling was 100% reduced after this time, then the horse could return to normal athletic use. If no improvement occurred within 7 days or return to work caused a relapse, repeat ultrasonographic evaluation would be indicated. This horse returned to normal use.

Category II No hypoechogenic or anechogenic lesions are detectable, but the affected limb has MIZ-CSA measurements greater than 39%, with or without T-CSA for 6 or 7 zones greater than 14% of the normal limb (i.e., measurable focal or diffuse thickening of the tendon or ligament). Causes of category II injuries may include an unusual developmental difference, a new low-grade tendonitis/desmitis, or an older, currently stable healed tendon or ligament injury. Although generalized thickening may not cause great concern initially, there is evidence that continued use will eventually lead to greater injury. For example, 29% of TB racehorses (n = 13) that continued to train and race with a *new* category II SDFT injury eventually developed a clinically bowed tendon.[21]

A 12-year-old TB gelding competing cross country had recurrent swelling of the SDFT in the mid-metacarpal region that reduced with rest and anti-inflammatory treatment but returned if work was resumed. The horse had a long toe and was shod in smooth-toed, heavy steel shoes. There was slight, diffuse thickening (2/5) of the SDFT with increased skin temperature and marked sensitivity to direct digital pressure in zone 2B (4/5). Ultrasonographic examination revealed subcutaneous fluid and possible SDFT enlargement (Fig. 16-37) in zone 2B. Inflammation of the communicating branch of the palmar nerves was noted, indicating a malpositioned bandage. However, quantitative evaluation indicated a substantial generalized tendon thickening, which is unusual for a focal bandage pinch. The T-CSA was 15% larger than the normal limb (i.e., category II). It was recommended that exercise be restricted to walk with little trotting under saddle for 3 to 4 days a week for 1 month with daily icing and use of a thick-stall bandage with alcohol. Foot length should be shortened and the horse shod with a fully grooved or creased, lighter steel shoe to decrease the strain on the tendon. Five weeks later marked clinical improvement was noted. Ultrasonographic examination revealed that the subcutaneous fluid accumulation had resolved with no qualitative abnormalities of the SDFT. Significant reduction in the T-CSA measurements indicated a resolution of intratendonous inflammation. These findings add credence to the initial diagnosis of low-grade tendonitis. It is difficult to make this diagnosis qualitatively with any confidence. Only use of quantitative analytical techniques allow the clinician to truly appreciate these changes and be confident in a category II diagnosis.

Category III In category III lesions, type 1 or 2 focal hypoechogenic fibers bundles are present, with or without significant MIZ-CSA or T-CSA enlargement. To qualify as a

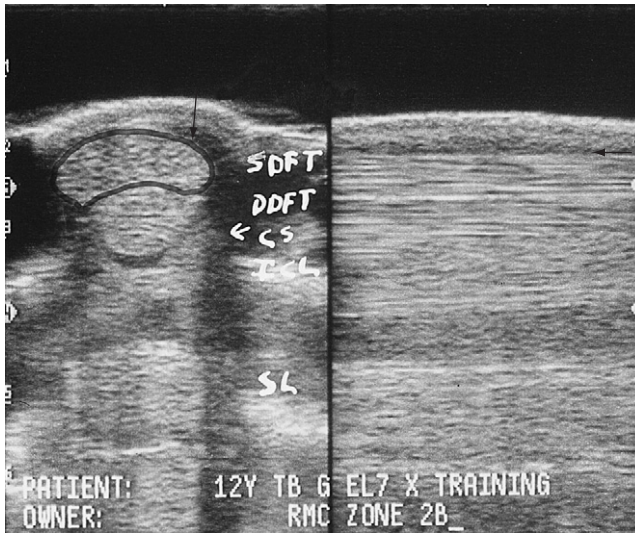

Fig. 16-37 Transverse *(left)* and longitudinal *(right)* images of zone 2B obtained using a standoff pad. The *arrows* indicate subcutaneous fluid accumulation. *CS*, Carpal sheath; *DDFT*, deep digital flexor tendon; *ICL*, accessory ligament of the DDFT; *SL*, suspensory ligament.

category III lesion, the T-TS (T-ES) cannot exceed 3 (i.e., ≤ 2). This abnormality may be an incidental finding, represent minimal tendon or ligament injury, or be the end result of a healed and clinically stable tendon or ligament injury. In these horses, clinical history, physical examination, and serial monitoring help to determine the significance of the ultrasonographic abnormalities.

A 16-year-old Trakhener gelding, used for upper-level dressage, was examined to assess healing of desmitis of the ALDDFT. The horse had been in controlled exercise for many months and the client was anticipating a progressive return to normal athletic use, assuming the ultrasonographic findings were favorable. Moderate thickening of the ALDDFT (3/5) was confirmed ultrasonographically, including a focal area of compromised fiber bundles along the dorsal lateral border of zone 2A (TS = 1), and a generalized alteration in fiber bundle alignment (T-FAS = 4). Given the knowledge that this horse had been rested for many months, a slow return to training was recommended. The ultrasonographic images can be used as a benchmark for evaluation of the stability of the repair as gradual increases in ligament loading commence. The horse eventually returned to upper-level dressage and has been asymptomatic for 2 years.

Even though category II and III injuries do not seem to represent a very serious compromise to a tendon or ligament, they do alert the clinician, trainer, and owner to a subtle problem that requires medical management, and that with early diagnosis is more easily managed. If the decision were made to continue athletic use accompanied with symptomatic therapy, serial ultrasonographic monitoring would be indicated to monitor stability. In this manner, early significant regressions may be detected before overt clinical signs of reinjury occur. These two injury categories are not easily diagnosed with qualitative assessment alone. Quantitative analysis identifies these low-grade abnormalities. However, these two categories often represent a dilemma for the practitioner. The clinical signs are slight, seldom associated with lameness, and often respond quickly to symptomatic therapy. Therefore it is difficult to persuade trainers to rest horses. However, category II and III tendons and ligaments often represent the earliest of ultrasonographically identifiable injury and have the best

Table • **16-1**

Category IV T-Lesions

ZONES USED FOR TOTAL (NO.)	T-LESION (%)*
11	1%-10%
6 or 7	1%-15%
5	1%-20%
3	1%-25%

*All have a total type or echo score ≥ 3.

chance of full recovery with extended rest. Quantitative evidence may help a client appreciate the significance of the injury. Ultimately, regardless of whether the horse is rested or treated symptomatically for a category II or III injury, periodic comparative data will greatly assist the practitioner in advising clients and help the clients to understand the injury.

Category IV A category IV lesion is characterized by focal hypoechogenic or anechogenic lesions with the T-S ≥3, with a specific %T-lesion (Table 16-1). The range of %T-lesion to qualify for category IV varies depending on the number of zones included for determining the "total." The MIZ-CSA or T-CSA may or may not be significantly enlarged. Although this category includes a wide range of injuries, it can be used to document slight injury or a significant compromise of tendon or ligament fiber bundles.

A 5-year-old TB racehorse gelding had a right fore SDFT injury of 6 months' duration. The horse had been galloping daily (exercise level 5) for 2 weeks, but the last time the horse galloped, right forelimb lameness and tendon swelling developed. Physical examination revealed slight swelling (1/5), low-grade lameness (2/5), moderate SDFT thickening (3/5), slight sensitivity to direct digital pressure, and localized heat (2/5) of the right forelimb. Ultrasonographic analysis of the right SDFT in zone 3B displayed a large type 3 anechogenic core lesion (Fig. 16-38). Quantitative data documented a T-CSA of 1243 mm^2. CSA was 67% larger than the left fore SDFT in zone 3B. In addition, bundles of compromised tendon were noted in 6 of the 7 zones. These localized lesions of mixed echogenicity, mostly type 1, probably were the result of the previous injury. The new injury was localized to zones 3B and 3C, with echo scores of 2 and 3. In this analysis of reinjury, all areas of reduced echogenicity were included in the total lesion summation. Additional measurements include %T-lesion of 12%, T-TS of 11, T-FAS of 8, and A-FAS of 1.1.

Category V Category V injuries typically have substantial MIZ-CSA or T-CSA enlargement with focal hypoechogenic, anechogenic, or both types of lesions. T-TS is greater than 3. This category has been arbitrarily associated with moderate tendon or ligament injury. The range of %T-lesion to qualify for category V varies depending on the number of zones included in arriving at the "total" (Table 16-2).

Many horses with category V or VI injuries or re-injuries exhibit lameness in the early stages, but many category III and IV injuries are not associated with lameness.

A 3-year-old Standardbred pacer, colt, developed swelling of the left fore SDFT after racing 1 week earlier and had previously sustained injury as a 2-year-old. The mid-metacarpal region was slightly swollen (1/5) with moderate SDFT thickening (3/5), sensitivity to direct digital palpation (2/5), slight heat (1/5), and slight lameness (2/5). Ultrasonographic examination revealed a type 2, focal, hypoechogenic lesion in the lateral border of the SDFT in zone 2A (Fig. 16-39). Computer analysis of the left fore SDFT documented hypoechogenic or anechogenic lesions along the lateral border in 6 of the 7

Table • 16-3

Category VI T-Lesions

ZONES USED FOR TOTAL (NO.)	T-LESION (%)*
11 zones	>20%
6 or 7 zones	>25%
5 zones	>30%
3 zones	>35%

*All have a total type or echo score ≥ 3.

zones (Fig. 16-40). Zone 2A was designated the maximal injured zone because it had the lesion with the largest CSA (37%). The MIZ-CSA of 166 mm^2 was 47% larger than the same zone of the contralateral normal SDFT. T-CSA of the 7 zones was 1179 mm^2, 31% greater than the contralateral SDFT. Additional measurements included T-TS of 11, T-FAS score of 8, and %T-lesion of 22% (i.e., category V). Unlike many newly injured tendons or ligaments with similar T-TS and T-FAS scores, this re-injured SDFT had a difference in these scores. This may serve as a means to identify new versus re-injured structures ultrasonographically.

Category VI Category VI injuries have substantial MIZ-CSA or T-CSA enlargement with more extensive hypoechogenic or anechogenic lesions than category V. The range of %T-lesion to qualify for category VI varies depending on the number of zone used to determine the "total" (Table 16-3).

A 4-year-old TB racehorse gelding developed swelling of the left fore SDFT after a race 6 days earlier. Physical examination revealed slight swelling (2/5), moderate SDFT thickening (3/5), slight sensitivity to direct digital palpation (2/5), slight heat (2/5), and low-grade lameness (2/5). A large type 3 anechogenic lesion of the lateral half of the SDFT was seen in zone 2B, the maximal injured zone (MIZ-LCA 92 mm^2 representing 54% of the tendon CSA). The MIZ-CSA was 114% larger than the contralateral normal zone 2B SDFT (see Fig. 16-15). Six of the 7 zones had hypoechogenic or anechogenic contiguous fiber bundles, with a 65% increase compared with the contralateral SDFT. T-LCSA was 300 mm^2, resulting in a 28% T-lesion. T-TS (14) and T-FAS (14) were the same, a common finding in newly injured tendons, although not acute SL injuries.

Summary

Tendon and ligament injuries can be graded from 1 to 6 to reflect the severity of injury. Advantages of using quantitative assessment in conjunction with clinical findings and qualitative evaluation include the following:

1. Confirmation or addition to a qualitative diagnosis.
2. Improved detection of subtle structural enlargement not accompanied by detectable echogenicity abnormalities, thus reducing interpretive errors.
3. Establishment of an objective means to categorize the severity of an injury, which can be used to determine prognosis for intended use and whether continued use or extended rest is the optimal choice. It also provides baseline information that can be compared with follow-up examinations.

FAS	Zone	Structure SIze (mm^2)	Lesion Size (mm^2)	Type/Echo Score
0	1A	115	5 (3.86%)	1

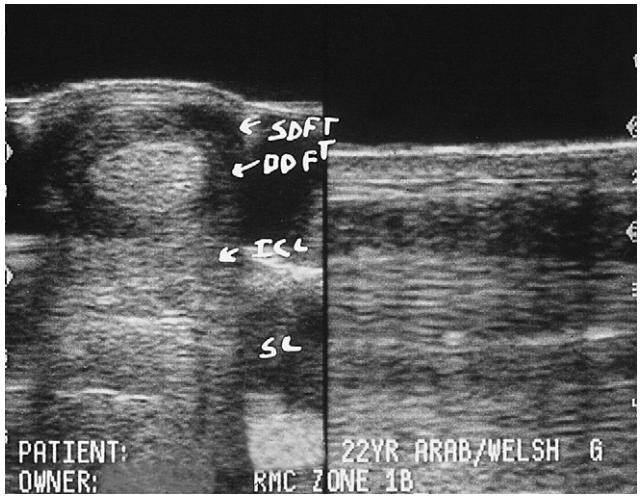
Fig. 16-40 A computer graphic of the left metacarpal region of the same horse as Fig. 16-39 shows seven data points for quantitative evaluation. The superficial digital flexor tendon is 31% larger than the normal limb, has a 22% T-lesion, a T-echo or type score of 11, a T-fiber alignment score of 8, and an average fiber alignment score of 1.1. The maximal injury zone is 2A. The overall category of fascicle compromise is V. *ANK. SINK;* Ankle sinking; *FLEX,* flexion; *H,* heat; *L,* lameness; *SWEL,* swelling; *THIC,* Thickening; *T.SH,* tendon sheath.

4. Enhanced veterinary participation in the rehabilitation of a tendon or ligament injury.
5. Improved client appreciation of the injury and improved compliance for suggested exercise restraint and treatment.
6. Creation of a common ultrasonographic interprofessional language and provision of a valid tool for research purposes to evaluate treatment responses.

Exceptions

As with most attempts to categorize medical injuries, exceptions most always are possible. The following are three common exceptions to quantitative categorization of tendons and ligaments:

1. Diffuse tendonitis/desmitis. This is an uncommon clinical presentation of SDFT thickening, which is seen mostly in 2-year-old TB racehorses and older event horses and show jumpers. The T-CSA measurements indicate substantial enlargement if the contralateral SDFT is normal. However, injury may be bilateral; therefore CSA measurements are compared with normal values for the breed, size, and age of the horse. Two-year-old TB racehorses in training tend to have larger T-CSA values than similar, older horses. In these horses, not only is the SDFT enlarged, but the entire CSA has a subtle reduction in echogenicity that extends through several zones. Although the %T-lesion is high, it does not necessarily indicate severe tendon fiber disruption because the echogenicity score for each zone is type 1 or 2 and the FAS score is 1or 2. This indicates a diffuse tendonitis with little loss of tensile strength. Given time and restricted exercise, documentation with serial ultrasonography indicates that most 2-year-old horses generally do well (Fig. 16-33).
2. If the SDFT or SL is totally disrupted, fiber bundles in adjacent zones may appear artificially more hypoechogenic or anechogenic because of the loss of tension in the structure, which is otherwise known as *relaxation effect*.[22] Clinically, tension is lost and the structure can be moved medially and laterally with ease. Ultrasonography shows a loss of parallel fiber alignment and a decrease in echogenicity. Measurement of CSA is difficult and can even be decreased at the maximal injured zone (Fig. 16-41). The diagnosis of complete rupture of a tendon or ligament is usually readily made clinically.



16-41 Transverse *(left)* and longitudinal *(right)* images of zone 1B obtained with a standoff pad. The borders of the superficial digital flexor tendon *(SDFT)* are not defined, and most of the echoes present represent hematoma. The SDFT was completely ruptured. *DDFT,* Deep digital flexor tendon; *ICL*, accessory ligament of the DDFT; *SL*, suspensory ligament.

3. Total collapse of the SL is characterized clinically by an extreme extension of the metacarpophalangeal or metatarsophalangeal joint (4/5 ankle sink), with little swelling or significant thickening of the SL or SL branch, and no sensitivity to direct palpation. Rupture cannot be palpated, and it appears as though the entire suspensory system has lost its cross-links and stretched, although ultrasonography shows little evidence of fiber tearing. Ultrasonographic images do not reflect the severity of the clinical signs.

Clinical Applications

If clinical evidence of swelling or thickening, with or without lameness, is present, the basic objective of an ultrasonographic evaluation is to determine the cause. Every effort must be made to determine whether tendons and ligaments are normal or abnormal and whether the lameness can be directly attributed to a soft tissue abnormality. Lameness may only be visible at high speeds in a racehorse or during special gait movements in a high-level dressage horse. In some instances the ultrasonographic data are insufficient to confirm the suspected cause, especially in subtle injury, although thorough evaluation and serial ultrasonographic examinations may provide clues.

Incidental abnormalities may be identified that have no bearing on the lameness or represent old, stable injuries of no clinical significance. Careful identification of these abnormalities and serial ultrasonographic monitoring may determine their significance. Sometimes other imaging techniques, such as radiography or nuclear scintigraphy, also are required to completely appreciate an injury process. For example, evaluation of SL insertion injuries should also include radiographic assessment.

Timing of Ultrasonographic Examinations: When to Scan

Timing of the initial ultrasonographic examination is critical. A clinician may be requested to examine a limb within hours of an injury. Peritendonous edema may obscure fiber damage because of acoustic enhancement, and the continued release of destructive enzymes may result in further ongoing fiber injury. Thus an examination shortly after an injury may not reveal the true extent of fiber damage. Ideally, an ultrasonographic evaluation should be delayed until at least 48 to 72 hours after the injury. If an ultrasonographic examination is performed before this time, the time after injury should be recorded, exercise restricted to walking, and symptomatic therapy instituted. Physical and ultrasonographic evaluations should be repeated after an additional 72 hours.

Significant hypoechogenic, anechogenic, or both types of lesions may be seen in an injury less than 72 hours old. The areas of reduced echogenicity may represent a combination of hemorrhage (seroma), edema, and fiber bundle injury. The diagnostic dilemma at this stage is that the clinician cannot accurately determine the relative contribution of each. It should not necessarily be assumed that the hypoechoic areas only represent fiber bundle injury. In most horses this assumption is true, but not always. We administer symptomatic anti-inflammatory treatment and advise complete stall rest (exercise level 0) or limited hand walking (exercise level 1A) for 14 to 30 days, followed by an ultrasonographic re-evaluation. (The exception to this advice would be if tendon splitting surgery were the treatment of choice to attempt to decompress a core lesion). When the horse is re-examined, persistent hypoechoic areas represent fiber bundle compromise, because most inflammatory edema and hemorrhage will have resolved. The severity of the injury can now be determined, and we refer to this as the *baseline evaluation*. The baseline evaluation often reveals the same or increased severity of injury compared with the initial scan (especially in core lesions caused by enzymatic degradation of damaged fiber bundles or pressure necrosis).

As an example, we can compare ultrasonographic images of a SDFT injury after 24 hours and after 22 days. The initial examination determined that the SDFT was 32% larger than the normal contralateral limb and had a 17% T-lesion (category V), a T-TS of 17, and a T-FAS of 16. After symptomatic therapy and a reduction of exercise to exercise level 1A, the baseline scans (22 days later) revealed a 12% increase in size of the SDFT compared with the normal limb, a 13% T-lesion (now category IV), a T-TS of 10, and a T-FAS of 12. The apparent decrease in severity was due to the resolution of the inflammatory response and absorption of the seroma. The baseline data represent the actual severity of fiber bundle compromise and serve as the starting point for rendering prognosis for intended use, treatment programs, and long-term rehabilitation exercise regimens.

Serial Ultrasonographic Examinations as Part of Case Management

Serial ultrasonographic examinations are best performed when it is anticipated that the exercise level may be increased. This justifies the examination to the owner or trainer. In addition to the ultrasonographic assessment, the clinician must always consider the physiological principles of tendon and ligament healing and the necessary physiological time for healing for the severity of an injury before advising exercise level increases. With time and as quantitative ultrasonographic analysis is more commonly used to evaluate tendon and ligament repair, more definitive recommendations will develop concerning convalescent time based on the severity and location of an injury and the intended athletic function of the horse. The same applies to the quality of the repair. Horses destined for light work will be able to perform with a less than perfect repair, but racehorses and other high-level athletes will require optimal repair and a reasonable time to give the best chance for return to athletic use without reinjury.

During rehabilitation a qualitative ultrasonographic evaluation of the clinically injured tendon is done to detect obvious lesions, evidence of re-injury, restricting peritendonous tendon sheath fibrosis, or restriction by the PAL. Objective, or quantitative, ultrasonographic assessments should also be determined.

Guidelines for an optimum chance to return to racing include the following[23]:

1. At least a 60% decrease in category IV %T-lesion and <12% total lesion cross-sectional surface area (T-LCSA) for all categories of severity of injury.
2. At least a 10% to 15% decrease in T-CSA from baseline for all categories of injury (a relatively greater decrease in more seriously injured tendons).
3. At least a 70% decrease in the T-TS (ideally <4; the closer to 0, the better).
4. At least a 75% decrease in the T-FAS (ideally <4; the closer to 0, the better) before advancing to exercise level 5.
5. The horse should meet at least three of the above requirements with only minimal failure of the other criterion.

Nonetheless, even a perfectly healed tendon or ligament injury can be re-injured. Re-injury is especially common in TB racehorses. However, if the repair is of poor quality, re-injury is likely and these horses should be held back from active training until healing has improved. Decision making is more accurate when it is based on ultrasonographic evaluation and consideration of necessary physiological time for intended use than when relying on clinical inspection.

The advantages of veterinary intervention and using quantitative ultrasonographic parameters in case management provide a means to optimize the chances of returning an injured horse to athletic usefulness and are reviewed in this clinical example. A 4-year-old TB racehorse with a left fore SDFT injury was examined 3 days after a race. The maximal injured zone was zone 2B (59% lesion), T-CSA was 1206 mm^2, T-TS was 11, and T-FAS was 16. This was a 49% T-lesion (i.e., category VI). The horse was treated with a series of 3 external blisters and 6 months' pasture rest, a typical theory in the early 1990s. The horse was re-assessed 8 months after injury to determine whether it could return to training (exercise level 5). The tendon was tight and cold. Qualitative ultrasonographic examination indicated improvement, although abnormalities persisted, which were interpreted to be the end result of repair. Thus the trainer was wrongly advised to return to training.

In light of current knowledge, the ultrasonographic data at the time of re-evaluation provided clear indication of an unstable repair. The T-CSA had increased 15%, %T-lesion decreased by only 50%, and therefore was still quite high at 22%. In addition, neither T-TS nor T-FAS met a target decrease of 75%. After 4 weeks of galloping, the horse worked at race speed (breezed) once and became lame again. An ultrasonographic evaluation identified extensive reinjury to the same tendon (i.e., category VI). Thus quantitative analysis of injuries is an extremely beneficial tool to monitor progress of tendon healing.

CHAPTER • 17

Ultrasonographic Examination of Joints

Jean-Marie Denoix

Ultrasonography has become an essential imaging technique for assessing joint lesions.[1-3] It provides information complementary to radiography but does have some limitations. Ultrasonography requires a precise knowledge of anatomy, not only bone anatomy,[4] and a systematic approach. Examining the joints of the distal part of the limb is physically uncomfortable for the imager and is time consuming: complete examination of a joint may take up to 30 minutes. Quick examination of joints requires several years of daily practice.

The indications for ultrasonographic examination of equine joints include synovial fluid distention, local swelling, pain on passive manipulation of the joint, improvement in lameness after intra-articular or regional analgesia, or positive radiographic or scintigraphic findings. The area to be examined should be clipped, not shaved, and washed with hot water. High-resolution transducers (7.5- to 13-MHz linear probes) and a standoff pad are used for superficial structures. Convex array 2.5- to 5-MHz transducers are preferable for deeper structures. Both left and right joints should be examined to improve sensitivity and specificity. The image quality depends not only on the frequency of the transducer but also on the quality of the machine (from treatment of the signal to display on the monitor) and the skill of the operator in placing and orienting the transducer.

A comprehensive description of all joints cannot be given in this book. The fetlock joint is a model for a general approach to ultrasonography of joints because of its simple anatomy. Some aspects of examination of the stifle and hock also are presented.

FETLOCK

Each aspect of the joint should be examined systematically using 7.5- to 13-MHz linear transducers and a thin standoff pad.

Dorsal Aspect

Fig. 17-1 shows normal ultrasonographic anatomy.[4,5] In normal fetlock joints the articular capsule is echogenic (except if too relaxed), and the articular margins of the proximal phalanx and the condyles of the third metacarpal bone (McIII) are smooth.

Ultrasonography is a useful technique for the differential diagnosis of soft tissue injuries on the dorsal aspect of the fetlock joint. These lesions include subcutaneous swelling or abscess, bursitis of the subtendonous bursa of the extensor tendons, extensor tendonitis, capsulitis, synovial fluid distention of the dorsal recess of the metacarpophalangeal joint (Fig. 17-2), and chronic proliferative synovitis of the proximodorsal synovial fold of this joint (Fig. 17-3). Thinning, fibrillation, and fissures of the articular cartilage of the dorsal and distal aspects of the condyle of McIII can be identified with high-resolution transducers. Subchondral bone lesions can sometimes be detected before they are visible radiographically.

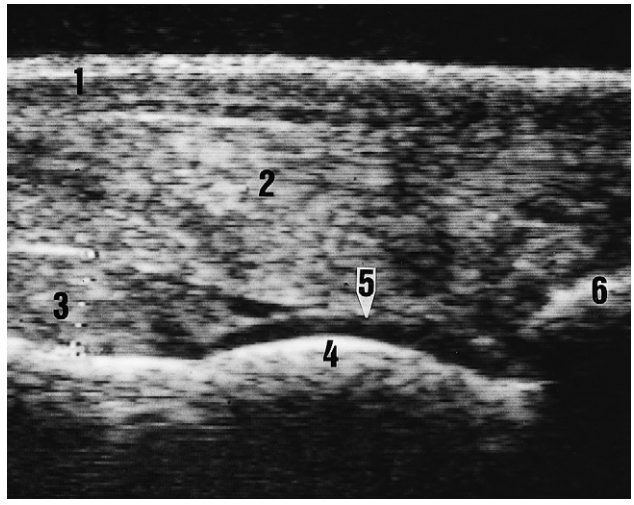

Fig. 17-1 Sagittal ultrasound scan of the dorsal aspect of the fetlock, normal appearance. Proximal is to the left. *1*, Skin; *2*, dorsal capsule; *3*, proximal synovial fold; *4*, subchondral bone of the condyle of the third metacarpal bone; *5*, articular cartilage of the condyle of third metacarpal bone; *6*, proximal phalanx.

Dorsomedial and Dorsolateral Aspects

Examination of the dorsomedial and dorsolateral aspects of the joint is especially useful for complete evaluation of the articular margins, which are smooth in a normal joint. The most common abnormal finding is the presence of periarticular osteophytes. Other injuries are subcutaneous lesions (fibrosis, swelling) and capsulitis.

Medial and Lateral Aspects

The medial and lateral collateral ligaments have superficial and deep layers.[4] If the transducer is parallel to the skin (the ultrasound beam is perpendicular to fiber interface), the superficial layer of the collateral ligament is echogenic and the deep layer is hypoechogenic. Either layer may be damaged (Fig. 17-4). If both layers are affected, joint instability, subluxation, or luxation occur.

Palmar Aspect

A normal fetlock joint has a small amount of anechoic synovial fluid in the proximopalmar recess of the fetlock joint. Abnormal findings observed in affected horses include synovial fluid distention, often associated with enlarged synovial folds, indicative of synovitis (Fig. 17-5).

Echogenic material may be observed in the synovial fluid in any view. Small echogenic spots may represent fibrin or cartilaginous debris. Larger echogenic masses are compatible with osteochondral fragments. These abnormal findings are more easily seen after movement of the joint. A homogenous increase in echogenicity of the fluid is compatible with hemarthrosis or infectious synovitis.

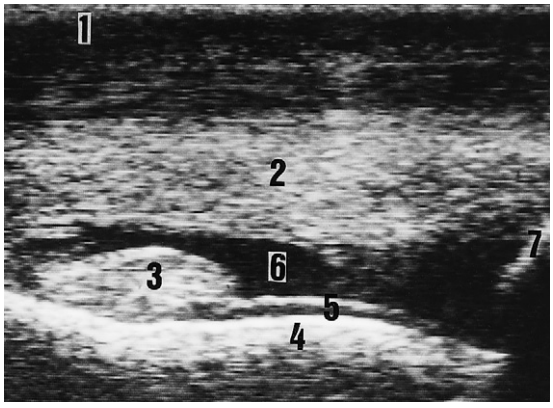

Fig. 17-2 Sagittal ultrasound scan of the dorsal aspect of the fetlock joint. An abnormal synovial fluid accumulation appears between the capsule and the articular surface. The diagnosis is synovial fluid effusion, indicative of synovitis. Proximal is to the left. *1*, Skin; *2*, dorsal capsule; *3*, proximal synovial fold; *4*, subchondral bone of the condyle of the third metacarpal bone; *5*, articular cartilage of the condyle of the third metacarpal bone; *6*, synovial fluid; *7*, proximal phalanx.

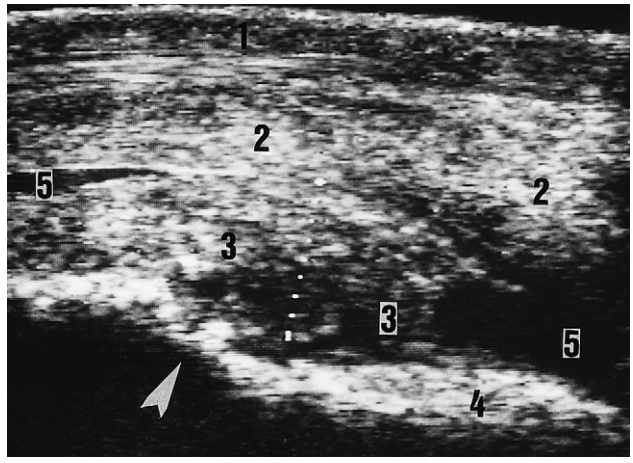

Fig. 17-3 Sagittal ultrasound scan of the dorsal aspect of the fetlock joint. An abnormal hypoechogenic mass appears between the capsule and the condyle of the third metacarpal bone. The proximal aspect of this condyle is irregular, indicating bone lysis (*arrowhead*). The diagnosis is chronic proliferative synovitis. *1*, Skin; *2*, dorsal capsule; *3*, proximal synovial fold tremendously thickened and echoic; *4*, condyle of the third metacarpal bone; *5*, synovial fluid.

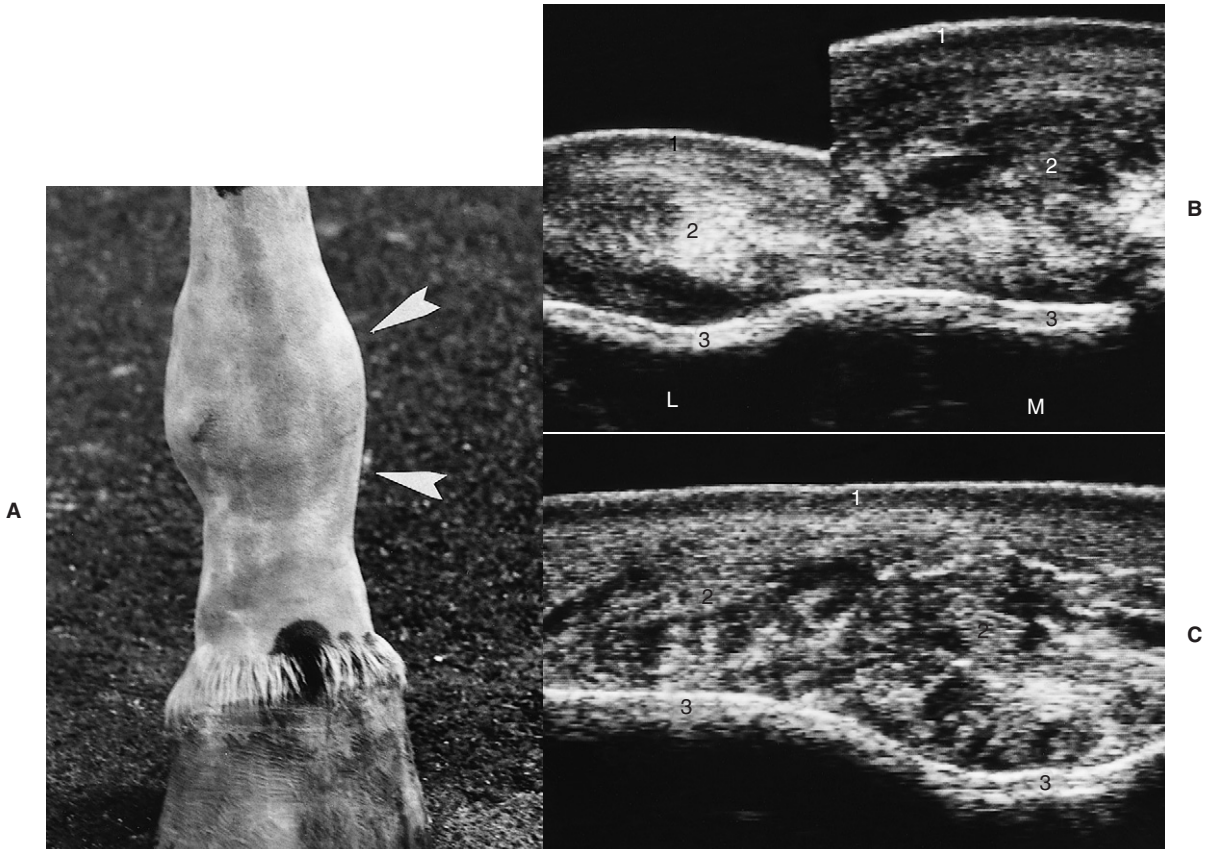

Fig. 17-4 **A,** Physical appearance of an injured hind fetlock joint (*arrowheads* show medial enlargement). Radiography found no bony abnormalities. **B,** Transverse ultrasound scans of the lateral (*L*) and medial (*M*) aspects of the injured fetlock. The size and architecture differ greatly between the normal lateral collateral ligament and the injured medial ligament. **C,** Longitudinal ultrasound scan of the medial aspect of the fetlock shows the thickening and architectural alterations of the medial collateral ligament. The diagnosis is chronic desmopathy of the medial collateral ligament. *1*, Skin; *2*, collateral ligament; *3*, condyle of the third metatarsal bone.

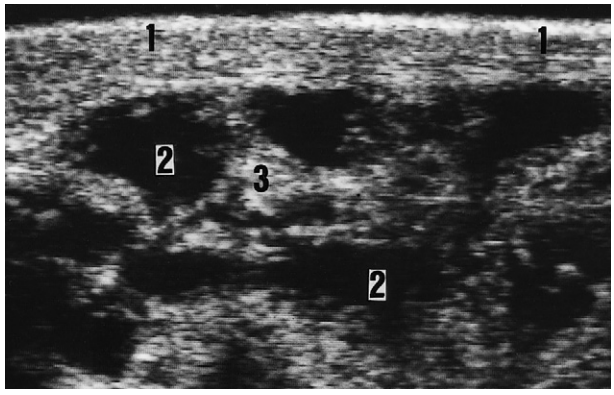

Fig. 17-5 Longitudinal ultrasound scan of the palmarolateral aspect of the fetlock demonstrating a marked fluid distention of the palmaroproximal recess of the fetlock. The diagnosis is synovial fluid effusion indicative of synovitis. *1*, Skin; *2*, synovial fluid; *3*, synovial membrane and villi.

STIFLE

Ultrasonography has considerably improved the knowledge and the diagnosis of soft tissue injuries of the femoropatellar and femorotibial joints.

Femoropatellar Joint

The femoropatellar joint is examined using 5- to 10-MHz linear transducers with a thin standoff pad. The normal patellar ligaments are homogeneously echogenic.[1-3] The articular cartilage is thicker over the lateral trochlear ridge compared with the medial. Each femoral trochlea has a regular hyperechogenic subchondral bone surface.

Medial patellar desmopathy usually is iatrogenic (i.e., caused by medial patellar desmotomy). Desmopathy of the intermediate (middle) patellar ligament is an injury that occurs in athletic horses. Lateral patellar desmopathy often is caused by trauma (Fig. 17-6).

Osteochondrosis of the trochlear ridges is easy to diagnose, and ultrasonography provides information on the extent of the lesion (especially in a lateromedial direction), the size and location of the osteochondral fragments, and the severity of alteration of the subchondral bone. Evaluation of the synovial fluid and membrane may also be useful to assess the consequences of ligamentous and osteochondral lesions in the joint.

Medial and Lateral Femorotibial Joints

Examination of the femorotibial joint requires 5- to 10-MHz linear transducers and a thin standoff pad. In normal joints the medial recess of the medial femorotibial joint is less than 3 cm long in a craniocaudal direction, and the synovial fluid is totally anechoic. The normal medial collateral ligament and medial meniscus are homogeneously echogenic,[1-3] provided that the ultrasound beam is perpendicular to the orientation of the fibers. The normal articular margins of the medial femoral condyle and tibial plateau are smooth and regular.

The medial recess of the medial femorotibial joint can be considered a mirror of the joint, because its size and content are influenced by all joint lesions. Abnormalities include synovial effusion (Fig. 17-7), chronic proliferative synovitis, hemarthrosis (Fig. 17-8), echogenic spots compatible with fibrin, cartilaginous, or meniscal debris (Fig. 17-9), osteochondral fragments, and calcinosis circumscripta. The caudal recess of the medial femorotibial joint can be examined with 2.5- to 5-MHz sector or convex array probes. Distention of this recess always indicates severe femorotibial disease. Distention of the subextensorius recess on the craniolateral aspect of the lateral femorotibial joint can be observed in lateral femorotibial arthropathy or femoropatellar joint lesions.

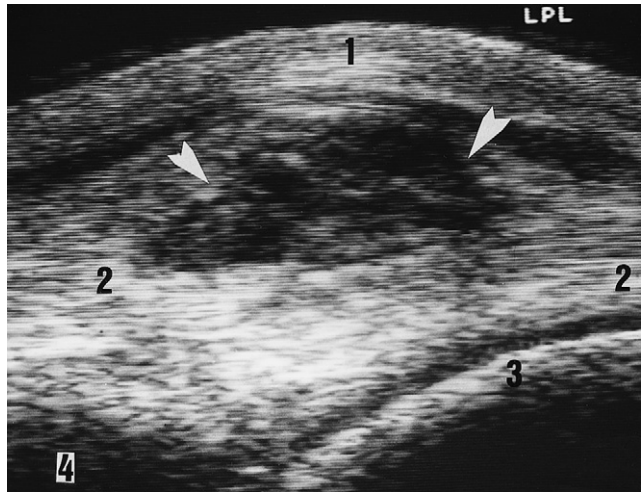

Fig. 17-6 Longitudinal ultrasound scan of the lateral patellar ligament demonstrating localized enlargement. At the site of the lesion (*arrowheads*) the ligament is hypoechogenic and shows severe architectural changes. Diagnosis is traumatic lateral patellar desmopathy. *1*, Skin; *2*, lateral patellar ligament; *3*, lateral ridge of the femoral trochlea (subchondral bone surface); *4*, patella.

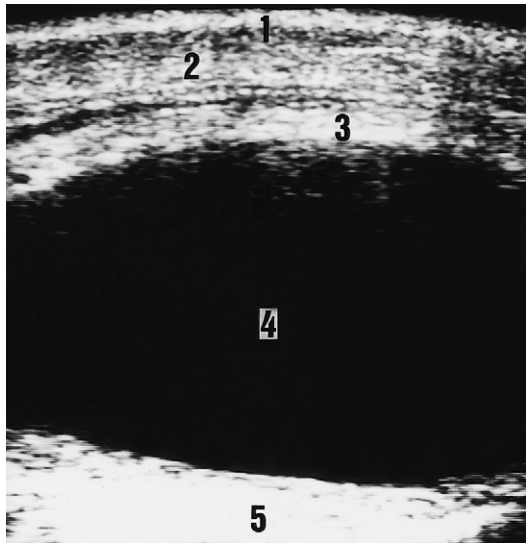

Fig. 17-7 Transverse ultrasound scan of the medial recess of the medial femorotibial joint. Anechogenic synovial fluid has distended this recess. The diagnosis is synovial effusion compatible with synovitis and other potential injuries of the femorotibial joint. *1*, Skin; *2*, medial femoral fascia; *3*, synovial membrane; *4*, medial recess of the medial femorotibial joint; *5*, medial aspect of the distal femur.

Desmopathy of the medial collateral ligament may be identified as disruption in the normal parallel fiber pattern (Fig. 17-10).

Meniscal injuries can be observed alone or with other ligamentous or bone injuries (Fig. 17-11). In our patients, approximately 75% of these lesions are found in the medial meniscus and 25% in the lateral meniscus. A wide range of type and severity of medial meniscal injuries may be seen (Figs. 17-11 and 17-12).

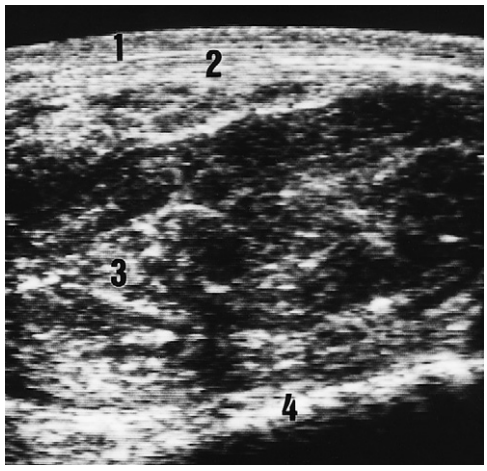

Fig. 17-8 Transverse ultrasound scan of the medial recess of the medial femorotibial joint. Echogenic material distends the recess. The diagnosis is hemarthrosis compatible with other potential ligament or bone injuries of the femorotibial joint. *1*, Skin; *2*, medial femoral fascia; *3*, medial recess of the medial femorotibial joint; *4*, medial aspect of the distal femur.

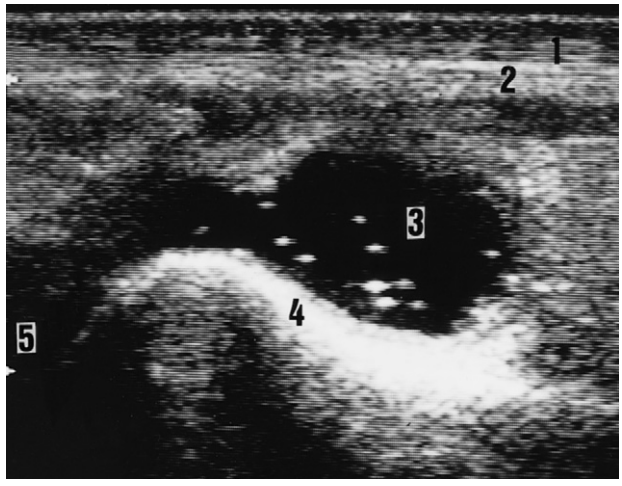

Fig. 17-9 Longitudinal ultrasound scan of the medial recess of the medial femorotibial joint. Echogenic material floats in the synovial fluid. These echogenic spots represent fibrin, cartilaginous debris, or meniscal debris. Proximal is to the right. *1*, Skin; *2*, medial femoral fascia; *3*, medial recess of the medial femorotibial joint; *4*, medial femoral condyle; *5*, medial meniscus (anechogenic because of the orientation of the ultrasound beam).

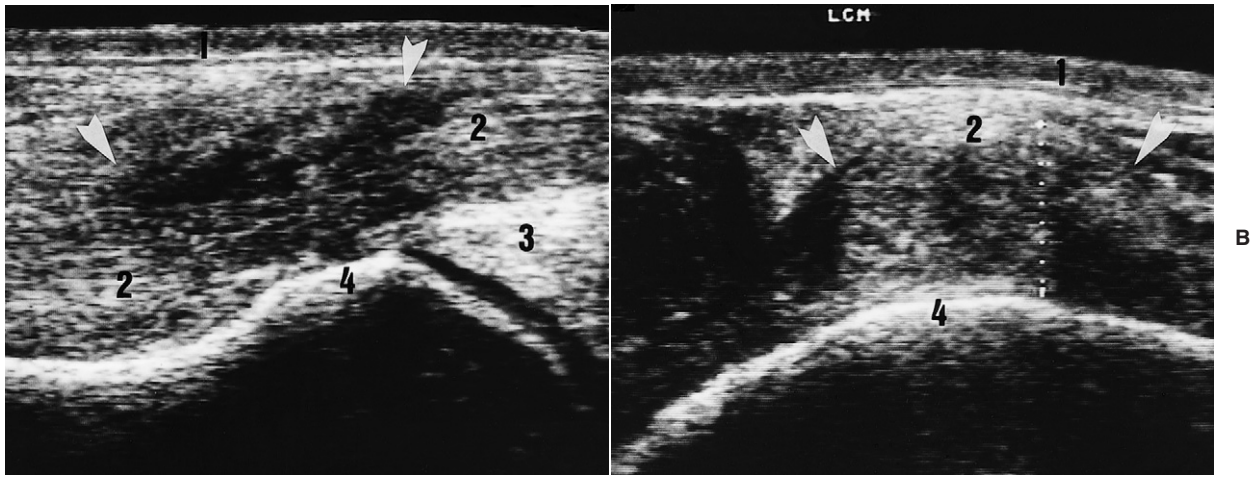

Fig. 17-10 **A,** Longitudinal ultrasound scan (proximal is left) of the medial collateral ligament of the femorotibial joint. This ligament is enlarged and hypoechogenic (*arrowheads*). Diagnosis is traumatic medial collateral desmopathy. **B,** Transverse ultrasound scan of the medial collateral ligament. *1*, Skin; *2*, medial collateral ligament; *3*, medial meniscus; *4*, medial femoral condyle.

If a transducer is held vertically and moved in a caudocranial direction, complete examination of the articular margins of the femoral condyles is possible. Ultrasonography may be more sensitive than radiography in detecting periarticular osteophytes. If the stifle is examined in flexion, the cartilage and subchondral bone surface of the femoral condyles can be imaged.[1-3] Alterations of the subchondral bone surface and echogenicity may be detected.

COLLATERAL LIGAMENTS OF THE HOCK

The causes of soft tissue enlargement of the hock may be difficult to assess clinically and with radiography. This section discusses collateral ligament injuries. The medial and lateral collateral ligaments of the hock are highly echogenic fibrous structures. Each is divided into a long collateral ligament, which inserts distally on the distal tarsus and proximal metatarsus, and a short collateral ligament with two fasciculi: a calcanean fasciculus and a talien one.

Proximal avulsion fracture of the calcanean fasciculus of the medial collateral ligament has been identified (Fig. 17-13). Lesions of this ligament also can be identified in hocks with no radiographic abnormality (Fig. 17-14). In old lesions the long medial collateral ligament remains thickened and may have focal echogenic sites associated with mineralization.

Several types of injury of the lateral collateral ligament have been identified, including desmopathy of the long lateral collateral ligament, avulsion fracture of the short lateral collateral ligament at the proximal insertion on the lateral malleolus of the tibia (distal portion of the fibula), and desmitis of the short lateral collateral ligament associated with sudden synovial distention of the tarsocrural joint capsule.

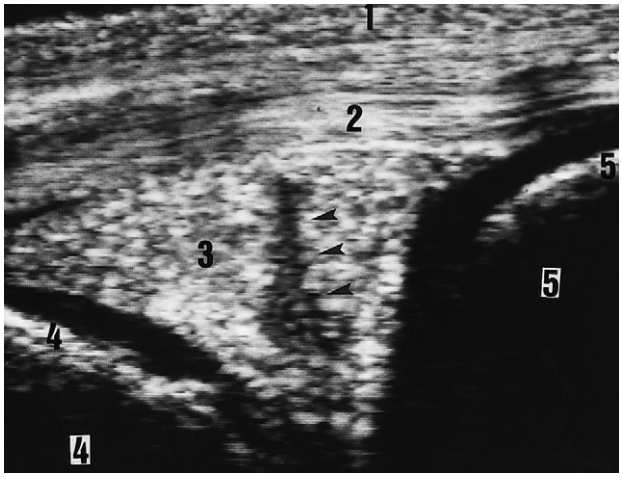

Fig. 17-11 Proximodistal ultrasound scan of the medial aspect of the medial femorotibial joint showing a transverse section of the body of the medial meniscus. An obvious hypoechoic defect (*arrowheads*) is seen. The diagnosis is medial meniscal lesion. *1*, Skin; *2*, medial collateral ligament; *3*, medial meniscus; *4*, medial femoral condyle (with anechoic articular cartilage); *5*, medial tibial condyle (with anechoic articular cartilage).

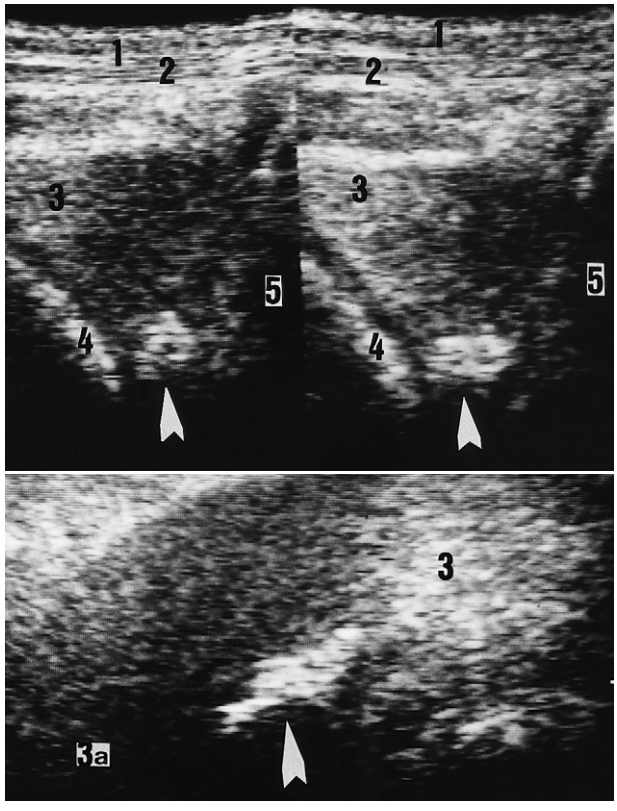

Fig. 17-12 **A,** Proximodistal ultrasound scan of the craniomedial aspect of the medial femorotibial joint showing transverse sections of the cranial horn of the medial meniscus. Hyperechogenic material is present in the deep (axial) part of this horn (*arrowheads*). **B,** Transverse ultrasound scan of the craniomedial aspect of the medial femorotibial joint showing a horizontal section of the cranial horn of the medial meniscus. This scan confirms presence of hyperechoic material in the horn. The diagnosis is that hyperechoic material is a focal site of mineralized metaplasia in a meniscus. *1*, Skin; *2*, medial femoral fascia; *3*, medial meniscus; *3a*, cranial attachment; *4*, medial femoral condyle; *5*, medial tibial condyle.

Fig. 17-13 **A,** Acute medial collateral desmopathy in a 15-month-old filly. Physical appearance of the hock with a medial swelling. **B,** Longitudinal ultrasound scan of the calcanean fasciculus of the medial collateral ligament. This structure is thickened and hypoechogenic with evidence of fiber disruption. An echogenic osteochondral fragment (*arrowhead*) appears close to the medial malleolus of the tibia. The diagnosis is severe desmopathy with avulsion fracture involving the calcanean fasciculus of the medial collateral ligament. *1*, skin; *2*, medial malleolus of the tibia; *3*, long medial collateral ligament; *4*, short medial collateral ligament: calcanean fasciculus *(CALC)*; *5*, medial aspect of the talus *(TAL)*.

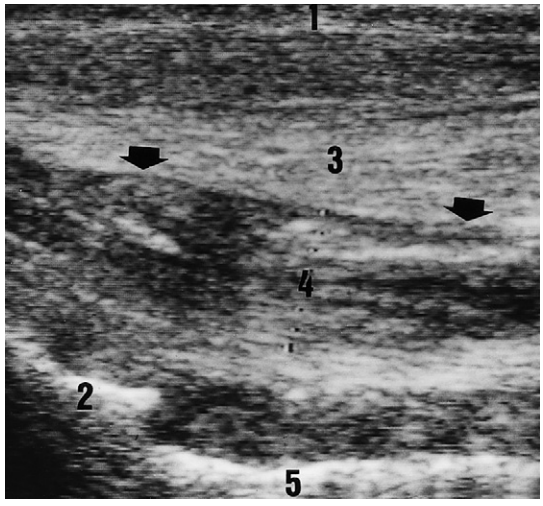

Fig. 17-14 Longitudinal ultrasound scan of the calcanean fasciculus of the medial collateral ligament of a 9-year-old Three-Day Event gelding after injury 3 months previously. This structure *(black arrows)* is thickened and has architectural changes. The diagnosis is desmopathy of the calcanean fasciculus of the medial collateral ligament. *1*, Skin; *2*, medial malleolus of the tibia; *3*, long medial collateral ligament; *4*, short medial collateral ligament: calcanean fasciculus (*arrowheads*); *5*, medial aspect of the talus.

CHAPTER • 18

Ultrasonography and Orthopedic (Non-Articular) Disease

Virginia B. Reef

The use of diagnostic ultrasonography for evaluation of tendons, ligaments, tendon sheaths, bursae and joints is discussed in Chapters 16 and 17, and patient preparation for other musculoskeletal uses is similar.

SKELETAL MUSCLE

Normal skeletal muscle appears heterogeneous with hypoechogenic muscle fibers laced with and surrounded by echogenic fascia, connective tissue, and fat. In transverse section the normal muscle has a marbled or speckled appearance, which is unique for each individual muscle, as is its striated appearance in longitudinal section.[1,2] A non–weight-bearing muscle appears more echogenic than the same muscle when the horse is fully weight bearing.[1,2] Therefore comparisons between contralateral muscles should be made when the horse is bearing weight evenly.

Traumatic muscle injuries, myositis, or masses infiltrating the muscles usually can be differentiated from each other by ultrasonography.[1] Muscle tears in horses most frequently are seen in the hindlimb and shoulder musculature. The affected muscle or muscles can be identified by tracing the involved muscle from its origin to insertion. Fluid-filled anechogenic areas with hypoechogenic loculations are located within the muscle belly, associated with areas of hemorrhage and muscle fiber tearing (Fig. 18-1).[1,3] As the muscle injury becomes more severe, large areas of interfascial and subcutaneous hemorrhage are detected. The free edge of a completely disrupted muscle may be imaged floating in the anechogenic loculated fluid in the hematoma. Echogenic areas of clot are often imaged within the intramuscular, interfascial, or subcutaneous hematoma. As these echogenic clots become more organized, they may cast an acoustic shadow from the far surface. Partial muscle tears are more difficult to diagnose because the ultrasonographic abnormalities are subtler.[1] The normal striated muscle pattern is lost with increased echogenicity of the injured muscle.[1] Swelling of the affected muscle usually is present. Tears in the muscle fascia or thickening of the muscle fascia or fasciitis also may be detected ultrasonographically.[1]

Ultrasonography is an excellent tool for monitoring the resolution of the hematoma and the healing of the muscle.[1] The affected horse's exercise should be restricted until the hematoma has resolved and the muscle tear has filled in with tissue. As the muscle heals, the fluid becomes more echogenic

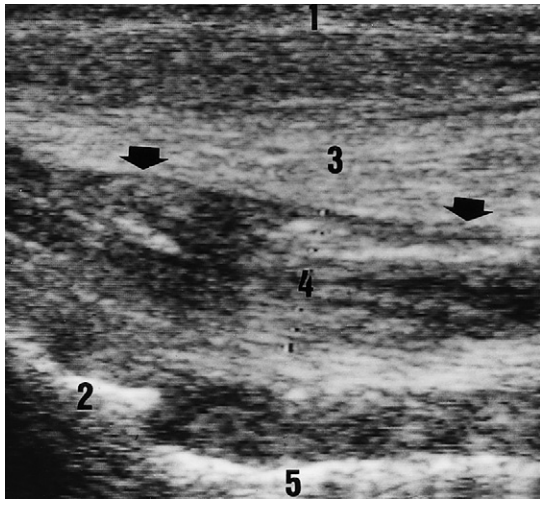

Fig. 17-14 Longitudinal ultrasound scan of the calcanean fasciculus of the medial collateral ligament of a 9-year-old Three-Day Event gelding after injury 3 months previously. This structure *(black arrows)* is thickened and has architectural changes. The diagnosis is desmopathy of the calcanean fasciculus of the medial collateral ligament. *1*, Skin; *2*, medial malleolus of the tibia; *3*, long medial collateral ligament; *4*, short medial collateral ligament: calcanean fasciculus (*arrowheads*); *5*, medial aspect of the talus.

CHAPTER • 18

Ultrasonography and Orthopedic (Non-Articular) Disease

Virginia B. Reef

The use of diagnostic ultrasonography for evaluation of tendons, ligaments, tendon sheaths, bursae and joints is discussed in Chapters 16 and 17, and patient preparation for other musculoskeletal uses is similar.

SKELETAL MUSCLE

Normal skeletal muscle appears heterogeneous with hypoechogenic muscle fibers laced with and surrounded by echogenic fascia, connective tissue, and fat. In transverse section the normal muscle has a marbled or speckled appearance, which is unique for each individual muscle, as is its striated appearance in longitudinal section.[1,2] A non–weight-bearing muscle appears more echogenic than the same muscle when the horse is fully weight bearing.[1,2] Therefore comparisons between contralateral muscles should be made when the horse is bearing weight evenly.

Traumatic muscle injuries, myositis, or masses infiltrating the muscles usually can be differentiated from each other by ultrasonography.[1] Muscle tears in horses most frequently are seen in the hindlimb and shoulder musculature. The affected muscle or muscles can be identified by tracing the involved muscle from its origin to insertion. Fluid-filled anechogenic areas with hypoechogenic loculations are located within the muscle belly, associated with areas of hemorrhage and muscle fiber tearing (Fig. 18-1).[1,3] As the muscle injury becomes more severe, large areas of interfascial and subcutaneous hemorrhage are detected. The free edge of a completely disrupted muscle may be imaged floating in the anechogenic loculated fluid in the hematoma. Echogenic areas of clot are often imaged within the intramuscular, interfascial, or subcutaneous hematoma. As these echogenic clots become more organized, they may cast an acoustic shadow from the far surface. Partial muscle tears are more difficult to diagnose because the ultrasonographic abnormalities are subtler.[1] The normal striated muscle pattern is lost with increased echogenicity of the injured muscle.[1] Swelling of the affected muscle usually is present. Tears in the muscle fascia or thickening of the muscle fascia or fasciitis also may be detected ultrasonographically.[1]

Ultrasonography is an excellent tool for monitoring the resolution of the hematoma and the healing of the muscle.[1] The affected horse's exercise should be restricted until the hematoma has resolved and the muscle tear has filled in with tissue. As the muscle heals, the fluid becomes more echogenic

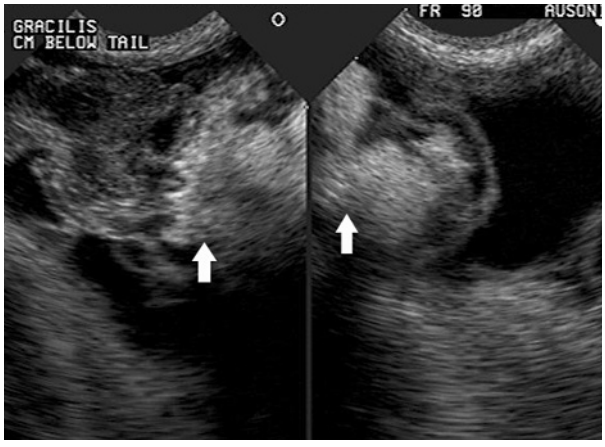

Fig. 18-1 Longitudinal *(left)* and transverse *(right)* ultrasonographic images of a torn gracilis muscle showing small, anechoic fluid-filled areas, hypoechoic amorphous areas, and more normal striated muscle at the periphery of the images. The anechogenic areas and hypoechogenic amorphous area are consistent with a hematoma replacing the muscle. The anechogenic area is the fluid component of the hematoma, whereas the hypoechoic areas *(arrows)* represent the fibrin and clot.

and the area fills in. The healing muscle may become more heterogeneous. Hyperechogenic areas of muscle scarring are seen associated with fibrotic myopathy, especially in the semitendinosus and semimembranosus muscles.[1] As these areas of fibrosis become more organized, acoustic shadowing from the far side of the fibrotic area may be detected. Hyperechogenic areas casting acoustic shadows are seen in horses with an ossifying myopathy and frequently are found adjacent to areas of fibrotic myopathy.[1] Areas of mineralization develop as scattered, pinpoint hyperechogenic areas that progressively become linear and result in acoustic shadowing from the near side of the areas.

Post-anesthetic myopathy results in increased echogenicity of the affected muscle, with loss of the normal muscle striations.[1,2] Muscle edema may result in the muscle appearing less echogenic than normal if the lesion is evaluated early in the course of the disease. Once a large influx of inflammatory cells has occurred, the affected muscle becomes more echogenic. A necrotizing myositis usually results in a more heterogeneous ultrasonographic appearance associated with the inflammatory cell infiltrate and bacterial infection.[1] Cavitation of a severely affected muscle is associated with liquefactive necrosis. Hyperechoic echoes, associated with the local production of gas by bacteria, may be seen with an anaerobic necrotizing myositis.[1]

Muscle tumors are rare; the most common muscle tumor is hemangiosarcoma. Discrete echogenic masses in the muscle or anechogenic loculated, more heterogeneous masses may be detected.[1] Central anechogenic or hypoechogenic areas representing tumor necrosis are identified in large or rapidly growing tumor masses. Primary muscle tumors such as rhabdomyosarcomas are extremely rare. Accurate identification of tumor type in muscle necessitates obtaining an ultrasound-guided biopsy and histopathological evaluation of the tissue obtained.

NERVE

Distinguishing peripheral nerves requires high-resolution images because the majority of nerves are small. Accurate knowledge of the locations of the nerves and the surrounding landmarks is important for identification. The nerves usually are slightly more echogenic than the surrounding soft tissue structures and are round to oval in transverse section.[1] Enlargement of the nerve with an increase or decrease in its echogenicity, with or without heterogeneity in its ultrasonographic appearance, is consistent with neuritis,[1] which may be a primary cause of lameness (see Chapter 83).

PENETRATING INJURIES

Ultrasonographic examination may be helpful in assessing penetrating injuries. The examiner should start at the site of the puncture wound and follow the path left by the penetrating object, a hyperechogenic tubular tract extending into the soft tissues.[4,5] The tract appears hyperechogenic from gas lining the tract. Any foreign material usually is hyperechogenic and casts acoustic shadows in two mutually perpendicular planes. Foreign material is usually irregular in shape, differs in size when imaged in two mutually perpendicular planes, and typically has high acoustic impedance relative to soft tissue.

DRAINING TRACTS

The cause of draining tracts should be determined systematically before a contrast radiographic examination is performed. Usually the source of drainage can be confirmed by ultrasonography if a thorough ultrasonographic examination is performed, eliminating the need to perform a contrast study. The injection of contrast material into the tract also results in the injection of air. This air may limit or prevent evaluation of foreign bodies within the tract because air is a nearly perfect reflector of ultrasound waves. The air that is injected with the contrast material may mix with the fluid within the tract, surround the foreign body, and obscure it from view.

A draining tract should be scanned systemically, keeping in mind that more than one factor may cause drainage. The clinician should start at the skin surface and follow the tract that usually appears as hypoechogenic tissue that is oval to round in transverse section and somewhat tubular in longitudinal section. The draining tract usually is easiest to follow in transverse section, unless the tract is short and straight.[1] The draining tract should be kept in the center of the ultrasound screen as it is followed into the deeper tissues. The tract may be single, or multiple tracts may be present. Often the tract is tortuous, and each branch of the tract should be followed to its source.[1] The source of the drainage at the end of the tract or tracts should be identified. Chronic draining tracts can originate from an area of osteitis or osteomyelitis; a sequestrum, foreign body, or necrotic tissue acting as a foreign body; an abscess; or a synovial structure.[1,4] Once the source or sources of the drainage have been identified, appropriate decisions can be made regarding medical or surgical management.

FOREIGN BODIES

Foreign bodies vary in ultrasonographic appearance.[4-13] The most commonly detected foreign bodies include suture material, wood, plant material, lead, and glass. Sequestered pieces of bone, hoof that becomes embedded in the soft tissues, and necrotic tissue also can create a foreign body reaction. Suture material usually is linear or tubular, hyperechogenic, and casts an acoustic shadow. Wood usually appears as a linear hyperechogenic structure casting a strong acoustic shadow from its near surface.[4,5,13] Plant material tends to appear as small echogenic material that either casts a weak acoustic shadow

or no acoustic shadow. Embedded hoof appears as a hypoechogenic to echogenic structure that often casts no acoustic shadow, or only a weak acoustic shadow is seen. The tubular composition of the hoof wall can sometimes be appreciated during the examination.

The ultrasonographic examination can be used to substantially shorten surgical time by accurately identifying the foreign body locations and identifying the relevant adjacent structures.[4-12,14,15] The surgical approach can be made directly over the foreign body. The foreign bodies should be measured ultrasonographically in two mutually perpendicular planes preoperatively and then compared with the foreign bodies removed at surgery, helping the surgeon to confirm that all foreign material has been removed. Intra-operative localization of the foreign body also can be performed, if localization of the foreign body proves difficult at surgery, aiding the surgeon in its rapid removal.[4,5,8,9,15]

BONE

A bone surface appears as a smooth, uniform-thickness hyperechogenic line that casts an acoustic shadow from its near surface.[1,4,12] Normal bony protuberances appear as bony shelves that are continuous with the parent portion of the bone. The continuity of an irregular bony surface echo can be followed ultrasonographically in a least one plane, differentiating this irregularity from a fracture. Vascular channels create breaks in the normal bony surface echo at the site of vessel penetration.

Fractures

Ultrasonography is useful in the diagnosis of fractures in areas that cannot be assessed radiographically, such as the withers, scapula, humerus, ribs, pelvis, femur and tibia, and in finding fractures that are suspected but have not been detected with routine radiography.[4,15-22] The ultrasonographic diagnosis of fractures depends on imaging the fracture line or fracture fragment in two mutually perpendicular planes.[1] A nondisplaced fracture is seen as a break in the normal hyperechogenic bone surface echo (Fig. 18-2). Detection of a hyperechogenic bony structure distracted from the underlying parent bone in two mutually perpendicular planes is consistent with a displaced fracture fragment. In an acute fracture, anechogenic fluid with hypoechogenic to echogenic loculations in the surrounding soft tissues is present. Echogenic masses of all shapes (frequently oval) within the loculated fluid are consistent with clot. These masses usually cast an acoustic shadow from the far surface as they become more organized. Disruption of the surrounding musculature frequently is seen if a fracture is significantly displaced.

Osteitis and Osteomyelitis

The detection of an extra-articular fluid layer, immediately adjacent to bone and without an intervening soft tissue layer, is diagnostic of osteitis or osteomyelitis, unless the area has sustained recent trauma[1,12] (Fig. 18-3). This ultrasonographic sign can be detected in horses with acute osteitis or osteomyelitis and precedes the detection of radiographic changes by 10 to 14 days. Soft tissue swelling often is present in the tissues adjacent to the osteitis or osteomyelitis. In horses with early osteitis and osteomyelitis the bony surface echo immediately adjacent to the fluid layer usually has a normal ultrasonographic appearance. With increasing chronicity, irregularities are detected in the bony surface echoes that are also detectable radiographically. Thinning of the bony surface echo with scooped-out areas in the underlying bone is consistent with lysis. Irregular hyperechogenic bony spicules correspond to areas of bony proliferative change. Sequestrae are imaged as hyperechogenic fragments that cast an acoustic shadow, are surrounded by anechogenic to hypoechogenic fluid, and are distracted away from the parent bone.[1,4,12] A linear wooden foreign body can mimic the ultrasonographic appearance of a sequestrum.

Ultrasonography is useful for the diagnosis of osteitis or osteomyelitis in horses with fractures where the radiographic signs of fracture healing can be difficult to distinguish from those of infection.[1,4,12] Bony lysis is a component of both fracture healing and infection. Immediately after trauma, or in the immediate post-operative period, fluid is detected adjacent to the bone for several days or longer until the local hemorrhage associated with the original injury or surgical trauma has resolved. A soft tissue layer should then cover the bone in all extra-articular locations.

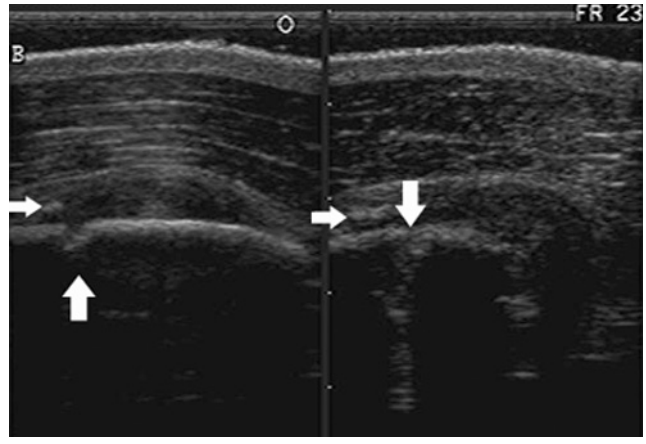

Fig. 18-2 Longitudinal *(left)* and transverse *(right)* ultrasonographic images of a fractured eighteenth rib. The fracture is nondisplaced with the crack clearly visible in the bone in two mutually perpendicular planes *(large arrows)*. A small fragment *(left small arrow)* also is visible at the fracture site in addition to hypoechogenic fluid representing hemorrhage *(right small arrow)*.

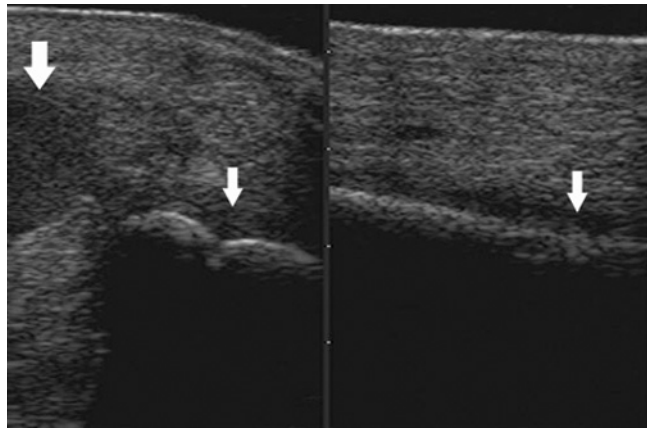

Fig. 18-3 Transverse *(left)* and longitudinal *(right)* ultrasonographic images of the mid metacarpal region of a horse with an acute onset of swelling, fever and lameness associated with osteitis of the second (McII) and third (McIII) metacarpal bones. A large amount of hypoechoic fluid in the subcutaneous tissues extends down to McII and McIII in the mid-metacarpal region. A small hypoechoic fluid layer overlies McII and McIII and is indicative of osteitis *(small arrows)* communicating with a larger subcutaneous area of hypoechoic fluid *(large arrow)*. The echo from McII and McIII is slightly thicker than normal, consistent with the infection of the bone.

The detection of a fluid layer directly overlying the bone in horses with suspected osteitis or osteomyelitis should prompt ultrasound-guided aspiration of the fluid, with or without biopsy of the area and submission of the fluid or tissue obtained for culture and sensitivity testing and histopathological examination (tissue). If surgical curettage of the affected area is chosen. this can be performed at the time of surgery. Horses that receive long-term antimicrobial drugs for osteitis or osteomyelitis should be re-evaluated ultrasonographically before discontinuing the treatment. A soft tissue layer should be present over the affected bone without any intervening fluid.[1] If treatment is discontinued while a fluid layer remains overlying the bone, recurrence of the osteitis or osteomyelitis is likely.

Bone Abscess

A bone abscess may be imaged ultrasonographically as a hypoechogenic, scooped-out area in the cortical and medullary regions of the bones[1] and usually is seen in foals, often associated with *Rhodococcus equi* infections. Large adjacent subcutaneous abscesses may communicate with the bone abscess. A dynamic ultrasonographic examination displacing the fluid within the subcutaneous abscess may help to identify the defect in the underlying cortical bone.

Implants

The cause of a worsening lameness in horses with implants may be difficult to determine from the physical examination and radiographic findings. Ultrasonographic examination can provide valuable information about the implant, bone, and surrounding soft tissue structures. In horses with surgical implants the detection of a fluid layer immediately adjacent to the implant, without an intervening soft tissue layer, is diagnostic of infection.[1] Infection of the implant, infection of the adjacent synovial structures, or problems associated with the implant itself often can be differentiated ultrasonographically. In horses in which fetlock or pastern arthrodesis was performed, worsening of lameness may be caused by infectious tenosynovitis of the digital flexor tendon sheath that can be diagnosed ultrasonographically as hypoechogenic effusion within the sheath. Problems with screw placement can be identified as a probable cause of lameness, such as when a screw is inadvertently located within the deep digital flexor tendon, causing fiber disruption and tendonitis. The various implant materials (plate, screw, wire, or antimicrobial-impregnated polymethylmethacrylate bead) can be differentiated ultrasonographically by characteristic appearances. Thus the most likely cause of the patient's deterioration can be identified and treatment targeted appropriately.

CHAPTER • 19

Nuclear Medicine

Mike W. Ross and Vivian S. Stacy

GENERAL CONSIDERATIONS

Nuclear medicine is a relatively recent advance in diagnostic imaging of the horse, pioneered by Ueltschi[1] in Europe and Devous and Twardock[2,3] in the United States. Seeherman et al.[4] and Lamb and Koblik[5] further demonstrated the value of bone scintigraphy in the evaluation of sports horses.

Bone scintigraphy is a way to reach within the horse and extract clinically useful and relevant information and helps to answer many lameness questions that we previously could not answer. Scintigraphy is used to assess the current status of known radiographic abnormalities, pursue diagnosis in horses with negative or equivocal radiographs, screen horses with obscure forelimb or hindlimb lameness, and evaluate horses with poor performance. However, a gamma camera is not an answer machine, and it is critically important to correlate scintigraphic findings with clinical lameness examination findings. Scintigraphy can play a role as a screening tool but should never replace diagnostic analgesia. In fractious or highly strung horses with hindlimb lameness, scintigraphic examination may be used to provide a diagnosis, but clinical relevance still should be confirmed.

Nuclear medicine involves the in vivo or in vitro use of radioisotopes in the diagnosis and management of clinical disease. Several terms are used synonymously with nuclear medicine, including nuclear scintigraphy, bone scintigraphy, and gamma scintigraphy, and although these terms differ slightly, for horses most clinicians refer to bone scintigraphy, the technique most commonly performed. Bone scintigraphy is highly sensitive compared with radiography. It can detect as little as 10^{-13} g of radiopharmaceutical in bone, whereas changes measured in grams must occur before a lesion can be detected using radiography.[3] Important factors that decrease sensitivity include time from radiopharmaceutical administration to image acquisition, body part to camera distance, shielding, motion, time from injury to image acquisition, ambient temperature and peripheral perfusion, and amount of background radiation. Specificity is low compared with other modalities because disparate diseases can similarly alter blood flow and binding sites in bone. Direct trauma (osteitis) and fracture; stress-related bone injury, including fracture and osteoarthritis; infection (infectious osteitis and less frequently osteomyelitis); osteochondrosis; and neoplasia are in theory difficult to differentiate scintigraphically. Accuracy can be improved by acquiring several images from different perspectives, minimizing factors affecting sensitivity, and knowing the history. For example, a focal area of increased radiopharmaceutical uptake (IRU) in the caudolateral tibial cortex of a 2-year-old Thoroughbred (TB) filly would undoubtedly represent stress-related bone injury rather than a rare bone tumor.

Radiographs depict activity in bone that has already occurred in the past several days to years. Scintigraphy is a *functional* evaluation of bone at the time of imaging. Scintigraphic evidence of bone activity means active bone formation is occurring that might take weeks to be visible radiographically. Therefore a major advantage of scintigraphy is *early detection* of bone injury. Scintigraphy will unlikely accurately reflect changes in bone that occurred longer than 3 to 4 months before imaging. Horses given substantial rest before examination are not good candidates unless the examination is a follow-up to assess healing.

RADIOISOTOPE AND RADIOPHARMACEUTICAL

A radioisotope emits radiation (particles) that is captured using a scintillation camera. Radioisotopes such as ^{111}In are used occasionally, but the most common and useful radioisotope is technetium-99m (^{99m}Tc). ^{99m}Tc, a short-lived (metastable) radioisotope with a half-life of 6 hours, is ideal for radiation safety and animal retention. ^{99m}Tc is excreted almost entirely through the kidneys, so containing and monitoring urine is extremely important. ^{99m}Tc is produced when ^{99}Mo decays to ^{99}Tc. The metastable (^{99m}Tc) radioisotope gives off a gamma ray (140 keV) that is used for imaging. Commercially, ^{99}Mo/^{99m}Tc generators can be purchased for use in large hospitals, but an alternative, cost-effective method is the daily purchase of individual doses, a practice that obviates the need to house generators. Directly from the generator, ^{99m}Tc is in the ionic form of sodium ^{99m}Tc pertechnetate ($Na^{99m}TcO_4$) that can be injected or mixed with a bone-seeking agent or pharmaceutical. Radiation is measured in curies (Ci) or millicuries (mCi), or becquerels (Bq), megabecquerels (MBq), and gigabecquerels (GBq) have been used. One mCi is equal to 37 MBq. The recommended dose of ^{99m}Tc is 0.4 to 0.5 mCi (14.8 to 18.5 MBq)/kg, totaling 150 to 200 mCi (5.5 to 7.4 GBq) per horse. Low doses reduce radiation exposure but prolong acquisition time or may result in inadequate image quality if insufficient counts are obtained. High doses may actually reduce overall radiation exposure by limiting exposure time.

$Na^{99m}TcO_4$ can be injected intravenously directly, but only flow and pool-phase studies can be performed. For most equine studies, $Na^{99m}TcO_4$ is mixed with a pharmaceutical. For bone, ^{99m}Tc is bound to methylene diphosphonate (MDP), or hydroxymethane/hydroxymethylene diphosphonate (HDP/HMDP). MDP is slightly less expensive and is the most common pharmaceutical used worldwide, but we prefer HDP, because the kidneys clear it slightly faster, allowing early acquisition of delayed-phase images. Henceforth MDP and HDP are used interchangeably.

The exact mechanism of binding of ^{99m}Tc-HDP to bone remains unclear. ^{99m}Tc-HDP is thought to bind to exposed sites on the inorganic hydroxyapatite crystal. Binding sites are exposed under normal and pathological conditions in areas of actively remodeling bone or in soft tissues undergoing mineralization.[6,7] ^{99m}Tc-MDP uptake occurs by the processes of chemical adsorption onto, and by direct integration into, the crystalline structure.[8] Other possible mechanisms to account for increased uptake include incorporation into the organic matrix or local hypervascularity.[7] In rat models, ^{99m}Tc was found to be incorporated into the organic matrix rather than the inorganic portion of newly formed bone.[9,10]

Radiopharmaceutical may dissociate with incorporation of ^{99m}Tc and MDP individually into the organic and inorganic phases, respectively.[11] ^{99m}Tc-MDP adsorption might depend on pH and the presence of phosphates, calcium compounds, and other cations.[12]

Accumulation of ^{99m}Tc-MDP is not simply the result from changes in local blood flow, although blood flow is likely increased in sites of actively remodeling bone. Although increased blood flow does not significantly affect a bone scan,[6] *adequate* blood flow is necessary to deliver radiopharmaceutical to available binding sites in bone. Decreased blood flow, caused by infarction or ischemia, can greatly affect a bone scan but is seldom a clinical problem. However, decreased peripheral blood flow in old horses or those imaged in cold weather or on days with high diurnal temperature change can adversely affect image quality.

The most important aspects of ^{99m}Tc-MDP binding relate to timing of the scan and the stage of bone formation or modeling. In actively remodeling bone, osteoclastic activity predominates during bone resorption, whereas osteoblastic activity dominates during bone modeling. Modeling occurs independently or in conjunction with remodeling in cancellous and cortical bone. Histological and scintigraphic findings were evaluated in a rat tibial evacuation model, and ^{99m}Tc-MDP was found to bind to sites of *active* calcification, most prevalent 12 days after injury.[13] ^{99m}Tc-labeled phosphonates were identified during bone formation and ongoing resorption was not necessary for increased uptake to occur.[8] ^{99m}Tc-MDP accumulated in areas of calcification or in fixed bone fragments,[8,14] and accumulation was mediated by osteoblastic activity.[8] The high sensitivity of bone scintigraphy is attributed to increased osteoblast activity that precedes morphological changes visible radiographically.[15] Other mechanisms may exist, however, because positive bone scan results may be seen in human beings with diseases such as osteomalacia, in which high bone matrix turnover and failure of calcification occur.[13]

Site and stage of binding are important from a clinical perspective. Binding sites for ^{99m}Tc-MDP are created by osteoblast activity during bone modeling, and maximal IRU occurs 8 or 12 days after bone injury.[13,16] An acute fracture caused by direct trauma may not be scintigraphically evident for several days. Acute, traumatic injury differs from stress-related bone injury, because the latter, particularly common in racehorses, results from a continuum of bone changes that might lead to stress or catastrophic fractures and osteoarthritis. Microfracture, periosteal callus, and subchondral bone damage precede the development of stress or complete fracture in the dorsal cortex and distal articular surface of the third metacarpal bone (McIII), the third metatarsal bone (MtIII), humerus, tibia, and pelvis.[17-19] In horses with acute lameness from stress-related bone injury, bone scan findings usually are immediately positive because bone modeling is ongoing. In horses with stress-related bone injury a bone scan result is positive long before catastrophic fracture occurs, an important advantage of scintigraphy compared with radiography. In horses with traumatic injury, such as an acute pelvic or other upper limb fracture, a false-negative scan may result from lack of modeling. Other factors resulting in false-negative results include distance, shielding, high background activity, and motion. For example, a horse developed acute hindlimb lameness during hospitalization, and suspecting a pelvic fracture involving the acetabulum, clinicians performed scintigraphic examination on day 2, but the scan result was negative. On day 9 a faint IRU appeared consistent with fracture.

In horses with stress-related bone injury and traumatic injury a considerable decrease in radiopharmaceutical uptake occurs within 6 to 8 weeks after injury. Decreased intensity after fracture varies with the specific bone and fracture type. The ideal time to image is 10 days to 8 weeks after injury.

IMAGING EQUIPMENT

Scintigraphy can be performed in two ways, but the most common and useful method is acquisition of two-dimensional images with a gamma camera. Alternatively, a handheld probe is used to acquire count density computer-generated charts, or graphs are created to determine IRU. Known as *probe point counting*, this form of scintigraphic examination was first introduced in 1984.[20,21] Some probes are like miniature gamma cameras built with a single photomultiplier tube. Crystal probe detectors are more expensive than the photomultiplier detectors, but they are small and easily used on the body surface, or per rectum in horses with suspected pelvic fracture.[21] Probe point counting is done with a substantially lower radioisotope dose, minimizing cost and radiation exposure. Probe point equipment is inexpensive. Because the probe is placed directly on the skin surface, body part to probe distance is minimal. A gamma camera is often difficult to get close to body surface, a problem that can prolong acquisition time and decrease image quality. A good correlation appears between results of probe point counting and gamma camera imaging in acute injuries in young horses, but in older horses the technique has limited sensitivity. However, quantitative information is only available as a histogram, and an actual image allowing qualitative assessment is not obtained.

Gamma camera images are obtained in analog or digital form, and permanent hard copies of a two-dimensional scintigraphic image are generated. In people, one or several gamma cameras operating simultaneously can be used to generate a cross-sectional image similar to computed tomography (CT) or magnetic resonance imaging (MRI). This is known as single photon emission computed tomography (SPECT) and photon emission tomography (PET). Although SPECT and PET imaging are theoretically possible in anesthetized horses, we are not aware that the techniques have been performed.

A reconditioned gamma camera is perfectly satisfactory, less expensive than new equipment, and durable, often being useful for at least 7 to 10 years. Gamma cameras are either large field of view (LFOV) or small field of view (SFOV) based simply on the size (Figs. 19-1 to 19-3). LFOV cameras can be rectangular or circular in shape, but crystals for rectangular cameras are more costly. When adapting equipment for use in horses, an important consideration is how to move the camera safely and easily to the horse and vice versa. Most standard gantry (support structure of the gamma camera) designs are unsuitable for equine imaging, because good-quality images can be obtained only by having the body part close to the camera. The number of gamma rays reaching the detector is inversely proportional to the square of the distance (inverse square law). To quickly obtain dorsal and lateral, and lateral and plantar images of the forelimbs and hindlimbs, respectively, the camera must be able to be lowered below floor level (see Fig. 19-3). Alternatively, the horse must be positioned on an elevated platform. Limbs can be held manually near the camera, but this practice increases radiation exposure to personnel and should be avoided whenever possible. Suitable gantries are commercially available or can be custom made. A lead collimator is also required.

IMAGE ACQUISITION

For flow and pool-phase images, horses are sedated and positioned in front of the camera and ^{99m}Tc-HDP is injected intravenously. Delayed-phase images are then obtained 2 to 4 hours later. Scintigraphic images are produced when the horse, now the radiation source, emits gamma rays from normal and abnormal bone. The gamma rays must pass through overlying tissues and traverse the distance between the body part and the

Fig. 19-1 The nuclear medicine facility at New Bolton Center, University of Pennsylvania, has large field of view and small field of view cameras. A custom-made central column overhead gantry holds the rectangular large field of view camera, which can be lowered below floor level to image the distal extremities.

Fig. 19-2 The small field of view camera in the floor allows easy acquisition of solar images of the foot. After a wooden cover is applied, the horse stands over the small field of view camera for the solar image. A lead-lined wrap placed around the coronary band region shields the foot and camera from radiation emanating from the more proximal aspects of the affected limb.

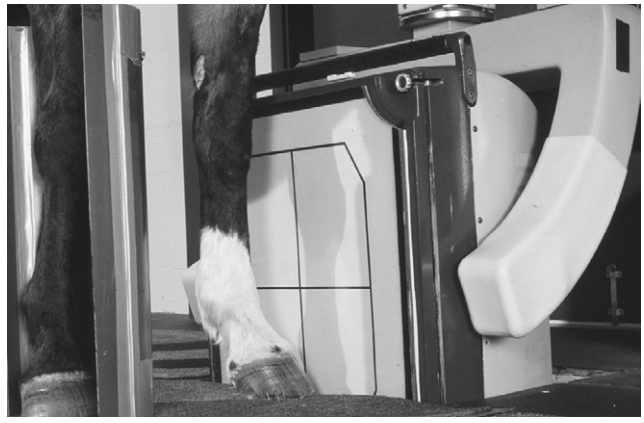

Fig. 19-3 Construction of a recess or pit into which the large field of view camera can be lowered allows imaging of the distal extremities with minimal movement of the horse. The lateral aspect of the hoof touches the face of the camera (clear polycarbonate protects the collimator). This position minimizes distance, improves image quality, and decreases acquisition time. A curved, lead-lined shield protects the camera and left forelimb from radiation emitted by the right forelimb.

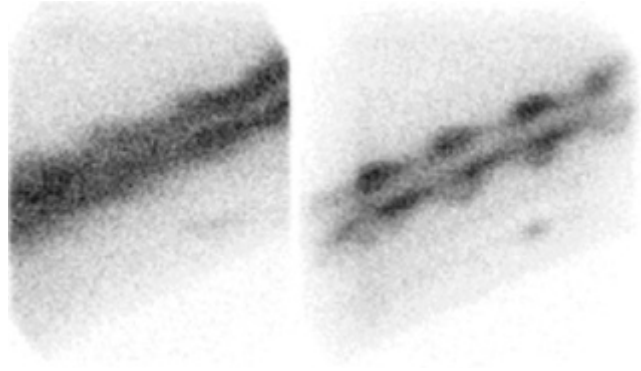

Fig. 19-4 Original uncorrected (*left*) and corrected (*right*) right lateral images of the cervical vertebrae. Motion correction allows acquisition of more counts and reduces the harmful effects of motion on image quality, particularly of the upper limbs and axial skeleton.

camera. An area of IRU emits more gamma rays than does adjacent normal bone and contributes more counts to the scan. Sites farther from the camera, those being shielded by overlying soft tissue or adjacent bone, or those in areas of high background activity may not be visible, because they may not contribute enough gamma rays. Gamma rays strike a sodium iodide crystal, and scintillations produced are detected and amplified by photomultiplier tubes that subsequently transmit information through electronic circuits. The image is displayed on an oscilloscope or sent directly to a film processor, called analog imaging. Alternatively, information is transmitted to a computer, stored digitally, manipulated, and subsequently sent to a film processor or printer.

An important recent advancement is the ready availability of user-friendly computer programs to acquire, analyze, store, and process images. Systems based on Apple, Windows, and Unix are currently available and are straightforward. Motion correction software is the latest, exciting advance that improves upper limb and axial skeleton image quality by negating the effects of motion and allowing higher count numbers than with conventional software (Fig. 19-4). Modern software also allows post-processing of images, for example, masking out the bladder, which might otherwise steal counts.

Images are obtained in either static or dynamic mode. Static images, most commonly obtained, are acquired using a predetermined number of counts per image. For example, because motion and soft tissue covering are limited in the distal limbs, good-quality images can be obtained using 100,000 to 150,000 counts per image. In general, increasing counts per image improves image quality, but to acquire more counts, time and motion become factors. Motion correction can add flexibility.

A fundamental principle of image interpretation is comparing images of one limb with those of the contralateral limb, but the clinician should keep in mind that both limbs, and for that matter all limbs, can be abnormal. To compare limbs accurately using this technique, body part to camera distance and camera position relative to the limb must be standardized between limbs. Time to acquire each image ranges from 30 to 90 seconds depending on radioisotope dose, type and age of horse, and ambient temperature. Time rather than count number can be standardized, assuming that limb perfusion

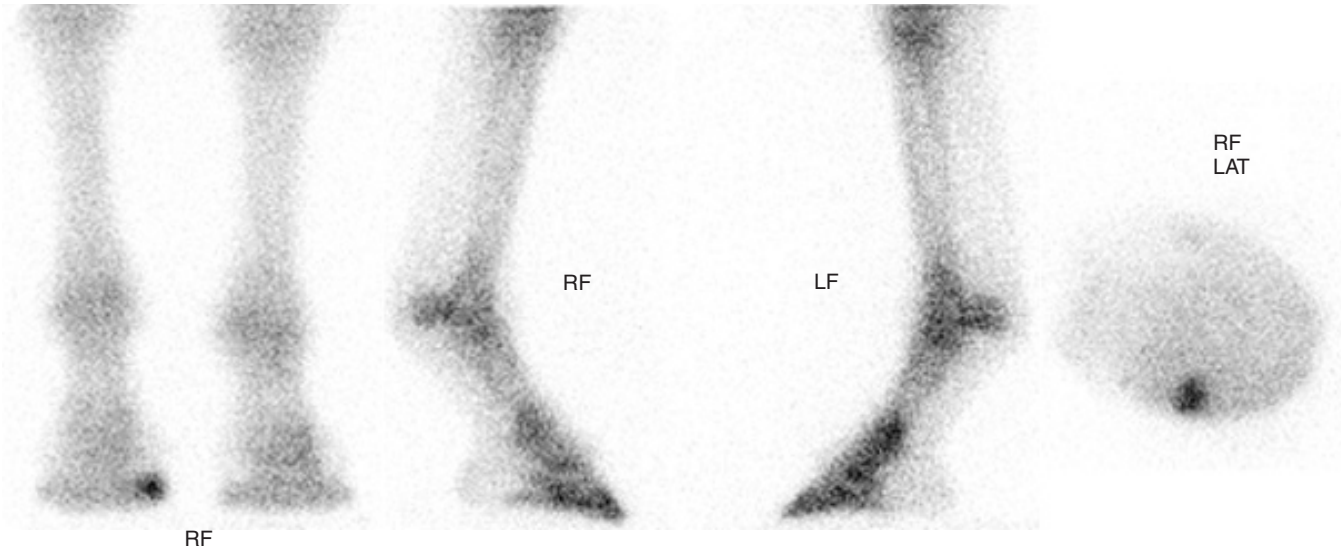

Fig. 19-5 Delayed-phase scintigraphic images of a horse with a fracture of the medial aspect of the right forelimb (*RF*) distal phalanx. The lateral *(LAT)* view of the right forelimb does not show the area of increased radiopharmaceutical uptake, and little difference is noted between both front feet. The dorsal and solar images, however, clearly show increased radiopharmaceutical uptake. It is extremely important to obtain more than one scintigraphic view. *LF,* Left forelimb.

is adequate and symmetrical. For example, lateral images of both metacarpal regions are obtained for 90 seconds and compared.

The number of views to obtain is based on the body part being imaged, but usually at least two views are required. In some areas this may not be possible, but the clinician should be aware that false-negative results can occur. A dorsal scintigraphic image only gives detailed information about the dorsal aspect of the limb, and abnormal palmar regions might be missed. The image and information are not the same as depicted in a dorsopalmar radiographic view. Similarly, areas of IRU on the medial side of the limb might not be visible on a lateral image. Areas more distant from the camera contribute substantially less radiation than those closer because of the inverse square law. Bone interposed between a medial lesion and the camera can effectively shield the site. A lateral view of a right forelimb failed to reveal a fracture of the distal phalanx (Fig. 19-5). Radiographic examination and dorsal and solar scintigraphic images, however, revealed an incomplete fracture that we completely missed in the lateral scintigraphic view. Additional views may be necessary for accurate diagnosis.

We prefer to localize lameness, because this allows for detailed examination of a specific area. For instance, routine screening views of the front digit include lateral and dorsal delayed images, but in horses in which lameness is abolished using palmar digital analgesia, pool-phase images and lateral, dorsal, solar, and occasionally medial, palmar, and flexed delayed images are obtained. Diagnostic accuracy can be improved by taking many views, and pinpointing a lesion using scintigraphy can allow a focused radiographic, ultrasonographic, CT, or MRI study to be performed. When augmenting the routine dorsal and plantar images of the metatarsophalangeal joint with flexed lateral and sometimes flexed dorsal and medial views, instead of saying, "There is IRU in the fetlock joint," the diagnostician can say, "There is focal IRU involving the distal, plantarolateral aspect of MtIII," a much more accurate description (Fig. 19-6).

Dynamic acquisition can be used before motion correction in delayed images or to evaluate blood flow. One- or 2-second per frame images are generated sequentially and can be evaluated individually or combined into a single composite image, with or without motion correction. First-pass angiography can be used to assess blood flow in the aorta, iliac, and femoral arteries[22] in horses with suspected thromboembolism (Fig. 19-7) or to assess blood flow in the distal limb.

Image Quality

Factors that contribute to poor image quality are related to the horse and to processing. Analog (old way) and digital (new way) processing provide good-quality images provided the equipment is working properly. Regular quality control is absolutely essential to maximize image quality and avoid artifacts. A cracked or poor-quality collimator, sodium iodide crystal damage, malfunction or incorrect tuning of photomultiplier tubes, age, and general condition of refurbished equipment can cause artifacts, gradual deterioration in quality, or completely shut down the process. The dose of radioactivity administered, the number of counts acquired, image distance (distance from body part to camera surface), motion, and background radiation are most critical. As many gamma rays as possible from the affected bone must reach the crystal without motion to maximize image quality.

Number of Counts

Image acquisition, principles of using count numbers as opposed to time, and the importance of standardizing images between limbs were discussed earlier. One limb may overall be hotter than the contralateral limb and count faster on individual images or contribute more counts when combined in images of both limbs. Horses with unilateral lesions in the digit, such as those with distal phalanx fractures and soft tissue injures, appear to have compensatory IRU normally in the rest of the limb. Our experience suggests that horses with distally located lesions in the affected limb often have more prominent normal uptake in that entire limb, but others suggest that the non-lame contralateral limb may be hotter because of increase in weight bearing.[23] An area of intense IRU present with a condylar fracture or stress-related bone injury may overwhelm the contribution of normal bone, making it difficult to see, a phenomenon called *count stealing.*

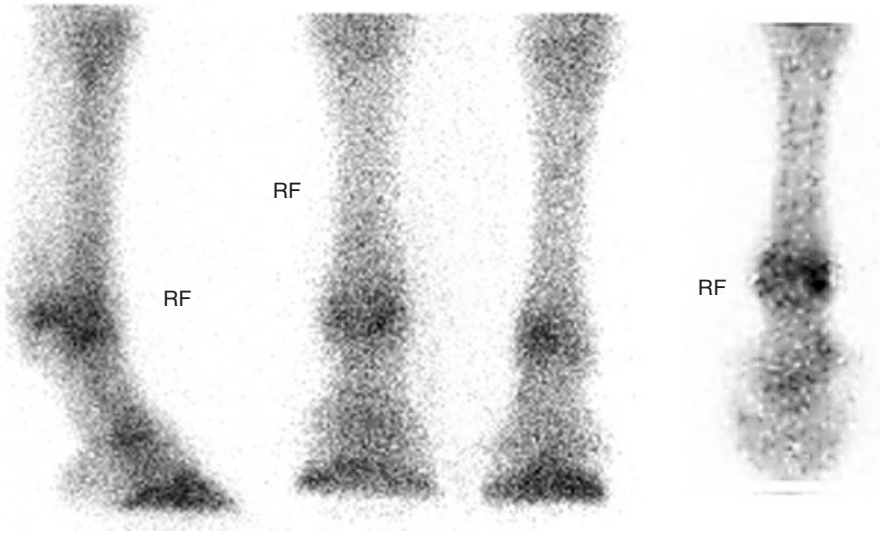

Fig. 19-6 Lateral *(left)*, dorsal *(middle)*, and flexed dorsal *(right)* delayed-phase scintigraphic images of the right forelimb *(RF)*. The flexed dorsal image best shows the focal area of increased radiopharmaceutical uptake involving the distal, medial aspect of the third metacarpal bone. Although increased radiopharmaceutical uptake appears in other views, the flexed dorsal image allows differentiation of increased radiopharmaceutical uptake involving the third metacarpal bone and the proximal phalanx.

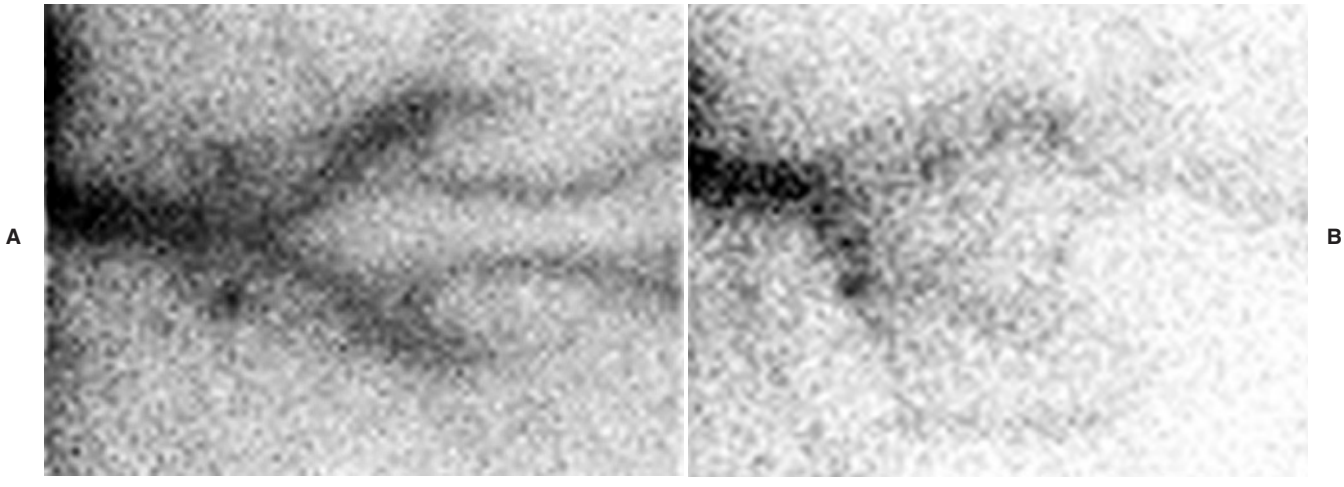

Fig. 19-7 Composite image generated after dynamic acquisition of 32 sequential images (2 seconds per frame) with the gamma camera positioned over the terminal aorta and branches. Imaging started 20 seconds after administration of ^{99m}Tc-hydroxymethane diphosphonate in the external jugular vein. **A,** In a normal horse the external iliac arteries and a linear caudal course of the internal iliac vessels show a V-shaped divergence. **B,** In this horse with aortoiliac thromboembolism, the direction and contour of the external iliac arteries is disrupted and the internal iliac vessels lack recognition.

Distance

Having the affected body part too far from the camera is likely the most important factor contributing to false-negative bone scan findings. Osteoarthritis and subchondral bone cysts involving the medial femorotibial joint can be completely missed unless a caudal view is obtained simply because the lesions cannot contribute enough counts to the scan to be visible. Distance is too great. Pelvic images are dramatically and negatively affected by distance. Even if the camera is resting on the skin of the rump, some bones are still many centimeters away.

Shielding

Shielding is important in radiation safety, but it can be a negative factor in image quality and interpretation. Shielding helps or harms image quality and interpretation. High background radiation reduces image quality, because unwanted tissues steal counts. Pool-phase images of the thoracolumbar spine and pelvis are rarely informative because within 1 to 2 minutes after injection, radiopharmaceutical in the kidneys and urinary bladder creates such high background levels of radiation that soft tissue lesions are missed. Delayed-phase pelvic images are similarly affected by urine retention in the

bladder. Bladder uptake causes poor image quality by creating high background levels of radiation and by superimposition on the sacrum in dorsal images. To avoid this problem, the bladder should be catheterized or a diuretic should be given. Lead shields can be placed on the skin between the bladder and camera and count subtraction techniques can be used to take away bladder counts, but maximizing image quality by initially limiting radioactive urine is best.

Internal shielding can be a problem for interpretation. Gamma rays originating from a lesion distant to the camera must traverse bone, interposed soft tissue, and air before striking the camera. In a lateral view of the stifle, gamma rays originating from subchondral bone of the distal medial femur must traverse the thick lateral condyle, dense ligaments, and other soft tissues, all the while competing with gamma rays from other sources. Intuitively it would seem that counts would be additive, meaning a lesion medially would add to the counts normally originating from the lateral aspect, clearly showing the abnormal area. Acquiring images with sufficient counts reduces the risk of false-negative scan results. Bone stacking, when bones are superimposed, may explain normal areas of IRU visible in a lateral view of the coxofemoral joint. However, often bone interposed between a lesion and the camera seems to provide unwanted shielding. Overlying skeletal muscle may also provide unwanted shielding in pelvic images. Asymmetrical muscling caused by gluteal atrophy can explain mild differences in IRU between left and right sides of the pelvis.

Motion

Two sources generate excess motion: movement of the camera or the horse. Swaying of cameras hung by hoists or chains and movement induced by the horse leaning on the camera result in poor image quality. In the distal limbs, horse movement is usually not a factor and acquisition times are short. Horses sway minimally when scanning the distal limbs, but sway excursion is large in the upper limbs because of a longer pendulum effect from the anchor point (feet). Sedation may accentuate the effect. Motion detracts greatly from upper limb and axial skeleton image quality. We use detomidine (0.008 to 0.01 mg/kg) and butorphanol (0.006 to 0.075 mg/kg), a combination that allows optimal acquisition while minimizing motion. Manual support on each side and resting the horse's head on a stationary object partially negates the tendency of the horse to sway and drift. Motion correction software is useful in improving image quality but cannot compensate for all movement.

Background Radiation

High background radiation contributing to count stealing and handling bladder interference have been discussed. Shielding the limb or body being imaged with custom-made lead-lined barricades (see Fig. 19-3) or placing drapes on the horse or around the body part (see Fig. 19-2) helps isolate the region being examined. Old horses, large breed, and fat horses and those with extensive swelling or fibrosis in the distal limbs often have high background activity in soft tissues, which inevitably results in poor-quality delayed images.

Poor-Quality Bone Uptake

Image quality in large breed horses such as TB crosses, Warmbloods, and Draft horses or in old horses may be poor despite following accepted protocol. Average image quality in large breed horses may be worse than in young racehorses for many reasons, but age and type of exercise might explain some differences. Large breed performance horses tend to be older than the racehorse population, lack normal physeal activity, and often have dense soft tissues and large bones in the distal limbs. Exercise type and level in this type of horse is much different than in racehorses. A relative lack of stress-related bone injury in subchondral and cortical bone limits the number and type of scintigraphic changes seen.

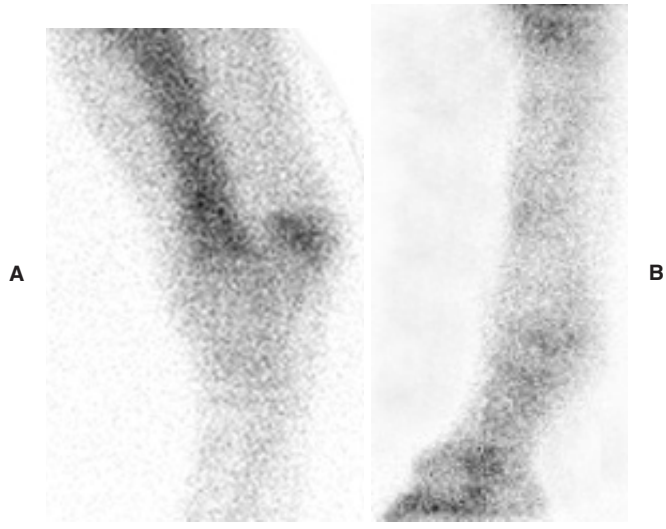

Fig. 19-8 **A,** Delayed-phase image of an aged Warmblood gelding shows reasonable quality bone upake in the proximal limb and diffuse moderate increased radiopharmaceutical uptake in the distal tibia. **B,** This delayed-phase image is consistent with the pool-phase scan of the tarsus and distal extremity. This abnormal pattern of poor bone uptake commonly appears in horses scanned in cold weather or in large breed horses.

Image quality in all types of horses may be compromised in areas with cold weather or great diurnal temperature differences, especially in fall, winter, and early spring.[24-26] Generally reduced uptake of radiopharmaceutical occurs distal to the antebrachium and crus, either bilaterally symmetrical or asymmetrical. Delayed-phase images taken above the carpus and tarsus have high background radiation but can be interpreted. A compensatory area of intense IRU may occur in the distal radius and tibia. Distally, from the carpus and tarsus to the sole of the foot, images resemble pool-phase images even when acquired 3 hours after injection (Fig. 19-8). Occasionally a different pattern appears with compensatory focal intense IRU in the distal radius and tibia, relative photopenia of the carpal and tarsal bones, and reduced to normal or interspersed (spotty) uptake in the metacarpal/metatarsal regions and digit. This phenomenon is not related to renal clearance, radiopharmaceutical affinity, or dose of radioisotope but appears to be caused by poor peripheral perfusion.[26] Normal horses appear to be able to shunt blood away from the periphery, presumably a homeostatic mechanism involving high sympathetic tone during times of abrupt drop in ambient temperature. Other related factors that might increase sympathetic tone are dehydration, stress, and transporting the horse shortly before injection of radiopharmaceutical. High sympathetic tone may reduce blood flow in the distal extremity, and the radioisotope may be unable to reach available binding sites in bone. Blood supply must be *adequate* to ensure distribution of radiopharmaceutical to sites of osteoblast activity. Persistence of radiopharmaceutical in soft tissues and vessels in the distal extremity and occasional photopenia of the carpal, tarsal, or other bones cannot be explained.

We prefer that all horses be hospitalized the night before examination to avoid the problem of poor-quality bone uptake and maximize image quality. This may reduce stress and improve hydration status. Keeping the distal limbs warm with bandages, and when the temperature is cold, applying a

body blanket to maintain core temperature may help. In a recent study, Dyson et al.[26] found that exercise, but not warming, before injection was most important in improving peripheral blood flow and maximizing image quality in all types of horses. Horses are lunged or trotted on a treadmill for 15 to 20 minutes before injection. When we suspect poor-quality scans may result, we administer acetylpromazine (15 to 20 mg per adult horse) before injection. If poor-quality images result despite following these procedures, the procedures should be repeated the next day.

RADIATION SAFETY

Rules for radiation safety and licenses to obtain and house radioactive materials differ for each state and country. In Pennsylvania a license to use radioactive materials must be obtained from the federal Nuclear Regulatory Commission (NRC). Horses are quarantined for 24 hours after injection and can then leave with instructions to avoid unnecessary contact with them for an additional 36 hours. Radiation levels at the horse's body surface range from 0.4 to 0.7 mR/hr at 24 hours after injection, well below the trigger level of 2.0 mR/hr established by the NRC. Horses are kept in defined stalls in which solid waste removal (stall drains are plugged; shavings are used for bedding) is used. Waste is kept for 60 hours, at which time radiation levels do not differ from background.

We practice the concept of ALARA (as low as reasonably achievable) and attempt to maximize distance from horse to handler and minimize total imaging time. Persons handling radioactive materials wear body and ring badges, and all those in contact with horses wear body badges. Total yearly radiation exposure for full-time technicians is approximately 500 mR/yr (450 horses scanned each year). Daily monitoring of selected sites and weekly wipe tests are performed. Nuclear medicine techniques in horses can be done safely, within NRC or other supervisory guidelines, without undue contamination or exposure.

BONE SCAN PHASES

The bone scan is divided into three phases named for the tissues in which the majority of radiopharmaceutical resides at that time. Flow-phase (phase I, vascular phase) images are obtained for 1 to 3 minutes after injection, during which time radiopharmaceutical resides in blood vessels. First-pass studies of the heart and major central and peripheral vessels can be performed (see Fig. 19-7). The flow phase appears to last longer in horses than in people, because radiopharmaceutical persists in distal limb veins often for greater than 10 to 15 minutes, a finding that can complicate interpretation and potentially decrease sensitivity of pool-phase images. Pool-phase (phase II, soft tissue phase) images are classically obtained between 3 and 15 minutes after injection, during which time radiopharmaceutical resides in the extracellular fluid pool. Pool-phase images are used to evaluate soft tissues such as tendons, ligaments, tendon sheaths, and bursae. A common misconception is that many distant soft tissues can be evaluated, but the short time interval dictates careful selection of sites for pool-phase imaging. Delayed-phase (phase III, bone phase) images are obtained between 2 and 4 hours after injection, during which time radiopharmaceutical resides in bone and unbound drug has cleared the kidneys. Although information gained in the flow or pool-phase images is useful, delayed images are the mainstay of equine imaging. A three-phase bone scan involves acquisition of flow, pool, and delayed images, but most commonly only delayed images, or delayed and selected pool-phase images, are obtained. An area of IRU visible in all three phases could indicate fracture or infection, but in horses it generally indicates fracture. Pool- and delayed-phase images should be carefully evaluated to determine if areas of IRU are the same or different. In our experience, early pooling of radiopharmaceutical usually represents early bone uptake. Pool- and delayed-phase images can be superimposed, or region of interest analysis can be used to determine size and position of IRU. In the proximal palmar/plantar metacarpal/metatarsal region, uptake of radiopharmaceutical can occur in only bone, only soft tissue, or both, and prognosis in horses with suspensory desmitis or bony injury can vary with tissue involved. Fractures are evident in delayed images, but sometimes they are visible as early as 20 to 30 seconds after injection or as progressive IRU in all phases. In horses with suspensory desmitis without bony involvement, pool-phase images may indicate positive findings in horses with acute injuries but are often negative, whereas delayed-phase image findings are often negative or equivocal. Differentiating soft tissue injury from that of bone is particularly important in the foot. Bruises, laminar tearing, and sub-solar abscesses should cause positive results on pool-phase images, but negative or equivocal delayed-phase images. In horses with long-standing infection or inflammation, osteitis of the distal phalanx can cause IRU in delayed images, complicating differentiation of involvement of the two tissues. Conversely, early bone uptake in horses with osteitis or fracture of the distal phalanx may prompt suspicion of soft tissue involvement as well. Although scintigraphy is considered highly sensitive, negative scan findings occur in horses thought to have severe soft tissue lameness in the foot. In pool-phase images, areas of intense uptake at the dorsal and palmar/plantar aspects of the coronary band are normal, making interpretation of uptake in important structures such the deep digital flexor tendon (DDFT), navicular bursa, and distal interphalangeal joint difficult.

Pool-phase images of the shoulder, thoracolumbar, and pelvic regions are often requested, but we have found them unrewarding. Radiopharmaceutical retention in large vessels, early (within 1 minute) intense uptake in the renal pelvis and urinary bladder, and problems such as distance, shielding, and motion all reduce probability of finding inflamed soft tissue. Pool-phase images may be useful in evaluating *acute inflammation* of the DDFT, navicular bursa, superficial digital flexor tendon, suspensory ligament, and digital flexor tendon sheath but may provide negative or equivocal findings if disease is chronic and active inflammation is only mild. Images should be obtained within 4 to 6 weeks after injury to identify lesions within these structures accurately. Pool-phase scintigraphic images appear to be less sensitive and specific than ultrasonographic images.

SCAN INTERPRETATION

Qualitative assessment is the most common and useful method to interpret scintigraphic images. Quantitative assessment such as region of interest analysis (comparing the region of one limb with another after considering background values), first-pass, or gaited studies and linear profile studies are easily performed but are time consuming. However, in mature competition horses quantitative assessment may be essential to confirm relatively small differences in radiopharmaceutical uptake that can be clinically significant. Images are qualitatively evaluated for *location*, *intensity*, and *character* of radiopharmaceutical uptake, and areas of increased (hot spots) or decreased uptake are noted.

Location of Increased Radiopharmaceutical Uptake

Areas of IRU should be accurately identified and located. Is the area of IRU located in cortical or subchondral bone?

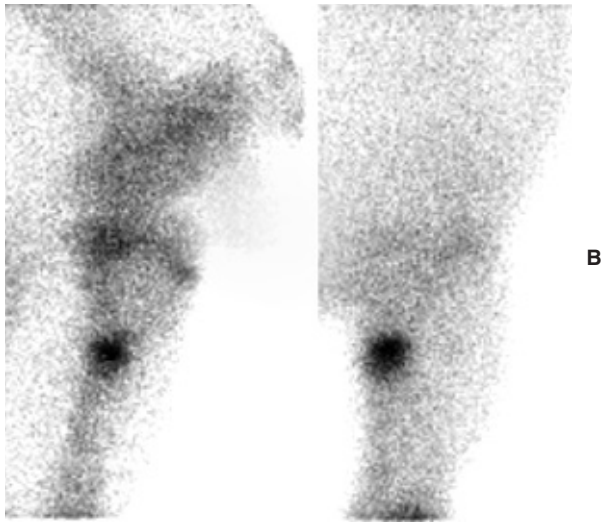

Fig. 19-9 **A,** Lateral and **B,** caudal delayed-phase images of the tibia showing focal intense increased radiopharmaceutical uptake in the medullary cavity of the tibial diaphysis associated with an enostosis-like lesion. Using only the lateral scintigraphic view, the increased radiopharmaceutical uptake could be confused with a laterally located tibial stress fracture.

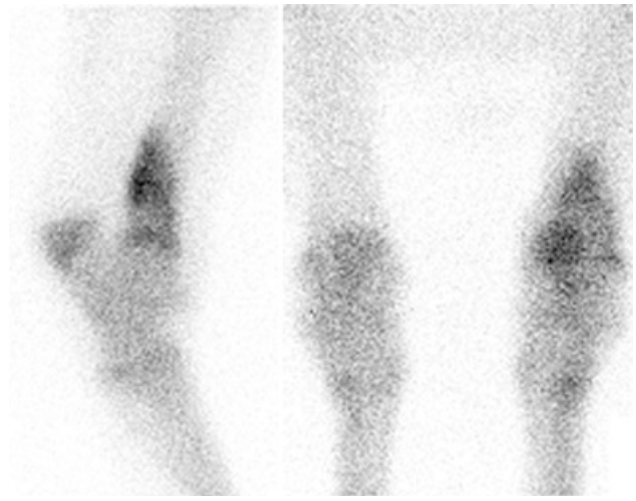

Fig. 19-10 Lateral (*left*) and caudal *(right)* delayed-phase images of a Thoroughbred racehorse with a caudolateral tibial stress fracture. In the caudal view, increased radiopharmaceutical uptake involving the lateral cortex clearly appears, an important difference from that seen in horses with enostosis-like lesions.

Cancellous (subchondral) bone located in the epiphyses is normally more active than is bone in the diaphyses, because these regions of bone are larger and have more active bone turnover. A small area of mild IRU in subchondral bone may not be relevant, whereas the same area in the mid-diaphysis of the tibia or McIII would indicate stress-related bone injury. Any area of IRU, even if small (1 to 2 pixels in width or length), in the cortex of a long bone is abnormal, but not all areas of IRU are clinically significant.

Is the area of IRU on one or both sides of the joint? Scintigraphic evidence of early osteoarthritis appears as a focal area of IRU on one side of a joint (see Fig. 19-6). Involvement of opposing articular surfaces, determined by evaluating several views, is a negative prognostic sign. If located in the diaphysis, is the area of IRU in cortical or medullary bone? At least two views are needed to determine location in the diaphysis. Enostosis-like lesions can appear similar to stress-related bone injury (see Chapters 15, 38, 41, and 46), but prognosis and management decisions differ (Figs. 19-9 and 19-10). A rare finding, an authentic fibular fracture, can be differentiated from enostosis-like lesions, soft tissue mineralization, or tibial stress fractures using lateral, caudal, and oblique views. Incidental findings such as an area of IRU associated with calcinosis circumscripta can be spectacular.

Intensity of Increased Radiopharmaceutical Uptake

Areas of IRU are described as mild, mild-moderate, moderate, moderate-intense, or intense. When analyzed using region of interest analysis, areas of IRU must have between 10% and 15% increased count density to be visually recognized as abnormal compared with surrounding bone or the contralateral limb. When both limbs are abnormal, an obvious difference may not be visible. Experience is critical for accurate image interpretation. Because time from injury to imaging is inversely proportional to intensity, IRU associated with fracture may not be intense but only mildly abnormal. Scintigraphic examination in horses suspected of having pelvic fractures may be critical for diagnosis, but expecting to see intense IRU is unrealistic, because distance, shielding, and motion complicate image quality. Pelvic fractures are usually not as obvious as fractures in the distal limb until muscle atrophy is pronounced. Cursory examination of images or placing undue importance on changes in intensity, without considering the nature of uptake, is dangerous. Even if mild and small, focal IRU should always pique the examiner's interest. Images should be evaluated before horses leave the imaging area, because additional 90° or 180° flexed or other views of the area might give important information. Commonly, advanced radiographic changes may be seen in bone when IRU is only mild, whereas negative or equivocal radiographic changes appear in bone when IRU is intense. Radiographic evidence of fracture often lags behind scintigraphic changes, an important advantage of using scintigraphy for early diagnosis. Conversely, scintigraphic activity may abate long before radiographic changes subside.

Character of Increased Radiopharmaceutical Uptake

Focal IRU means well-localized bone modeling exists, such as that seen with fracture or other substantial bone injury. Even without radiographic confirmation, focal IRU should be considered consistent with fracture, particularly in horses in which lameness has been localized to the specific region. In any horse, focal IRU indicates active bone modeling, but intensity of IRU varies with time between injury and scan. Differentiation between focal and diffuse IRU is important. For example, the dorsal cortex of McIII of TB racehorses undergoes a spectrum of bone changes caused by high-strain cyclic fatigue that can be seen scintigraphically and radiographically. Periostitis (bucked shins) can be differentiated from dorsal cortical fracture scintigraphically, even if accompanying radiographic findings are negative (Fig. 19-11). Fracture or traumatic osteitis accounts for most focal areas of IRU, but infectious osteitis or osteomyelitis can look similar. Labeled white blood cell studies using ^{111}In or ^{99m}Tc are useful to differentiate infectious processes from other bone injury and are particularly useful when evaluating potential infection after surgery. *Diffuse* IRU appears when a large area of cortical, subchondral bone, or soft tissue is abnormal, but in horses with diffuse IRU, radiographic changes usually are not found. *Generalized* IRU is another term used synonymously with diffuse IRU. A moderate, generalized IRU associated with both sides of a joint may be an incidental finding.

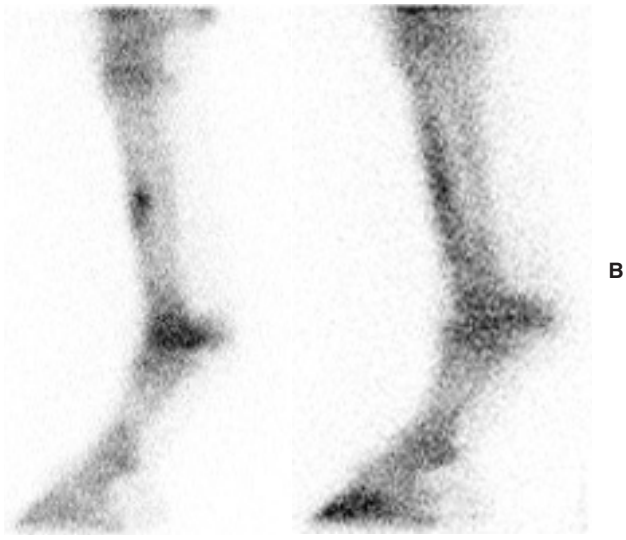

Fig. 19-11 Lateral delayed-phase scintigraphic views. **A,** A horse with a dorsal cortical fracture of the third metacarpal bone with focal, mild-moderate increased radiopharmaceutical uptake. **B,** A horse with periostitis (bucked shins) with diffuse increased radiopharmaceutical uptake of the dorsal cortex.

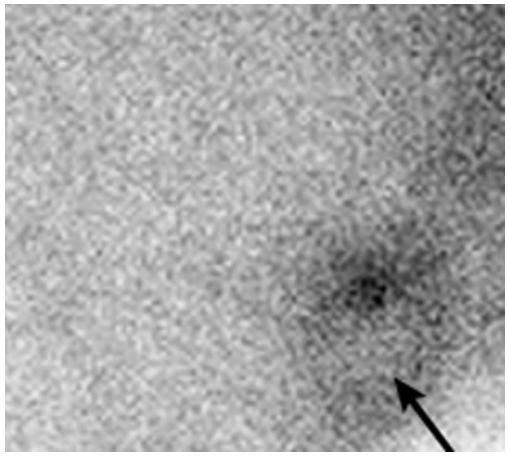

Fig. 19-12 Pool-phase image of a horse with a sub-periosteal abscess involving the olecranon process in which photopenia appears in the area of fluid accumulation (*arrow*). Surgical drainage and antibiotic administration successfully resolved the infection.

Photopenia is an unusual scintigraphic finding. Theoretically, if blood supply is not adequate during flow and pool-phases, radiopharmaceutical concentrations sufficient to delineate normal or abnormal bone are not achieved. Bone infarct, abscess, intense resorption, or sequestration might cause photopenia. Resolution of scintigraphic equipment is not sufficient to see small areas of resorption in dense cortical or subchondral bone, and even if possible to resolve technically, modeling in surrounding bone would obscure, or steal, counts. No known equine disease involves only bone resorption without modeling. Photopenia is seen rarely when portions of bone are surgically removed or displaced out of view. Bone photopenia normally appears in pool-phase images performed using ^{99m}Tc pertechnetate, because early bone uptake cannot occur. One horse with a sub-periosteal abscess of the olecranon process had photopenia in pool-phase images that was thought to be caused by fluid accumulation and compression of nearby vessels (Fig. 19-12).

False-Positive Findings

Few false-positive bone scans occur if the clinician is aware of normal areas of IRU and background radiation (bladder, large vessels) is considered. Normally, cortical bone is less apparent than cancellous bone (subchondral), but both are adequately visible in good-quality images. Physeal activity in young horses is pronounced, but normal and many variations exist (Fig. 19-13). Physeal activity decreases with age, but IRU at the distal radial and tibial physes persists for years. In a study of distal radial physeal closure, radiographic closure (24 to 32 months) preceded decrease in scintigraphic activity by several months (mean, 42 months).[27] In lateral pelvic images the coxofemoral joint (bone stacking of proximal femur and acetabulum) and tubera coxae are always prominent. Additional normal hot spots include the lateral aspect of the metatarsophalangeal joint in plantar views, a bi-lobed area in the proximal tibia in a lateral view of the stifle, the distal lateral femur and proximal tibia in a caudal view of the stifle, the proximal humerus, the proximal lateral aspect of the radius (radial tuberosity), the pastern joints, the dorsal articular facets of the sixth and seventh cervical vertebrae, the dens, and many places in the skull, such as the temporomandibular joint. In some sport horses such as jumpers, hunters, event horses, timber horses, and driving horses, focal mild to intense IRU is found on the dorsal (most common) or palmar cortex of the proximal phalanx in one to four limbs (Fig. 19-14). The Editors have been unable to attribute lameness to dorsal cortical IRU and feel it is likely to represent a normal area of modeling, but in 6 of 23 horses lameness was attributed to this site.[28] In another study of jumping, hunting, and event horses, IRU of the proximal phalanx was considered to be clinically important, but clear differentiation of dorsal cortical IRU from that of the proximal and distal aspects of the bone was not made.[29] Careful clinical examination and infiltration of local anesthetic solution may help to differentiate this site from other, much more common sources of pain.

In dorsal pelvic images the bladder is often superimposed on the sacrum or other pelvic bones and can be mistaken for abnormal IRU. Additional oblique, hemipelvic, or caudal transverse pelvic views should always be obtained. The kidneys are commonly, if not always seen, in delayed images. The right kidney is more prominent than is the left, because it has a more superficial location and normally accounts for approximately 60% of total glomerular filtration rate.[30] Diagnosis of renal dysfunction should only be made if gross anatomical derangement is seen and should be confirmed using specific renal function studies and ultrasonographic evaluation.

Peri-vascular injection or extravasation of radiopharmaceutical can cause obvious, intense IRU in soft tissues at the injection site. If a large volume of radiopharmaceutical is sequestered, distribution is slow and poor-quality delayed images result. Extravasated radiopharmaceutical can be taken up by caudal cervical lymph nodes, causing interesting but inconsequential IRU. Other non-osseous areas of IRU may be incidental (calcinosis circumscripta, other sites of mineralization, nerve block sites) or clinically important (skeletal muscle).

False-Negative Findings

A false-negative scan occurs when the image(s) fails to identify an existing lesion. False-negative scans usually result from failing to obtain appropriate views, obtaining poor-quality images, or incorrectly interpreting images. Failure to perform diagnostic analgesia and interpret the clinical relevance of scintigraphic changes may lead to apparent but not authentic false-negative results. Problems with distance, shielding, and motion likely account for many false-negative findings. A false-negative result is possible if a horse with acute pelvic fracture

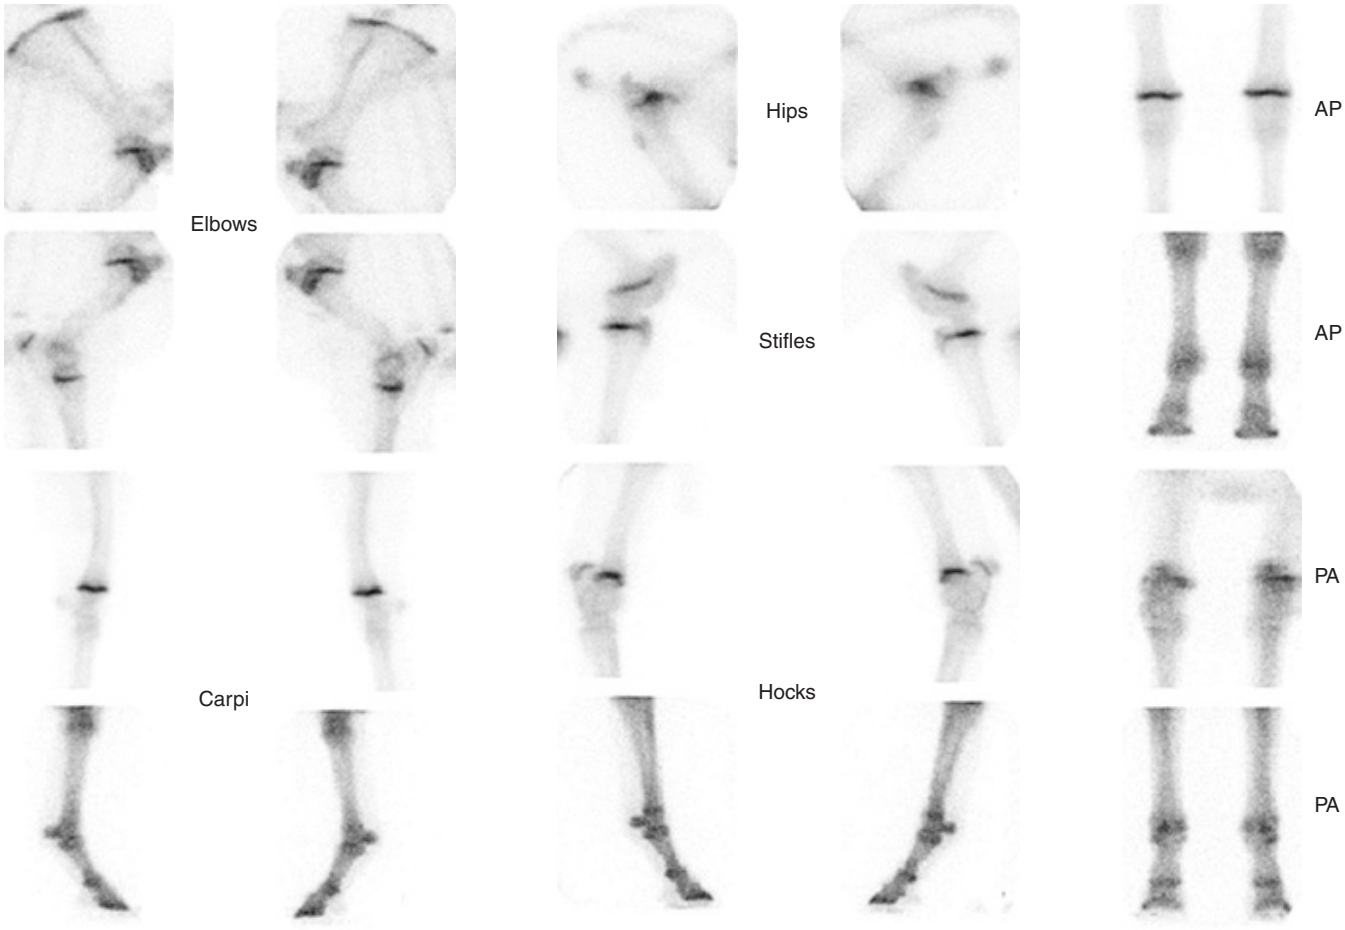

Fig. 19-13 Delayed images showing intense physeal uptake in a yearling. These areas are normal but may erroneously be interpreted as abnormal (false positive) or obscure nearby lesions causing false-negative scans. *AP,* Anteroposterior; *PA,* posteroanterior.

is scanned within 7 to 10 days after injury. False-negative scan results rarely occur in horses with stress-related bone injury, because bone changes are long-standing and resorption and modeling occur simultaneously. False-negative results have been reported in people undergoing chronic corticosteroid therapy and in those with disseminated metastatic disease, the elderly, and those with osteomalacia or renal osteodystropy.[31] Bone resorption, high osteoclastic activity, and slowed bone turnover may occur with these diseases, although bone modeling usually is present to a certain extent, ensuring a positive result.

Accuracy can be greatly improved by obtaining as many as possible standard and special scintigraphic views (see Fig. 19-5). Knowledge that the lameness is localized to a specific site can help the clinician carefully evaluate this region by obtaining all possible views, and such targeting can reduce the chance of a false-negative result.

Negative Bone Scan Results

Owners and veterinarians look for scintigraphy to provide the answer to the nagging lameness or performance issue, but in many instances a scan result is truly negative. Every bone scan provides useful and interesting clinical information, regardless of whether the finding is positive or a diagnosis can be made. Negative findings are useful in horses in which an increase in exercise is planned, such as in a racehorse with a suspected hairline or stress fracture that is entered in an upcoming race. Negative findings in any type of sport horse examined for

Fig. 19-14 Delayed image of the distal part of a forelimb of a jumper showing focal moderate increased radiopharmaceutical uptake in the dorsal cortex of the proximal phalanx. This is a normal finding in non-racehorses and may involve one to four limbs.

poor performance or a suspected obscure lameness can help clarify the picture. Negative findings on delayed images support clinical information that pain is likely originating from soft tissues. In horses with hindlimb lameness, negative scan findings often lead us to suspect the stifle may be a source of pain, because delayed images of this region may not be highly sensitive. Findings in horses with chronic proximal suspensory desmitis also are often negative.

Osteochondrosis in Delayed Images

We have identified areas of IRU in weanlings, yearlings, and older horses with osteochondritis dissecans or osseous cyst-like lesions, but scintigraphic evidence of bone modeling can be difficult to detect, or it is missed. We have heard anecdotally that some believe osteochondrosis cannot be successfully identified scintigraphically, but our experience suggests otherwise. Intense physeal uptake in weanlings and yearlings is the most important factor in correctly identifying osteochondrosis. Count stealing is certainly important, but so is the possibility that bone modeling around osteochondritis dissecans or osseous cyst-like lesions is either minimal or only present at certain stages. Subchondral bone cysts of the distal femur are generally scintigraphically active, but images must be interpreted carefully, and a caudal view of the stifle is mandatory. Osteochondritis dissecans of the shoulder joint involving the glenoid or proximal humeral head usually is scintigraphically active. We have identified several 2- and 3-year-old Standardbreds (STBs) and Warmbloods with large abaxially located extra-articular or small intra-articular plantar process osteochondritis dissecans fragments, or both, of the proximal phalanx in which bone modeling could be seen scintigraphically. Interestingly, in TB racehorses focal IRU in this region is common but does not usually result from plantar process fragmentation. Osteochondritis dissecans of the lateral trochlear ridge of the distal femur and cranial intermediate ridge of the distal tibia is rarely scintigraphically evident.

Artifacts

Urine contamination is particularly prominent in the caudal and plantar aspects of the hindlimbs in fillies. Urine contamination of the bottom of the feet is common, unless boots are applied to the horse before imaging, a procedure that is mandatory if the feet are of specific interest. Alternatively, urine can be washed away and horses can be re-scanned. Damage to the collimator, crystal, maladjustment of the photopeak for ^{99m}Tc, deterioration in flood quality, and electrical problems can produce artifacts. Incidental scintigraphic findings have been discussed.

Nerve Blocks

It is reasonable to assume that injections of any type may interfere with interpretation of scintigraphic images. Local or intra-articular injections likely produce short-lived inflammatory changes that may be visible on pool- or delayed-phase images, but we have found this to be an overrated problem. Low and high palmar analgesic techniques resulted in IRU seen in pool-phase images for up to 17 days after injection, but little effect was seen after palmar digital and abaxial sesamoid techniques. No effects of injections were seen in delayed images. The authors concluded that although effects were mild, pool-phase images should be delayed for 3 to 4 days after palmar digital blocks and 2 weeks after low and high palmar techniques.[32] We have not found it difficult to interpret pool-phase images done 24 hours after blocking, if we are aware the horses have been blocked. At least two scintigraphic views will clearly show persistence of IRU at the subcutaneous injection sites and not in important, deeper soft tissues. In most horses, little to no IRU can be seen in pool-phase images and no effect occurs on delayed images with one exception. After fibular (peroneal) and tibial nerve blocks, pool and delayed images show persistence of activity at the fibular block site, and it is extremely important to know the blocking history and obtain at least two scintigraphic views. Increased radiopharmaceutical uptake is likely caused by local myositis (Fig. 19-15). Intra-articular injections do not affect delayed images, but they may interfere with pool-phase imaging. If pool-phase images are critical, evaluation of a joint should be delayed for at least 2 weeks.

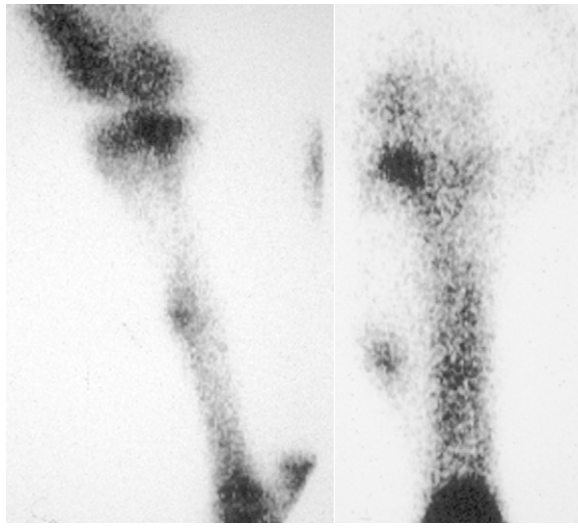

Fig. 19-15 Lateral (*left*) and caudal *(right)* delayed-phase images showing focal increased radiopharmaceutical uptake in what appears in the lateral view as the cranial tibial cortex. In the caudal view, increased radiopharmaceutical uptake clearly involves soft tissue. Cranial tibial stress fractures are not known to occur, but this horse had a fibular and tibial nerve block the day before these images were taken.

INDICATIONS AND CASE SELECTION

Bone scintigraphy is a valuable clinical tool but, like all other modalities, has limitations. Scintigraphy is useful in *early diagnosis* before injuries become radiographically apparent, a finding especially true in horses with subchondral stress-related bone injury, because scintigraphy may identify the problem months or years before radiographic findings are positive. Once familiar with scintigraphy the clinician can become comfortable diagnosing fracture without adjunct radiographic confirmation. Although fractures are common, scintigraphic findings of other less obvious lesions must be differentiated and defined. The high expectations placed on scintigraphy to provide the lameness answer can be partially met by careful consideration of clinical characteristics of lameness and case selection. We have listed, in decreasing order, the types of clinical situations in which scintigraphy is likely to provide the most information to optimize the chance of answering that tough lameness question. Most important, horses should be lame at the time of the examination, and when possible lameness should be localized to a defined region in one or more limbs. Targeted imaging is invariably much more productive than whole-body screening.

Scintigraphy is most valuable in horses with unilateral or multiple limb lameness that has been localized using diagnostic analgesia but in which radiographic findings are negative, equivocal, or confusing. In this group of horses, lameness at the time of scintigraphic examination allows for the distinct

possibility that bone modeling subsequent to injury will be detected, if indeed bone is the source of pain. Key to accurate interpretation and obtaining all necessary views is localizing the source of pain. Scintigraphy then is most useful in horses that are *lame at the time of examination and for which lameness has been localized*.

Horses that are lame at the time of examination but in which lameness has not been localized comprise the next best group. The importance of lameness at the time of examination cannot be overemphasized. We often scan horses after periods of rest or on returning to training, but if lameness is not apparent, determining clinical relevance of findings is difficult. A subset of horses in which the lower limb has been ruled out by careful diagnostic analgesia makes even better candidates. These are horses in which an upper limb problem such as a humeral, tibial, or pelvic stress fracture may be suspected. These horses are *lame, but although the definitive source of pain has not been identified, the lower limb has been ruled out*.

Horses with an accurate history of high-speed lameness but that are not currently lame are in the next category. These are usually racehorses with stress-related bone injury and strong histories to support that lameness is indeed the cause of poor performance. Performing whole-body scans is most useful in these horses, because compensatory lameness is often present. Lameness may be subtle or difficult to detect during routine lameness examination, and diagnostic analgesia would be difficult to perform. However, this group comprises young, light horses undergoing intense training and racing in which high-strain cyclic fatigue is maximal. In this group then are *racehorses without obvious baseline lameness but in which stress-related bone injury is suspected*.

Scintigraphy is *least* likely to yield a diagnosis in show horses with nebulous histories of gait abnormalities and poor performance and with problems that can be perceived only by the rider. These horses usually are not lame, may have equivocal or negative manipulative test results, and may be difficult individuals with which to work. Diagnostic analgesia may be difficult to perform or interpret. In some horses, selective analgesic techniques may improve the feel of the horse and in some, bilaterally symmetrical lameness may be diagnosed by abolishing pain in one limb and observing lameness in the contralateral limb. Whole-body scintigraphic screening can be frustrating and unrewarding for the clinician and referring veterinarian, but it is occasionally helpful. High-quality images are essential for recognizing subtle abnormalities, for example, in the proximal palmar/plantar metacarpal/metatarsal region, in the foot, thoracolumbar spine, or pelvis. A negative scan result can help direct attention to soft tissues and adjunct evaluation using chiropractic techniques or recommend conditioning and exercise intensity changes.

Scintigraphic examination has been used as part of a comprehensive purchase examination, but results must be carefully interpreted and clinical relevance established. Although unusual, this adjunct imaging procedure usually is requested in high-profile, expensive, upper-level sport horses and results can often be confusing. Finding an upper-level horse of any type without any scintigraphic changes would be unusual, mirroring radiographic findings in these horses.

KNOWLEDGE GAINED FROM SCINTIGRAPHIC EXAMINATION OF THE LAME HORSE

Scintigraphy is a powerful tool for examining a lame horse by which we have been able to give answers, pinpoint diagnoses, study disease progression, and learn about pathogenesis of many lameness conditions. Although we cannot discuss every scintigraphic finding in the lame horse, a few select issues and areas should be reviewed.

Stress-Related Bone Injury in Cortical and Subchondral Bone

Recent studies using scintigraphy and clinical and pathological findings support the concept of a continuum of adaptive and non-adaptive responses of bone leading eventually to fracture (stress or complete) and osteoarthritis.[17-19,33,34] Microfracture and callus formation in pelvic bones and the humerus, and prodromal lesions and microfracture in ipsilateral and contralateral limbs of horses with condylar fractures, indicate that pathological changes preceded fracture.[17-19] Pathological changes appeared histologically in subchondral bone of distal McIII/MtIII and the third carpal bone that preceded overlying cartilage damage, indicating a continuum of changes lead to fracture or osteoarthritis in racehorses.[33] Scintigraphic findings in the metatarsophalangeal joint of STBs indicated the existence of focal IRU of distal MtIII was a common scintigraphic finding in horses in which lameness was localized to this region, but in which radiographic findings were negative or equivocal.[34] A continuum of subchondral bone changes was proposed to account for the later development of fracture or osteoarthritis, but early changes could only be seen scintigraphically, not radiographically (Fig. 19-6).[34] Common areas for stress-related bone injury in subchondral bone include distal McIII/MtIII, proximal sesamoid bones, and the third carpal bone (see Fig. 19-16), but we feel strongly that a continuum of stress-related bone injury could account for development of fractures of the distal phalanx and osteoarthritis of the distal interphalangeal joint.[35] Abnormal IRU is common in the lateral aspect of the distal phalanx in the left forelimb and medial aspect of the distal phalanx in the right forelimb, the same sites in which fracture of the distal phalanx is most common in racehorses in North America (Fig. 19-17).[35,36] We know of at least two horses that subsequently developed articular palmar process fracture in these locations.[35] In non-racehorses, a common finding in those in which lameness is abolished using palmar digital analgesia is focal IRU in subchondral bone of the distal phalanx, corresponding to radiolucent defects and other radiographic evidence of osteoarthritis of the distal interphalangeal joint (Fig. 19-18). Observations in racehorses and non-racehorses led us carefully to evaluate medial to lateral hoof balance, because many of these horses were high on the affected side, strongly suggesting mechanical forces may be involved in early stress-related bone injury.

Scintigraphic examination has allowed us to demonstrate clinically that a continuum of cortical and subchondral bone changes exist before the development of fracture or osteoarthritis. This process is better understood and accepted in cortical bone but also occurs in subchondral bone and explains why horses can show lameness without obvious signs of synovitis, because pain originates from subchondral bone, without obvious overlying cartilage damage. Cortical and subchondral bone undergo *stress remodeling*, the term used to describe the process by which exercised bone is modeled (new bone) and remodeled (resorption and replacement). Bone adaptation is triggered by changes in number of strain cycles and the magnitude, rate of change, and distribution of strain.[37-39] Adaptive bone remodeling is normal, but exercise may lead to non-physiological strains, or during remodeling, resorption may outpace replacement, and both situations may lead to a non-adaptive response in which damage to cortical or subchondral bone occurs, eventually leading to fracture or osteoarthritis.[4,34,35,40] Lameness appears to develop long before radiographic evidence of bone damage exists, but during this time scintigraphic examination often reveals focal areas of moderate or intense IRU.

In summary, many common equine lameness conditions, including catastrophic and stress fractures and many forms of osteoarthritis, result from a continuum of cortical and

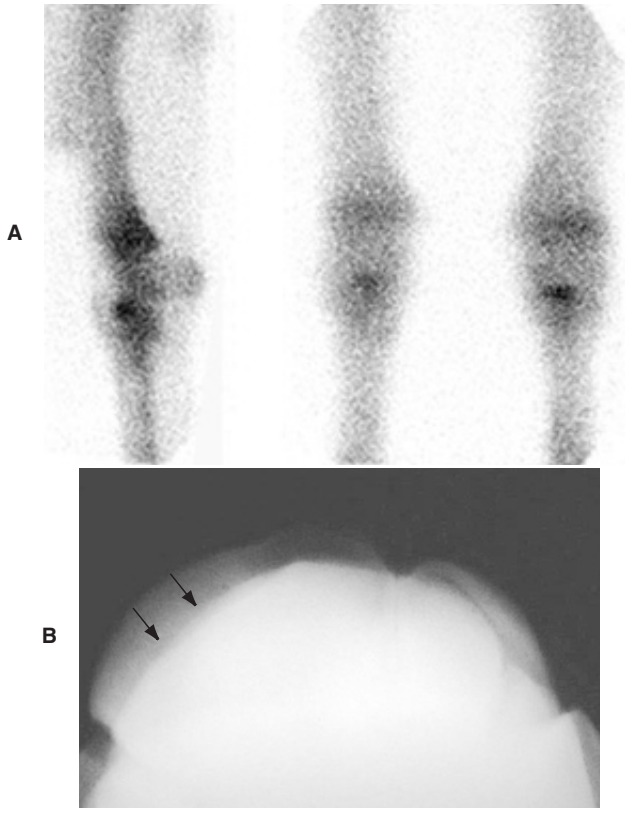

Fig. 19-16 **A,** Lateral (*left*) and dorsal (right forelimb is right) delayed-phase scintigraphic views of the carpus of a Standardbred with stress-related bone injury of the radial facet of the third carpal bone. Focal increased radiopharmaceutical uptake in the radial facet is a common scintigraphic finding in horses with lameness abolished by middle carpal analgesia but in which other clinical findings are equivocal. **B,** Proximodorsal-distodorsal (skyline) radiographic view of the same horse showing sclerosis *(arrows)* of the third carpal bone, a finding consistent with non-adaptive subchondral remodeling.

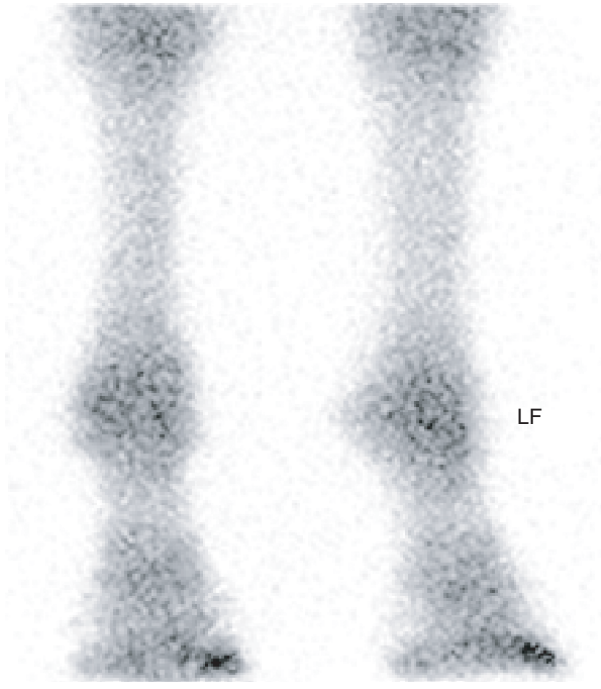

Fig. 19-17 Dorsal delayed scintigraphic view of the distal forelimbs in a racehorse showing a common finding of increased radiopharmaceutical uptake in the lateral left forelimb *(LF)* and medial right forelimb distal phalanx. Stress-related bone injury in these locations likely leads to later development of fracture or osteoarthritis.

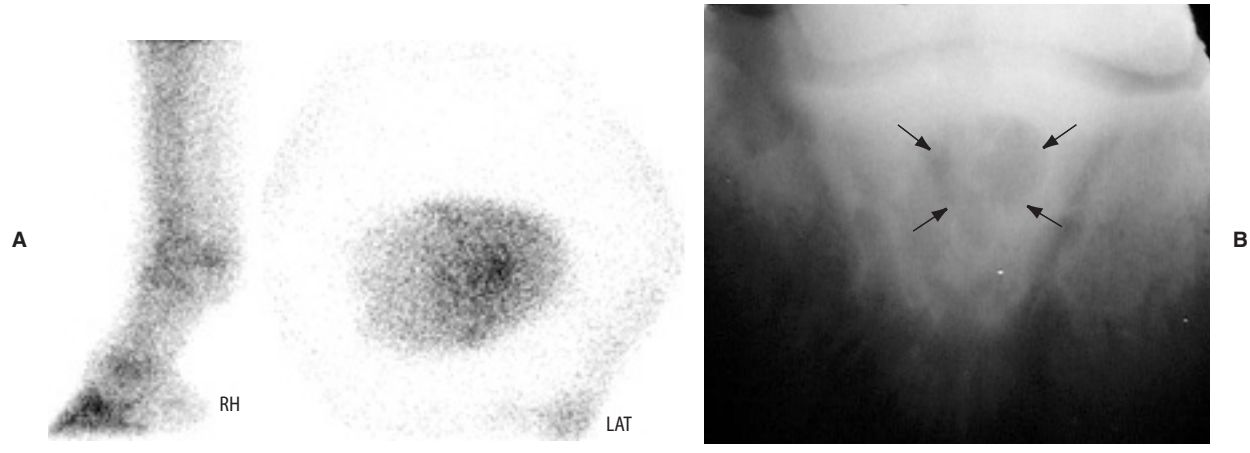

Fig. 19-18 **A,** Dorsal delayed scintigraphic view in a Warmblood showing focal increased radiopharmaceutical uptake in the subchondral bone of the distal phalanx. **B,** Dorsopalmar radiographic view showing subchondral radiolucency *(arrows)* consistent with long-standing trauma and osteoarthritis of the distal interphalangeal joint. *RH,* Right hindlimb; *LAT,* lateral.

subchondral bone changes occurring in response to exercise. Scintigraphic examination is the only way to provide early, accurate diagnosis. Single-event injuries occur from direct trauma or acute overload of bone and soft tissue material properties, but they are in the minority in most sport horses with stress-related bone injury. We find it interesting that in the forelimb, with the exception of the distal phalanx, most stress-related bone injuries involve the medial aspect, whereas in the hindlimb most changes involve the lateral aspect of the limb. This finding is consistent in TB and STB racehorses and must reflect loading of the limb and commonality of movement, rather than the expected effects of counterclockwise racing.

Confusing or Equivocal Radiographic Changes

We have often been able to pinpoint diagnosis in horses with confusing or equivocal radiographic changes using scintigraphy. Although racehorses with commonly seen areas of stress-related bone injury fall into this category, we have been able to accurately identify sources of pain in other types of sport horses. Navicular disease formerly was a common default diagnosis in horses in which lameness was abolished by palmar digital analgesia. However, scintigraphic examination has allowed us to define 15 to 20 different possible sources of pain in horses with this blocking history. Navicular disease is still a common finding and accounted for part or all of lameness in 65% of non-racehorse sport horses.[35] Central areas of IRU are most common, and often conventional radiographic views yield negative or equivocal findings. The proximopalmar distopalmar (skyline) view was most useful in identifying subtle radiographic changes and should be obtained routinely (see Chapter 30). However, navicular disease should not be the default diagnosis, because osteoarthritis of the distal interphalangeal and proximal interphalangeal joints, stress remodeling or stress reaction of the distal phalanx, soft tissue pain, and a myriad of other diagnoses can be made. Differentiation of lameness in the proximal palmar metacarpal region from that of the carpus can sometimes be difficult from overlap of diagnostic analgesic techniques, but scintigraphy has proved valuable in correctly identifying horses with avulsion injury at the origin of the suspensory ligament from those with lameness of the middle carpal joint (Fig. 19-19). Similarly, lameness associated with the tarsus can be clearly differentiated from that of the proximal metatarsal region. Scintigraphic examination has identified horses with incomplete fractures of the talus, distal tibial subchondral bone injury, fractures of the central and third tarsal bones, and osteoarthritis of the centrodistal and tarsometatarsal joints. In young racehorses the predominant scintigraphic and radiographic changes are seen involving the dorsolateral aspect of the tarsus, unlike what was once thought, that the dorsomedial or medial aspect was most commonly involved (see Fig. 109-7). Focal or diffuse areas of IRU are found in the thoracolumbar dorsal spinous processes and may account for clinical signs of back pain, poor performance, or gait restriction but occur only in horses that are ridden (Chapter 54). We have not identified areas of IRU in the STB racehorse. A rare scintigraphic finding in horses with acute forelimb lameness or with acute back pain and respiratory distress is fracture or other injury to a single or two adjacent vertebrae in the mid-thoracic region.

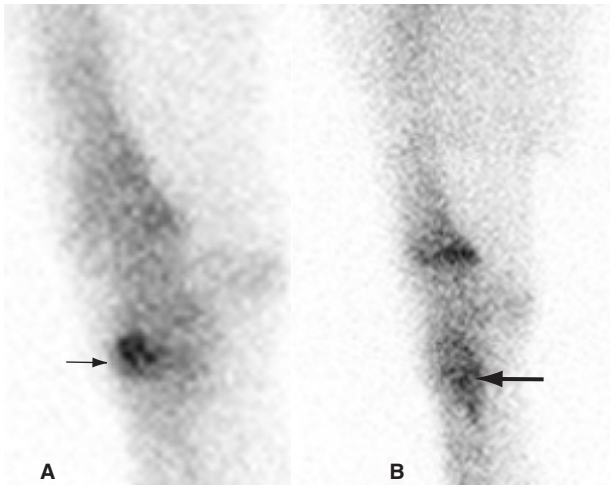

Fig. 19-19 A, Lateral delayed scintigraphic view of horse with lesion involving the third carpal bone *(small arrow)*. **B,** Same view of another horse with an avulsion fracture of third metacarpal at the origin of the suspensory ligament *(large arrow)*. High palmar and middle carpal joint analgesic techniques improved lameness in both horses.

Lameness of the Pelvis

Good-quality scintigraphic images of the pelvis can obviate the need to obtain radiographs with horses under general anesthesia. Image quality can further be improved using motion correction software (see Fig. 19-4). Horses with IRU of the coxofemoral joint often have distant areas of IRU, a scintigraphic finding that worsens prognosis for future soundness. In two horses in which scintigraphy identified single or multiple areas of IRU, fracture of the pubic symphysis, not identified in either horse scintigraphically, was found at necropsy examination in addition to those areas properly identified.[41] Although horses seemingly have one predominant source of lameness, with pelvic injury scintigraphic identification of additional sites is an important negative prognostic sign. False-negative results are also possible. Pelvic stress fractures, fractures or enthesopathy of the third trochanter and tubera ischii, sacroiliac injury, direct trauma to the tubera coxae, and fractures of the tail head and caudal sacrum have been identified as causes of obvious to subtle signs of hindlimb lameness (see Chapters 51 and 52).

Damaged Skeletal Muscle

Damaged skeletal muscle behaves like damaged bone. Areas of IRU in skeletal muscle appear in *delayed images* and not in pool-phase (soft tissue) images. We have observed two distinct patterns of IRU in skeletal muscle. Most commonly, generalized IRU in the gluteal and epaxial muscles appears in racehorses and is thought to be consistent with previous exertional rhabdomyolysis. Occasionally, IRU appears concomitantly in the latissimus dorsi muscle or rarely in the triceps muscle. In these horses, creatine kinase and aspartate aminotransferase enzyme concentrations usually are only mildly elevated. In the original report, IRU in skeletal muscle was seen 24 hours after horses underwent strenuous exercise on a high-speed treadmill, and the authors suggested that imaging should be performed within 24 to 48 hours of exercise.[42] Our experience is different, however, because we have seen generalized IRU of skeletal muscle in horses that have trained at least 7 to 10 days before scintigraphic examination. Of 129 horses with scintigraphic abnormalities of the pelvis, 34 had IRU of skeletal muscle.[41] Lameness associated with IRU of skeletal muscle was not apparent, but abnormal IRU in muscle was thought to explain a portion of the horse's poor performance.[41] However, not all horses with previous exertional rhabdomyolysis have scintigraphic abnormalities.

In the less common second form, IRU appears in individual muscles or portions of muscles. The hindlimb is most commonly affected, and individual portions of the biceps femoris, semitendinosus, or gluteal muscles are abnormal. Although this form is most common in racehorses, occasionally epaxial

or gluteal IRU is identified in non-racehorse sport horses. Although horses may show pain on palpation of the affected region, we have not been able to identify these areas as the cause of hindlimb lameness. Elevated levels of creatine kinase and aspartate aminotransferase are not found. Horses with this form of IRU in muscle usually are lame in the ipsilateral hindlimb but from a distally located site. We have speculated that muscle strain or tearing may have occurred from altered limb carriage resulting from the primary lameness condition. Rarely, we have identified IRU in a forelimb involving subclavius, pectoral, or triceps muscles.

CHAPTER • 20

Computed Tomography

José M. García-López

Tomography was not fully developed until the end of the 1960s and early 1970s but was first considered in the 1920s when radiologists were trying to develop alternative options to avoid some of the drawbacks of radiographic imaging: a way to determine the depth of pathology within the body and a means to look past the bones.[1,2] Godfrey Hounsfield, an electrical engineer working for the British Electrical & Musical Industries Ltd. in 1970, was responsible for the development of the first computed tomography (CT) scanner.

EQUIPMENT AND PHYSICS

A CT scanner is made up of three major components. The gantry houses the x-ray tube and radiation detectors (Fig. 20-1). It can be angled from 15° to 30°, which becomes useful for imaging areas such as the skull.[1,2] In human and small animal medicine, a table is attached to the gantry, which positions the animal within it in precise increments. Such tables are becoming more readily available for horses (Luminys Table, Universal Medical Systems, Solon, OH).[3] The gantry is connected to a computer system and the operating console. In the console, information such as the kilovolt peak (kVp), milliampere seconds (mAs), and slice thickness can be manipulated in addition to the contrast to attain optimum image visualisation by adjusting the brightness in the screen.

A CT image is made of many cells, called *pixels*, each of which is assigned a number and later displayed as a brightness level on the video monitor. The numerical information stored in each pixel is known as a Hounsfield unit (HU) or CT number, which is relative to the attenuating power of pure water.[1,2,4] The pixel is a two-dimensional representation of a corresponding tissue volume. The tissue volume (voxel) is determined by the pixel size and the slice thickness, which usually ranges from 1 to 10 mm. HUs range from –1000 (air) to +1000 (dense bone) for each pixel; water has a HU of 0, whereas soft tissues and fat have a range of 0 to 100 and –100, respectively.[1,2] This represents enormous gradient in the gray scale and an incredible amount of wasted information, because a video screen can only display approximately 256 HUs (shades of gray) out of the possible 2000.[1,2] To display the image in the monitor, the imager selects a HU that is approximate to the average HU of the body tissue (bone or soft tissue) being examined in the study. With this information the scanner's software is instructed to assign one shade of gray to each of the 128 HUs above and below the HU established for the body tissue.[1,2] This middle number is referred to as the *window level*, and the range of HUs is referred to as the *window width*. A window level for bone is usually approximately +200 and for soft tissue it usually ranges from +20 to +40.[1,2]

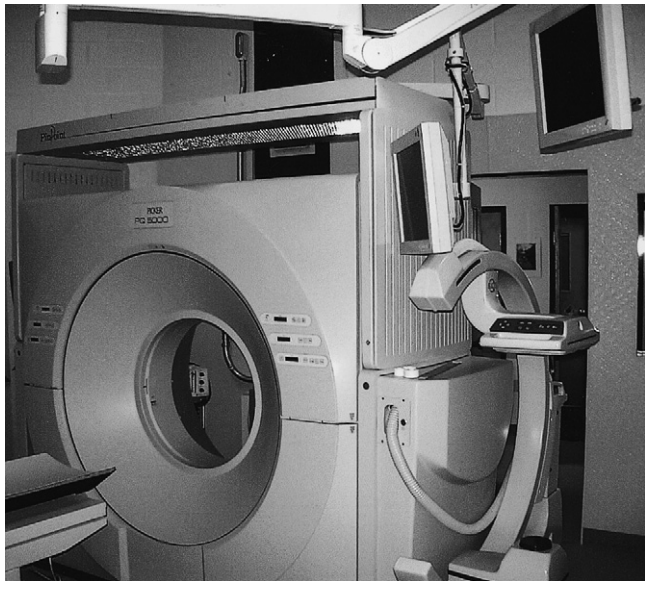

Fig. 20-1 Picker PQ 5000 Helical CT scanner. (Courtesy Tufts University School of Veterinary Medicine, North Graton, Mass.)

Several generations of CT scanners have evolved. The first, which was the original scanner developed by EMI, had a pencil-thin x-ray beam and single paired detector. The scan time was approximately 25 minutes, up to 5 minutes per slice. The second-generation scanners had the primary objective of increasing the speed of the procedure. They had multiple detectors, and the x-ray beam was fan shaped. Although these machines used a translate-rotate mechanism similar to the first-generation scanners, fewer linear scans were needed because of the increased number of detectors, and rotation of the beam increased from 1° to up to 30° between scans. This resulted in a substantial decrease in image acquisition time. The third-generation scanners introduced a rotate-rotate mechanism, which permitted the x-ray tube and detector to rotate concentrically about the patient, rather than the linear translations used in the first- and second-generation machines. The x-ray beam had a wider, fan-shaped configuration (30° to 60°), and a pre-patient collimator was developed that controlled the thickness of the beam, therefore determining the slice thickness. The number of detectors also was greatly increased (288 to 700), which further decreased the scan time to approximately 1 second. Unfortunately, one major problem with third-generation scanners was the creation of ring artifacts from faulty detectors. Partially because of this factor, fourth-generation scanners were developed that used a rotate-fixed mechanism in which only the tube, and not the detectors, rotates about the patient. Since 1990, thanks in part to great strides made in CT technology, helical scanners were developed to further improve the quality of the images and the speed of the study. The slip-ring technology allows continuous rotation of the tube, allowing for simultaneous translation and data acquisition. This results in a dramatic increase in speed, requiring only 20 to 40 seconds for an entire study rather than the 4 to 6 minutes with conventional CT. The increase in speed also results in less mis-registration, fewer motion artifacts, and production of

overlapping images without additional radiation exposure.[1,2] It also allows for manipulation of the position and spacing of axial slices after data acquisition. Disadvantages of the helical scanner include an increased demand on the x-ray tube and the fact that image reconstruction can take additional time and cannot be viewed immediately.

COMPUTED TOMOGRAPHY IN EQUINE SPORTS MEDICINE

Diagnostic imaging is fundamental for the diagnosis of equine lameness. Conventional radiography displays a three-dimensional object in two dimensions. A 30% to 50% variation in bone density is required because it is radiographically apparent.[3,5] In addition, problems such as summation of bony densities and superimposition of different contours can result in a failure to detect conditions such as subchondral bone cysts and small hairline fractures (Fig. 20-2, *A*).[5] In common conditions such as navicular syndrome and osteoarthritis of the distal tarsal joints (bone spavin), the clinical presentation and the radiographic appearance of the area often correlate poorly. The addition of ultrasonography and nuclear scintigraphy has resulted in improved diagnosis.[6-8] CT offers the ability to evaluate structures deep to gas-containing organs, as well as deep to bone, which are inherent limitations of ultrasonography.[3] Nuclear scintigraphy has been invaluable in the evaluation of lameness, but although it is generally a very sensitive diagnostic tool, it does not have great specificity (Fig. 20-2, *B*). This lack of specificity sometimes can result in an inaccurate or incomplete idea of the cause of the lameness. The location of the problem may be identified but not the cause. Such shortcomings can be avoided with CT because it offers extraordinary detail and a three-dimensional representation of the area examined (Fig. 20-2, C).

Over the past decade the potential value of CT and magnetic resonance imaging (MRI) has been recognized.[9-23] CT is generally indicated for the evaluation of bony structures and, to a lesser extent, soft tissue, although MRI provides a clear advantage over CT for examination of soft tissues.[10] Applications for CT include the examination of joints for the assessment of osteoarthritis, subchondral bone disease, osseous cyst-like lesions (see Fig. 20-2), and complex fractures.*

Several reports have already shown the benefits of CT imaging of the distal phalanx and navicular bone.† Lesions in the proximal and distal surfaces of the navicular bone, as well as in its medullary cavity (e.g., erosions, changes in cortical thickness, increased medullary sclerosis, synovial invaginations, and small fractures) can be more adequately identified using CT.[9] Radiography underestimated the extent of the degeneration of the navicular bone, which included prominent synovial invaginations along the distal border, cyst formation, and significant erosion of the flexor surface.[9] It was concluded that bony changes in the navicular bone were better assessed using CT than MRI.[9] Abnormalities of the flexor surface of the navicular bone in both normal and lame horses were more accurately determined using CT than radiography.[17,25] A trend developed toward over-interpretation of changes seen radiographically on the flexor surface of the navicular bone when compared with CT images.[17] The normal appearance of the deep digital flexor tendon in the distal pastern and within the hoof capsule has been described.[26] Thus CT also may provide additional information about other causes of palmar foot pain.

Maladaptive bone disease or stress-related bone injury, sometimes referred to as *bone bruising*, is a condition that affects a large number of young racing Standardbred and Thoroughbred racehorses.[6,27] Nuclear scintigraphy has demonstrated that the metacarpophalangeal and metatarsophalangeal joints and the third carpal bone are commonly affected.[6,13-16,27] However, in many horses no radiographic changes are

*References 5, 9, 17, 18, 20, 21, 23, 24.
†References 9, 17, 18, 20, 22, 25.

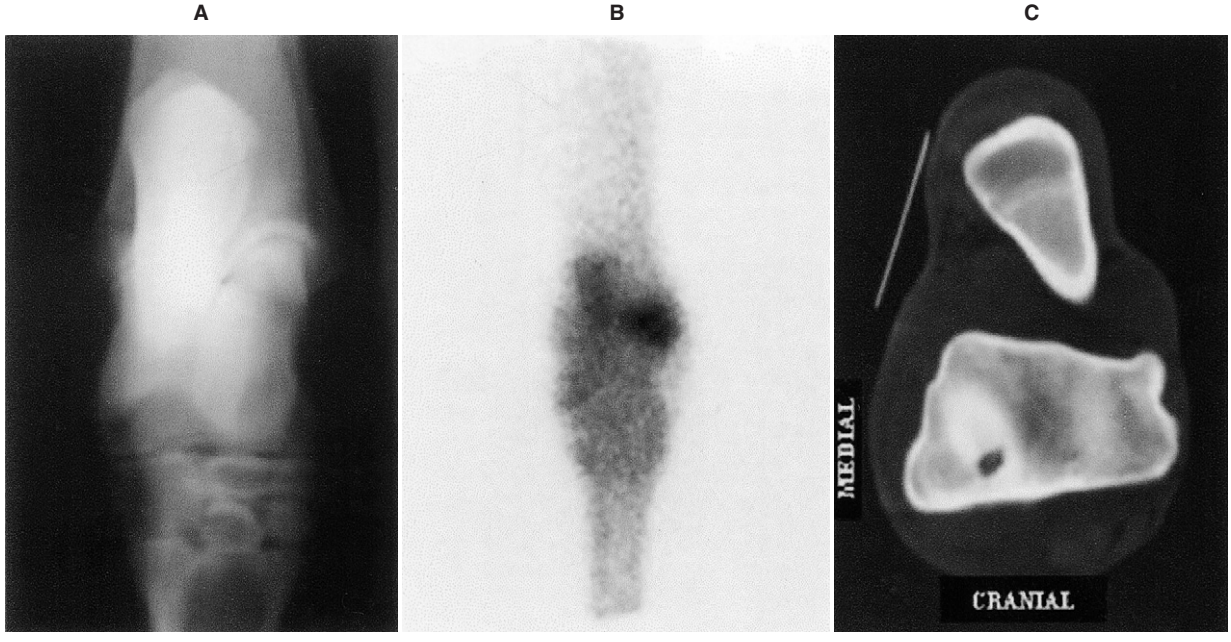

Fig. 20-2 Comparison of imaging modalities in the diagnosis of an occult cyst-like lesion in the medial malleolus of a horse. **A,** Dorsoplantar radiographic projection fails to identify any abnormalities. **B,** Plantar delayed-phase scintigraphic projection of the same area shows a focally intense area of radiopharmaceutical uptake in the region of the medial malleolus. **C,** Cross-sectional CT images of the distal tibia reveals a hypodense area with a sclerotic rim (cyst-like lesion) just proximal to the medial trochlear groove and a mild periosteal reaction on the cranial aspect of the distal tibia.

detectable and thus the actual state of the subchondral bone is poorly defined. CT was used to examine the effects of training or exercise on bone mineral composition of the distal aspect of the third metacarpal or third metatarsal bones in young horses.[15,16,28] This produced a substantial increase in subchondral bone sclerosis on the palmar/plantar aspect of the condyles, which can be a manifestation of subchondral bone disease and a possible prelude to condylar fractures.[15] The use of CT may be helpful in better defining stress-related bone injury and determining appropriate management strategies.

CT also has been used to identify occult osteochondral defects in the metacarpophalangeal joint, describe the microvasculature of the proximal sesamoid bones (PSBs), and characterize the axial border of the PSB in horses suffering from osteomyelitis.[19,23,29] Occult subchondral bone cysts in regions such as the distal tibia, talus, and proximal phalanx have been identified.[5,24] Occult osseous cyst-like lesions were identified in the tarsocrural joint in 11 horses (see Fig. 20-2).[24] CT was the only imaging modality that consistently identified the presence of a cyst-like lesion. CT permitted both identification of the lesion and a means of planning surgical access.

The disadvantages of CT include the need for general anesthesia, inability to image proximal to the distal third of the radius and tibia, the production of artifacts deep to dense bone as well as around metal objects (e.g., implants), and cost for the client.[3] The latter is arguable, because in most horses the cost for the study, including general anesthesia, is comparable to that of nuclear scintigraphy.

Currently the United States has approximately six CT facilities, and a larger number of facilities are available in continental Europe, both in academic institutions and private practices. It is likely that the number of centers offering CT will increase in the coming years, and hopefully our diagnostic capabilities will increase.

CHAPTER • 21

Magnetic Resonance Imaging

Chris Whitton, Rachel C. Murray, and Sue J. Dyson

Until recently, magnetic resonance imaging (MRI) of horses has been limited to cadavers because of the difficulty of positioning equine limbs in long, narrow magnets. Advances in equipment design have made MRI of live horses a reality.

PHYSICS OF MAGNETIC RESONANCE IMAGING

The creation of MR images is a complex process, and this is a simplified description. The image is produced by exciting hydrogen nuclei in the body at a specific resonance frequency within a static magnetic field and then detecting the energy released as the nuclei relax. The area to be imaged is placed within a static magnetic field. Magnetic field strength is generally divided into high field (1 to 1.5 tesla [T]), mid-field (0.5 to 1 T), and low field (<0.5 T). Superconducting magnets generate high fields, whereas resistive or permanent magnets generate low fields. The hydrogen nuclei within the tissues align with the magnetic field. The equipment then applies radiofrequency pulses specific for hydrogen nuclei from a radiofrequency coil placed around the area of interest. The hydrogen nuclei absorb the radiofrequency pulses and change alignment. Nuclei that are not aligned with the radiofrequency coil in turn produce a radiofrequency signal that is detected by the coil. The strength of the signal depends on the sequence of radiofrequency pulse or pulses applied and the amount of fat or water within the tissue. The most abundant sources of hydrogen nuclei are water and fat, so most signal in MRI is derived from these.

Creation of a three-dimensional (3D) image requires that the signal be positioned in space. This is achieved by using three gradient coils that change the intensity of the static magnetic field in different directions, thus affecting the intensity of the signal based on the position of the hydrogen nuclei. The resulting images can be constructed mathematically by computer software using Fourier transformations, with signal intensity shown in gray scale. High signal areas are shown as white, and low signal areas are shown as black. MR images can be acquired as two-dimensional slices of varying thickness, with the signal averaged across the slice of tissue imaged, or as 3D data sets. Three-dimensional acquisition allows thinner slice thicknesses and improves signal to noise ratio, and the data can be shown either as 3D reconstructions or as slices in any plane.

EQUIPMENT SUITABLE FOR IMAGING HORSES

The major factor limiting the use of MRI in horses has been an inability to position areas of interest in magnets designed for people. For high-quality images the area to be examined must be placed in the imaging portion of the magnet, close to its isocenter. High-quality image production requires creating a uniform magnetic field. This and the need for high-strength magnetic fields initially resulted in the production of closed, long, narrow cylindrical-bore magnets. However, high-field, short-bore magnets with flared ends are now available and have been successfully used to image up to and including the carpus and tarsus and head and cranial neck of adult horses (Fig. 21-1). Open magnets also have been produced for the medical market and use a lower field magnet, but the problems with creating a uniform magnetic field mean that the image quality tends to be inferior.

Radiofrequency coils designed for the medical field can be used in equine imaging, although imaging could ultimately be optimized by design of specific radiofrequency coils for equine extremities. In live horses, successful imaging of limbs up to and including the carpus and tarsus has been achieved using a human extremity (or knee) coil, whereas a torso array coil designed for the human torso has proved practical for imaging the head.

PRACTICALITIES OF IMAGING HORSES

The use of high-strength magnetic fields creates special problems for MRI in horses. To acquire images, the area of interest must be within the center of the magnet and must be immobile for the duration of each scan sequence; thus general anesthesia is required. Loose ferrous material close to the magnet is hazardous, and fixed ferrous material can produce imaging artifacts. A height-adjustable anesthetic table made of nonferrous material is required as are an MR-compatible anesthetic machine, ventilator, and anesthetic monitoring devices.

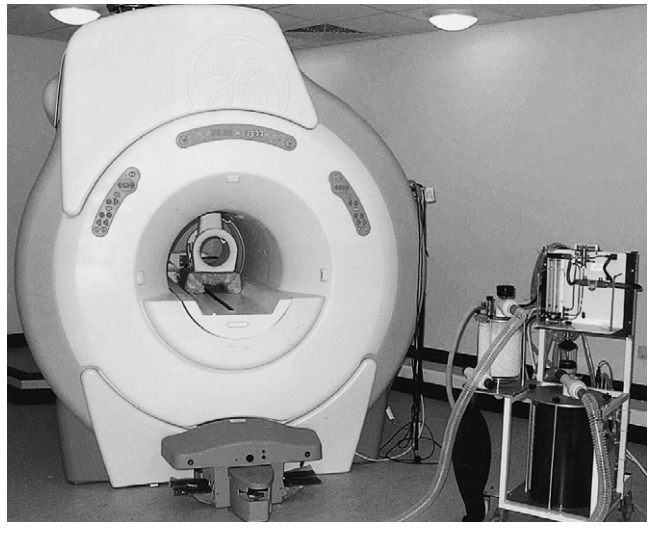

Fig. 21-1 The 1.5-T GE Echospeed (General Electric Medical Systems, Milwaukee, WI) magnet at the Animal Health Trust, Newmarket, is used for MRI of live horses. Located in the bore of the magnet is a radiofrequency coil suitable for use on the equine distal limb. Both limbs are placed into the magnet bore. A specially shaped pad allows the coil to be placed only over the limb being imaged and in the center of the magnet.

Before anesthesia is administered, any shoes and associated nails must be removed from the horse and debris must be cleaned from the area of interest. Any clipping or preparation of the horse that requires metal equipment must be performed before entering the imaging area. Placing the area of interest in the radiofrequency coil and then positioning it in the isocenter of the magnet requires a well-trained team.

SEQUENCES FOR ORTHOPEDIC IMAGING

The pulse sequence used to create the MR image describes the sequence of radiofrequency pulses applied during an MRI study and the associated application of magnetic field gradients. Numerous pulse sequences can be used to highlight different tissues and various pathological changes. These may be T1 or T2 weighted, depending on the detection of T1 or T2 relaxation of hydrogen nuclei. On T1-weighted images, tissues with fast T1 relaxation such as fat show high signal intensity (bright). On T2-weighted images, tissues with slow T2 relaxation such as water show high signal intensity. The relative weighting of the image determines the signal intensity of and contrast between different tissues. In general, structures with a high water content are bright on T2-weighted images, and those with a high fat content are bright on T1-weighted images. T1-weighted images show anatomy well, whereas T2-weighted images are more likely to demonstrate pathological conditions as reflected by increased water content.

A variety of sequences is available, including basic spin echo (SE) and fast spin echo (FSE) sequences, gradient echo (GRE), spoiled gradient echo, and inversion recovery. New sequences are continually being developed. In a live equine patient, time under anesthesia may be critical in preventing post-anesthetic complications, and thus it is important to aim for short acquisition times while maintaining image quality. More than one sequence may be used for each diagnostic procedure to maximize the information provided.

The conventional spin echo sequence is acquired as a two-dimensional image and may be either T1 or T2 weighted. However, acquisition times are long and impractical for live horse imaging. Fast spin echo sequences can be used to reduce acquisition times while maintaining signal to noise ratio. The reduced acquisition times make this sequence a practical option for live horse scanning. Although a fast spin echo sequence potentially reduces coverage compared with a spin echo sequence, this does not seem to cause significant problems clinically. The weighting of fast spin echo is similar to that of spin echo, except that the fat remains bright on T2-weighted images.

The purpose of the gradient echo sequence is to increase the speed of the scan, and therefore this sequence has significant clinical application in the horse. In addition, fast acquisition using the gradient echo sequence has the advantages of allowing 3D acquisition (showing higher detail) and increased sensitivity to the magnetic effects of hemorrhage. These advantages make the gradient echo the optimum sequence for equine orthopedic imaging, but increased susceptibility to inhomogeneities in the magnetic field occurs with a risk of magnetic susceptibility artifacts. A basic gradient echo sequence is largely T2 weighted, whereas the spoiled gradient echo produces a largely T1-weighted image. Clinically the gradient echo sequence appears useful for detecting pathological conditions of the cartilage, tendon, and bone, whereas the spoiled gradient echo sequence appears most useful in defining anatomy, showing cartilage and subchondral bone morphology and detecting cartilage surface defects. A flip angle of approximately 30° produces the best images.[1]

Sequences using fat suppression increase the sensitivity of T2-weighted images to edema in bone. Short inversion recovery sequences are the most useful in orthopedic imaging and can be used to improve subtle T1 contrast (e.g., between articular cartilage and synovial fluid) that is usually overshadowed by the far greater difference in signal intensity between fat and most other tissues on T1-weighted images.

Specialist techniques can enhance aspects of the image and reduce artifacts. Magnetization transfer has been used in human imaging to enhance visibility of articular cartilage. The magnetization transfer pulse selectively saturates tightly bound protons within tissues and reflects the equilibrium between freely mobile protons and protons constrained by macromolecules within the same tissue. Articular cartilage, hyperplastic synovium, and muscle show marked magnetization transfer effects, whereas fat and joint fluid remain relatively unaffected, thus increasing the contrast between structures within a joint.[2]

INTERPRETATION OF MAGNETIC RESONANCE IMAGES

An understanding of MRI, a detailed knowledge of anatomy, and considerable experience are required to interpret MR images reliably. Lesions that may be detectable using MRI but are difficult to detect with other imaging modalities include ligament and tendon injuries (within the hoof capsule), occult fractures, articular cartilage damage, and subchondral bone remodeling. For best assessment of structures, images are routinely obtained and analyzed in three planes (sagittal, dorsal, and transverse). Interpretation is improved by assessing T2-weighted, T1-weighted, and fat-suppressed images at each site.

In T1-weighted images, fat has a high signal intensity (bright) and water has a low signal intensity (dark); therefore the bone marrow of the medullary cavity of bones is bright, with darker synovial fluid (Fig. 21-2). Cortical bone and other mineralized tissue is dark (nearly black). T2-weighted images

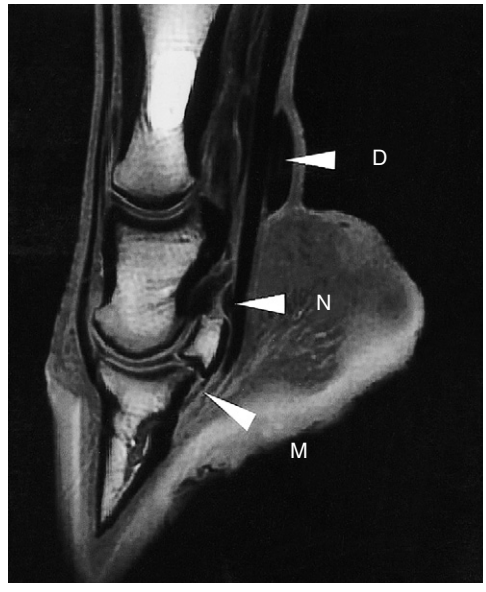

Fig. 21-2 Sagittal slice of the distal limb using a T1-weighted spoiled gradient echo sequence. The high signal in the medullary cavity of the phalanges and navicular bone is caused by fat. No signal appears in the deep digital flexor tendon, straight sesamoidean ligaments, and dense bone. Increased signal in the most distal portion of the deep digital flexor tendon is probably a magic angle effect (*M*). Synovial fluid is dark in the navicular bursa (*N*), distended digital flexor tendon sheath (*D*), and proximal and distal interphalangeal joints, but cartilage shows a relatively brighter signal.

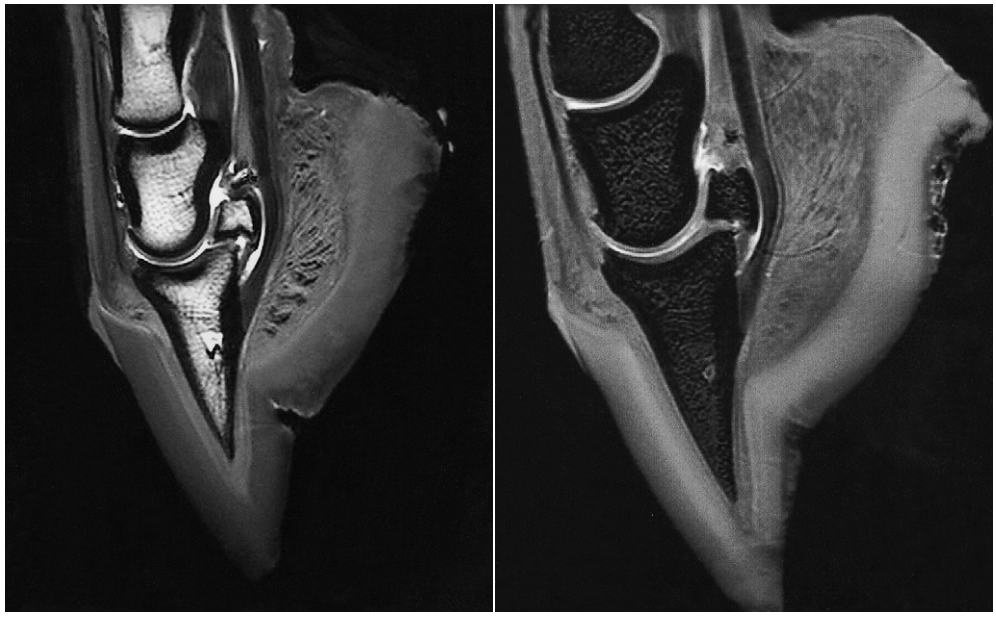

Fig. 21-3 Sagittal slices of the distal limb using a T2* gradient echo sequence. **A,** Three-dimensional T2* gradient echo shows a relatively bright signal associated with medullary fat of the phalanges and navicular bone, but on this sequence fluid is bright (compare with Fig. 21-2). Synovial fluid in the navicular bursa and joints is bright, but cartilage exhibits a relatively low signal. **B,** Fat-saturated, 3D T2* gradient echo shows the absence of fat signal in the medullary bone and improved contrast between articular cartilage and surrounding structures.

produce a high signal in water and a lower signal in fat, and thus synovial fluid appears white because of its high water content. Although T2 spin echo sequences show bones as dark throughout, using the more clinically applicable fast spin echo and gradient echo sequences, fat maintains relatively high signal intensity so bone marrow remains relatively bright, unless fat is suppressed (Fig. 21-3). On T2-weighted images, cartilage has low signal intensity. In all images, dense tissues such as subchondral bone and tendon have low signal intensity.

Although cortical bone produces low signal, MRI is extremely useful for detecting pathological conditions of the bone using either T1- or T2-weighted images. Fractures show as defects in bone outline and structure and may show as lines of increased signal on T2-weighted images (Fig. 21-4). The surface contour of bone can be accurately assessed, allowing the detection of osteophytes, which are better delineated by MRI than by conventional radiography,[3] and periosteal and endosteal new bone (Fig. 21-5). Trabecular architecture changes can be maintained.[4] Subchondral bone irregularity appears best on standard (non–fat-suppressed) images.

MRI is currently the most sensitive technique for detecting osteonecrosis, osteomyelitis, and trauma, including bone contusion and non-displaced fractures.[4] Pathological conditions of the bone are detected as a local increase in fluid content. In clinical imaging of horses, fat-suppressed and standard T2-weighted sequences must be compared. The fluid signal in medullary bone often is obscured by the high signal produced by fat on standard T2-weighted images, and therefore fat suppression techniques are needed to reduce interference from the fat signal. The fluid signal is frequently referred to as bone *edema*, although it reflects bone necrosis, inflammation, trabecular microdamage, and fibrosis as well as bone edema.[5,6] The ability to detect edema within bone as an increased signal on T2-weighted images means that MRI is extremely sensitive for detecting subtle bone injury. In people, subchondral bone injury, referred to as *bone bruising,* is commonly observed with acute cruciate ligament and meniscal injury and is not detectable by any other means. In horses, bone edema on MRI has been observed adjacent to large fractures and subchondral bone edema at sites of trabecular microdamage, hemorrhage, and edema (Fig. 21-6) and in the navicular bone at sites with histological evidence of edema or bone necrosis.[7]

Fig. 21-4 A transverse 3D T2* gradient echo image of the distal limb showing a comminuted fracture of the navicular bone and fracture of the middle phalanx that had been detected radiographically (*F*), and laceration of the medial branch of the deep digital flexor tendon (*D*), which is interposed between the fracture fragments of the navicular bone.

Fig. 21-5 A sagittal T2* gradient echo slice of a carpus demonstrating osteophyte formation on the distal radius and proximal radial carpal bone in the antebrachiocarpal joint (*arrows*). Synovial effusion of the antebrachiocarpal and middle carpal joints occurs with synovial proliferation on the dorsal aspect of the antebrachiocarpal joint.

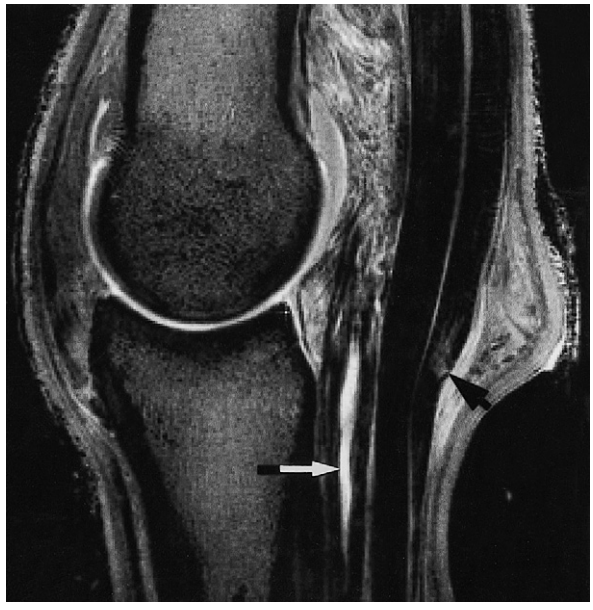

Fig. 21-7 A sagittal T2* gradient echo slice of a fetlock of a horse with lameness that was alleviated by intra-articular analgesia of the metacarpophalangeal joint. A linear area of high signal appears in the straight sesamoidean ligament (*white arrow*). Increased signal within the superficial digital flexor tendon (*black arrow*) corresponds to an area of cartilage metaplasia.

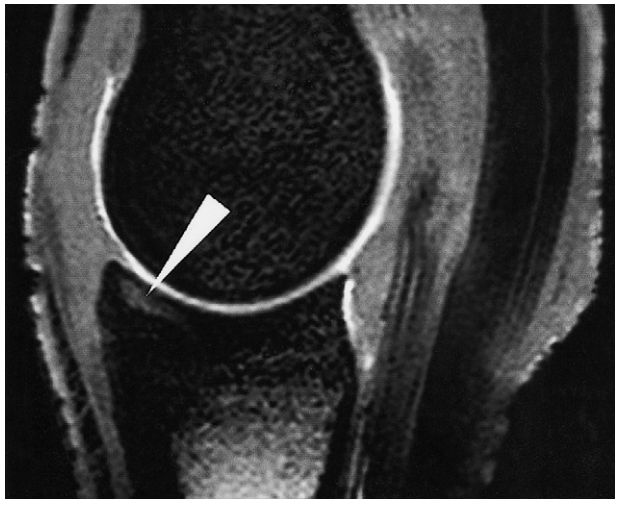

Fig. 21-6 Sagittal fat-saturated, T2* gradient echo slice of metacarpophalageal joint showing an area of bright (fluid) signal in the subchondral bone of the proximal phalanx (*arrow*), representing a pathological condition of the bone. Histopathological examination revealed subchondral bone edema, inflammation, and trabecular microdamage.

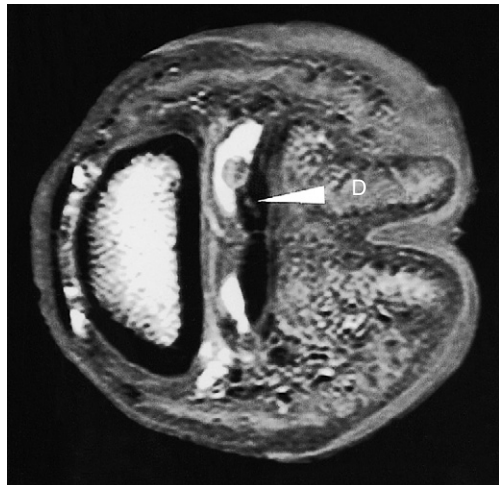

Fig. 21-8 A transverse 3D T2* gradient echo slice of the distal limb of a horse with lameness that was alleviated by intra-thecal analgesia of the navicular bursa. There is an area of increased signal within the medial branch of the deep digital flexor tendon (*D*), with adjacent granulation tissue protruding into the navicular bursa.

Like cortical bone, tendons and ligaments generally have low signal intensity on T1- and T2-weighted images and so appear nearly black. Identifying the interface between dense collagenous tissues and bone may therefore be difficult. As with bone, tendon and ligament injury is identified by an increase in signal (Figs. 21-7 and 21-8). In acute stages of equine tendon and ligament damage, focal pathological conditions tend to appear as areas of bright signal on T1- and T2- weighted images with detectable local swelling. In the inflammatory phase, dark linear signal separated by areas of high signal may represent damaged fibers surrounded by cellular infiltration. During the later phases of healing and fibrosis, signal intensity tends to decrease but remains higher than that of normal tendon.[8] These changes must be differentiated from normal areas of increased signal. Areas of cartilage metaplasia in tendons often occur at sites subject to compressive forces such as the deep digital flexor tendon (DDFT) at the level of the metacarpophalangeal joint (see Fig. 21-7). Increased signal may also be observed when the collagen fibers of a ligament or tendon are placed at an angle of 55° to the

static magnetic field. This is termed the *magic angle effect* and is an artifact (see Fig. 21-2). Changing the position of the limb within the static magnetic field confirms this as an artifact.

Muscles contain less collagen than tendons and therefore have intermediate signal intensity on T1- and T2-weighted images.[4] Muscular inflammation appears as increased signal intensity on T2-weighted images related to elevated water content (edema) and loss of collagen. Fibrosis lowers signal intensity on T2-weighted images.

Although low-field MR systems tend to produce poor images of articular cartilage, use of high-field systems has demonstrated that articular cartilage can be assessed accurately using MRI. Articular cartilage has a complex appearance on MRI because of the different collagen orientation and composition of layers present in hyaline cartilage, and imaging is prone to artifacts.[9] However, improvements in pulse sequence design and image interpretation have eliminated several of these problems. Commonly, T2-weighted fat-suppressed fast spin echo and gradient echo sequences are used clinically to detect pathological conditions of cartilage in people.[10,11] This is also supported by experience with equine cartilage, where use of fat-suppressed 3D gradient echo sequences, with minimal thickness, contiguous slices, maximizes information obtained in the shortest time.[1] Use of fat-suppressed images not only improves contrast in the cartilage but also highlights subtle areas of subchondral bone edema, which may draw attention to a defect in the overlying articular surface.[12] MR findings suggesting cartilage degeneration include signal abnormality and contour or thickness abnormalities. On T2-weighted images the low signal of cartilage and the high signal intensity of synovial fluid give clear delineation of cartilage fluid interfaces. Pathological conditions can be detected as altered signal intensity. Loss of collagen can lead to focal signal loss, whereas increased signal intensity may indicate matrix damage.[4]

Detailed images of the synovium allow assessment of synovial proliferation and synovial distention (see Fig. 21-5). Synovial villi and evidence of adhesion formation are easily observed, which is particularly useful for assessing the synovial structures within the foot, including the navicular bursa, where clinical experience has indicated the significance of navicular bursa distention, synovial proliferation, and adhesion formation detected by MRI.

ARTIFACTS

As with any imaging technique, MRI is prone to production of artifacts that may confuse the interpreter. *Ghosting* (repeated picturing of a structure throughout the image) originates from movement during the acquisition of data because of respiration or pulsatile movement of vessels. This can cause problems in equine patients because respiratory chest movement causes large displacements of the upper forelimb during imaging. Motion can be minimized by weighting the limb with sand bags or reducing respiratory excursion by avoiding mechanical ventilation. Alternatively, techniques such as respiratory compensation or triggering and flow compensation can be used. Anything metallic can severely distort the image, which is known as *a magnetic susceptibility artifact* and is more prominent in gradient echo sequences. Shoes and residual nails must therefore be removed from feet, and dirt must be cleaned from the sulci of the frog. Wounds may be contaminated with fine metal particles, and these particles may be detected by MRI after apparently remaining embedded for a prolonged duration.[13] *Chemical shift artifact* occurs only at high field strengths and occurs when fat and water that are adjacent in the patient are shown farther apart on the image. If part of the patient is just outside the field of view but produces a signal detectable by the receiver coil, this may be shown incorrectly within the field of view, known an *aliasing*. This problem can be combated by using "no phase wrap" or "no frequency wrap" techniques in the relevant phase or frequency direction. The *Gibbs effect* (truncation artifact) results from under-sampling of data and occurs when bright or dark lines appear parallel and adjacent to borders of abrupt intensity change, for example, a line of low signal is incorrectly shown running through a high intensity area. *Partial volume effects* result from structures passing obliquely through the slice of tissue being imaged. Reducing the slice thickness minimizes this effect. The *magic angle effects* appear when collagen fibers are located at an angle of 55° to the static magnetic field. This is most important in ligaments and tendons, although it has been reported to occur in cartilage. Increasing the echo time reduces the effect, which is less evident on T2-weighted images.

INDICATIONS FOR MAGNETIC RESONANCE IMAGING IN EQUINE LAMENESS

MR imaging is time consuming, and the need for general anesthesia limits the number of sites that can be imaged because of time constraints and the practicalities of moving a horse within the scanner. It is therefore important to localize the site of lameness with clinical examination and nerve blocks before imaging and to rule out differential diagnoses with other diagnostic techniques. Because of anatomical variations between horses, imaging of both limbs is recommended to provide a comparison. The detail detectable by MRI means that the significance of potential abnormalities observed needs to be evaluated in the light of the clinical presentation. MRI is most useful when lameness has been localized to a site with no detectable radiographic or ultrasonographic changes. In some situations, because of the non-specificity of local analgesic techniques, the clinician may be directed toward a structure that is not the cause of the lameness. The ability of MRI to examine all tissues in an area at once may identify an adjacent structure as the cause of lameness. In the horse illustrated in Fig. 21-7, intra-articular anesthesia of the metacarpophalangeal joint alleviated the lameness. No significant radiological abnormalities were identified. MRI demonstrated a core lesion within the straight distal sesamoidean ligament. No significant abnormalities of the metacarpophalangeal joint were detected at post-mortem examination.

MRI is also particularly useful for lameness localized to the foot, where use of ultrasonography is limited by the hoof capsule. DDFT lesions in the foot are easily identified with MRI (see Fig. 21-8). MRI may also be indicated where scintigraphy shows changes but no radiological abnormality is detected and further information is required, such as the extent of subchondral bone injury. Using MRI, palmar heel pain has been shown to encompass a variety pathological entities, including lesions of the DDFT, distal sesamoidean impar ligament, medulla and flexor cortex of the navicular bone, and navicular bursa and osteochondral lesions of the distal interphalangeal joint.[14]

Because of advances in ultrasonographic technology the identification of pathological conditions within structures such as tendons and the suspensory ligament can be readily achieved in the standing horse. However, MRI is extremely sensitive to subtle changes in these structures, and except for magic angle effects, fiber alignment is not a problem as with ultrasonography. Therefore MRI is likely to be of great benefit when ultrasonographic examination findings are equivocal. In particular, use of MRI to evaluate proximal suspensory desmitis should be considered because of the difficulty in accurately diagnosing and monitoring this condition. Fig. 21-9 shows a

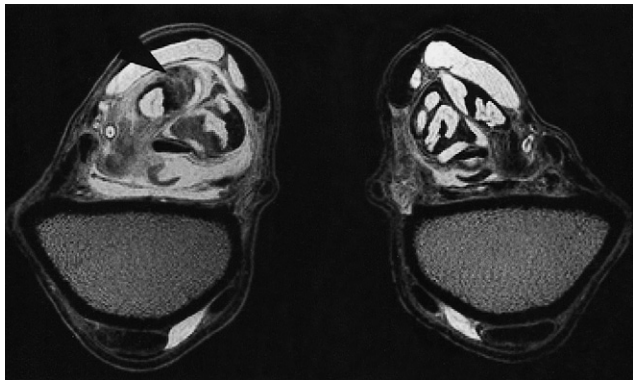

Fig. 21-9 Transverse T2* slices at the level of the musculotendonous junction of the superficial digital flexor tendon of the left *(shown on the left)* and right forelimbs. There is enlargement of the left superficial digital flexor tendon and its accessory ligament. Normal muscle tissue (areas of high signal) is replaced by an area of low signal consistent with scar tissue (*arrow*).

lesion within the musculotendonous junction of the superficial digital flexor tendon that was suspected with ultrasonography but was difficult to demonstrate conclusively. The lesion is easily identified with MRI.

Imaging of joints allows differentiation of degrees of cartilage damage and osteoarthritic change. Subchondral bone structures and pathological conditions can be identified with MRI, and the presence of bone edema can indicate active damage at this site compared with cartilage erosions without marked subchondral bone damage. Evidence of inflammation is seen clearly with increased quantities of synovial fluid, synovial proliferation, and capsular thickening. Small mineralized particles, such as bone fragments that are invisible radiographically, can be detected by MRI.

ADVANTAGES AND DISADVANTAGES COMPARED WITH OTHER IMAGING TECHNIQUES

Advantages

MRI is more versatile than most other imaging modalities in the ability to provide images sliced in many planes and 3D images in a variety of orientations. Like ultrasonography and radiography, MRI has the ability to provide anatomical information, but MRI also has a physiological sensitivity like that of nuclear scintigraphy.

MRI is the only method presently available that can assess all tissues during a single examination. Ultrasonography is extremely useful for imaging soft tissues but is impractical in a number of areas, most importantly the foot. MR technology allows imaging of those soft tissue structures that are inaccessible with ultrasonography. Radiography shows mineralized tissues but is less sensitive than MRI because each image is obtained through the full thickness of the area, and only the orientations selected can be assessed, so small abnormalities may be missed. In contrast, MR images can be obtained in any plane with no loss of image quality, and data can be assessed in slices so that the image is not limited to a summation through the entire structure. MRI has been shown to be more sensitive to pathological conditions of bone and tendons than radiography and ultrasonography, respectively.

Like MRI, computed tomography (CT) can be used in horses for accurate assessment of the 3D distribution of pathological conditions of the bone. Some soft tissue detail is also demonstrated with CT but with inferior contrast. Articular cartilage can be assessed only with CT by use of invasive arthrography. Arthroscopy is the standard of reference for the evaluation of articular cartilage, but it cannot assess deep chondral lesions and lesions of the subchondral bone.

Disadvantages

The greatest disadvantages of MRI are the expense of the equipment and the requirement for general anesthesia. MRI is limited to areas that can be placed within the magnetic field, and thus the caudal neck, trunk, and proximal limbs of adult horses cannot be imaged. MRI provides a huge amount of information, so interpretation is time consuming.

FUTURE DIRECTIONS

The high cost of MRI has been the major limiting factor in its use in equine orthopedics. Because of the technical difficulties in producing high-field magnets, the price of MRI equipment will not likely decrease dramatically in the near future. However, developments in low-field equipment are interesting: low-field image quality is improving rapidly, and purchase and running costs are significantly cheaper than for high-field units. Dedicated low-field units have found a place in human orthopedics for identifying gross lesions of menisci and cruciate ligaments and subchondral bone injury. Open magnets offer much greater flexibility in design. Open magnets for imaging the limbs of standing horses have been proposed, but the low field strength achievable with such magnets would severely limit the image quality and resolution. Movement also significantly degrades image quality, further limiting the development of MRI of the standing horse. Motion correction software could conceivably improve image quality.

Major improvements in the accessibility of the imaging area of high-field magnets have occurred in recent years, but further developments are limited. High-field units remain the gold standard in MRI, and these devices will become more common in referral institutions and will greatly improve the diagnosis of orthopedic conditions in horses. Other potential MR techniques that could have applications in the future of equine orthopedic imaging are spectroscopy to look at metabolite distribution, diffusion studies, angiography, and use of contrast agents.

CHAPTER • 22

Gait Analysis for the Quantification of Lameness

Alicia L. Bertone

The quantification of equine gait and lameness can be achieved by several methods that assess kinematics (limb position in time and space) and kinetics (direction and magnitude of forces upon limb loading). Integration of these data permits the calculation of impulses (average loading forces/stride or phase of stride), net joint moments (torque around a joint), and joint power (rate of mechanical energy generation and absorption across the joint).

KINEMATICS

Kinematic analysis of gait includes measurement of joint angles, stride length, duration of stance phase, and head excursion and can be extrapolated to estimate forces of loading[1,2] or combined with force plate data to calculate joint power and moments.[3-6] Although kinematic studies can be performed in the field, control of outside influences on gait, gait velocity, and camera relationship to the limbs is difficult. Therefore most studies are performed with the horse on a treadmill so that velocity can be controlled and with several cameras simultaneously so that all limbs can be assessed. Three coordinates (X, Y, and Z) are analyzed to define the position of the limb in space. A high-speed video camera capable of 60 frames/sec is adequate for assessing equine stride-timing characteristics at slow trotting velocities (3 m/sec), but a higher speed camera is preferable for higher gait velocities (up to racing speeds of 18 to 20 m/sec) or detailed limb/hoof placements.[7]

The most popular systems include a camera, computer, and light-emitting or light-reflecting markers that can be resolved by the camera based on location, reflection pattern, color, or a combination of these factors. Data acquisition software can be customized, but most systems have a method to control the duration of data collection (time or stride number) and automatically average values over the defined data acquisition phase for a predefined number of variables. Collection and averages continue as long as the program is activated. Data usually are displayed in real time on a monitor as a "stick figure" of the markers to allow marker recognition and tracking. Data can be immediately stored and later used for analysis and data printing. Data sets can be immediately deleted if other factors invalidate the trial, such as loss of a marker or failure of marker detection, errors in the treadmill, head shaking, or gait velocity variations, such as the horse skipping. Stride stance phase, joint angles (the joint number limited by the number of markers the system can distinguish simultaneously), and head excursions are analyzed. One marker must serve as a reference marker for calculations and usually is placed on the scapula. Placement of other markers on long bones, hoof, and head (atlas) allows calculation of joint angles and head excursion (nod), respectively. Typically, 30 seconds to 2 minutes of data are collected (representing approximately 30 to 120 strides) for 5 to 10 trials, which are averaged to produce 1 valid trial. Immediate printing of valid data for storage in the experimental or clinical record is recommended.

System accuracy and repeatability are currently limited by camera placement, marker diameter (~6 cm), marker movement with skin, marker resolution (markers too close, or of indistinguishable shade or reflection), and marker placement consistency from trial to trial. The camera must be placed at the center of stride length and at a distance that allows collection of the entire movements of all markers to avoid distortion of image and miscalculation of values. Background camera images of handlers, treadmill railings, and floor surfaces should be minimized and made as homogenous as possible. Control of light reflection with directed halogen lamps, a light-controlled treadmill environment, and black covers to reduce background reflection greatly assist. A protocol should be established at each testing center. White and multicolored horses can present problems. Clipping of hair and use of glue-on hook-and-loop fasteners (Velcro; Velcro USA Inc., Manchester, NH) can assist with repeatable marker placement on successive days. An established protocol system and technical assistance that can effectively train horses for the treadmill and operate the cameras and computer are essential for reliable data comparison among trials and horses.

For quantification of equine lameness, several landmark papers identified findings that moved kinematics closer to practical use in the diagnosis of lameness and related the findings to classical lameness scores. Head and withers excursion (head nod) were the only parameters evaluated that significantly changed after lameness was induced to a grade 3

Gait Analysis for the Quantification of Lameness

Alicia L. Bertone

The quantification of equine gait and lameness can be achieved by several methods that assess kinematics (limb position in time and space) and kinetics (direction and magnitude of forces upon limb loading). Integration of these data permits the calculation of impulses (average loading forces/stride or phase of stride), net joint moments (torque around a joint), and joint power (rate of mechanical energy generation and absorption across the joint).

KINEMATICS

Kinematic analysis of gait includes measurement of joint angles, stride length, duration of stance phase, and head excursion and can be extrapolated to estimate forces of loading[1,2] or combined with force plate data to calculate joint power and moments.[3-6] Although kinematic studies can be performed in the field, control of outside influences on gait, gait velocity, and camera relationship to the limbs is difficult. Therefore most studies are performed with the horse on a treadmill so that velocity can be controlled and with several cameras simultaneously so that all limbs can be assessed. Three coordinates (X, Y, and Z) are analyzed to define the position of the limb in space. A high-speed video camera capable of 60 frames/sec is adequate for assessing equine stride-timing characteristics at slow trotting velocities (3 m/sec), but a higher speed camera is preferable for higher gait velocities (up to racing speeds of 18 to 20 m/sec) or detailed limb/hoof placements.[7]

The most popular systems include a camera, computer, and light-emitting or light-reflecting markers that can be resolved by the camera based on location, reflection pattern, color, or a combination of these factors. Data acquisition software can be customized, but most systems have a method to control the duration of data collection (time or stride number) and automatically average values over the defined data acquisition phase for a predefined number of variables. Collection and averages continue as long as the program is activated. Data usually are displayed in real time on a monitor as a "stick figure" of the markers to allow marker recognition and tracking. Data can be immediately stored and later used for analysis and data printing. Data sets can be immediately deleted if other factors invalidate the trial, such as loss of a marker or failure of marker detection, errors in the treadmill, head shaking, or gait velocity variations, such as the horse skipping. Stride stance phase, joint angles (the joint number limited by the number of markers the system can distinguish simultaneously), and head excursions are analyzed. One marker must serve as a reference marker for calculations and usually is placed on the scapula. Placement of other markers on long bones, hoof, and head (atlas) allows calculation of joint angles and head excursion (nod), respectively. Typically, 30 seconds to 2 minutes of data are collected (representing approximately 30 to 120 strides) for 5 to 10 trials, which are averaged to produce 1 valid trial. Immediate printing of valid data for storage in the experimental or clinical record is recommended.

System accuracy and repeatability are currently limited by camera placement, marker diameter (~6 cm), marker movement with skin, marker resolution (markers too close, or of indistinguishable shade or reflection), and marker placement consistency from trial to trial. The camera must be placed at the center of stride length and at a distance that allows collection of the entire movements of all markers to avoid distortion of image and miscalculation of values. Background camera images of handlers, treadmill railings, and floor surfaces should be minimized and made as homogenous as possible. Control of light reflection with directed halogen lamps, a light-controlled treadmill environment, and black covers to reduce background reflection greatly assist. A protocol should be established at each testing center. White and multicolored horses can present problems. Clipping of hair and use of glue-on hook-and-loop fasteners (Velcro; Velcro USA Inc., Manchester, NH) can assist with repeatable marker placement on successive days. An established protocol system and technical assistance that can effectively train horses for the treadmill and operate the cameras and computer are essential for reliable data comparison among trials and horses.

For quantification of equine lameness, several landmark papers identified findings that moved kinematics closer to practical use in the diagnosis of lameness and related the findings to classical lameness scores. Head and withers excursion (head nod) were the only parameters evaluated that significantly changed after lameness was induced to a grade 3

(American Association of Equine Practitioners scoring system) by carpal amphotericin B injection.[8] Head excursion was a reliable indicator of lameness in horses with navicular disease.[9] Fetlock extension angle also decreased significantly. However, gait analysis with a single 60-Hz (frames/sec) camera may not provide the resolution necessary to consistently identify small changes in kinematic variables, such as fetlock angle, that occur with change in lameness. In our gait laboratory, analysis of more than 296 independent, blinded kinematic trials (approximately 35,000 measured strides) of 12 variables associated with lameness scores ranging from 0 to 4, resulted in low correlation coefficients ($r \cong 0.4$). Using fetlock extension angle as the example, the high coefficient of variation in fetlock angle measurements from stride to stride (over 30 seconds to 2 minutes) relative to the percent mean change in fetlock angle as horses went from lame to sound (range 1% to 6%) resulted in low sensitivity for kinematic analysis of fetlock angle to detect lameness change. Improvements resulting in greater sensitivity, specificity, and repeatability, such as smaller marker size, control of marker motion relative to true centers of joint motion,[10,11] and incorporation of measures of limb acceleration and deceleration into programs,[12,13] will promote kinematic lameness quantification. Use of simultaneous collection of right and left limb data allows for enhanced sensitivity because joint angles in the contralateral limb change in the opposite direction to the lame limb. This doubles the measured difference between limbs in lame horses. Problems with variation in skin marker and camera placement from side to side produce additional variability that affects these measurements.[12] With forelimb lameness, load may be shifted to hindlimbs complicating relative limb measurements. Assessment of gait symmetry should analyze all four limbs simultaneously. Analysis of bilateral forelimb lameness or concurrent forelimb and hindlimb lameness is not straightforward. Until these issues are resolved, kinematic gait analysis will probably remain a second choice to kinetic analysis for the quantification of lameness.

Analysis of clinician scoring of lameness and kinematic quantification has exposed the limited ability of clinicians, especially those who are inexperienced, to grade mild lameness consistently. This highlights the need for improvement in methods to quantify lameness accurately. However, in the author's and editors' view an experienced trained clinician is currently more sensitive than kinematic assessments and offers the flexibility of observation in many conditions and gaits. This is further supported by the close correlation of trained clinician lameness scores and kinetic analysis (see the "Kinetics" section).

Kinematic analysis also has been used for measurement of activity indices,[14] dimensions of growth,[15] estimates of flexibility,[16] accelerometry,[12,13] and joint moments and joint power.[3-6] Joint moments, joint power, and applied forces[17] can be calculated by the simultaneous measurement of kinematic parameters and force plate recordings. Measurement inaccuracies of each system may limit the power of this type of analysis, but theoretically these calculations could provide another index that could be correlated to lameness and may be used to detect joints receiving most of the torque and absorbing most of the energy during various sports. This may provide insight as to which joints are likely to be injured and how to adjust shoeing, riding surface, and gait during or after injury to assist with healing, rehabilitation and prevention of re-injury. These areas of equine locomotion science are expanding and are expected to assist with lameness quantification and detection.

KINETICS

Weight-bearing profiles that either directly measure the direction and magnitude of force on loading, or can be used to extrapolate these forces, can be obtained with hoof strain gauges,[17,18] instrumented horse shoes,[19-21] force plates,[1,2,22-26] and pressure-sensitive shoes.[27] Currently marketed and published systems for equine kinetic quantification include force plates and pressure-sensitive systems.

Force plate quantification of ground reaction force (GRF) is the current gold standard for objective quantification of lameness in horses and dogs.[1,2,23-25,28-30] Peak vertical GRF decreases with increased lameness scores.[1,2] In our gait laboratory, analysis of 150 blinded force plate valid trials (1200 individual measurements), associated with lameness scores ranging from 0 to 4, resulted in high correlation ($r > 0.85$) of peak vertical GRF with subjective lameness score. These correlations were significantly higher than for kinematic gait variables evaluated using the same lipopolysaccharide-induced arthritis model of lameness.[31] Variability among force plate trials is low, and reduction in peak forces range up to 50% for lameness of grade 4. This large percentage change of peak forces associated with change in lameness and low standard deviation among repeated measurements provides a sensitive system that can detect small percentage changes in lameness associated with treatment, surgery, or time. Standard GRF patterns and variation in normal and lame horses have been described and have confirmed the high repeatability of force plate data provided velocity is controlled within a narrow range.[1,2,25] Measurement of gait velocity has been incorporated into data acquisition systems using wall-mounted photoelectric detection.[1] Velocity is immediately displayed at the end of the force plate pass, and pre-established cut-off ranges can determine validity of the trial.

Force plate equipment uses quartz crystal sensors and at least four sensing elements in the corners of an approximate 1-m × 0.5-m plate that is mounted in the ground to be level with a 10-m lead-in and lead-out runway. Quartz crystals respond to changes in shape and generate an electrical charge (piezoelectric effect) oriented to the external force. Three orthogonal GRFs are measured: mediolateral, craniocaudal or braking/ propulsion, and vertical. The voltage produced is directly proportional to the applied force. The electrical output of the crystals is collected by electrodes, and data from the four corners of the plate are integrated to determine orthogonal GRFs. Although other strain-sensing elements exist and can be accurate, piezoelectric systems are highly sensitive and accurate over a large measuring range, do not require recalibration even after years of use, do not require an external energy source, and are not damaged by overloading. These practical advantages provide significant incentive for continued use.

The installation of force plates requires forethought for maximal benefit and ease of use. Force plates should be secured in a concrete foundation. The sensors are encased in a heavy metal mounting plate. The selection of a site for the force plate should consider the following factors. The surroundings should be non-distracting to minimize the number of passes necessary to collect a valid trial. At least 10 m of space should be allowed on either side of the plate for adequate room for the horse to establish a stable speed and uniform stride rhythm. A 20-m long roll-out thin rubber carpet is placed over the force plate so that the horse does not avoid it, and to provide a non-slip surface, a path for the horse to follow and easy clean-up. The mat must be cut around the outside border of the force plate so as not to influence the measurement of forces in any of the three planes. Wall-mounted sensors for stable velocity measurements that can feed directly into the computer are useful. A sliding windowed door to the area housing the computer should be positioned to allow direct visibility of the force plate so that observers are hidden. The limb must be placed on the force plate to complete a valid trial. The limb to be measured should land squarely inside the edges of the plate without any

of the hoof landing off the plate. Typically the ipsilateral hindlimb strikes the plate after the forelimb, and this is readily identifiable on the force-time curves. If the contralateral forelimb strikes the plate, the curves must be immediately identified to avoid later confusion. Use of a large plate for small animals makes it difficult to identify the limb of interest on the generated curves. The observer should immediately delete any trial that did not meet the velocity requirements, limb strike position, or curve pattern indicating stride interference. Handler physical conditioning and practice is critical to maximize efficiency of valid trial collection. The horse must pass the photoelectric detectors at a predefined velocity, and the horse must trigger both the force plate and photocell. It may take as few as 5 passes or as many as 50 passes to achieve a valid trial. An acceptable valid trial is usually composed of 5 to 10 measurements that meet all the criteria. Statistical power calculations can be customized from the data collected at each testing center to ensure that adequate numbers of measurements are made to comprise a valid trial. Software is provided with the system to calculate normalized force (newtons per kilogram of body weight). Typical parameters evaluated include peak (maximum) force, average force, impulse (force over time), loading rate (slopes) and unloading rate. These can be calculated for each of the three directional forces: vertical, craniocaudal, and mediolateral. If reduction of the data to a single value that reflects lameness is desired, peak vertical force should be used.

Instrumented horse shoes have continued to evolve to provide a method to analyze weight-bearing forces in successive strides or on a treadmill.[17-21,27] These systems may prove to be repeatable and accurate at quantifying lameness, as initially reported.[27] Further studies verifying repeatability over days of use, after reapplication of shoes, and in clinical cases will be important for these systems to gain acceptance for most practical applications in quantification of equine lameness. Proof of sensor durability, evidence of correlation with the entire range of lameness scores, including no lameness, and use of kinematics to document the changes in gait associated with the weight and bulk of the system on the limbs are required. Telemetric control of these systems would provide a substantial advantage because data acquisition would not be limited to a treadmill. Systems reporting pressure across the entire hoof contact surface offer a potential advantage of quantifying the force distribution within the hoof.

FUTURE USES

Future directions for the quantification of lameness include the incorporation of telemetry to allow use in natural settings and avoidance of wires attached to limbs that probably affect gait. Hoof-based systems that are accurate, but not bulky or heavy, and a single system that directly measures three-dimensional forces and the distribution within the hoof are required. A simplified data acquisition and analysis system that can integrate all four limbs simultaneously also is needed. See Box 22-1 for a list of camera, data acquisition, and analysis software systems.

CHAPTER • 23

Arthroscopic Examination

Mike W. Ross

Arthroscopic surgery is arguably the most important advance in management and one of the most important in diagnosis of equine joint disease. Arthroscopic surgery has been a mainstay in managing joint disease since the early 1980s and has mostly replaced arthrotomy. An effective equine surgeon cannot lack extensive arthroscopic surgical experience, and lameness diagnosticians must understand indications and limitations of the technique. Innovators have used the same instruments for bursoscopy and tenoscopy (see Chapter 24).

ADVANTAGES AND DISADVANTAGES OF ARTHROSCOPIC SURGERY COMPARED WITH ARTHROTOMY

Arthroscopic surgery offers several advances compared with arthrotomy; however, this type of surgery also has some disadvantages. Both are discussed in the following text.

Advantages

Improved Visibility Improved visibility during arthroscopic examination allows for evaluation of most of the joint compared with the limited view provided by arthrotomy. Even long arthrotomy incisions rarely provide added visibility because overlying capsule, retinaculum, and sheaths make retraction difficult. During arthroscopic examination, cartilage at locations distant to the primary lesion site, synovium, and intra-articular soft tissue structures such as ligaments can be examined. For instance, newly described disease conditions involving intercarpal ligaments were not known before arthroscopic examination existed.

Reduced Trauma and Morbidity Arthroscopic examination is less traumatic and causes less morbidity. Arthroscopic examination allows surgery to be performed through small incisions and requires less surgical exposure and damage to overlying soft tissues, upholding a time-honored principle of limiting trauma. Little pain occurs after arthroscopic surgery, and complications such as wound dehiscence and seroma formation are minimal. Horses often show pronounced lameness for several days after arthrotomy. After arthroscopic examination and surgery, owners and trainers expect horses to return to full work soon after surgery, an idea that is fueled by widespread reports of human athletes returning to professional sports quickly after arthroscopic surgery. A general misunderstanding is that incision size is the limiting factor. Although arthrotomy does cause short-lived lameness after surgery, the fear that it will delay onset of training is unfounded, because the underlying lesion dictates recovery time. Although not recommended, horses with mild conditions such as osteochondritis dissecans, horses with effusion but no lameness, and horses that receive prophylactic arthroscopic surgery can resume training a few weeks after arthroscopic examination or arthroscopic surgery. Arthroscopic surgery can be performed within weeks before a sale, and if hair was not clipped, surgical sites are barely noticeable.

Better Cosmetic Results Improved cosmesis is a definite advantage. Small incisions cause less fibrous tissue formation, and incisions are difficult to identify by 2 to 3 months after surgery. Generally the instrument portal (incision), the site through which the arthroscopic instruments are passed and lavage is performed, suffers more trauma than does the arthroscopic portal, and swelling, reactions, and fibrous tissue production are more common.

Earlier Functional Capability Earlier return to function was once believed to be an advantage of arthroscopic surgery. However, incision size has little to do with lameness except within the first few weeks after surgery. Lameness observed in horses returned to work 4 to 6 weeks after arthroscopic surgery for substantial articular lesions has nothing to do with incision size. When horses undergoing arthroscopic surgery were given only a brief rest, results were unsatisfactory. Incisions heal from side to side, not end to end, and incision size has no effect on articular healing. Lesions must heal as completely as possible before full work can begin, a process that often takes several months. Type and location of lesions are important, because horses with osteochondritis dissecans not involving weight-bearing surfaces can start training within 2 to 3 weeks of surgery, if necessary, whereas those with lesions in critical sites, such as the typical carpal osteochondral fragment, must be given 3 to 4 months of rest.

More Versatility Improved versatility is a definite advantage because joints considered inaccessible, such as the coxofemoral joint, can be evaluated. Techniques such as repair of third carpal slab fractures, distal third metatarsal (MtIII), or third metacarpal (McIII) fractures and those in other joints and resurfacing techniques can be done using arthroscopic surgery.

Fewer Complications Arthroscopic surgery has fewer complications. Arthrotomy of the scapulohumeral, femorotibial, femoropatellar, cubital, and tarsocrural joints has been associated with dehiscence, seroma formation, and infection, but arthroscopic surgery of these joints is safe.

Disadvantages

Expensive Instrumentation Expense of surgical instrumentation is a disadvantage because start-up costs are high, but basic instrumentation is no more costly than routine surgical instruments. Although arthroscopic surgery can be done without video equipment, video arthroscopy is valuable for archiving images. It is much more comfortable than direct view arthroscopy (looking directly through the eyepiece), because surgery is performed using a comfortably positioned monitor. It allows the procedure to be viewed by others and is valuable in maintaining aseptic technique, because during direct view arthroscopic surgery, breaks in technique often occur.

Lack of Surgical Experience Experience necessary to learn arthroscopic surgery is a disadvantage. Arthroscopic surgery requires skill in stereotactic techniques and orienting and operating without looking at the surgical site, and surgeons must be able to use instruments properly and safely while looking at a monitor. Poor technique may result in iatrogenic

damage or extravasation of large amounts of lavage fluid that can severely compromise distention of the joint capsule and thus ability to see adequately within the joint. Experience cannot be gained by simply attending a weekend course, but by working long hours with cadaver specimens and observing experienced surgeons. Initially, arthroscopic surgery can be time consuming until experience is gained, but with experience arthroscopic surgery is faster than arthrotomy.

Equipment Problems Equipment failures can be a disadvantage, and because arthroscopic examination depends on electricity, a generator should always be available. Instruments are not made to withstand forces applied to cut, grasp, and debride equine bone and, along with the arthroscope, may break.

Improper Case Selection Case selection is the most important disadvantage. Poor case selection can make arthroscopic surgery difficult and disappointing. Although much information can be gained by arthroscopic examination of any joint, prognosis should be carefully considered when operating on joints in which extensive osteoarthritis exists. Inadequate communication before surgery may leave owners and trainers with too high expectations of results. Often they have little appreciation for the magnitude of cartilage damage and osteoarthritis, and they only see or hear about the chip fracture(s) visible radiographically. Owners and trainers tend to want to do something, but removal of osteochondral fragments from a carpus or fetlock joint with hopeless osteoarthritis can be time consuming, cause instrument failures, and worse, often results in a poor outcome. The fragment size that can be easily removed during arthroscopic surgery is limited, and the instrument portal must be enlarged to accommodate such fragments unless ostectomy is performed. The fragment must be located in the joint, a decision that must be made before surgery, because arthroscopic surgery is of little benefit if the fragment is not in the joint. In the metatarsophalangeal joint, large plantar process fragments from the proximal phalanx are often located extra-articularly and cannot be removed arthroscopically. In the stifle joint, fragments in the distal aspect of the femoropatellar joint may appear radiographically as if they are in the femorotibial joint. Rare fragments in the caudal pouches of the medial and lateral femorotibial joints can be difficult to retrieve, especially if the precise location cannot be determined radiographically before surgery. Highly mobile fragments in a large joint such as the femoropatellar joint can prove challenging to locate.

PRINCIPLES, INSTRUMENTATION, AND TECHNIQUE

Surgical technique, basic and advanced instrumentation, and approaches are well described elsewhere,[1] and in-depth discussion is beyond the scope of this textbook. The basic principle of arthroscopic surgery is to use a rigid 4-mm endoscope to evaluate and perform intra-articular surgery through small incisions. Limited arthroscopic surgery was previously performed through a single incision, and instruments were passed through a second slot in the arthroscopic cannula. Versatility was severely compromised. Triangulation, a versatile technique in use today, uses two distant portals so the arthroscope and instruments create two sides of a triangle. For example, during routine tarsocrural arthroscopy the arthroscopic portal is dorsomedial and the instrument portal is dorsolateral. This allows the tips of the instruments to be in the surgical field from distant points and obviates the need for the arthroscope to be close to the lesion. The end of the arthroscope is angled 25° to 30°, and a different view is obtained by simply rotating it. The image must be positioned on the screen to optimize special orientation and facilitate stereotaxis.

Arthroscopic surgery can be performed with basic instruments, the most important of which are rongeurs (Ferris-Smith), grasping forceps, bone curettes, lavage cannulae, intra-articular blades, and probes. Arthroscopic surgery depends on the availability of a suitable light source and monitor, digital camera, and recording devices. A fluid delivery system is mandatory, and pumps or other methods to pressurize fluid are preferred to gravity flow systems. Many common lesions removed by arthroscopic surgery are located on the joint margin, and visibility often is compromised when joint capsule and synovium collapse or when bleeding is excessive. Carbon dioxide insufflation is sometimes used. Lasers are used rarely. Motorized equipment is useful but expensive. Abrasion arthroplasty units include various motorized burrs to remove and smooth cartilage and bone surfaces and are used in horses with large lesions such as osteochondritis dissecans lesions of the lateral trochlear ridge of the femur. Synovial resectors are alternating, motorized, rotating blades that are helpful in removing synovium and fibrous tissue and are particularly valuable for removal of osteochondral fragments from the dorsal aspect of the distal interphalangeal joint, apical sesamoid fracture fragments, and fragments from the lateral malleolus of the distal tibia and when synovectomy is indicated.

The division between diagnostic and surgical arthroscopy is now artificial because the same instruments are used for both. Diagnostic arthroscopy, that is, arthroscopic examination, generally refers to evaluating cartilage, bone, and soft tissues to gain information for diagnosis and prognosis. The client must be warned that although valuable information is always learned, arthroscopic examination may provide little therapeutic benefit. However, I believe a tendency exists to under-sell arthroscopic examination, because a positive intervention cannot be made unless the joint is evaluated, and much can be learned about lesions with early arthroscopic examination. This is particularly true in the stifle, carpus, and fetlock joints. Arthroscopic examination is indicated in horses with lameness localized to a joint, but in which radiographic findings are negative or equivocal. Scintigraphic evidence of subchondral bone injury is common in these horses, and defects in overlying articular cartilage can be debrided and attempts at resurfacing performed arthroscopically. Scintigraphy and ultrasonography have low sensitivity in the complex stifle joint, and arthroscopic examination should be encouraged. Arthroscopic examination may uncover proliferative synovitis, intersesamoidean ligament injury, meniscal or cruciate lesions, and intercarpal ligament injury. Intercarpal ligament injury often is associated with osteoarthritis or osteochondral fragments and can cause hemarthrosis and presumably joint instability[2,3] (Fig. 23-1). However, owners and trainers must also be made aware that in some joints, such as the distal interphalangeal and femorotibial joints, anatomical constraints limit inspection of all structures.

Changes in articular cartilage are the most important information gained from arthroscopic examination. Prognosis was found to worsen in proportion to the extent of articular cartilage damage in the carpus,[4] but all joints are similarly affected. Surface area and depth of damage are important. Widespread damage affecting many cartilaginous surfaces is usually worse than well-defined lesions extending into subchondral bone. Cartilage damage is graded as mild (<20% damage to cartilage and subchondral bone at the primary lesion site), moderate (involvement of apposing bone, but <30% total cartilage and subchondral bone damage of primary and apposing sites), severe (≤50% of cartilage and subchondral bone damage of primary and apposing sites), and global (extensive cartilage damage visible on most articular surfaces) (Figs. 23-2 to 23-4). If cartilage lesions do not extend past the zone of calcified cartilage, healing after surgery will be minimal.

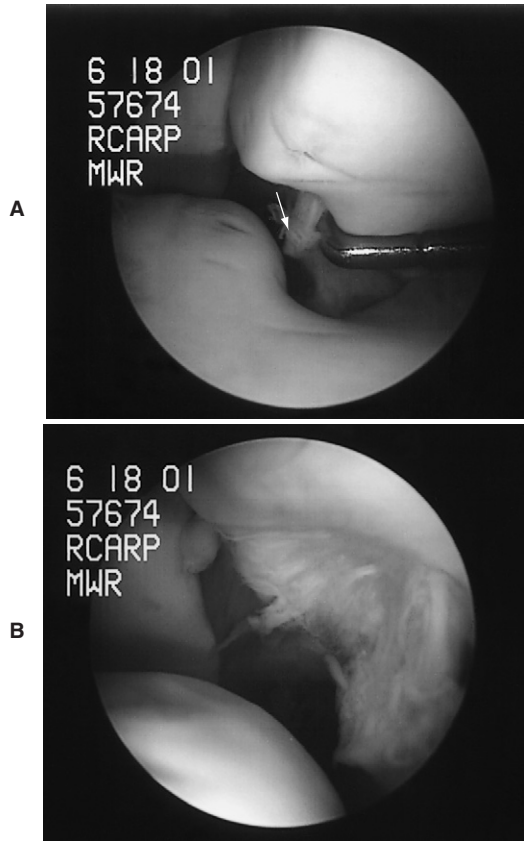

Fig. 23-1 A, Intra-operative arthroscopic image of the left middle carpal joint showing tearing of the medial palmar intercarpal ligament *(arrow)*. Proximal is uppermost, medial is right, and the arthroscopic probe is between the radiocarpal and third carpal bones. The torn medial palmar intercarpal ligament appears as it courses from the third carpal bone to the radial carpal bone. Tearing of the medial palmar intercarpal ligament causes hemarthrosis, a condition previously thought to be idiopathic without arthroscopic examination. **B,** When the medial palmar intercarpal ligament is torn, the palmar aspect of the middle carpal joint can be examined, a finding that is impossible if the ligament is intact.

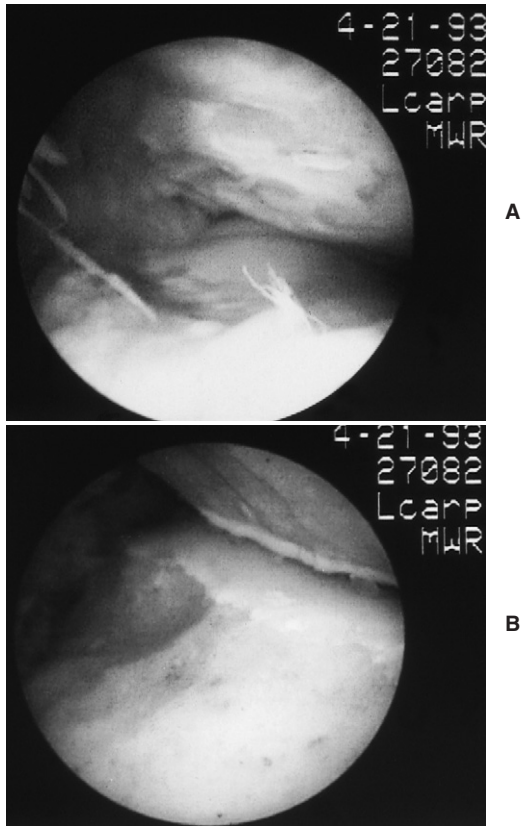

Fig. 23-3 Intra-operative arthroscopic image of the right middle carpal joint showing moderate cartilage damage of the radial carpal (*top*) and third carpal (*bottom*) bones before (**A**) and after (**B**) debridement. The exposed subchondral bone shows considerable damage.

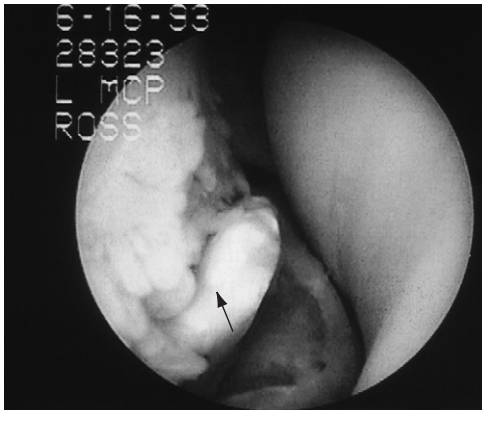

Fig. 23-2 Intra-operative arthroscopic image of the dorsal aspect of the fetlock joint (dorsal is left, proximal is top) showing a large osteochondral fragment *(arrow)* from the dorsomedial aspect of the proximal phalanx. Mild cartilage damage surrounds the base of the fragment with mild scoring of the distal, medial third metacarpal condyle.

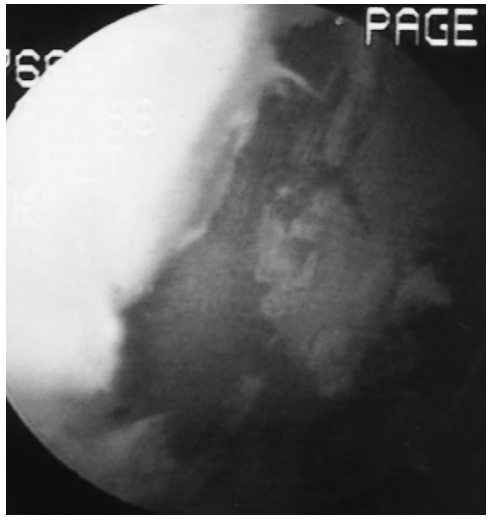

Fig. 23-4 Intra-operative arthroscopic image of the palmar aspect of the right metacarpophalangeal joint showing complete loss of articular cartilage of the lateral proximal sesamoid bone. Not shown are complete full-thickness cartilage and subchondral bone loss on the palmar, medial condyle of the third metacarpal bone indicating severe, near global cartilage loss.

Occult (not radiographically apparent) osteochondral fragments may be diagnosed by arthroscopic examination. Recognition requires inspection and probing, if necessary, after synovial resection. Common sites include the medial aspect of the intermediate carpal and lateral aspect of the radial carpal bones and small fragments involving the proximodorsal aspect of the proximal phalanx. Unexplained tarsocrural effusion (bog spavin) is commonly caused by osteochondritis dissecans fragments of the distal, medial malleolus of the tibia, and although fragments may be suspected radiographically, the presence is confirmed and they are removed arthroscopically. Occult or radiographically suspicious subchondral defects of the third carpal bone, distal medial femoral condyle, and distal MtIII and McIII can be confirmed and debrided.

Most arthroscopic surgery is performed to remove the radiographically apparent osteochondral fragment(s). Grading cartilage damage and subchondral bone damage along with removing one or more osteochondral fragments is important in assessing prognosis. Discovery of severe cartilage damage in horses with few radiographic changes is common, especially in the carpus and fetlock joints. Whenever possible, all aspects of the joint should be evaluated. In racehorses, although cartilage damage and osteochondral fragmentation are often seen dorsally, the palmar/plantar aspect of the metacarpophalangeal joint or metatarsophalangeal joint often has extensive cartilaginous score lines or large, full-thickness areas of cartilage loss on medial McIII and the medial proximal sesamoid bone (PSB) and on the lateral MtIII and lateral PSB. In non-racehorse sport horses, changes are most prominent dorsally. Lesions of the patella, sometimes with fragmentation, found during arthroscopic examination explain why some horses with large osteochondritis dissecans lesions of the lateral trochlear ridge of the femur perform poorly. Arthroscopic examination is useful in horses with infectious arthritis to evaluate articular surfaces and synovium, identify and remove foreign material, facilitate removal of fibrin, and perform much more effective and complete lavage than is achieved by through-and-through lavage. Arthroscopic examination usually is reserved for horses with long-standing infections and those with extensive fibrin accumulation, but the Editors strongly promote its use for acute infection as well. I have not found a good correlation between arthroscopic and ultrasonographic identification of fibrin early in the disease process (amount of fibrin over-estimated by ultrasonography). Arthroscopic examination can facilitate drain insertion, synovectomy, and debridement or removal of osteochondral defects. Arthroscopic portals can be left open to facilitate drainage after surgery, but this procedure should be used only in horses with refractory infections.

SURGICAL PROCEDURES

The specific indications and surgical procedures are discussed in other chapters. Dorsal and palmar/plantar, medial and lateral, and cranial and caudal approaches have been described; the approach, choice of portals, fluid delivery, and instrumentation vary among joints and surgeons. Positioning the horse on the operating table is important to allow access to the involved joint(s) and repositioning may be necessary. Lateral and dorsal recumbency are used successfully, and choices are based on the surgeon's experience and the number of joints affected. Although standing arthroscopy of the fetlock and other joints has been described,[5] I prefer to use general anesthesia.

Minimally invasive surgery such as arthroscopic surgery continues to be developed in horses. Standard procedures include fragment removal, debridement and curettage, partial synovectomy, and incision of adhesions. Reduction, fragment removal, and screw placement in horses with condylar fractures of McIII or MtIII can be done using arthroscopic surgery, obviating the need for arthrotomy. A technique to insert one or more cortical bone screws to repair frontal slab fractures of the third carpal bone was an early advance that has led to use of a similar technique to repair radial carpal and ulnar carpal bone slab fractures, PSB fractures, and other unusually located articular fractures.[6]

Cartilage Resurfacing

Recently cartilage resurfacing techniques in experimental and in a limited number of clinically affected horses have been used. Repair strategy involves creating access to stem cells, growth factors, and blood in subchondral bone to assist in cartilage repair or transplantation (grafting) of tissues, osteochondral grafts, or cells (chondrocytes). Partial- or full-thickness cartilage defects that do not penetrate the subchondral plate heal incompletely or not at all. An important principle in cartilage repair is to curette through the layer of calcified cartilage and perforate the subchondral plate to allow influx of healing elements. Extensive curettage seems to be self-defeating, because exposure of large areas of denuded subchondral bone is associated with a poor prognosis and often is found in horses with naturally occurring osteoarthritis. Unfortunately, many defects already involve complete erosion through subchondral bone, at least around and apposing the primary lesion site. A technique known as *microfracture* of the subchondral plate has been introduced and involves using a 45° or 90° orthopedic awl (micropick) to create small perforation sites into subchondral bone in the area of cartilage damage.[7,8] Studies have shown that removal of the calcified cartilage layer alone, or perforation of the layer with the microfracture technique, improves the amount and quality of repair tissue, but this tissue lacks the biomechanical and histological character of hyaline cartilage.[9] The procedure is currently being used, but objective results compared with routine procedures have not been published.

Nixon[10] has considerable experience in transplantation resurfacing techniques and is focusing current efforts on using autogenous fibrin laden with insulin-like growth factor-1 and chondrocytes harvested from neonatal foals. An arthroscopic technique using a two-component system was used to implant the graft in experimental and clinically affected horses with defects in the carpus and subchondral cystic lesions of the distal medial femoral condyle and in the fetlock joint. Early results appear promising.

A technique called *mosaic arthroplasty* involves using arthroscopic procedures to harvest osteochondral pegs (grafts) from the trochlear groove of the distal femur and implant them in distant recipient sites.[11] Grafts harvested and implanted using special instruments have better congruence than previously reported osteochondral grafting techniques, most using donor sites in the sternum. Mosaic arthroplasty has been used to manage osteochondral defects in the fetlock joint and to attach large osteochondral flaps (osteochondritis dissecans) on the lateral trochlear ridge of the femur using pegs as biological pins.[12] Results appear promising, but the technique is difficult.

Post-Operative Care

Aftercare instructions differ depending on the joint(s) involved, severity of cartilage damage, surgeon's experience, economic factors, and competition schedules. Bandage and wound care, administration of anti-inflammatory analgesic and anti-microbial therapy, and suture removal are routine. Decisions about rehabilitation time should be based on extent of the damage and location but often are made based on the perceived need for a quick return to training and performance. Intra-articular therapy with hyaluronan and polysulfated glycosaminoglycans (PSGAG) is often recommended, and

although such therapy may be beneficial to reduce inflammatory changes in joints early after surgery, little evidence exists that repair is augmented. I generally recommend intra-articular hyaluronan 14 and 28 days after surgery in horses with mild or moderate cartilage damage and PSGAG, administered intra-articularly 3, 5, and 7 weeks after surgery, for horses with severe or global cartilage damage. Treatment with PSGAG given intramuscularly beginning 2 weeks after surgery (once weekly for 8 weeks) is recommended.

COMPLICATIONS

The infection rate after arthroscopic surgery is low, but not zero, and is generally less than other soft tissue and orthopedic procedures performed in the same hospital. Poor case selection and failure to remove the intended fragments are the most common important complications. Intra-operative radiographs should be obtained if any doubt exits about fragments (number and size) removed. Extravasation of fluid, most commonly at the instrument portal but occasionally at the arthroscopic portal, occurs frequently and is of little concern. Fibrous tissue formation at the instrument portal is common if a large amount of cartilage and bony debris is flushed from the joint or removal of several osteochondral fragments required extensive manipulation. Prolonged drainage from any portal should be managed as a potential infectious arthritis. Synovial fistulae occur rarely, but they may require repair. Damage to overlying tendons may cause esthetically unpleasing tenosynovitis that usually responds to injections, but occasionally repair of synoviosynovial fistulae is necessary.

CHAPTER • 24

Tenoscopy and Bursoscopy

Eddy Cauvin

The advantages of arthroscopy as a diagnostic and therapeutic approach to joints[1] have prompted the development of applications for other synovial cavities. *Tenoscopy* is the term used to describe endoscopy of synovial tendon sheaths, usually using a rigid arthroscope.[2] *Bursoscopy* is used for endoscopy of bursae.

Tenoscopy has many advantages. Traditional approaches to tendon sheaths, requiring long incisions over highly mobile areas, are associated with substantial post-operative risks including wound dehiscence and ascending sheath infection.[3] These techniques are invasive, time consuming, and offer limited visibility of tendovaginal structures.[2,3] Endoscopic approaches to the carpal tunnel in people have been described[4,5] and have provided substantial improvements in terms of decreased morbidity, scarring, and loss of function compared with open techniques.[4,6] Tenoscopy in the horse was first described for the examination of the digital flexor tendon sheath (DFTS).[1,2] Since the early 1990s, other applications have been described.[7-11]

GENERAL PRINCIPLES OF TENOSCOPY AND BURSOSCOPY

Equipment

Standard athroscopic equipment is used, including arthroscope, sleeve, and obturators; arthroscopic cannulae; probes; grasping forceps; and Ferris-Smith rongeurs. Sharp tenotomes should be available. A standard 4.0-mm, 25° to 35° forward angle arthroscopic telescope is adequate for most sheaths and bursae, although thinner endoscopes may be useful for extensor sheaths. Light source and video camera apparatuses are as for arthroscopy. Motorized synovial resectors are particularly useful, because debridement or synovec-

although such therapy may be beneficial to reduce inflammatory changes in joints early after surgery, little evidence exists that repair is augmented. I generally recommend intra-articular hyaluronan 14 and 28 days after surgery in horses with mild or moderate cartilage damage and PSGAG, administered intra-articularly 3, 5, and 7 weeks after surgery, for horses with severe or global cartilage damage. Treatment with PSGAG given intramuscularly beginning 2 weeks after surgery (once weekly for 8 weeks) is recommended.

COMPLICATIONS

The infection rate after arthroscopic surgery is low, but not zero, and is generally less than other soft tissue and orthopedic procedures performed in the same hospital. Poor case selection and failure to remove the intended fragments are the most common important complications. Intra-operative radiographs should be obtained if any doubt exits about fragments (number and size) removed. Extravasation of fluid, most commonly at the instrument portal but occasionally at the arthroscopic portal, occurs frequently and is of little concern. Fibrous tissue formation at the instrument portal is common if a large amount of cartilage and bony debris is flushed from the joint or removal of several osteochondral fragments required extensive manipulation. Prolonged drainage from any portal should be managed as a potential infectious arthritis. Synovial fistulae occur rarely, but they may require repair. Tenoscopy and Bursoscopy

Eddy Cauvin

The advantages of arthroscopy as a diagnostic and therapeutic approach to joints[1] have prompted the development of applications for other synovial cavities. *Tenoscopy* is the term used to describe endoscopy of synovial tendon sheaths, usually using a rigid arthroscope.[2] *Bursoscopy* is used for endoscopy of bursae.

Tenoscopy has many advantages. Traditional approaches to tendon sheaths, requiring long incisions over highly mobile areas, are associated with substantial post-operative risks including wound dehiscence and ascending sheath infection.[3] These techniques are invasive, time consuming, and offer limited visibility of tendovaginal structures.[2,3] Endoscopic approaches to the carpal tunnel in people have been described[4,5] and have provided substantial improvements in terms of decreased morbidity, scarring, and loss of function compared with open techniques.[4,6] Tenoscopy in the horse was first described for the examination of the digital flexor tendon sheath (DFTS).[1,2] Since the early 1990s, other applications have been described.[7-11]

GENERAL PRINCIPLES OF TENOSCOPY AND BURSOSCOPY

Equipment

Standard athroscopic equipment is used, including arthroscope, sleeve, and obturators; arthroscopic cannulae; probes; grasping forceps; and Ferris-Smith rongeurs. Sharp tenotomes should be available. A standard 4.0-mm, 25° to 35° forward angle arthroscopic telescope is adequate for most sheaths and bursae, although thinner endoscopes may be useful for extensor sheaths. Light source and video camera apparatuses are as for arthroscopy. Motorized synovial resectors are particularly useful, because debridement or synovec-

tomy using hand-operated instruments can be tedious in large tendon sheaths.

Surgical Principles and Techniques

The basic principles of arthroscopy are also valid in tendon sheaths and bursae. The sheath usually is distended with fluids to facilitate insertion of the cannula. However, this is not necessary for the carpal and tarsal sheaths, which are not approached through distended pouches.[9,10] It is generally recommended that the portal be created with a scalpel and the cannula inserted using a blunt, conical obturator to avoid damaging the tendons. A thorough knowledge of the normal endoscopic anatomy of the sheath is paramount for several reasons. First, all the surfaces are covered by synovium and look alike, making identifying the structures seen difficult. Second, normal anatomical structures such as vinculae (adhesion-like formations carrying blood vessels to the tendon from the parietal sheath), endotenon (reflection of the synovial membrane, which forms a continuous band attaching the tendon to the sheath along its length), and synovial folds are apparent. These should not be damaged, because they participate in the blood supply of tendons within the sheathed portion.[12-14]

Triangulation techniques are applied for instruments using separate portals. These should be created as close as possible to the lesion, although the shape of the sheath often dictates the position of the portals.

TENOSCOPY

Tenoscopy of the Digital Flexor Tendon Sheath

The DFTS is the most common site of tenosynovitis. Endoscopy is indicated as a diagnostic procedure to examine lesions of the surfaces of the deep digital flexor tendon (DDFT), superficial digital flexor tendon (SDFT), and parietal surface of the sheath. High-definition ultrasonography allows non-invasive examination of the sheath, its contents and peripheral tissues, and provides more accurate information about the internal architecture of tendons.[15] However, differentiating some adhesions, tears, and superficial fraying of the tendons may be difficult ultrasonographically.[16] Tenoscopy is useful for debridement of masses, such as villonodular synovitis-like lesions and other lesions within the sheath, adhesiolysis, removal of debris, and synovectomy in infectious tenosynovitis.[2,16,17] Recently a technique for desmotomy of the palmar annular ligament under endoscopic control has been described to avoid inadvertent damage to the tendons, manica flexoria, and other peritenovaginal structures.[18]

The advantages of tenoscopy over traditional open surgery are similar to those recognized for arthroscopy over arthrotomy. They include decreased morbidity and more rapid return to normal function of the sheath and reduced risks of complications, such as wound breakdown, infection, fibrosis, and ankylosis.

Anatomy

The DFTS is organized primarily around the DDFT, which it completely surrounds from the junction between the third and distal quarters of the metacarpal or metatarsal region to the level of the proximal interphalangeal joint, before tapering dorsally to the DDFT to the proximal border of the distal sesamoid bone.[12,13,15,19] At the level of the metacarpophalangeal joint the DFTS also surrounds the SDFT, except for a wide mesotenon over the palmar/plantar aspect of the tendon. At this level the DFTS is bound dorsally by the proximal scutum, a fibrocartilage covering the palmar (plantar) surfaces of the proximal sesamoid bones (PSBs) and intersesamoidean ligament, and palmarly by a tough transverse ligament, the palmar (plantar) annular ligament (PAL), thus forming a non-elastic canal through which both flexor tendons run independently. In the pastern region the SDFT separates into two branches and is no longer within the sheath. The sheath is bound dorsally by the distal sesamoidean ligaments and palmarly (plantarly) by two broad digital annular ligaments.

The proximal pouch bulges when distended proximal to the PAL and PSBs and contains a number of long villi in normal horses. Several small, subcutaneous pouches appear between the insertions of the PAL and digital annular ligaments abaxially and over the palmar (plantar) aspect of the DDFT in the mid-pastern region. A number of vascular structures are found, including two large vinculae forming a V-shaped adhesion-like structure between the dorsal surface of the DDFT and the dorsal sheath wall in the proximal pastern. Densely packed villi often are found in that area. The wide palmar mesotenon prevents examination of the palmar aspect of the SDFT in the fetlock region. Immediately proximal to this level, the manica flexoria forms a smooth, thin membrane originating from the axial surfaces of the SDFT and surrounding the DDFT dorsally.

Surgical Technique

The technique for tenoscopic exploration of the DFTS has been described in detail.[2] The term *palmar* is used in the following description for either palmar or plantar. The horse is placed in lateral recumbency with the affected limb uppermost for a lateral approach or lowermost for a medial approach. The DFTS is distended with 10 to 20 ml of physiological solution through a needle inserted in the palmar aspect of the mid-pastern region. Overdistention of the sheath is avoided because it causes flexion of the digit. A 5-mm longitudinal incision is made through the skin, immediately distal to the PAL, lateral or medial to the DDFT, and 1 cm palmar to the neurovascular bundle, which must be carefully avoided. A stab incision is made into the sheath, taking care to avoid damaging the DDFT, and the cannula, with a conical obturator inserted in a proximal direction, between the DDFT and dorsal sheath wall (Fig. 24-1). The sheath is lavaged through an 18-gauge needle inserted in the proximal pouch. The obturator is

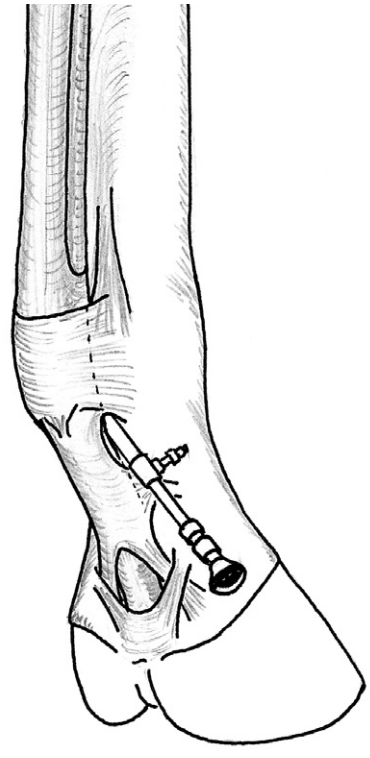

Fig. 24-1 Digital sheath tenoscopy. The arthroscope is inserted lateral to the deep digital flexor tendon, immediately distal to the annular ligament.

replaced with the endoscope, and examination is carried out from proximal to the level of the portal by rotation and gradual withdrawal. The proximal pouch is examined, followed by the abaxial aspects of the two tendons. Flexion of the fetlock joint allows insertion of the endoscope between the SDFT and DDFT without damage to the manica flexoria. The endoscope is finally rotated around the SDFT on the side of the portal to inspect the mesotenon. Examination of the opposite side is possible by flexion of the fetlock and rotation of the arthroscope window palmarly.

The endoscope is then pushed across the sheath, between the DDFT and dorsal sheath wall, to avoid exiting the sheath. The endoscope is then re-directed distally. The distal part of the sheath is examined by gradual withdrawal of the endoscope. The vinculae are visible in the proximal pastern region, between the dorsal surface of the DDFT and dorsal wall (Fig. 24-2). Palmarly and farther distally, bifurcation of the SDFT branches forms a manica-like ring around the DDFT (Fig. 24-3).

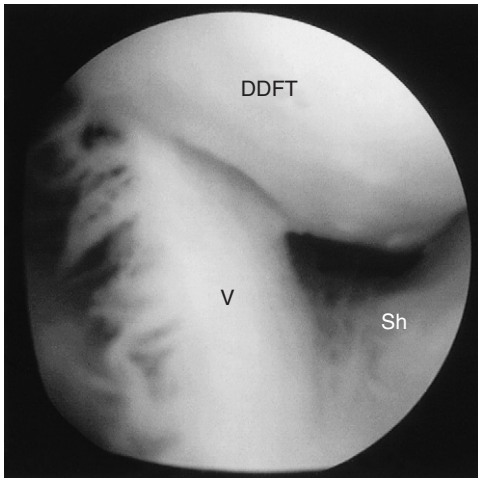

Fig. 24-2 Tenoscopic view of the dorsal aspect of the deep digital flexor tendon (*DDFT*) in the proximal pastern region, showing one of the vinculae (*V*) between the deep digital flexor tendon and dorsal sheath wall (*Sh*).

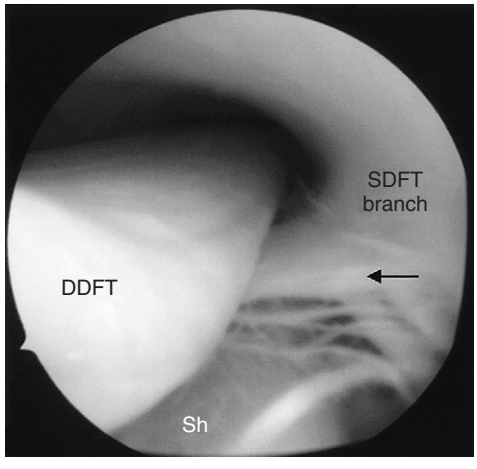

Fig. 24-3 Tenoscopic view of the palmar aspect of the deep digital flexor tendon in the proximal pastern region, showing the manica-like ring (*arrow*) surrounding the deep digital flexor tendon, between the two superficial digital flexor tendon (*SDFT*) branches (within the abaxial sheath walls). The dorsal sheath wall (*Sh*) is rich in long villi.

Debridement of potential lesions is carried out through separate instrument portals made as close as possible to the lesion to allow for adequate triangulation. At the end of surgery the sheath is lavaged through a large-bore cannula and the skin incisions are closed. It is recommended that a pressure bandage be applied for 5 to 7 days postoperatively. In horses with infection with substantial debris accumulation, it is possible to place a drain, exiting in the distal palmar recess through a separate incision.

A technique for transection (desmotomy) of the PAL by endoscopic control has been described,[18,20] using a desmotomy kit designed for palmar carpal ligament transection in people.[4,5] This permits adequate examination of the sheath before PAL transection and prevents inadvertent damage to the tendons and manica flexoria. This is not described here because standard percutaneous techniques are generally adequate.

I have used an alternative technique for digital tenoscopy, using an endoscopic portal made proximal to the PAL, dorsolateral to the DDFT. This technique allows adequate examination of the whole sheath, is useful to examine lesions in the proximal phalangeal region, and provides improved triangulation when surgically treating such lesions. Using a wound as an initial endoscopic portal is often possible, although creating a new endoscope portal and using the wound for instruments is usually preferable after examination is completed.

Post-Operative Care

At the end of surgery the sheath is emptied of fluids and the skin portals are closed with staples or sutures of the surgeon's choice. Damage to the neurovascular bundle by needles and sutures is carefully avoided. The horse recovers with the limb in a pressure bandage from foot to distal carpus (or tarsus) to prevent sheath swelling and to reduce motion. Post-operative antibiotics are only necessary in horses with infectious tenosynovitis, but systemic non-steroidal anti-inflammatory drugs (NSAIDs) should be given for several days after surgery. The horse should be restricted to box rest for 3 days, and then it may be walked out in hand to decrease restrictive adhesion formation. Box stall rest with controlled exercise should be continued for 2 weeks until the sutures are removed, and then at the surgeon's discretion exercise is increased progressively. Hyaluronan has been advocated as an adjunctive therapy[2,17] but should be avoided if infection is present.

TARSAL SHEATH

Injuries to the tarsal sheath are relatively common (see Chapter 77). Open surgery has been associated with a high rate of post-operative complications,[3,10,21] but early results indicate that the morbidity may be greatly reduced with tenoscopy.[10]

Anatomy

The tarsal sheath is the sheath of the lateral digital flexor tendon, the largest of the two tendons (lateral and medial digital flexor tendons), the fusion of which in the proximal metatarsal region forms the deep digital flexor tendon (see Chapter 77).[10,19,22] It is paramount to recognize the anatomical location of the plantar nerves and vessels that pass within the plantar flexor retinaculum and the presence of a continuous mesotenon, passing longitudinally along the plantaromedial aspect of the lateral digital flexor tendon. However, accidental damage to these structures does not appear to have major consequences.

Surgical Technique

A technique allowing examination of the whole sheath has been described.[10] Prior distention of the sheath is not necessary. The medial edge of the sustentaculum tali and medial

insertion of the retinaculum are located, and an 8-mm vertical incision is made in the skin and underlying fascia, 8 mm plantar to the edge of the bone at the point where the tendon changes direction over the sustentaculum tali. The absence of blood vessels in the retinaculum deep to the incision is ascertained using hypodermic needles before making a 5-mm stab incision through the retinaculum. Care is taken to avoid damage to the underlying lateral digital flexor tendon. The endoscope sleeve and conical, blunt obturator are inserted dorsal to the lateral digital flexor tendon in a proximal direction. The obturator is replaced with the endoscope, the sheath is distended moderately with fluids, and examination is carried out as described for the DFTS by rotation of the window of the arthroscope and gradual withdrawal. After examination of the proximal half of the sheath the endoscope is re-directed into the distal pouch. The proximal pouch is large and lined by a thin wall (Fig. 24-4, *A*). Muscle fibers from the lateral digital flexor muscle and separate head of the tibialis caudalis muscle may be seen by transillumination through the synovial membrane. Within the tight, rigid canal formed by the sustentaculum tali and retinaculum, the fibrocartilage appears glistening white, and small vessels are seen within the parietal membrane plantarly and in the mesotenon. In the distal half of the sheath a fold of synovial membrane forming a small, blind pouch medially is seen dorsomedial to the lateral digital flexor tendon at the level of the tarsometatarsal joint (Fig. 24-4, *B*). Distal to this fold, the sheath continues as a cylindrical, blind recess dorsal to the tendon and contains small villi. The separate sheath of the medial digital flexor tendon is not visible from the tarsal sheath.

If a wound exists, most commonly at the plantaromedial edge of the sustentaculum tali, it may be used as an endoscope portal. Instruments may be inserted as required close to lesions to allow for triangulation. Needles are used to determine the optimal location for the instrument portal.

Carpal Sheath

Tenosynovitis of the carpal flexor tendon sheath (carpal sheath) is relatively rare in horses but can cause severe lameness associated with carpal canal syndrome (see Chapter 76). Wounds leading to contamination of the sheath are rare but possible. Common causes of non-infectious tenosynovitis include lesions of the SDFT in the carpal region, fractured accessory carpal bone, osteochondromata of the caudal distal radius, and sprain injuries to the sheath,[23,24] although other causes may exist.[25] Effusion may be secondary to lesions outside the sheath, such as desmitis of the accessory ligament of the DDFT (ALDDFT), accessory ligament of the SDFT, limb edema, and unassociated wounds. Ultrasonography is the technique of choice for investigating carpal sheath distention, but adhesions and subtle fraying of the tendons may not be visible.[24,26] Radiography is also mandatory to rule out fractures and osteochondromata.[23-25,27]

Tenoscopy may be useful as a diagnostic tool if lameness is associated with pain localized to the carpal sheath by intrathecal analgesia but where no lesions are visible with other imaging methods. The main indication for tenoscopy of the carpal sheath is debridement and repair of structures within the sheath.

Anatomy

The anatomy of the sheath has been described elsewhere in detail.[14,18,26] Briefly, the sheath is organized around the DDFT from the distal caudal antebrachium, 4 to 7 cm proximal to the accessory carpal bone, to the metacarpal region. The sheath extends around the DDFT and SDFT in the carpal region, where it is enclosed within a tight canal (the carpal canal) formed by a thick palmar carpal flexor retinaculum palmarly and medially, the accessory carpal bone laterally, and the palmar carpal ligament dorsally. At this level the SDFT is attached palmarly to the sheath wall by a thick mesotenon that contains the median artery and medial palmar nerve. A thinner mesotenon links the DDFT to the SDFT medially. Proximal to the canal a large pouch occurs dorsal to the flexor muscles, bulging laterally and medially caudal to the radius if distended. Distal to the carpometacarpal joint the sheath continues as a blind sack between the DDFT and ALDDFT and bulges dorsolaterally to the DDFT in the proximal third of the metacarpal area. The lateral palmar nerve and palmar veins pass within the retinaculum.

Surgical Technique

Several techniques have been described depending on the lesions identified before surgery. Removal of osteochondromata of the caudal distal radius has been described using an approach through the distended proximal pouch.[8] With the horse in lateral recumbency with the affected limb uppermost the arthroscopic portal is made between the lateral digital extensor and ulnaris lateralis tendons, 3.5 cm proximal to the

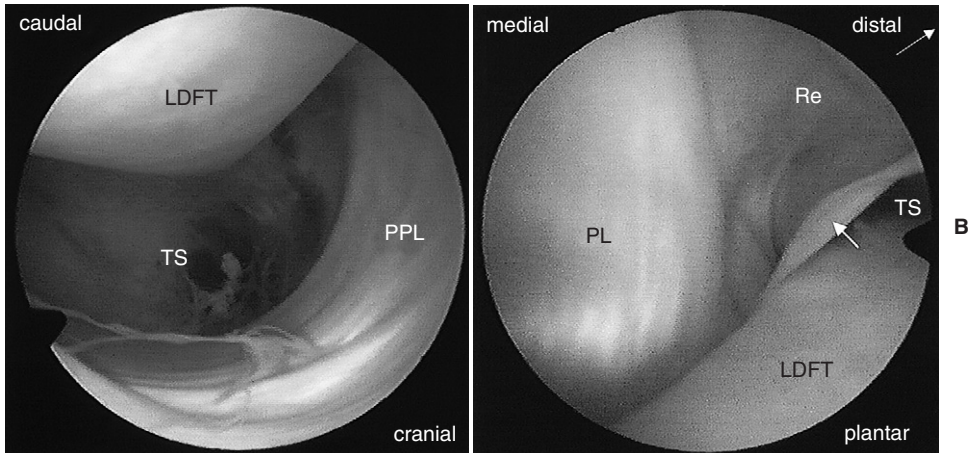

Fig. 24-4 Tenoscopic views of the tarsal sheath. **A,** Proximal pouch of the tarsal sheath (*TS*) showing the cranial aspect of the lateral digital flexor tendon (*LDFT*) and the proximal plantar ligament (*PPL*) thickening of the plantar capsule of the tarsocrural joint. **B,** Distal recess of the tarsal sheath (*TS*). At the tarsometatarsal joint the end of the plantar ligament (*PL*) is visible. A synovial fold (*white arrow*) forms a small recess dorsomedially (*Re*).

distal radial physeal scar, after distention of the sheath. The instrument portal is made on the same side as the arthroscope portal, 2 cm distal to it. A medial approach has also been described.[7]

These techniques do not permit examination of the distal two thirds of the sheath. Therefore another technique has been developed to facilitate endoscopic examination of most of the sheath.[9] The horse may be placed in lateral recumbency with the affected limb uppermost, or in dorsal recumbency with the affected limb suspended loosely, so that the carpus is slightly flexed. An 8-mm longitudinal skin incision is made without prior distention of the sheath 1.5 to 2 cm distal to the distal border of the accessory carpal bone along the lateral aspect of the DDFT. A medial approach is not recommended because examination is restricted by the mesotenons and the risk of injury to the median artery and medial palmar nerve. A needle is used to ensure that no vessels are present in the fascia deep to the incision. The incision is extended with a scalpel through the fascia into the sheath. The arthroscope is inserted proximally, between the DDFT and dorsal wall of the sheath. The proximal pouch is large and contains small villi. The radial head of the DDFT forms a conical prominence in the medial aspect of this pouch. Rotation of the endoscope window and manipulation around the tendons allows examination of the DDFT and SDFT surfaces, caudal surface of the distal radius, and fibrocartilaginous sheath wall in the carpal canal. Minimal fluid pressure should be used to avoid flexion of the carpus. The endoscope may be inserted between the tendons to view the surfaces and the lateral aspect of the mesotenon, covered by short, thin villi. Redirecting the endoscope distally permits examination of the distal recess. A normal, longitudinal synovial fold appears dorsomedially in the sheath in the distal carpal region.

Instrument portals are made where necessary to allow for adequate triangulation. In particular, improved triangulation is obtained for removal of osteochondromata of the distal caudal radius with this method. Major anatomical structures should be taken into account. Post-operative care is as described for other sheaths.

Other Tendon Sheaths

Most tendon sheaths may be examined by tenoscopy, including extensor tendon sheaths in the dorsal carpal and tarsal regions. However, no published reports indicate the use of tenoscopy for these smaller synovial cavities, possibly because acceptable results have been obtained with traditional surgical exposure.[28] I have attempted tenoscopy of the carpal extensor sheaths experimentally in isolated limbs, using a 4-mm, 30° forward endoscope inserted medially or laterally to the tendons, proximal to the carpus. This technique provides acceptable examination of the sheath and tendon surfaces, but little movement is possible because of the tight extensor retinacula.

BURSOSCOPY

Reports of bursoscopy in horses are limited,[11,29] but it is probable that the technique would yield similar advantages to tenoscopy in horses with masses or infection in normal or acquired bursae. Surgical exposure and debridement of hygromas, capped hocks, and metacarpophalangeal subtendonous bursae are often associated with wound dehiscence and chronic infection.[30] However, I am unaware of published data describing bursoscopic examination in these locations. A technique for bursoscopy of the calcaneal bursa of the SDFT has been described and advocated for diagnosis and treatment of injuries to this structure and is probably most useful in horses with infectious bursitis.[29]

Bursoscopy of the Intertubercular Bursa

Bursoscopic surgery has also been used for the management of infectious intertubercular (bicipital) bursitis,[31] and a report describes its use as a diagnostic method in a horse with traumatic bicipital bursitis.[11] The horse is placed in lateral recumbency with the affected limb uppermost. The endoscope is introduced through a craniolateral skin portal, made over the point of the shoulder, immediately cranial to the lateral tubercle of the humerus. The bursa is distended with 40 ml of fluid. The skin incision is continued through the brachiocephalicus muscle and into the bursa, and the endoscope sleeve and conical obturator are inserted in a caudoproximal direction. A technique using two separate portals has been described to improve visibility.[32] The first portal is made into the distal recess through an incision immediately proximal to the deltoid tuberosity. For the second portal, an incision is made cranioproximal to the lateral humeral tubercle to view the proximal half of the bursa. Experience with these techniques is currently limited, but they should provide similar advantages to tenoscopy, including easier access to the sheath, improved visibility, and decreased post-operative morbidity. This needs to be confirmed by more extensive reviews.

Bursoscopy of the Navicular Bursa

Endoscopic examination of the navicular bursa (bursa podotrochlearis)[33] recently has been described as an alternative to the traditional streetnail procedure.[34,35] It is the technique of choice for treating infectious navicular bursitis.

The main indication for bursoscopy of the navicular bursa is as a surgical approach for treating a contaminated or infected bursa.[33] Other indications include diagnostic examination in horses with pain localized to the palmar aspect of the foot but with no lesions identifiable using other imaging modalities and the debridement of adhesions between the navicular bone and the dorsal surface of the DDFT.

Surgical Technique

Standard arthroscopic equipment is used, although a thinner, 4-mm diameter or less, endoscope is more practical. The horse is placed in lateral recumbency with the metacarpal or metatarsal region supported and the digit moving loosely. A medial approach with the affected limb lowermost or a lateral approach with the limb uppermost may be used. A vertical, 5-mm skin incision is made along the abaxial border of the DDFT, 1 cm proximal to the cartilage of the foot and palmar/plantar to the neurovascular bundle. The cannula, with a conical obturator, is inserted distally and slightly axially, dorsal to the DDFT. The obturator is replaced with the endoscope. Rotation of the endoscope allows examination of the whole bursa, including the smooth dorsal aspect of the DDFT and palmar fibrocartilage of the navicular bone. The collateral (suspensory) ligaments of the navicular bone, blending over the proximal surface of the navicular bone into the fibrocartilage and the impar ligament, in the distal recess of the bursa, are covered by synovium with thin villi. The larger proximal pouch and the T-ligament are also covered by synovium.

A wound in the sole, sulci, or frog can be used for insertion of cannulae or instruments into the bursa. Some enlargement of the tract using curettes or a motorized synovial resector may be required but should be minimal to limit damage to the DDFT. If access through the wound is difficult, or to reach a lesion that cannot be accessed this way, a similar approach to that used for the endoscope may be made on the opposite side of the limb.

The bursa is lavaged and any lesions are debrided sharply. Partial synovectomy may be carried out if necessary. The use of motorized synovial resectors is recommended. At the end of the procedure the opening of a sinus tract on the solar surface of the foot may be enlarged and debrided to avoid abscess formation. Debridement of the defect through the

DDFT should be minimal. An aminoglycoside antibiotic may be placed in the bursa, and the skin incisions are closed routinely. A bandage including the whole hoof and extending to the proximal metacarpal or metatarsal region is applied.

Post-Operative Management and Results

Post-operative use of antibiotics and NSAIDs is at the surgeon's discretion. The horse can be walked out in hand after 2 or 3 days, and exercise can be gradually resumed after healing of the wound is complete, in the absence of complications.

Complications of infection include recurrence, extension of the infection into adjacent synovial structures, and osteitis or fracture of the navicular bone.[33,35] Contamination of the distal interphalangeal joint or DFTS may be treated during the initial surgery by an endoscopic approach using the same skin portal.[33] If infection recurs, lavage through needles or bursoscopy may be performed, and an open approach through the solar surface may be used, but the prognosis should then be considered graver.

The prognosis for horses with infectious navicular bursitis using this approach[33] appears to be greatly improved compared with the more invasive streetnail procedure.[35] Seventy-five percent of horses returned to the initial use after bursoscopy versus 31.5% using the open technique, although the criteria used to judge success may be slightly different.[33] Bursoscopy is considered to be the technique of choice for infectious navicular bursitis, although I recommend using a streetnail approach for the salvage of horses with chronic bursitis with extensive damage to the podotrochlear structures.

CHAPTER • 25

Thermography: Use in Equine Lameness

Tracy A. Turner

DEFINITION

Thermography is the pictorial representation of the surface temperature of an object.[1,2] This non-invasive technique is used to detect superficial inflammation and therefore may be helpful in the early diagnosis of some causes of lameness. The examination must be performed in a draft-free room protected from sunlight. The hair coat must be of uniform length. Clipped areas or regions that have been bandaged or had topical applications produce erroneous results.

Heat dissipates through the skin by radiation, convection, conduction, or evaporation.[2] Skin temperature is generally 5° C cooler than body core temperature (37° C). Skin derives its heat from the local circulation and tissue metabolism.[3] Tissue metabolism is generally constant; therefore variation in skin temperature is usually caused by changes in local tissue perfusion. Normally, veins are warmer than arteries because they are draining metabolically active areas. Venous drainage from tissues with a high metabolic rate is warmer than venous drainage from normal tissues.

The circulatory pattern and the relative blood flow dictate the thermal pattern that is the basis for thermographic interpretation.[2] The normal thermal pattern of any area can be predicted based on vascularity and surface contour. Skin overlying muscle is subject to temperature increase during muscle activity. The midline of the back, the chest, and between the rear legs and the ventral midline are generally warmer than the rest of the trunk. Heat over the limbs follows the cephalic and saphenous veins.[1,2]

SPECIFIC USES TO DETERMINE INJURY

Foot

Thermography may provide information concerning laminitis, palmar foot pain, sub-solar, or sub-mural abscesses, corns, and other inflammatory conditions of the hoof, especially if the results of clinical and radiographic examinations are inconclusive.[1,2,4]

Normally the coronary band is the warmest area of the limb, and diagnosis of inflammation can be difficult in this location.[1] All hooves should be compared thermographically. A difference of more than 1° C between hooves may be significant. However, in the Editors' experience, there may be quite marked differences in foot surface temperatures in normal horses, especially in cold ambient temperatures. If all feet are affected, the hoof temperature should be compared with that of the area between the bulbs of the heel.

A change in thermal pattern of the hoof wall is useful in recognizing laminitis (see Fig. 118-3, *B*). Generally the coronary band is 1° to 2° C warmer than the remainder of the hoof. As the hoof begins to approach the temperature of the coronary band, this indicates an inflammatory problem. Thermography can be helpful for monitoring a limb at risk to develop laminitis from excessive load bearing because of severe lameness in the contralateral limb. It may be possible to detect inflammation in the contralateral foot before lameness is evident. Preventive therapy can then be instituted sooner, and hopefully before the laminitis is irreversible. Results of thermography may be affected by existing preventative measures used in high-risk patients such as ice baths, and if laminitis is bilateral, a difference will not be detected.

I have never identified a consistent thermal pattern associated with palmar hoof pain, but I have recognized reduced blood flow in some horses.[5] The foot is thermographically evaluated before and after exercise. A normal horse has a 0.5° C increase in foot temperature after exercise, but about 50% of horses with palmar foot pain syndrome have no increase temperature in the palmar aspect of the foot, possibly from low blood flow or other factors. Focal inflammatory conditions of the hoof such as abscesses, bruises, and fractures are characterized by focal areas of increased temperature that correspond to the site of injury (Fig. 25-1; Color Plate 1). Exercise intensifies the area of increased temperature.

Joints

Most joints are best evaluated from the dorsal aspect.[4,6] A normal joint is cool compared with the surrounding structures, but the hock joint has a vertical area of increased temperature medially corresponding to the saphenous vein. With inflammation, an oval (or circular in distal joints) area of increased temperature is centered over the joint and is widest

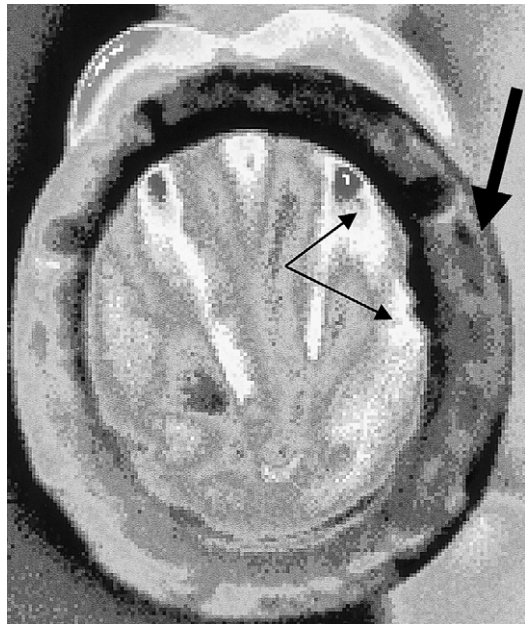

Fig. 25-1 Thermal image of the sole of a horse's foot showing asymmetrical heat in the sole of the hoof (*small arrows*). The shoe on that side (*bold arrow*) is colder, indicating less friction on the shoe, probably as a result of avoiding the injured sole.

horizontally, medial to lateral. The areas of joint capsule attachment tend to be hotter, but the center of the joint is relatively cooler. This may be the result of joint swelling or pressure and subsequent loss of microcirculation. Thermography does not appear reliably useful to detect joint damage, because joint temperature is influenced by chronicity and inflammatory changes affected by the amount of cartilage damage and the presence or absence of osteochondral fragments. However, thermal patterns of joints changed 2 weeks before lameness because of osteoarthritis; therefore by detecting inflammation before clinical signs are evident, training programs can be modified to reduce the risk of more serious injury.[6]

Long Bones

A bone must be superficial to affect skin temperature.[7] Bones that are heavily covered with muscle cannot be accurately assessed by thermography. Thermography may be useful for evaluation of the bucked-shin complex (see Chapter 104) or stress fractures of the radius or tibia. Thermographic changes may precede radiographic changes by up to 2 weeks.[4]

The bucked-shin complex is categorized into three grades.[8] Grade 1 is characterized by eliciting pain on palpation of the third metacarpal bone (McIII), but with no detectable radiographic abnormality. Grade 2 is characterized by pain and radiographic evidence of subperiosteal callus. Grade 3 is characterized by pain and radiographic evidence of a stress fracture. Grades 2 and 3 may be indistinguishable, and radiographic confirmation of a stress fracture may not be possible for 2 to 3 weeks. Thermal variations between grades 2 and 3 may result in earlier diagnosis. Grades 1 and 2 are characterized by an area of increased temperature 1° to 2° C warmer than the surrounding tissues over the dorsal aspect of McIII. Grade 3 disease has a more widespread area of increased temperature, 2° to 3° C warmer than the surrounding tissues, and this is usually visible on the lateral and medial views, in addition to the dorsal view.

Tendons

Normal flexor tendons have elliptical isothermic zones that are bilaterally symmetrical.[9,10] The lowest temperature is centered over the palmar aspect of the tendons, and the peripheral areas near the carpus and fetlock are approximately 1° C warmer.

Acute tendonitis causes an area of increased temperature over the site of the tendon lesion[10] and may be demonstrated up to 2 weeks before physical evidence of swelling and pain (see Fig. 118-4). Thus tendon lesions of potentially clinical significance can be identified, and adjustments in the training protocol can be made to prevent further damage to the tendon.

As a tendon heals, the thermal pattern becomes more uniform but remains abnormally elevated compared with normal tendon.[10] As the lesion heals and scar tissue is deposited, the skin over the injured area may actually show a decrease in temperature, whereas the remaining neovascularized tendon continues to have increased thermal emissions. During the assessment of healing the thermal changes do not correlate well to the structural reorganization of the tendon matrix as assessed by ultrasonography.[11] The thermal pattern diffuses so an area of increased temperature no longer is apparent, but an overall increased thermal emission from the damaged tendon may occur compared with normal. Mechanical stress proximal to an injury can aggravate existing tendon damage, and thermography can be used to detect new injury so that changes in management are made accordingly.

Ligaments

Ligament injuries appear similar to tendon injuries, with an area of increased temperature centered over the injured area. However, somewhat paradoxically, proximal suspensory desmitis may be associated with an area of increased temperature over the proximodorsal aspect of McIII. Thermography is most useful in correlating whether heat is associated with a sensitive ligament, especially the suspensory ligament (SL). Horses often resent palpation of the body of the SL. Thermography can determine if associated inflammation exists (Fig. 25-2; Color Plate 2). Thermography can detect whether inflammation of the SL is associated with an exostosis on the second or fourth metacarpal bones.

Muscles

Identification of damaged muscles may be difficult clinically. Thermography may be able to locate an area of inflammation associated with a superficial muscle or muscle group and may identify atrophy before it is clinically apparent.[12]

Muscle inflammation is usually identified as an area of increased temperature in the skin directly overlying the affected muscle.[12] Rarely, swelling and edema in the affected muscle is severe enough to inhibit blood flow through the muscle; the injured muscle is seen as an area of decreased temperature. The right and left sides must be compared and are normally nearly identical. Consistent variations from side to side indicate muscle damage at either the area of increased temperature or decreased temperature.

The most common cause of muscle inflammation is muscle strain. A classification of first-, second- or third-degree strain

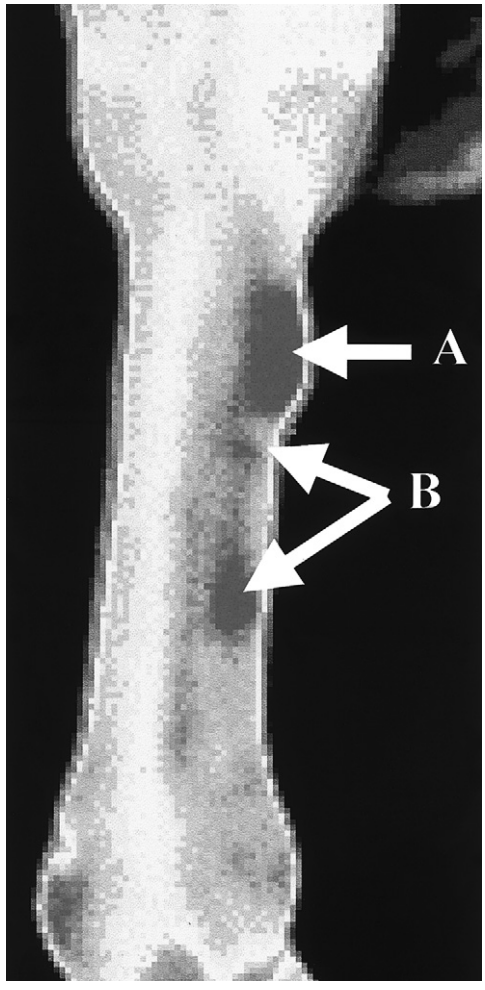

Fig. 25-2 Thermal image of the left medial metacarpal region showing an active splint (*A*) that is causing secondary inflammation in the suspensory ligament distal to the injury (*B*).

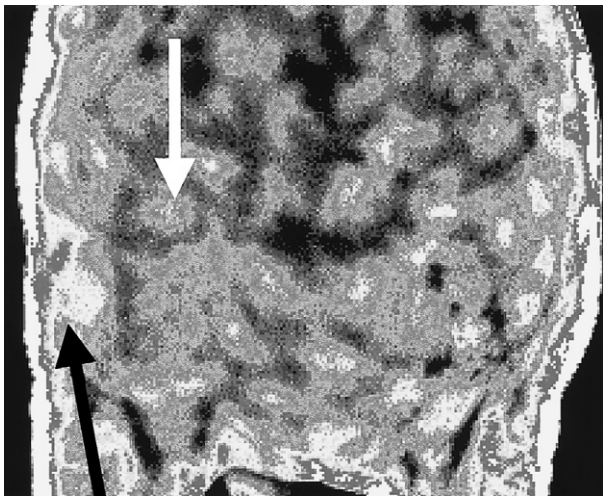

Fig. 25-3 Thermal image, front view, of a horse's chest showing increased heat over the lateral aspect of the right shoulder (*black arrow*) and decreased heat over the right bicipital tendon *(white arrow)*. Ultrasonography showed increased fluid in the intertubercular (bicipital) bursa. The decreased heat over the muscle was presumed to be due to lack of use because of pain.

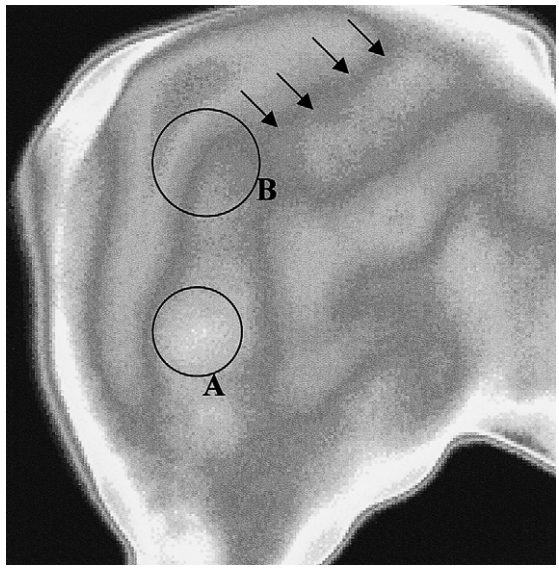

Fig. 25-4 Thermal image of the lateral view of the right hip region showing increased heat over the third trochanter (*A*) and greater trochanter (*B*). In addition, the body of the gluteal muscle has increased heat (*small arrows*). This condition was diagnosed as a gluteal muscle strain.

injuries, described in human athletes, has been applied to horses.[12] Muscle strains have not been commonly documented in the forelimb, but I have identified pectoralis and shoulder extensor muscle injuries (Fig. 25-3; Color Plate 3). Croup and caudal thigh myopathies are better recognized. Croup myopathies are strains of the longissimus, the origin of the gluteus medius (level of the sacroiliac), the body of the gluteus medius, and the insertion of the gluteals on the greater and the third trochanters of the femur (Fig. 25-4; Color Plate 4). Caudal thigh myopathies consist of injuries to the biceps femoris, semitendinosus, or semimembranosus muscles. Injuries to the biceps femoris and semimembranosus most commonly are mid-body muscle strains, but semitendinosus injuries usually occur at the musculotendonous junction.

Vertebral Column

Injuries to the vertebral column are characterized by areas of increased temperature, decreased temperature, or root signatures. Results of thermography may suggest the need for radiography if a luxation, subluxation, or fracture is suspected.

The thermographic evaluation is performed from above the animal (top line view) for the thoracic, lumbar, and sacral vertebrae. Images made from the left and right sides are used to evaluate the cervical vertebrae. Injuries generally are located along the midline. The thermal area directly corresponds to the injury. Areas of decreased temperature noted over the vertebral column, unlike other areas, are not seen in horses with chronic injuries and may suggest more recent injuries associated with marked swelling, which may affect the autonomic nerve supply. *Root signatures* are linear increases in temperature that follow nerve roots from the vertebral column. They theoretically occur because of irritation to the local sympathetic nerves. They can involve the entire sympathetic trunk where an entire side will have an increased temperature, such as occurs in Horner's syndrome.[13]

Sacroiliac subluxations have been associated with a distinct thermal pattern, with a focal area of decreased temperature between the two tubera sacrale. This correlates with ultrasonographic evidence of sacroiliac ligament damage.[14]

The use of thermography for assessing saddle fit is discussed in Chapter 118.

EDITORS' NOTE: In our experience, the results of thermography do not always correlate with the results of other diagnostic techniques, and therefore, while recognizing the potential value of the technique, consider that results must be interpreted with care.

CHAPTER • 26

Clinical Investigation of Foot Pain

Kevin Keegan and Sue J. Dyson

Many aspects of clinical examination are discussed in Chapters 2 to 8 and are not repeated here. This chapter considers some specific aspects in more depth.

DETAILED EXAMINATION OF THE HOOF

Visual Examination

The hoof is specialized epidermis that responds to stress and tissue damage by altering growth. The gross appearance of the hoof therefore provides visible clues to abnormalities of the entire foot. Potential lameness can be anticipated by early recognition of hoof abnormality. Overall size and shape of the hoof and the character of the hoof wall, sole, frog, and coronary band should be noted. The veterinarian should inspect the hoof from many directions, from a distance and close up, and palpate a clean hoof wall, sole, and coronary band. The veterinarian should note broken-back or broken-forward hoof wall-to-pastern axes, under-run heels, sheared heels, contracted heels, and excessively small feet, which are discussed in detail in Chapters 4, 27, and 28.

The white line is the junction between the tubular horn of the sole and the soft horn (epidermal laminae) of the hoof wall and is a potential space. The white line should parallel the weight-bearing surface of the hoof wall and should be of uniform thickness (approximately 3.5 mm) throughout its curvature. Mechanical trauma, nutritional dysfunction, excessively wet or polluted environments, microorganism invasion, or underlying physical or metabolic dysfunction, such as with laminitis, may cause horn damage and cleft formation within the white line. Poor or abnormal hoof growth for any reason increases vulnerability. A widened white line is evidence of hypertrophic laminar growth in response to epidermal injury. Metaplastic differentiation of damaged epithelial cells at the laminar surface creates friable, granular horn within the white line, a condition called *seedy toe.* Cleft formation is more common with a widened white line and in the seedy toe condition, predisposes the sensitive tissues of the foot to contamination.

Evaluation of the foot should consider the ratio of the horse's weight to overall foot size. Heavy horses with small feet are more prone to develop foot-related lameness conditions and generally have more guarded prognoses. A crude formula has been created that relates body weight to weight-bearing surface area of the foot. The weight-bearing surface area of the foot can be estimated by measuring the circumference of the foot just below the coronary band. Performance horses with body weight to single foot surface area above 5.5 kg/cm^2 have an excessive weight/area ratio. Decreasing body weight by feed manipulation or increasing weight-bearing surface area of the foot by shoeing should be recommended for large horses with small feet.

Evaluating Hoof Wall Surface

The hoof wall is a keratinized avascular, stratified squamous epithelium. Two different types of gross structure may be seen during close examination and palpation of the hoof wall. Small, slender lines that run parallel to the long axis of the hoof are *horn tubules.* Horn tubules are normal hoof wall structures that propagate distally from a basal layer of cells at the coronary band. Irregular, raised, or recessed transverse lines (rings) that run parallel to the coronary band are evidence of dysfunction in hoof wall growth. Laminar hyperplasia occurs in response to injury. Substantial ring formation in a single foot indicates previous abnormality or stress to that limb. Changes in nutritional status, activity level, environmental conditions, or other physiological stress, such as septicemia, cause rings to appear in all feet. Rings move distally as the hoof wall grows.

Width of rings correlates roughly with the duration of previous stress or hoof-related abnormality, and the distance of rings from the coronary band gives some indication of how long ago the stress or abnormality occurred. An increase in the distance between rings at the heel compared with the toe (diverging rings) indicates slower relative hoof wall growth at the toe, previous laminar damage, and diminished blood supply to the dorsal regions of the foot.

In a normal horse within a normal environment the hoof wall grows distally at a rate of approximately 8 to 10 mm per month or about 0.14 to 0.2 mm per day. In horses with laminar inflammation this increases to about 0.25 mm per day.[1] In a study of Lipizzaner horses the rate of growth for control animals and those given biotin supplements was 7 mm in 28 days, resulting in a renewal period for the entire hoof wall of about 11 months.[2] Other estimates put complete hoof wall regeneration at 12 months, 6 to 8 months, and 4 to 5 months for the hoof wall at the toe, quarter, and heel, respectively.[3]

Palpation

Hoof wall temperature may vary between limbs in a normal horse and may partially reflect environmental temperatures. The hoof wall may be unusually warm in association with a sub-solar abscess or laminitis. Assessing the amplitude of the pulses in the medial and lateral digital arteries can be an excellent aid in identifying foot pain, particularly associated with a sub-solar abscess, sub-solar hemorrhage, nail bind, or laminitis. Assessment is easy in most horses but difficult in heavy cobs and draft breeds in which thick skin and a thick, long hair coat may make accurate palpation impossible. Diffuse filling in the metacarpal and pastern regions may reflect severe inflammation in the distal part of the limb caused by sub-solar abscessation. Careful palpation of the coronary band may reveal a softer region, from a long-standing sub-solar abscess, through which pus could potentially drain. Assessing the coronary band is also important in laminitis, because depression at the coronary band may be the first sign of sinking (distal displacement) of the distal phalanx.

The foot should be palpated bearing weight and not bearing weight. With the limb picked up the stability of the bulbs of the heel can be assessed by grasping each bulb with the left and right hands and determining whether movement occurs between the two, indicating sheared heels. Firm pres-

sure should be applied over the distal palmar aspect of the pastern to determine whether pain can be elicited, which may reflect injury of the deep digital flexor tendon (DDFT).

Hoof Tester Application

A complete examination of the foot includes a thorough and proper application of hoof testers to the hoof capsule. Many different kinds of commercially and custom-made hoof testers are available. The most useful are those that are adjustable, to enable the user to apply them across differing widths of the foot, and large enough to allow the user to grip and apply pressure to both handles with one hand. For complete evaluation the hoof testers should be applied across the heels, from one frog crura to the opposite hoof wall at the quarter, and along the periphery of the foot from the sole to the hoof wall. When applied across the heels, the contact points of the hoof testers should be centered approximately between the coronary band and the bottom of the hoof. Force of application should be strong enough to move the heels slightly axially. When applied from the frog to the quarters, the contact points of the hoof testers should be at the middle of the frog and midway between the coronary band and the bottom of the foot at the quarter. Force of application should be strong enough to depress the frog noticeably. When applied across the sole and hoof wall, the force of application should be strong enough to incur slight indentation in the solar surface. A positive response is interpreted when the foot is continually withdrawn in synchrony with consistent application of pressure. In horses with a very compressible thin sole, careful comparison should be made with the responses in each foot. Hoof testers are helpful for localizing foot abscesses, identifying nail bind or prick and sub-solar bruising, and checking preliminary suspicion of acute laminitis, distal phalangeal fracture, and navicular disease, provided that the foot is not excessively hard. However, in one study, only 11% of animals with navicular disease responded to the use of hoof testers. Percussion can be applied to the hoof wall or the sole using hoof testers or a hammer and can also be valuable in identifying a subsolar abscess, nail bind or prick, laminitis, laminar tearing, and an unstable hoof wall crack or a fracture.

OTHER PROVOCATIVE TESTS

Frog Pressure Test

Direct pressure is applied to the frog and underlying structures during the frog pressure test. The horse is forced to stand on a hard object placed under the frog by the veterinarian picking up the opposite limb. The object should be firm, small enough to prevent sole and hoof wall contact, but large enough to avoid trauma to the frog. The wooden handle of a farrier's hammer is well suited for this. The horse is forced to stand on the object for 1 to 2 minutes and then observed for lameness at a trot. This test is valuable for assessing horses with suspected navicular disease, navicular bursitis, distal DDFT pain, and bruising of the sensitive frog tissues. Horses that respond more positively to this test than to the reverse wedge test are presumably more adversely influenced by ground impact and may benefit more from application of shock-absorbing pads to the foot than by changing the dorsal hoof wall angle.

Reverse Wedge Test

The reverse wedge test applies tensile stress to the DDFT, and indirectly, compressive force to the navicular bursa and bone. The reverse wedge test also tenses the navicular suspensory ligaments. An object is placed underneath the toe; the handle of a farrier's hammer works well. The horse is forced to stand with the toe elevated for 1 to 2 minutes by the veterinarian picking up the opposite limb and is then observed for lameness at a trot. Some horses with navicular disease show increased lameness. Horses that respond with increased lameness to this test, but not to the frog pressure test, presumably have a better chance of responding favorably to heel elevation or extension than to the addition of shock-absorbing pads to the foot.

Distal Limb Flexion Test

For the distal limb flexion test the distal limb is elevated with as little carpal flexion as possible. The toe of the foot is grasped and pulled proximally, while the distal metacarpal or metatarsal region is stabilized. This stresses all of the distal limb joints and the soft tissue structures on the palmar/plantar aspect of the distal limb (distal sesamoidean ligaments, flexor tendons, and navicular bursa). Withdrawal of the limb during flexion, following 1 minute of continuous flexion, may reflect pain or dysfunction in any of these distal limb structures. The distal limb flexion test greatly depends on evaluator technique and therefore is not very specific.[4]

NERVE AND JOINT BLOCKS

Localization of lameness to the foot is facilitated by perineural or intra-thecal analgesia of the distal limb (see Chapter 10). The abaxial sesamoid nerve block may be used to determine quickly if the foot is the source of pain, whereas the palmar/plantar digital nerve block is used to isolate more specifically the source of pain. Intra-articular analgesia of the distal interphalangeal joint and intra-thecal analgesia of the navicular bursa are used to localize the source of pain to these specific areas. Each of these techniques is described briefly, but care must be taken in interpretation because no block is specific. A combination of techniques probably gives the most information.

Palmar/Plantar Digital Nerve Block

The palmar/plantar digital nerves may be blocked anywhere along the length between the distal aspect of the proximal sesamoid bone (PSB) and the proximal extent of the cartilage of the foot. Deposition of local anesthetic solution more distally can be expected to be more specific than deposition more proximally and is less likely to block dorsal branches inadvertently, thereby desensitizing the entire foot, but this has not been substantiated. The needle (20- to 25-gauge) is inserted subcutaneously directly over the nerve. It is advisable to use small amounts of local anesthetic solution (1 to 1.5 ml) to decrease the likelihood of inadvertent analgesia of dorsal branches. Many more structures than previously thought are affected by palmar/plantar digital analgesia.[5]

A successful palmar/plantar digital nerve block desensitizes some of the skin surface along the back of the heel bulbs but should not desensitize the skin over the dorsal coronary band, although it often does. The area of heel desensitization varies from horse to horse and can be limited to a small area between the heel bulbs or encompass the entire area on the palmar surface of the distal limb distal to the level of needle insertion. In the hindlimb, medial and lateral dorsal metatarsal nerves may also supply plantar structures distal to the metatarsophalangeal joint.[6] Therefore in the hindlimb, additional subcutaneous deposition of local anesthetic solution may be necessary over the dorsal pastern at the same level, but this also desensitizes dorsal structures of the foot, negating the utility of the block for lameness diagnosis. Careful checking for effectiveness and area of desensitization is important for proper evaluation of lameness. A horse may be somewhat apprehensive after the needle insertions and frequently picks up the limbs randomly when approached. The clinician should ask the person holding the horse to cover its eye.

Checking the blocked limb from the contralateral side is useful after first touching the contralateral limb. This gives the horse the impression that the veterinarian will now be manipulating that limb. If the block is successful, the horse will not withdraw the limb when the skin is touched lightly or pressed hard with a blunt point, such as a key or tip of a pair of artery forceps. If local anesthetic solution is deposited immediately around the nerve trunk, the block is effective within a few minutes. Deposition of local anesthetic solution a few centimeters from the nerve trunk may be effective after a longer period. Effectiveness for lameness reduction should not be finally decided until at least 10 minutes after injection.

Some evidence indicates that a palmar digital nerve block changes the biomechanics of the blocked and contralateral unblocked limbs, even in a normal horse.[7,8] Presumably, the horse's proprioceptive ability is partially affected, but the change is slight and unlikely to affect subjective evaluation of lameness.[7,8]

A biaxial palmar digital nerve block is most frequently used to diagnose navicular disease in the forelimb but also improves lameness from many other causes, but the diagnosis of navicular disease should not be based only on a decrease in lameness subsequent to this block. Many horses with navicular disease also do not respond completely to the palmar digital nerve block because of concurrent flexor tendon, suspensory ligament, distal interphalangeal joint, distal phalanx, or shoulder area pain. Uniaxial palmar/plantar digital nerve block may be used to confirm lameness caused by uniaxial injury or infection of the cartilage of the foot (sidebone, quittor), distal interphalangeal or proximal interphalangeal joint exostoses, or nonarticular palmar process fracture of the distal phalanx.

Abaxial Sesamoid Nerve Block

The abaxial sesamoid nerve block is performed distal to the dorsal branching from the main trunk of the digital nerve over the abaxial surface of the PSB. Although the block is performed distal to the dorsal branching, the dorsal branches are desensitized because of the close proximity of the dorsal branches to the main nerve trunk at this location. A successful abaxial sesamoid nerve block desensitizes most of the skin distal to the fetlock joint. Occasionally horses retain some dorsal skin sensitivity, especially in a hindlimb. It is important to recognize that with severe pain associated with a sub-solar abscess, a fracture of the distal phalanx, or laminitis, apparent desensitization of the foot may in some horses have no effect or only a partial effect on lameness. It is also important to be aware that local anesthetic solution, through local spread and proximal diffusion, may alleviate pain at the level of the block or proximal to it.

Distal Interphalangeal Joint Block

Intra-articular analgesia of the distal interphalangeal joint is not specific, and peri-articular structures of the foot are also desensitized, presumably because of direct analgesia of the palmar/plantar digital nerves because they lie near the abaxial surfaces of the joint. Local anesthetic solution also diffuses into the navicular bursa in levels sufficient to desensitize intrabursal tissues, improving lameness caused by primary navicular bursal inflammation[9] or navicular disease. However, up to 20% of horses with navicular bone pain have a negative response to intra-articular analgesia of the distal interphalangeal joint.[10] Many approaches are used, including a lateral approach, which is easier to perform when the limb is not bearing weight (see Chapter 10).[11]

Navicular Bursa

A variety of techniques have been described for injection of the navicular bursa (see Chapter 10). The needle should ideally be directed toward the middle third of the navicular bone, from proximally to distally, to avoid inadvertent penetration of the palmar pouch of the distal interphalangeal joint or the digital flexor tendon sheath (DFTS). Retrieval of synovial fluid generally means that the needle is in the distal interphalangeal joint or the DFTS. The response to intrathecal analgesia should be assessed within 5 minutes of injection. Occasionally if lameness is not improved, a horse may appear transiently much lamer after intra-bursal analgesia, probably because of injection of excessive volume (>4 ml). Intra-thecal analgesia of the navicular bursa can improve pain associated with the bursa, the navicular bone, the distal sesamoidean impar ligament, the collateral ligaments of the navicular bone, and sometimes the DDFT and the distal interphalangeal joint.

RADIOGRAPHIC EVALUATION

Because slight radiographic changes can denote serious problems, good radiographic technique and patient positioning are vital. Proper preparation of the foot is important, because prominent radiographic artifacts may be created by the uneven surfaces of the sole and frog or by radiodense dirt and gravel packed into the bottom of the foot. To eliminate such artifacts, the shoe should be removed and the foot trimmed and the frog sulci packed with clay or modeling compound (e.g., Play-Doh; Hasbro, Inc., Pawtucket, R.I.) before radiographs are obtained.

Equipment and Technique

Because of the small size of the equine foot, good-quality radiographs can be obtained with small portable x-ray machines. Inconsistent power supplies in the field, exacerbated by excessively long extension cords, may compromise the quality of radiographs. A length of 7.5 m is acceptable, but a cord longer than 15 m can cause a loss of up to 30% of the electrical energy supplied to the x-ray machine. A standard radiographic technique for evaluation of the foot using a portable machine and a standard 400 speed film-screen system would be 80 kVp, 10 mA, for 0.06 to 0.08 seconds or 100 kVp, 10 mA, for 0.04 to 0.06 seconds at a film focus distance of 50 cm.

Views: Positioning and Evaluating Images

A standard radiographic series of the equine foot includes lateromedial, dorsopalmar, dorsoproximal-palmarodistal oblique (upright pedal; DPr-PaDio), and palmaroproximal-palmarodistal oblique (PaPr-PaDio) views. Two DPr-PaDiO (upright pedal) views should ideally be obtained, one exposed to evaluate the margins of the distal phalanx and the other well collimated and exposed to assess the navicular bone. Alternatively, views of the distal phalanx and navicular bone can be obtained with the horse standing on the cassette using dorsal 65° proximal-palmarodistal oblique views, but this results in more distortion. Flexed oblique (dorsolateral-palmaromedial and dorsomedial-palmarolateral oblique) views are useful for evaluating the articular margins of the interphalangeal joints and the palmar processes of the distal phalanx.[12]

Oblique dorsopalmar views obtained with the horse bearing weight are also useful for assessing the cartilages of the foot and palmar processes of the distal phalanx and for differentiating the source of mineralization proximal to the navicular bone.

Lateromedial

The foot should be positioned on a block high enough to raise the bottom of the foot off the floor so that the radiographic beam can be directed at the coronary band and parallel to the floor, with the lower edge of the cassette beneath the level of the sole. The limb should bear weight, which may be facili-

tated by elevating both feet on blocks or by picking up the opposite limb during radiographic exposure. To assess rotation or sinking of the distal phalanx, taping a metal strip on the dorsal aspect of the hoof wall, extending from the level of the coronary band distally, is helpful. However, if the hoof capsule is excessively distorted in shape, this can be misleading. A thumbtack placed in the apex of the frog gives positional relationship between the frog and the tip of the distal phalanx, which may be helpful for planning proper placement of a heart-bar shoe for the treatment of laminitis or for helping to determine position of break over for shoeing purposes. Softer exposure factors should be used when assessing the orientation of the distal phalanx compared with evaluation of the architecture of the distal phalanx and navicular bone.

Examining a hind foot may be easiest by positioning the foot on a higher block, with only the toe bearing weight, taking care not to rock the foot medially or laterally, because a horse may be reluctant to allow the foot to be held flat on the block.

The slope of the dorsal hoof wall capsule should be the same as the slope of the dorsal aspect of the distal phalanx. Rotation of the distal phalanx has occurred if the angle of the dorsal surface of the distal phalanx with the ground is greater than the corresponding angle of the dorsal hoof wall. This may occur secondary to laminar or horn damage as in laminitis and white line disease, respectively. If the hoof wall is excessively long and distorted, it may give a false impression of rotation of the distal phalanx, and radiographic assessment should be repeated after radical trimming of the foot. Distal displacement of the distal phalanx within the hoof wall capsule is evaluated by measuring the space between the dorsal hoof wall and the dorsal aspect of the distal phalanx relative to the palmar cortical length of the distal phalanx. A ratio greater than 28% is abnormal and is evidence of distal phalangeal distal displacement within the hoof capsule (sinking).

In a normal foot the solar border of the distal phalanx slopes, with the palmar processes located slightly more proximally than the toe. In some horses the solar border is horizontal, or the palmar processes are actually lower than the toe. This may be associated with palmar heel pain, especially in a forelimb. In the lateromedial view the thickness of the sole can also be evaluated. Horses with particularly thin soles seem prone to "footiness."

The lateromedial view is useful for detecting osteochondral fragmentation of the extensor process of the distal phalanx, modeling of the articular margins of the distal interphalangeal joint or navicular bone, and mineralization within the DDFT or navicular suspensory ligament. The shape of the navicular bone can be assessed, and the presence of entheseous new bone, trabecular sclerosis, and erosion of the flexor surface can be detected in some horses.

Dorsopalmar

The foot is positioned on a block, and a cassette placed palmar to it, perpendicular to the ground. The x-ray beam is directed perpendicular to the limb, parallel to the ground, at the level of the coronary band. The dorsopalmar view is useful for assessing mediolateral foot balance, mediolateral symmetry of the phalanges, and interphalangeal joints and for detecting modeling of the articular margins. Mineralization or ossification of the cartilages of the front foot (sidebone) is common and unusually incidental and is more prominent in large horses, especially in working breeds, than in lighter horses used for racing and riding.[13,14] Ossification of the cartilages of the foot increases rapidly in the first 2 to 3 years of life. Extensive ossification of the cartilages of the foot reaching the level of the proximal interphalangeal joint is unusual and a potential cause of pain and lameness. There is limited evidence that incomplete fusion of the cartilages to the distal phalanx may be clinically significant.[15]

Dorsoproximal-Palmarodistal Oblique View (Upright Pedal)

The toe of the foot to be examined is placed in the V of a purpose-designed block, with the dorsal wall of the foot slightly in front of the vertical. The cassette is positioned vertically against the sole. A horizontal x-ray beam is used, centered on the coronary band. Avoid over-flexion of the fetlock by bringing the block forward so that the navicular bone is positioned proximal to the distal interphalangeal joint, so its distal border can be evaluated. Ideally two exposures should be used, first a softer exposure so that the margins of the distal phalanx can be assessed and then a higher exposure, using a well-collimated x-ray beam, to evaluate the navicular bone. In a well-positioned view the proximal articular and flexor margins of the navicular bone can be seen separately.

Examining a hind foot is easier by positioning the toe of the foot on a horizontal block, holding the x-ray cassette vertically on the dorsal aspect of the foot, and directing the x-ray beam from plantar to dorsal.

The DPr-PaDiO view is useful for evaluating the margins and internal architecture of the distal phalanx, although nondisplaced fractures, especially of the palmar processes, may not be detectable. Considerable variation exists between horses in the regularity of the solar margin of the bone, the size and number of the vascular channels, and the size and shape of the crena at the toe, but most horses have bilateral symmetry between left and right limbs. This view is also valuable for evaluating the shape of the navicular bone, the contour of the proximal articular margins, the presence of entheseous new bone along the proximal border, or mineralized fragments distal to the bone and assessing the number, size, and shape of radiolucent zones along the distal or proximal borders of the bone or within the medulla. A fracture of the navicular bone is usually clearly evident in this projection, but care should be taken not to confuse an artifact created by a frog cleft.

Palmaroproximal-Palmarodistal Oblique

The PaPr-PaDiO view can be used to assess the navicular bone and palmar processes of the distal phalanx. Ideally the x-ray beam should be well collimated to the region of interest. The two techniques for obtaining this view both involve the horse standing on the cassette, which ideally should be protected by a non-radiodense cassette tunnel or hardboard. With the first technique the limb to be examined is positioned caudal to the contralateral limb to extend the metacarpophalangeal joint and increase the angle of the pastern. The exact position depends on the conformation of the distal part of the limb, but the aim is to avoid superimposition of the palmar aspect of the metacarpophalangeal joint over the navicular bone. The x-ray machine is placed under the horse's abdomen and the x-ray beam is centered between the bulbs of the heel, perpendicular to a tangent to the heel bulbs. The angle of the x-ray beam is directed by the conformation of the foot and in a well-conformed foot is 45° to the horizontal.

The x-ray beam should be tangential to the flexor surface of the navicular bone. With a low collapsed heel the angle of the x-ray beam should be reduced accordingly to as little as 35°. Conversely, with an upright foot conformation the angle should be increased to approximately 50°. The angle of the x-ray beam is critical because artifacts are readily created, including an impression of reduced corticomedullary demarcation, sclerosis of the medulla, and an abnormal contour of the flexor surface. Alternatively, the foot to be examined is placed on a 10° wedge, and the contralateral foot is picked up. The x-ray beam is centered similarly, at a 30° angle to the horizontal for a normally conformed foot.

These views are more difficult to obtain in small, overweight ponies, and are generally easier to perform in forelimbs than hindlimbs. The PaPr-PaDiO (skyline) view of the navicular bone

permits evaluation of the body of the bone without superimposition over other structures, if correctly positioned, and is most sensitive for evaluating trabecular architecture, demarcation between the medulla and the dorsal and flexor cortices, and thickness, regularity of outline, and opacity of the flexor cortex. In a normal horse a clear definition exists between the radiopaque flexor cortex and the more radiolucent medulla, which has a well-defined trabecular pattern, with small lucent zones representing the distal border synovial invaginations. The flexor cortex varies in width between horses and tends to be thinner in a horse with a clubfoot. There may be a normal crescent-shaped radiolucent area within the flexor cortex at the sagittal ridge.

The view is invaluable for detecting medullary sclerosis, decreased corticomedullary demarcation, increased thickness of the cortex, and an irregular outline of the flexor cortex caused by erosions, often associated with adhesions of the DDFT, or by new bone formation. Communication of a radiolucent zone within the body of the bone with the flexor surface can be determined.

Flexed Oblique Views of the Interphalangeal Joints

The toe of the foot to be examined is placed in a V-shaped block. The x-ray beam is directed horizontally, centered at the coronary band midway between the dorsal wall and the heel. The cassette is place perpendicular to the x-ray beam. Dorsal 30° to 45° lateral (or medial)–palmaro (plantaro) medial oblique and dorsal 30° to 45° medial (or lateral)–palmarolateral oblique views are best for evaluating the lateral and medial palmar processes, respectively, whereas a 60° angle is preferable for assessing the articular margins of the interphalangeal joints.

Weight-Bearing Oblique Views of the Distal Phalanx

If a fracture of the distal phalanx is suspected but cannot be identified in any of the preceding views, it may be worthwhile obtaining dorsal 45° lateral-palmarodistal medial oblique and dorsal 45° proximal 45° lateral-palmarodistal medial oblique views of the lateral and medial palmar processes, respectively. These views are obtained with the horse standing on the cassette. Obviously the degree of obliquity can be varied. These oblique views are useful to evaluate the articular surface, subchondral bone, and dorsomedial and dorsolateral aspects of the distal phalanx.

Contrast Studies

If a horse has sustained a penetrating injury to the solar surface of the foot and a tract can be identified, its extent is best determined by insertion of a metal probe and obtaining a lateromedial radiographic view. Injection of radiopaque contrast agent can also be invaluable for determining communication with the distal interphalangeal joint, the navicular bursa, or the DFTS.

SCINTIGRAPHIC EVALUATION

Most scintigraphic imaging of the foot is performed using ^{99m}Tc–methylene diphosphonate (^{99m}Tc-MDP; see Chapter 19).[16] Flow, pool, and delayed (bone) phase images of each foot can be obtained using dorsal (or plantar), lateral, and palmar (solar) images. Diagnostic scintigraphic images of the distal part of the limbs depend on adequate blood flow, and to avoid poor uptake of the radiopharmaceutical into bone associated with poor blood flow, it is useful to lunge the horse at trot and canter for 15 minutes before injection of the radiopharmaceutical and bandage the distal part of the limbs for the previous 15 hours.[17] Scintigraphy is more sensitive but less anatomically specific than radiography for detecting pathological conditions of the bone. Scintigraphy can help identify many different bone-related abnormalities of the foot and is most useful to detect, or eliminate from suspicion, early navicular disease or an acute distal phalangeal fracture.

Navicular disease may be difficult to diagnose unequivocally radiographically except for severe or end-stage disease. False-positive (low specificity) and false-negative (low sensitivity) results may occur.[18-22] Scintigraphy is more sensitive than radiography and may be helpful in differentiating navicular pain from non-specific palmar heel pain.[11] Although false-positive results may be due to confusion with radiopharmaceutical uptake in the cartilages of the foot in a lateral view, or in the distal interphalangeal joint in a solar view, horses without foot pain may have a high uptake of the radiopharmaceutical in the navicular bone.[23] False-negative results are not common. Interpretation is more accurate using quantitative analysis of radiopharmaceutical uptake and also interpreting results in the light of responses to analgesia of the distal interphalangeal joint and navicular bursa.[23] Fractures of the distal phalanx are common injuries but may not be detectable radiographically in the acute phase. Scintigraphy provides earlier diagnosis, with intense focal uptake of radiopharmaceutical. Solar views are most sensitive. Intensity of uptake decreases with time, but evidence of a fracture may persist up to 1 year after injury. Because some distal phalangeal fractures commonly heal by fibrous union and the horse still returns to successful function, scintigraphy may be useful to determine when to return to exercise.

Scintigraphic imaging of the feet for laminitis has primarily been performed as part of research studies to evaluate digital blood flow, using radiolabeled platelets or macroaggregated albumin.[20,21] One study, using blood pool imaging after intravenous injection of ^{99m}Tc-dithylene-triamine penta-acetic acid (similar to ^{99m}Tc-MDP), found significantly lower dorsal laminar activity in horses refractory to treatment with heartbar shoeing.[22] Scintigraphy may be useful for identifying peripheral distal phalangeal injury and inflammation consistent with pedal osteitis[24] and subchondral bone injury.[25] Uptake in the region of the DDFT in lateral pool phase images occurs with DDF tendonitis.[23,26] Less commonly, focal increased radiopharmaceutical uptake has been identified at the insertion of the DDFT in bone-phase images, in association with a distal DDFT lesion identified using magnetic resonance imaging (MRI).[26]

FLUOROSCOPY

Fluoroscopy is designed to evaluate dynamic characteristics, gives poor image detail, and is a potential radiation safety hazard. Image-intensified fluoroscopy is the only legal technology allowed in veterinary practice, is not recommended for use in routine veterinary practice, and should only be used after specialized training. Fluoroscopy is useful for monitoring positioning of the needle for injection of the navicular bursa.

DIAGNOSTIC ULTRASONOGRAPHY

The horny hoof capsule limits ultrasonographic evaluation of the foot. Limited access is available using either a convex array or sector transducer through the bulbs of the heel[27] or the frog.[28] This allows limited evaluation of the DDFT, the navicular bursa, and the proximal and palmar surfaces of the navicular bone. However, a transducer positioned between the bulbs of the heel is not parallel to the fibers of the DDFT; therefore artifacts are readily created. Access through the bulbs of the heel or the frog is principally restricted to the sagittal midline. The frog must be soft enough to penetrate, which may require soaking it for several days. A curved bed for the transducer must be created to ensure good contact. The ease with which this can be done is determined by the shape and consistency of the frog. The collateral ligaments of

the distal interphalangeal joint and the chondrocompedal and the chondrocoronal ligaments can be assessed from the dorsolateral and dorsomedial aspects of the distal pastern.[29] Lesions of the soft tissue structures on the palmar aspect of the pastern may cause lameness that is alleviated by perineural analgesia of the palmar nerves and may be present without detectable swelling or pain on pressure. Therefore the palmar aspect of the pastern should be examined routinely (see Chapters 16 and 83).

MAGNETIC RESONANCE IMAGING

MRI of the foot is discussed in detail in Chapter 21. MRI has been useful for identification of lesions of the DDFT; navicular bursa and bone; distal sesamoidean impar ligament, phalanx, and laminae; and the cartilage and subchondral bone of the distal interphalangeal joint.[26,30] MRI has the potential to greatly increase our knowledge of the causes of foot pain, but it requires general anesthesia.[30]

COMPUTED TOMOGRAPHY

Computed tomography (CT), like MRI, requires general anesthesia but permits evaluation of the bony and soft tissue structures of the foot. CT may be more sensitive than radiography in determining lesions of the navicular bone[31,32] and has proved valuable for identification of lesions of the DDFT within the hoof capsule.[33]

GENERAL BIOMECHANICS

An appreciation of the biomechanics of the foot is helpful to understand foot lameness and corrective trimming and shoeing (see Chapter 27). Computer-assisted kinematic analysis of gait and force plates has been used to study foot and limb movement and the forces acting on the foot. This, together with detailed anatomical modeling of the foot and distal limb, allows estimation of the forces acting on or through internal structures of the foot that are not directly measurable using such non-invasive techniques.[34,35]

Five opposing forces act on the distal phalanx within the hoof capsule: tension and shear at the foot-laminar junction, DDFT tension, extensor tendon tension, body weight applied down through the middle phalanx, and ground reaction force (GRF). Stresses at the foot-laminar junction have important implications in the development and treatment of laminitis. Tension in the DDFT has implications concerning navicular disease. Extensor tendon tension is minimal and active primarily during the swing phase of the stride. The amplitude and distribution of GRF to a large extent determines the stresses at the foot-laminar junction and in the DDFT tendon.

A stride begins at hoof-strike and ends at the next hoof-strike of the same limb. In normal horses at the walk, the heels strike the ground first, followed by the ground surfaces of the bars, quarters, and toe. The time between heel and toe impact is 9 to 15 ms.[36] At a slow trot this interval is much shorter, too fast to be definitively determined by the naked eye, and for most practical purposes the foot lands flat. Heel-first landing is obvious in the hind feet.[37] At hoof-strike the impact force is not maximal, because peak vertical GRF occurs at midstance.[38] However, at hoof-strike, peak initial foot and limb deceleration may reach 100 g (1 g = 9.8 m/sec^2).[36] After impact the foot then vibrates at high frequency for a short time. Most of the damping of the vibration after impact is provided by the interface between the hoof wall and the distal phalanx.[39,40] Therefore diminishing impact force and vibration is most important when addressing treatment of foot disorders involving the hoof wall laminae. Metal shoes in general increase the amplitude and frequency of hoof wall vibration after impact.[41,42]

The period during the stride in which the hoof is in contact with the ground is defined as the *stance phase* and is subdivided into *cranial* and *caudal phases*. The cranial stance phase begins with hoof-strike and ends at midstance, when the limb axis is perpendicular to the ground and the weight of the trunk is directly over the foot. Vertical GRF on the foot is maximal at midstance.[43] The center of vertical GRF is cranial to the center of rotation of the distal interphalangeal joint, creating an opposing lever arm to DDFT tension. At the trot, DDFT tension is maximal near midstance, corresponding approximately to the instant of maximum vertical GRF. However, at midstance, strain in the navicular suspensory ligament is negative, that is, it is relaxed.[44]

Vertical forces on the equine foot at a walk have been measured at about 4000 N.[45] Because trunk mass is medial to the limb, at midstance the center of maximum vertical GRF on the foot is slightly medial of midline. Initial impact on the lateral wall, followed by peak force occurring medially, causes many horses to develop low and flared lateral, but high and upright medial hoof walls. Reducing the effects of maximum vertical GRF is an important consideration in corrective trimming and shoeing.

The foot also experiences substantial horizontal GRF. Horizontal GRF is initially deceleratory or braking. In the forelimb, at about midstance, this horizontal braking force changes to become a horizontal propulsive force of approximately equivalent magnitude. The transition from braking to propulsion occurs much earlier in the forelimb than in the hindlimb.[46] In hindlimbs the horizontal propulsion is of greater magnitude than the horizontal braking; thus the forelimbs primarily perform support, whereas the hindlimbs perform support and propulsion.

Breakover occurs at the end of stance, beginning at heel-lift and ending at toe-lift. During breakover the hoof rolls about 45°. The position of the center of vertical GRF applied to the bottom of the foot increases and moves rapidly toward the toe during breakover. During breakover the strain in the navicular suspensory ligament is maximal.[44] Asymmetric hoof impact, high peak vertical GRF at midstance, and the rapid shift of vertical GRF to the toe during breakover all play important roles in the understanding of the treatment of certain foot problems.

During weight bearing the thinner, more elastic hoof wall at the heel expands. Hoof wall expansion creates tension in the laminae and periosteum of the distal phalanx.[47,48] As a result the distal phalanx descends and rotates in a clockwise direction around the toe (the dorsal border moves palmarly). Application of a shoe tends to reduce strain on the hoof wall.[9] The vasculature of the foot, predominantly the venous sinuses, augments the protective mechanisms of hoof wall expansion by providing additional hydraulic shock absorption. Increasing weight-bearing pressure on the frog has inconsistent effects, sometimes increasing heel expansion and sometimes causing contraction of the heels.[49]

The swing phase of the stride begins at toe-lift and continues until next hoof-strike. *Mid-swing* is defined as the halfway point in the foot flight pattern. Mid-swing can be estimated by the position of the contralateral limb, which will be at midstance. In a sound horse, hoof trajectories are individual and variable.[50] Some horses have relatively parabolic arcs, with maximum hoof height occurring at mid-swing, and some have more skewed paths, with maximum hoof height occurring during the first half of the swing phase. Many horses exhibit a flipping up of the toe of the foot just before hoof strike as the foot prepares to land flat-footed or slightly heel first. This toe elevation at the end of swing is decreased in horses with low

hoof wall angles, and some horses with substantially low hoof angles land abnormally, toe first. The pattern of hoof flight is used by some equine practitioners to detect lameness and by many lay performance judges to assess athletic ability.[51,52] In one study, horses judged to be of inferior ability had lower maximum hoof flight arcs during swing. All shoeing, because it adds weight to the foot, will increase maximum hoof height during swing.[50,53]

BIOMECHANICS AND LAMENESS

Two general questions of interest concern foot biomechanics and lameness. The first asks whether specific measurements can be used to isolate lameness to the foot. Most gait changes associated with weight-bearing lameness result from decreased vertical GRF, regardless of the specific location of pain within the limb. No biomechanical indicators specific for foot lameness have been identified. The second question asks what foot parameters can be used to indicate the horse's general mechanical response to lameness. It seems reasonable to assume that a lame horse spends less time bearing weight on a lame limb, but many studies have shown that in horses with mild to moderate lameness, stance-phase duration is actually increased with lameness.[54] Therefore, it follows that if total stride duration is not changed, then swing-phase duration of the lame limb decreases with lameness. Presumably, a reduction in maximum vertical GRF can be accomplished by spreading the force out over a longer period of weight bearing.[55] The stance phase duration does not begin to decrease until lameness becomes severe in nature and the horse is unable to maintain forward trunk velocity. In horses with unilateral lameness, maximum vertical GRF is lower in the lame limb compared with the sound limb, and the braking component of horizontal ground reaction is shorter and decreased in amplitude.

Equine practitioners commonly contend that protraction, or the length of the cranial phase of the stride, decreases in horses with lameness. A decrease in hindlimb protraction has been objectively measured in horses with induced tarsal lameness and this is easily seen at the trot.[56] This contention, however, has not been confirmed by objective studies of other lameness conditions, and a slight increase in protraction has been measured in some studies of equine forelimb lameness.[54,57,58] Decrease in limb protraction is not a good general indicator of lameness in horses. However, in the Editors' experience in the clinical situation, horses frequently appear to have a shortened cranial or sometimes caudal phase of the stride. Stride length is not significantly decreased until lameness is severe.[58] The appearance of decreased stride length with lameness may be visual deception caused by decreased swing-phase duration or altered relative positions of the trunk, limb, and foot during lameness.

Absolute hoof height during the swing phase of the stride is a poor parameter for quantitative evaluation of lameness. Classic textbook descriptions describe low hoof flight arcs to be characteristic of lameness.[59] Electromyographic measurements of forelimb muscles suggest that the swing phase is entirely passive, resulting from elastic energy released from the flexor tendons at the end of stance.[60] Because this passive recoil would be reduced in a lame limb, absolute hoof height during the swing phase of the stride should also be reduced. However, kinematic studies of horses with lameness of the forelimb have failed consistently to document this. Additionally, lower trunk height (and therefore lower hoof height) after lame limb lift-off is frequently offset by increased joint flexion necessary for the limb to clear the ground during the forward progression of the stride.[56] Therefore maximum hoof height during swing is not consistently changed with lameness.

During breakover, compressive force concentrates at the toe and navicular suspensory ligament tension increases. Although breakover is difficult to measure accurately because of its short period, like total stance, it increases in duration with mild to moderate lameness caused by navicular disease. Changes in breakover duration have been studied more extensively in association with changes in trimming and shoeing.

For a discussion of the biomechanics of trimming and shoeing, see Chapter 27.

CHAPTER • 27

The Foot and Shoeing

FOOT BALANCE, CONFORMATION, AND LAMENESS

• Andrew Parks

Athletic injury usually results from imposition of repetitive stresses that exceed the capacity of the tissues. The magnitude of stresses and hence the likelihood of injury frequently depend on balance and conformation. Therefore balance and conformation are extremely important in maintaining optimal limb function and limiting athletic injury.

Conformation describes shape, in this case, the shape of the distal equine limb and conveys the size and relative proportions of the limb. Balance embraces both the conformation and function of the hoof, conformation because it describes the shape of the hoof, and function because it describes the way the hoof relates to the skeletal structures of the limb and the ground at rest and at exercise. Balance is divided into geometric (static) balance and functional (dynamic) balance.

Balance and conformation are both three-dimensional concepts. Balance usually is divided into three planes: frontal, sagittal, and transverse. Balance in the frontal plane is called *mediolateral balance* and in the sagittal plane is called *dorsopalmar balance*.

To understand how balance and conformation affect stresses that cause injury it is necessary to consider the function of the distal limb and then examine how it changes with conformation and balance. Therefore consideration must be given to the musculoskeletal system, the hoof and the ground, and the interfaces. There are some substantial differences between the front and hind feet. Because almost all research and documented clinical observation is related to the front feet, all discussion in this chapter refers to the front feet unless specifically stated otherwise.

The hoof is the interface between the musculoskeletal system and the ground. The hoof functions both as an extension of the distal phalanx, as a lever about the distal interphalangeal joint, and as an entity in itself. As part of the integument the hoof behaves differently to the structures of the musculoskeletal system, both in its manner of constant growth and its biomechanical properties. As the hoof capsule is constantly worn at the ground surface, it is replaced by the germinal epithelium of the coronary band and the sole. In nature and in an appropriately trimmed foot, there is an approximate balance between growth and loss of the hoof capsule so that the growth rings are parallel.[1-3] The exact mechanism by which hoof growth is regulated is unknown, but several factors are known to influence it: season, inflammation, nutrition, and topical irritants.[4] Growth of the wall also is inversely related to pressure on the coronary band. Hoof wall growth proximal to a hoof wall resection or horizontal grooving of the hoof wall appears accelerated, whereas the immediately adjacent hoof wall growth may be retarded.[5] This effect may be mediated by an effect on the vasculature of the coronary band.

During normal hoof growth the hoof wall migrates distally in relation to the distal phalanx by active separation and reformation of desmosomes as the primary epidermal lamellae move past the secondary epidermal lamellae.[6] The distal growth of the hoof wall under normal loading patterns is approximately even around the circumference of the hoof, and the position of the coronary band in relation to the distal phalanx is static. However, in response to locally increased and decreased loads within the hoof wall, migration of the coronary band proximally and distally in relation to the distal phalanx is superimposed on the normal pattern of hoof wall migration, suggesting that a whole segment of the wall can displace distally and even proximally by movement within the lamellae.

The stiffness of the hoof wall changes radially, and the outer stratum medium is stiffer than the inner stratum medium but is much less stiff than bone throughout. The stiffness of the hoof wall at the toe and quarters is similar, but the difference in thickness indicates that the quarters are more flexible.[7] The hoof wall sustains strains greater than bone, but under normal circumstances it operates within its elastic range at a fraction of its yield capacity.[8] The stiffness of the hoof wall increases with increased strain rate.[9] The hoof wall is viscoelastic. It responds to a rapidly applied force in an elastic deformation so that it returns to its original form rapidly; however, to a slowly applied force, it deforms in a manner so that when the force is removed, it returns to its original form slowly.[10] Because of its physical properties the hoof wall is more fracture resistant than bone,[11] but because it is a much less stiff material than bone, it will bend and shear more readily. The biomechanical properties of the soft tissues between the hoof capsule and distal phalanx are less well understood, but the periosteum of the distal phalanx fails before the junction between the epithelial and dermal lamellae.[8] The lamellar junction is much less stiff than the hoof wall[12]; dorsally the lamellae are oriented perpendicular to the tangent to the hoof wall, but at the quarters they are in a more palmar direction.[13]

FOOT FUNCTION

At Rest

At rest a horse bears approximately 28% to 33% of its body weight on each forelimb. The exact roles of the wall, sole, and frog in weight bearing are undetermined. Weight bearing has traditionally been viewed with a horse on a flat firm surface so that the weight-bearing surface is the full circumference of the wall and the immediately adjacent sole, although the weight is not evenly distributed around the perimeter of the foot. Studies on feral horses indicate that the toe and quarters are worn so that if the horse stood on a flat firm surface, the weight would be transmitted through the wall at both heels and the junction of the toe and quarter biaxially, although there is some variation related to the terrain on which the horse has lived.[14] The dorsal toe and mid-quarters would not bear weight. Domestic horses that were allowed to wear the feet "naturally" at pasture and then stood on different surfaces showed remarkably different loading patterns.[15] When stood on a firm surface, greatest contact was at the medial and lateral heels and just medial and lateral to the dorsal toe, comparable to feral horses. When stood on sand, the greatest

contact was with the central sole, and the total contact area was approximately four times greater for horses standing on sand than on a flat firm surface.

Any part of the ground surface of the foot is potentially weight bearing. Each point of contact that bears weight transmits that force to the ground, although the pressure at each point varies. The sum of all the forces from all points of contact is called the ground reaction force (GRF). It is represented as a vector, with a magnitude and direction, and a location or point of force, which is also called *the point of zero moment*. In the stationary horse this force is vertical and located slightly medial to the dorsal third of the frog. However, in the naturally worn hooves of feral horses the distance between the toe and the point of force is likely to be reduced because of the greater wear at the toe. In either case, the GRF is dorsal to the center of rotation of the distal interphalangeal joint with a resultant moment about the joint. This moment is opposed by an opposite moment created by tension in the deep digital flexor tendon (DDFT). The GRF acting through the phalanges creates a moment about the metacarpophalangeal joint that is opposed by tension in the digital flexor tendons and the suspensory ligament (SL).

At Exercise

Stride Phases

Initial contact At exercise the stride is divided into several phases: initial contact, impact, stance, breakover, and flight.[16] The foot should move in a sagittal plane parallel to the longitudinal axis of the horse.[5] In an exercising horse the GRF changes in magnitude, point of force, and direction with and within the phases of the stride. The GRF is separated into components in three axes: *X* (mediolateral), *Y* (craniocaudal), and *Z* (vertical). At a walk, trot, or gallop the initial contact most frequently is heel first,[17,18] either one heel (usually lateral) before the other or both heels simultaneously.[19] However, some horses may land flat-footed, and the propensity to do so increases with increasing speed.[19] When the heels do strike first, the foot is flat within 1% to 2% of the stride duration.[20] Toe-first landing is rare.[19,20] It has been suggested that the position of the foot at landing is determined by proprioceptive reflexes that optimally orient the position of the distal phalanx before impact, regardless of the length of toe or angle of the foot.[21]

Impact phase The impact phase is characterized by oscillations in the GRF centered on the heels that last for approximately 50 ms.[16] The oscillations are associated with the highest rate of loading during the stride; thus the greatest likelihood of injury is during the impact phase. The vertical velocity and acceleration are greater in the forelimbs than in the hindlimbs, which explains the greater concussion and likelihood of lameness in the fore limbs.[20] Significant damping of the impact oscillations occurs within the hoof, the two distalmost phalanges, and the associated articulations.[22-24]

Stance phase The stance phase extends from the end of impact until the onset of breakover. At a walk the vertical GRF is biphasic, with peaks either side of the middle of the stride, but at the trot there is a solitary peak approximately halfway through the stride.[25,26] For most of the stance phase the GRF is slightly medial to the dorsal third of the frog.[27] The force is absorbed and energy is stored by the flexor tendons and SL as the metacarpophalangeal joint extends[28] so that the maximal GRF coincides with maximal extension of the metacarpophalangeal joint.[17,29] At the walk, forces in the superficial digital flexor tendon (SDFT) and DDFT peak before the peak in the GRF, but the force in the accessory ligament of the DDFT (ALDDFT) peaks during the second half of the stride as the distal interphalangeal and metacarpophalangeal joints extend.[30,31] The GRF in the dorsopalmar direction is negative during the first half of the stride as the limb decelerates. The foot continues to slide forward after initial impact until arrested, at 6% of the stride duration in the forelimb[32] and 23% in the hindlimb[33] in trotters on a dirt track. The fore foot bounces more on impact, whereas the hind foot slides more.[20] During the second half of the stride the horizontal GRF becomes positive as the limb accelerates to provide propulsion. The balance of propulsion and retardation is such that the forelimbs contribute more to retardation and the hindlimbs to propulsion.[26] Faster gaits create higher GRFs and greater strains in the hoof wall,[8] DDFT, SDFT, and SL.[34] Under in vitro loading conditions, hoof wall strains increase with load as strain field epicenters develop around the circumference of the hoof, at the junction of the middle and distal thirds of the hoof, regardless of load.[35]

As the distal phalanx is loaded during the stance phase, it descends within the hoof capsule and the palmar processes rotate ventrally.[36] The sole flattens and spreads as the heels expand,[2,37] more so distally than proximally.[8] At the same time, the dorsal hoof wall flattens and rotates palmarly to parallel movement of the distal phalanx. Frog contact with the ground during exercise appears to be variable,[24,37] but frog pressure does not appear to play a role in hoof expansion,[24] although it must function as an effective expansion joint to permit movement of the sole ventrally and the heels abaxially. It is hypothesized that the digital cushion, in conjunction with the cartilages of the foot, participates in dissipating energy during impact through a hydrodynamic mechanism.[38,39] The distal interphalangeal joint passively flexes[40] and the metacarpophalangeal joint extends. During the second half of the stride the distal interphalangeal joint extends[40] and the tension in the ALDDFT increases.[31] Tension in the collateral sesamoidean and distal sesamoidean impar ligaments also increases,[40] and pressure on the navicular bone increases.[41] The metacarpophalangeal joint flexes. The point of action of the GRF moves toward the toe toward the end of the stance phase.[16]

Breakover phase Breakover begins when the heels start to lift off the ground and ends when the toe leaves the ground. The point of breakover is the most dorsal part of the hoof or shoe in contact with the ground as the heel begins to lift off the ground. From the instant the heels and sole have left the ground, the GRF is concentrated at the toe. Tension in the ALDDFT peaks,[30] and increased strain in the dorsal hoof wall[8] causes the distance between the heels to be narrower than at rest. The horizontal forces between the ground and the hoof at the toe during the latter part of the stance phase and breakover are associated with the final stages of propulsion.

Flight phase The flight phase begins at maximal retraction of the limb and the foot reaches maximal height soon thereafter. A second peak in height occurs just before maximal protraction. The limb retracts slightly before impact to decelerate the limb as the distal phalanx is optimally aligned for impact. The deceleration of the forward movement of the foot is important in reducing the stresses of impact.[42] The stresses on the distal limb during the flight phase are low, because the distal joints flex and extend passively following movement of the upper limb during protraction.[16]

Stride Characteristics

The time and motion characteristics of the stride are important in determining the animation qualities of the gait and the speed of the horse. Higher movement of the foot and greater flexion and extension of the joints represent greater animation. Long retraction with a high starting point is considered desirable, and longer strides are associated with greater speed. Maximum stride frequency is inversely related to speed index.[43-45]

The ground surface affects the angle of the hoof to the ground during the stride, the duration of the stride, and the absorption of impact energy. On a flat, firm surface the plane

of the hoof is the same as that of the ground, but on a surface such as sand, the angle of the hoof with the ground increases gradually during the stance phase of the stride.[34] This rotates the plane of the sole so that it is more perpendicular to the vector of the GRF, which appears to aid traction and propulsion. Ground footing has been divided into three types: dense hard surfaces, surfaces with friction damping such as sand, and structural damping surfaces such as wood chips.[46] Friction damping occurs through displacement of small particles, whereas structural damping occurs through viscoelasticity of the particles. The duration of impact oscillations is related to the hardness of the surface. Harder surfaces are associated with a longer duration of impact oscillations than soft surfaces and less energy absorption.[47] A loose cushion on the surface reduces the peak impact force.[48] Racetracks with a hard surface result in faster race times, but horses are more likely to suffer injury associated with the increased energy of impact.[48] Ground footing also affects stride and swing duration, which are both longer on an elastic, softer surface than a hard, firm surface.[49] At a walk, strain in the DDFT and ALDDFT is lower on sand than on a hard, flat surface,[34] such that it resembles the effect of a heel wedge.

OPTIMUM BALANCE AND CONFORMATION

Optimum function should intuitively demand optimum conformation and balance. Practitioners have inherited many empirical notions that often are based on what types of conformation and balance do not work and cause problems. Generally these ideas predate modern motion analysis and therefore relate to conformation and static balance. Modern techniques that allow dynamic evaluation of function have supplemented and sometimes contradicted the geometric approach.

Static Balance and Conformation

Viewed from the lateral aspect, the foot-pastern axis should be straight; that is, the dorsal hoof wall should be parallel to the dorsal surface of the pastern, and the angle of the heel should approximate that of the dorsal hoof wall (Fig. 27-1). The angle of the dorsal hoof wall and the foot-pastern axis to the ground is variable, but it frequently is cited between 50° and 54° in forelimbs and approximately 3° steeper in the hindlimbs.[50] Other studies report higher or lower means and variable relationship between the angles of the dorsal hoof wall of the forelimbs and hindlimbs.[51,52] In domestic horses the length of the hoof wall has been approximately linked to the weight of the horse (7.6 cm for 360 to 400 kg; 9.3 cm for 430 to 480 kg; 8.9 cm for 520 to 570 kg).[50] In feral horses the toe length ranges from 6.7 to 8.9 cm[14,51] but is independent of weight.[51] In domestic horses with either trimmed or shod hooves, the length of the heel should be approximately one third that of the toe,[2,52] but in feral horses it varies with the terrain.[14] An imaginary line that bisects the third metacarpal bone (McIII) should intersect the ground at the most palmar aspect of the weight-bearing surface of the heels.[53,54]

On a lateral radiographic view the dorsal hoof wall should be 14 to 20 mm thick depending on breed[55-57] and parallel to the dorsal surface of the distal phalanx. The angle made by the distal solar border of the distal phalanx with the ground ranges from 2° to 10°.[55,57,58] The center of rotation of the distal interphalangeal joint should be vertically above the center of the ground surface of the foot.[58,59]

Viewed from the dorsal aspect, a line bisecting the metacarpal region should bisect the phalanges and foot, so that the foot is approximately symmetrical, including the mass of foot on either side of the line, the heights and angles of the walls.[1,3,54,58] The medial quarter is frequently steeper so that the medial wall is shorter than the lateral wall.[2,60] A line drawn between any two comparable points on the coronary band should be parallel to the ground, and a vertical line bisecting the McIII bone should be perpendicular to a line drawn across the coronary band or the ground surface of the foot[61] (Fig. 27-2).

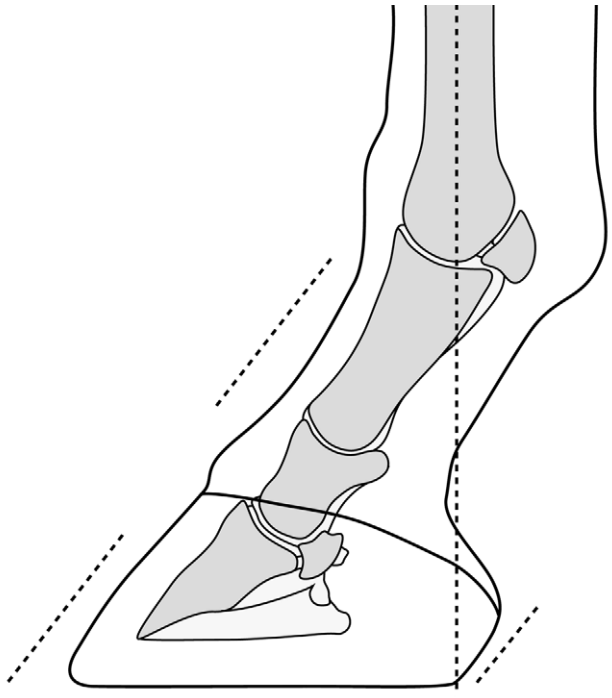

Fig. 27-1 Traditional guidelines defining normal dorsopalmar static or geometric balance. The dorsal hoof wall should be parallel to the dorsal aspect of the pastern and to the hoof wall at the heels. A line bisecting the third metacarpal bone should reach the ground at the weight-bearing parts of the heel.

On a dorsopalmar radiographic view the center of the distal interphalangeal joint should be centered over the ground surface of the foot. The articular surface and the distal border of the distal phalanx should be parallel to the ground, and the interphalangeal joint spaces should be symmetrical.

Viewed from the ground surface the width and length of the hoof capsule of the fore foot should be approximately equal, although it may be slightly wider than it is long.[51,60] The hind foot is invariably slightly longer than it is wide. The point of breakover is best assessed from the ground surface and should be located at the center of the toe. The ideal location for breakover in the dorsopalmar axis is disputed. In a traditionally trimmed and shod horse, breakover is positioned where the line of the dorsal hoof wall intersects the ground, although it may ideally be located more palmarly. Using the position of the hoof wall as the reference point, breakover is between the dorsal margin of the hoof and the white line.[62] Alternatively, breakover is 2.5 to 3.8 cm dorsal to the apex of the frog or 0.6 cm dorsal to the dorsal margin of the distal phalanx.[14,63] The relationship of the longitudinal axis of the frog to the underlying distal phalanx is relatively constant compared with the rest of the ground surface of the hoof. The medial and lateral aspects of the ground surface of the foot are symmetrical about the central axis of the frog,[3,54,62] although slight asymmetry, the lateral sole being about 5% wider than the medial sole, may be beneficial.[60] The latter is compatible with an even coronary band and a steeper medial wall. The size of the foot should be proportional to the weight of the horse.[51,52] The sole should be concave. The frog width should

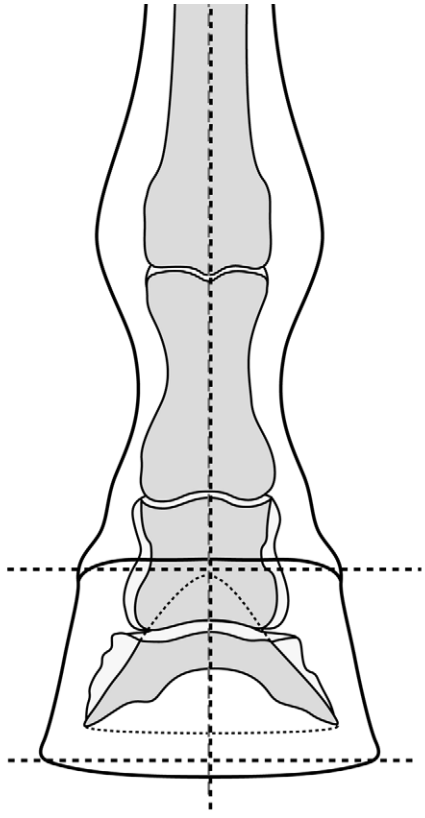

Fig. 27-2 Traditional guidelines defining normal mediolateral static or geometric balance. A single line should bisect the metacarpal region and phalanges. A line drawn across any two comparable points on the coronary band, or on the weight-bearing surface of the foot, should be perpendicular to the axis of the metacarpal region.

be at least 50% to 67% of frog length,[52,60] and the weight-bearing surface of the heels should coincide with the widest part of the frog.[52]

Dynamic Balance

Current definitions of dynamic balance describe the placement of the foot at initial impact. The foot is said to be in dynamic mediolateral balance when both heels contact the ground simultaneously[3,61] and breakover occurs at the center of the toe.[61] The foot is said to be in dynamic dorsopalmar balance when either the heels land slightly before the toe, or the toe and the heels contact simultaneously.[3] However, both these observations are a function of observation frequency. The fewer observations made per unit time, the more likely the foot is to appear in balance. The more frequently the observations are made, the less likely the foot is to appear in dynamic balance. By increasing frequency of observation, it appears that one heel commonly lands before the other.[19] It is likely that the scope of dynamic balance will expand in the future to incorporate the magnitude, location and direction of the GRF, distribution of stresses within the hoof capsule during the stride, and dynamics of breakover.

IMBALANCE AND POOR CONFORMATION

Balance and conformation cannot be considered in isolation, because poor conformation predisposes a horse to developing imbalance, and an imbalanced foot may cause a horse to stand as if it has poor conformation.[1] The effects of imbalance have been examined by experimentally inducing imbalance and by clinical observation. To understand the effects of imbalance it is simplest to consider the consequences of deliberately imbalancing the foot. Poor conformation cannot be altered under experimental conditions, and its effects must be assessed by comparison between horses with different conformation.

Mediolateral

Mediolateral imbalance is caused by either poor trimming of a horse with good conformation or poor conformation causing excessive stress on one side of the foot so that it grows slower than the other side. Inappropriate shoe placement can promote imbalance. If a shoe is set too much to one side or the other, or if the shoe is rotated so that the shoe covers less of one heel than the other, it alters the mediolateral stress on the hoof capsule.[64] A single heel calk causes elevation of one heel; the foot tilts and rotates and may contribute to interference.[64]

Mediolateral imbalance can be induced by applying a wedge pad to elevate the medial or lateral side of the foot or trimming the foot unevenly. The coronary band is no longer parallel to the ground, or perpendicular to the sagittal axis of the limb. The horn tubules of the dorsal hoof wall are no longer oriented in the sagittal plane. Dorsopalmar radiographic views demonstrate that the distal interphalangeal joint space is narrower on the side of hoof elevation and the middle phalanx slides to the lower side.[40] In addition, the condyle of the middle phalanx on the elevated side of the foot moves palmarly, in effect causing the distal phalanx to rotate on the middle phalanx so that the dorsal margin of the distal phalanx rotates away from the elevated side[40] (Fig. 27-3), but the horse has the appearance of being toed toward the elevated side.[1]

The GRF shifts toward the elevated wall.[65] In foals, compressive strains were immediately increased in the lateral cortex of McIII and decreased in the medial cortex by elevation of the lateral wall with a wedge.[66]

The immediate dynamic effects of mediolateral imbalance result in a greater frequency of mediolateral asymmetrical footfall, the lengthened side landing first.[19] The location of the GRF displaces abaxially toward the lengthened side of the foot.[19,67,68]

Prolonged mediolateral imbalance affects the relationship between the hoof capsule and the distal phalanx, causes distortion of the hoof capsule, and alters hoof wall growth.[69] If a foot is trimmed unevenly, so that one wall is longer than the other, the longer wall grows more slowly than the shorter wall. The longer wall develops a flare and the shorter wall becomes underrun.[1,69] In more severely affected horses the coronary band bulges abaxially to create a lip at the proximal margin of the hoof wall on the elongated side. The horse breaks over on the shorter side of the toe. It is my impression that the solar margin of the distal phalanx partially realigns with the ground surface, either because the wall actually migrates proximally or because distal movement of the hoof wall is inhibited, resulting in a net proximal displacement of the coronary band in relation to the distal phalanx. Ultimately, prolonged mediolateral imbalance causes remodeling of the phalanges because of redistributed stresses according to Wolff's law.

Rotational deformities and angular deformities may mimic each other. In most rotational deformities, it appears as if the metacarpophalangeal joint is the most proximal joint to be rotated, but it is not uncommon for the carpus to appear rotated. With rotational deformities, the McIII is vertical and the observer can rotate around the limb until the metacarpal and phalangeal axis are correctly aligned unless the rotation occurs within the phalangeal axis. In horses with angular deformities that occur proximal to the fetlock, including base-wide or base-narrow conformation, McIII may not be vertical

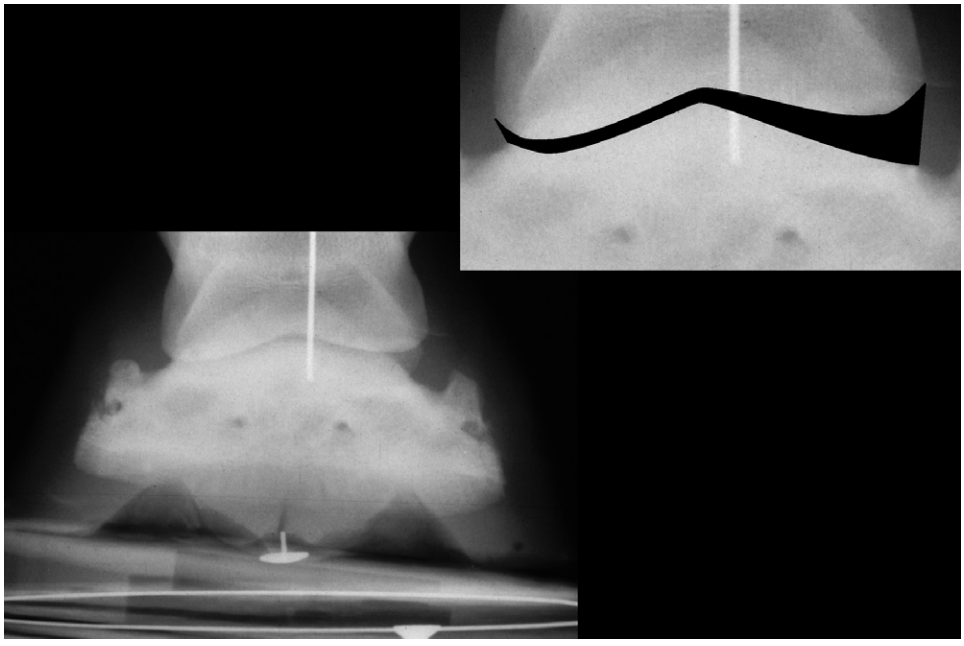

Fig. 27-3 Mediolateral imbalance causes misalignment of the articular surfaces and rotation of phalanges in relation to each other. Deliberate elevation of one wall causes the articular surface of the distal phalanx to tilt, but it does not tilt as much as the ground surface of the foot, indicating that there is accommodation within the viscoelastic structures of the foot. The distal articular surface of the middle phalanx is displaced away from the elevated side of the foot. The inset in the upper right corner shows the joint space (outlined in black) on the elevated side of the foot *(left)* is narrower than the lower side *(right)* of the foot, caused by compression of the distal interphalangeal joint surface on the left side.

and there may not be a view point from which the metacarpal and phalangeal axis are correctly aligned.

Rotational deformities, such as toe-in and toe-out conformation, alter the position of the ground surface of the foot in relation to the mid-sagittal vertical axis of the limb. Toe-in conformation causes the foot to wing out during the flight phase of the stride,[1] and if the limb does not deviate from a vertical axis, the foot lands on the lateral heel quarter and breaks over at the lateral toe. Toe-out conformation causes the foot to wing in during the flight phase of the stride. The foot lands most frequently on the later heal quarter, as with toe-in conformation. Breakover is reported to occur at the medial toe, but it is less consistently directed than breakover in horses with toe-in conformation. Angular deformities, including base-wide, base-narrow conformation, and varus and valgus deformities also alter the position of the ground surface of the foot in relation to the ideal vertical axis of the limb. If an angular deformity (e.g., valgus) causes the foot to be lateral to a plumb line dropped from the shoulder, the stresses on the medial hoof are increased, the medial wall growth decreases as the lateral wall growth increases, and the medial wall becomes underrun as the lateral wall develops a flare. With varus deformity the opposite is true because the limb deviates medially. Rotational and angular deformities may occur in combination, complicating the picture.

Dorsopalmar

Dorsopalmar imbalance has several causes. A broken-back foot-pastern axis may follow poor trimming, either leaving the toe too long or trimming the heels too short. A shod horse wears its heels against the shoe while the toe wears very little, so the hoof angle changes up to 3° over 8 weeks.[2] This change must be allowed for by trimming the toe slightly more than the heels, because even trimming around the foot causes a gradual decrease in the hoof angle.[3] Using too small a shoe or leaving a shoe on too long causes the palmar ground contact to move dorsally, imposing greater stresses on the heels, which then are prone to collapse.[61,64] Toe grabs and heel calks alter the foot axis and concentrate stress.[64] Thoroughbred horses may have a genetic predisposition for a broken back foot-pastern axis.

At rest, elevation of the heel causes the distal interphalangeal and pastern joints to flex and the metacarpophalangeal joint to extend.[70] The effect is greatest at the distal interphalangeal joint and least at the metacarpophalangeal joint.[70] In vitro, elevation of the heels with a wedge decreases the strain in the DDFT, the extensor branches of the SL, and medial hoof wall[71] and decreases the moment about the center of rotation of the distal interphalangeal joint.[72] The horizontal distance between the center of rotation of the distal interphalangeal joint and the toe decreases with heel elevation. In addition, the horizontal distance between the toe and a imaginary vertical line bisecting McIII dropped to the ground is decreased. This decreases stresses on the heels. Decreasing the hoof wall angle increases the stress on the heels.[2]

Lowering the heel or raising/lengthening the toe to create an acute hoof angle or long toe increases the likelihood of toe-first landing.[19,21] Elevating the heels increases the likelihood of heel-first landing.[19] The overall impulse (force × time) on the foot is least when the foot-pastern axis is straight, indicating that a straight foot-pastern axis is least injurious to the foot.[19] At a walk, elevating the heels decreases the strain in the DDFT and its AL[31,72] with little effect on the SDFT and SL. The decreased strain in the DDFT is reflected in decreased pressure on the navicular bone.[41]

Elevating the toe results in a marked increase in strain in the ALDDFT and a lesser increase in strain in the DDFT at the end of the stride as a result of increased extension of the distal interphalangeal joint.[31] Strains in the SDFT and SL are either reduced or unchanged.[31,72] Horses with small hoof wall angulation have a prolonged breakover, but the length of stride,

duration of the stance, and swing phases are unchanged.[19,21] When hind feet are trimmed with more acute hoof wall angulation, breakover is delayed but the timing of impact is unchanged as normal coordination is restored during the swing phase of the stride. There is an increase in over-reach distance, the distance between the print of the front foot and the landing point of the hind foot.[73] Heel wedges delay the dorsal shift in the GRF and decrease the maximum torque about the distal interphalangeal joint during the second half of the stride. Toe wedges have an opposite effect.[31,68] However, neither toe nor heel wedges alter the dorsopalmar position of the point of force during mid-stance of the stride, indicating that the heels are not unloaded. Both toe and heel wedges cause medial displacement of the point of force.[68] Increasing the length of the toe prolongs breakover but does not alter stride length; however, it increases maximal flexion of the metacarpophalangeal joint during the swing phase.[74,75]

The position of breakover in the sagittal plane appears to influence the angle of the dorsal hoof wall and the distal phalanx. Moving the point of breakover palmarly from the most dorsal margin of the hoof wall increases the angle of the dorsal hoof wall and the ground and increases the alignment between the middle and distal phalanges.[63,76] Whether this effect is related to the biomechanical properties of the dorsal hoof wall or relief of pain within the foot is undetermined. The effect of increased hoof angle on hoof wall strain is inconsistent. In an in vitro model, hoof wall strain did not change with increased hoof wall angle.[71] In contrast, in an in vivo experiment, increased hoof wall angle increased hoof wall strain more at the lateral quarter than at the toe and not at all at the medial quarter.[77]

The effect of pastern length and the angle of the foot-pastern axis are less well established. The angle of the hoof-pastern axis to the ground is a feature of a horse's conformation. It cannot be changed experimentally, but comparing horses with different conformations shows that the point of force in horses with a small hoof-pastern axis angle is more palmarly positioned than in horses with a larger axis angle.[27]

Prolonged dorsopalmar imbalance also has delayed effects because of the nature and growth of the hoof capsule. In barefoot horses, leaving the toe long causes the toe to grow faster than a short, trimmed toe. The hoof walls and frog become narrower, and the shape of the ground surface tends to skew away from a circular shape.[78] The length of the frog does not change. Clinically, the same appears to occur in shod horses. In horses with extremely long toes the foot becomes "hoof bound." The heels of long-toed horses are predisposed to become underrun because the heels bend dorsally. Both of these phenomena are seen in Tennessee Walking Horses or American Saddlebreds intentionally shod with long hooves.

Other Forms of Imbalance

Many horses with imbalanced feet have a combination of mediolateral and dorsopalmar imbalance. For example, a foot with a sheared heel has one heel longer than the other, which is frequently associated with a flared toe quarter on the opposite side of the foot.[79] Diagonal imbalance has been described dynamically. The hoof lands on one corner of the hoof capsule and then loads the diagonal corner, with consequent distortion of normal hoof capsule shape and alignment with the rest of the distal limb.[80] Other local deformations of the hoof wall occur, either uniaxially or symmetrically, that do not fit the classical description.

IMBALANCE AND POOR CONFORMATION AS A CAUSE OF LAMENESS

Poor conformation and imbalance of the distal limb are common, as is lameness that can be isolated to the distal limb. However, demonstrating the correlation is not always straightforward. In some horses an obvious disease process and obvious imbalance co-exist, and when the imbalance is treated the lameness improves. In other lame horses, imbalance is evident with no other clinical, radiographic, or scintigraphic evidence of disease, and treating the imbalance also improves the lameness. In yet other lame horses, there is evidence of imbalance, with or without other evidence of disease, but treating the imbalance does not improve the lameness. To my knowledge, only one study thoroughly investigated the effects of hoof balance on injury. The odds of catastrophic musculoskeletal injury and suspensory apparatus failure were lower when the lateral sole area was greater than the medial sole area.[60] Suspensory apparatus failure was more likely the greater the difference between the angles of the dorsal hoof wall and the heels. McIII condylar fractures were less likely with a steeper toe angle.

Mediolateral imbalance is associated with a shift in the point of force of the GRF, distortion of the hoof capsule, induced asymmetry of the articulations of the distal limb, and rotation of the distal interphalangeal joint. With increased compressive stresses the following problems are clinically presumed to follow imbalance: sub-solar bruising, hemorrhage in the white line from laminar tearing, pain from shearing heels, quarter or heel cracks, thrush in narrow frogs, pedal osteitis, fractures of the palmar process of the distal phalanx, sidebone, synovitis, and osteoarthritis, and more proximal fractures[1,54,61,64]

The effects of dorsopalmar imbalance should be separated into the effects of broken-forward and broken-back foot-pastern axes. A broken-back foot-pastern axis increases the load on the palmar aspect of the foot during weight bearing and increases the stresses in the toe at breakover. It causes hyperextension of the distal interphalangeal joint and increases the tension in DDFT and pressure on the navicular bone. Therefore it can be expected to be associated with heel bruising, lamellar tearing at the toe, pedal osteitis of the palmar processes, navicular disease, tenopathy at the insertion of the DDFT, and more proximal injuries of the tendons or suspensory apparatus.[3,54,61,64] In the hindlimb a broken-back foot-pastern axis appears to be associated with tarsal and back pain.

A broken-forward foot-pastern axis (upright) appears to be less pernicious.[3,54] It increases the load on the dorsal half of the foot and decreases tension in the DDFT. The principal findings are sub-solar bruising distal to the dorsal distal margin of the distal phalanx and subsequent osteitis of the distal phalanx.[54]

An upright foot-pastern axis has traditionally been considered to predispose toward concussive injuries of the weight-bearing structures in the limb, whereas a foot-pastern axis with an acute angle to the ground predisposes toward strains and sprains of the flexor apparatus. Similarly, a long pastern has been considered to predispose toward strains and sprains.

Any angular deformity more proximal in the limb that increases the mediolateral symmetrical loading of the foot can be expected to have effects similar to mediolateral imbalance. Rotational deformities do not seem to be a frequent cause of problems. Toe-out conformation is more likely to cause interfererence but anecdotally, toe-in conformation is considered more likely to cause lameness.

Undoubtedly, technological advances in diagnostic imaging and pain localization will lead to identification of other combinations of disease and structure. Epidemiological studies will confirm the relationships between the different features of poor conformation and imbalance on disease.

CLINICAL IDENTIFICATION OF HOOF IMBALANCE

The horse must be observed while it is standing squarely to assess each limb in relation to the whole and in motion on a flat, level surface. Each foot must be examined on and off the ground.

Mediolateral Imbalance

Visual inspection should note the position of the entire limbs to identify angular or rotational deviations more proximally in the limb that may have repercussions for the foot (Fig. 27-4). Visual inspection of the foot on the ground should note rotational deformities of the metacarpophalangeal joint and placement of the foot in relation to the sagittal axis of the limb. The hoof capsule should be inspected closely for asymmetry of the coronary band. This is frequently a strictly visual inspection, but graphing the height of corresponding medial and lateral points on the coronary band provides objectivity that can highlight an imbalance and provide a record for future comparison.[52,81] The medial and lateral walls should be inspected for flares and evidence of underrun heels, lipping at the coronary band, and even spacing between the growth rings.

The ground surface of the foot reflects changes elsewhere in the hoof capsule. The foot should be approximately symmetrical about the center of the frog. In mediolateral imbalance, the sole may appear wider on the side with a flare in the wall and narrower on the side with an underrun wall. Dorsal displacement of the ground surface of one heel in relation to the other accompanies proximal displacement of the coronary band at the heel commonly associated with sheared heels. Wear of the shoe or wall at the toe indicates the point of breakover. Alternatively, the breakover point may be identified by lifting the antebrachium cranially, allowing the metacarpal region and pastern to hang passively, and then lowering the foot; the point of breakover is the first part of the foot to touch the ground.[54] Asymmetrical breakover may indicate mediolateral imbalance, but it also may follow angular or rotational deformities of the limb. Asymmetrical bruising adjacent to the wall at either quarter may signify excessive concussion caused by mediolateral imbalance or laminar tearing in a wall with a flare.

Examination of the distal limb for rotational or angular conformation by viewing the limb on the ground from the dorsal aspect may be misleading because it is influenced by weight bearing. The ground surface of the foot automatically aligns with the surface of the ground regardless of the relative lengths of the medial and lateral hoof wall. This causes secondary rotation within the phalangeal axis. To circumvent this rotation the limb can be examined off the ground by lifting the foot in the same way described to find the point of breakover; the angulation or rotation within the distal limb is observed by sighting down the metacarpal region, pastern, and hoof.[54]

The traditional way to assess mediolateral balance is to sight across the ground surface of the foot with the leg off the ground, holding the proximal metacarpal region and allowing the digit to hang downward in the sagittal plane with the metacarpophalangeal and interphalangeal joints in passive extension. A line drawn across any two corresponding points on the circumference of the ground surface of the wall should be perpendicular to the axis of the limb as judged by the metacarpal region. If the limb is perfectly symmetrical about the axis of the limb, without angular or rotational deformities, and the observer is directly above the limb, this technique is probably satisfactory within the limits of the observer. I question the accuracy of this technique because most distal limbs are not symmetrical but have at least some element of rotation about the metacarpophalangeal joint. A smaller number of horses have true angular deformities at the metacarpophalangeal joint. For reliability, there must be consistency in the

Fig. 27-4 Feet of a yearling with bilateral mediolateral static imbalance. The lateral wall of both front feet reaches higher than the medial wall so that the lateral coronary band is higher than the medial coronary band; consequently, the dorsal coronary band is sloping distally and medially. The growth rings are also tilted in the same direction as the coronary band. The imbalance creates the impression that the pastern is no longer centered in the foot but is displaced laterally.

extension of the metacarpophalangeal joint and in the position of the observer. T-squares have been used to improve the reliability of this observation,[4,54] but misalignment of the T-square with the axis of the metacarpal region decreases accuracy.

Dynamic mediolateral balance is assessed by observing the horse from in front and from behind at a walk and at a trot. Because the degree to which symmetry of landing can be detected is a function of the frequency of observation and speed of the horse, only more severe imbalances can be detected at a trot compared with a walk, and more subtle differences in timing remain undetected unless video recorders or more sophisticated measuring equipment is used. During the flight phase of the stride, movement of the foot, phalangeal axis, and more proximal limb is observed in relation to the plane of travel to correlate with previously noted rotational and angular deformities.

A dorsopalmar radiograph is the only means to assess the relationship between the hoof capsule and the phalanges (Fig. 27-5). Overt imbalance can be detected on routine dorsopalmar radiographs, but detection of more subtle changes requires strict technique because apparent radiographic imbalance can be readily induced artificially. Both feet must be weighted equally, because unilateral weight bearing induces mediolateral asymmetry and rotation of the interphalangeal joints.[40] The foot must be allowed to assume its natural orientation to the rest of the limb, only reliably possible if it is placed on a swiveling block. Deformation of the hoof capsule may be induced by rotation within the limb, which may change the angulation of the distal phalanx with the ground.[82] The metacarpal region must be within 10° of vertical in the frontal plane. The x-ray beam must be horizontal and centered on the mid-sagittal plane so that a wire marker centered on the dorsal hoof wall bisects the central sulcus of the frog on the radiographs. Neither toe-in nor toe-out conformation alters the radiographic measurements of mediolateral balance if assessed in this manner.[83,84]

Although mediolateral imbalance can unquestionably cause lameness, the hoof capsule is not the site of pain that is associated with lameness. Rather the pain is associated with the effects of imbalance, that is, stress on the deeper structures of the hoof and the musculoskeletal structures of the distal limb. Therefore it is not surprising that the lameness may improve with perineural or intra-articular analgesia of the distal limb in a similar manner to osteoarthritis of the distal interphalangeal joint or navicular disease.

Dorsopalmar Imbalance

The limb is examined for angulation at the carpus and metacarpophalangeal joint. The foot-pastern axis is visually inspected to determine whether the axis is straight or broken forward or back. This method provides only a rough guide. Visual examination can be improved by using a gauge, one limb of which is aligned with the pastern and one with the dorsal hoof wall. However, deciding exactly what landmarks to use on the pastern for alignment introduces irregularity. In addition, the axis changes as the horse shifts its weight or posture. Similarly, concavity of the dorsal hoof wall in the sagittal plane raises the issue of what to align the pastern with. If the dorsal hoof wall is concave, usually the top third of the hoof wall is the most closely aligned to the dorsal surface of the distal phalanx.

The length of the toe from the proximal coronary band to the ground surface in the mid-sagittal plane of the hoof is readily measured with a tape and compared against reference values or previous measurements for the same horse. This information is greatly under-used. The length and angle of the heel also are evaluated. Only the wall at the heel distal to the bulb should be evaluated, because inclusion of the heel bulb causes the angle to be underestimated. Heels that are angled more acutely to the ground than the dorsal hoof wall are longer than heels that are parallel to the dorsal hoof wall.

A long toe is associated with elongation and narrowing of the ground surface of the foot. The frog width decreases in a comparable manner with the width of the foot. The length of the frog should remain almost constant, so that an increase in the length of the ground surface of the foot is reflected in an

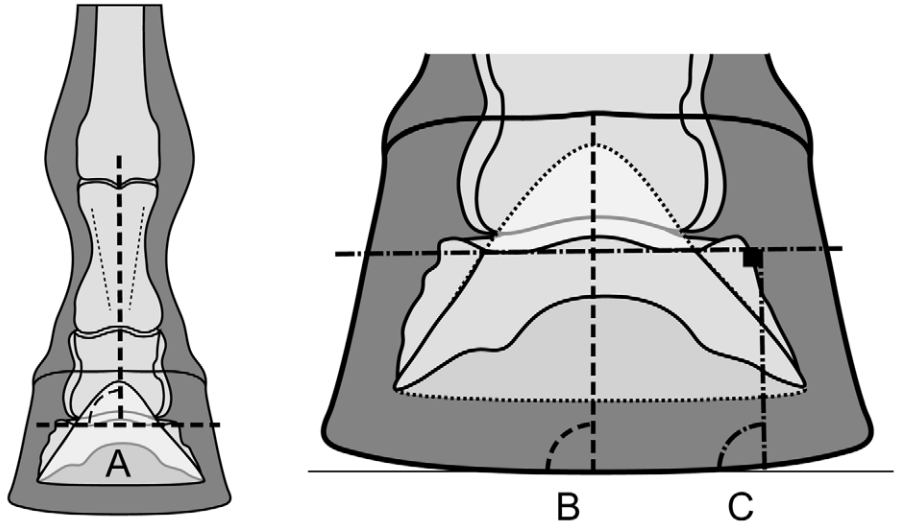

Fig. 27-5 Radiographic assessment of balance has been described by Caudron et al.[84] **A,** Rotation between the phalanges is indicated when a line bisecting the distal phalanx is not perpendicular to the articular surface of the distal phalanx. **B,** A tilt in the axis of the hoof capsule is determined radiographically when a mid-sagittally placed wire marker is not perpendicular to the ground surface of the foot. **C,** Tilting of the distal phalanx is evident when a line drawn perpendicular to a line drawn across the articular surface of the distal phalanx is not perpendicular to the ground. All measurements presuppose that the radiographic beam bisects the foot (the dorsal wire marker bisects the apical process of the distal phalanx and the central sulcus).

increase in the distance between the apex of the frog and the most dorsal aspect of the toe or breakover point. The ground surface of the heels should be adjacent to the base of the frog. If the ground surface of the heels projects dorsally to the base of the frog, the heels are either too long, angled too acutely, or both. Hemorrhage in the white line at the toe caused by lamellar tearing may be a secondary indicator that the toe is too long.

In a horse with a broken-forward foot axis, a flexural deformity of the distal interphalangeal joint must be distinguished from heel contraction secondary to pain. In a foot with a flexural deformity the heels and frog are wide and the ground surface of the foot is triangular, resembling a hind foot. In contrast, a contracted foot has a narrow heel and frog.

The relationships between the individual phalanges and between the phalangeal axis and the hoof are determined radiographically. The phalanges are closest to alignment when the foot-pastern axis is straight. However, the proximal interphalangeal joint usually appears slightly extended, even with a straight foot-pastern axis.[70] The dorsal hoof wall should be parallel to the distal phalanx. The angle of the solar surface of the distal phalanx with the ground and the thickness of the sole, or the distance from the solar surface from the dorsal distal margin of the distal phalanx, should be measured. The center of rotation of the distal interphalangeal joint should be equidistant from the weight-bearing surface of the toe and the heels.

In hind feet, dorsopalmar imbalance associated with hyperextension of the distal interphalangeal joint appears to take a slightly different form compared with the fore feet. The dorsal hoof wall is not necessarily long when viewed from the side. The toe frequently has been dubbed back, and it acquires a marked convexity. Viewed from the ground surface the concavity of the sole is exaggerated and if the foot is shod, the frog lies between the branches of the shoe. This may be from descent of the frog, or proximal displacement of the heels. In my experience, these horses almost invariably are shod.

Evaluation of dynamic dorsopalmar balance suffers from the same limitations as the evaluation of dynamic mediolateral balance. However, gross imbalances can be observed at a walk or trot. Normally, when viewed from the side the foot is expected to land flat or slightly heel first.

TREATMENT OF IMBALANCE AND POOR CONFORMATION

Treatment of imbalance provides at least two challenges. The first is to have a clear objective of what ideal balance is for any given horse because, although there are some hard and fast rules, other areas are unclear. For example, a straight foot-pastern axis is beneficial, but the exact length of toe that is optimal for the same foot is not clear.

The second challenge is interpreting the measured indicators of balance. For example, the measures of mediolateral imbalance, symmetry of the coronary band, sighting along the axis of the metacarpal region and across the ground surface of the foot, footfall, and dorsopalmar radiographs may not agree on whether the foot is imbalanced, the direction of the imbalance, or provide varying degrees of imbalance. Radiography appears to be the most accurate and is substantiated scientifically.[84]

Difficult balance problems may not have easy solutions, and judicious experimentation that can be both time consuming and expensive may be necessary. Balance may be corrected, but long-standing problems may not be correctable. Poor conformation can be compensated for but can never be corrected with trimming or shoeing in an adult horse. The ability to compensate for poor conformation is inversely proportional to the height in the limb from which the defect originates.[5] Major imbalances should be corrected gradually over time, or lameness may result from the correction.[4,54,61]

Rebalancing the foot can be performed by visual assessment of the hoof and foot-pastern axis before and after trimming, repeating until a satisfactory result is obtained. Rebalancing may be facilitated by radiographic assessment of balance. Radiographs, with markers to indicate the angle of the dorsal hoof wall, the location of the apex of the frog, and the position of the coronary band, obtained before the trim has been performed are used as a baseline on which to base the trim. Deformation of the hoof capsule in the pre-treatment radiographs may result in underestimation of the imbalance,[83] and radiographs obtained after trimming may be helpful to assess the accuracy of treatment.

Treatment of imbalance is complicated by the necessity to consider both the immediate and delayed effects. The reversal of the immediate effects of imbalance is the most straightforward, because it requires nothing more than restoring the normal length of the wall around the circumference and ground surface of the foot. The effects of viscoelastic deformation of the hoof wall caused by uneven pressure should correct spontaneously if the force is removed and sufficient time is allowed before the horse is reshod. Other deformation of the hoof wall caused by contraction or aberrant hoof growth may have to wait for new hoof wall to grow from the coronary band to the ground surface after the biomechanical forces have been optimized by trimming and shoeing.

Mediolateral and dorsopalmar imbalance may respond to trimming and allowing the horse to go barefoot.[64] Application of poultices to the foot has been advocated to encourage hoof realignment.[81] This allows the effects of prolonged imbalance from the viscoelasticity of the hoof and misdirected hoof growth to adjust without the influence of the shoe. However, the quality of a wall that is usually shod may deteriorate over several weeks, before it improves, and flat-footed horses may become more lame.

In foals, trimming, shoeing, or surgery corrects poor conformation associated with abnormal angulation in either the sagittal or frontal planes. Conformation in adult horses is fixed, but changing foot balance or shoeing sometimes can compensate for poor conformation. However, when the stresses are realigned to benefit a musculoskeletal structure, they become less than optimally aligned for the hoof capsule and predispose to a different problem. For example, in a horse with a long pastern at a normal angle or with a sloping pastern of normal length, the foot is further dorsal than is ideal. This creates a greater moment about the metacarpophalangeal joint. This can be compensated for in part by extending the heels of a shoe further past the heels of the foot than normal. This technique moves the most palmar ground support palmarly, but it also moves the point of application of the GRF further palmarly, increasing both the stresses on the heels and the propensity to deform. Treatment of poor conformation is almost always a compromise.

Mediolateral Imbalance

Uncomplicated mediolateral imbalance is corrected by decreasing the length of the wall on the side of the foot in which it is longest, or lengthening the wall of the side that is shortest. If the horse has sufficient foot, it is always preferable to correct the imbalance by trimming the longer wall. However, when the hoof is insufficient to permit trimming the longer wall sufficiently to restore the equilibrium, then the shorter wall must be lengthened. A wall can be lengthened in several ways. However, care must be taken because alteration of the balance may actually cause lameness. The simplest method is to add a pad, either a shim or a full wedge

pad. The shim pad is riveted to the branch of the shoe so that it is interposed between the foot and the shoe, or a full wedge pad is positioned so that the thickest portion of the pad is on the shortest side of the foot. Alternatively, the shorter wall can be lengthened by addition of acrylic. This can be allowed to set and a shoe nailed to the hoof and composite, or the shoe can be attached to the foot with the acrylic so that the position of the shoe in relation to the hoof capsule is adjusted as the acrylic dries.[85] A shoe with branches of different thickness can be used. This makes the thinner branch lighter. The width of the web can be increased to compensate for the thinner branch so that the asymmetrical effect of uneven weight distribution is minimized.

Flares and under-run walls that accompany mediolateral imbalance must be addressed by seeing where the hoof wall should be at the ground surface. The longitudinal axis of the frog is a good guide to the location of the center of the ground surface of the foot in the sagittal plane. The shoe should be positioned symmetrically about the frog so that the flare that extends abaxially to the shoe is dressed back and the shoe extends abaxially past the underrun wall.[1] The flare and underrun wall then should correct as new hoof wall grows distally.

The most controversial issue in balancing a foot is restoring mediolateral imbalance in the following circumstances: (1) when the coronary band is asymmetrical with one heel/quarter higher, usually the medial quarter/heel, which is obvious with the horse standing; (2) when the ground surface of the shorter wall appears farthest from the metacarpophalangeal joint when the axis of the limb is sighted with the foot off the ground; and (3) when the shorter wall contacts the ground first at a walk. This is typical with a sheared heel. Should the long wall be shortened, potentially increasing the discrepancy in footfall, or should the long wall be lengthened, exacerbating an already imbalanced appearance? I cannot see any benefit in lengthening an already long wall or determine how this might improve the wall. Radiographic evidence of joint asymmetry may resolve the dichotomy. If this fails, the horse can be shod with a shoe positioned perpendicular to the axis of the limb with the long heel floated and extra support provided by a heart bar shoe. Alternatively, a groove can be cut through the stratum medium immediately distal to the displaced coronary band to encourage it to move distally; this process may need to be repeated.

Compensation for angular or rotational deformities in the limb is seldom attempted because they are not the cause of pain and attempts to compensate for them may increase the asymmetry of stresses imposed on the hoof capsule. However, if an angular limb deformity causes a secondary mediolateral imbalance, this may need correction whenever the horse is trimmed.[61] If a rotational deformity causes one heel to land long before the other, aligning the shoe branches perpendicular to the axis of the metacarpal region rather than the pastern may be beneficial.[54] A medial or lateral extension may be used to extend the ground surface of the foot/shoe under the axis of the limb to improve the distribution of forces in the more proximal limb.[3,54] However, these corrections improve function in one part of the limb at the expense of another. When angular or rotational deformities cause limb interference, it may be necessary to change shoeing to change the flight of the limb to reduce the likelihood of injury.

Dorsopalmar Imbalance

An imbalanced foot usually is related to a toe that is too long or heels that are underrun, less frequently to heels that are too long, and seldom to heels or a toe that is too short. The toe or heels are trimmed until the horse has a straight foot-pastern axis. Since dorsopalmar imbalance starts to develop immediately after shoeing because of disparate growth of the toe and heel, deliberately trimming the foot 1° to 2° broken forward may be useful.

Correction of a broken-back foot-pastern is more complicated after secondary changes have occurred. If excessive toe length has caused the sole to change shape so that it is longer and narrower than normal, the breakover should be brought back to a more natural position. The angle of the dorsal hoof wall should be re-evaluated to determine whether it has improved before other measures are taken. In a barefooted horse the breakover is set by the trim, and in a shod horse by both the position and roll of the toe of the shoe. The foot width should increase naturally in time, and the shoe should be set full at the quarters to accommodate the abaxial movement of the quarters. An extended period may be required to regain the optimal ratio of the length to width of the ground surface of the foot. If underrun heels are a result of a long-toe conformation, the weight-bearing surface of the heels can be moved palmarly (backed up), but the angle of the heels often is too acute to allow alignment of the foot-pastern axis regardless of toe length. This can be corrected immediately by raising the heels. The heels can be raised with a wedge pad, either a full pad or shim, a shoe with wedged heels, or building up the heels with acrylic.[3,86] However, this process increases the pressure on the coronary band at the heels, and may decrease the rate of heel growth. Alternatively, a bar shoe may be used to limit the heels from digging into the ground.[4] Allowing the horse to go barefoot may result in the fastest improvement in conformation, but this precludes the horse working, and flat-footed horses may become more lame. Contraction of the width of foot often accompanies dorsopalmar imbalance, and grooving or thinning the heels has been recommended.[1,62] For long-term soundness, I believe it is preferable to realign the foot-pastern axis as well as possible and then allow wider, straighter heels to grow from the coronary band. This may require time out of work. Raising the heels is frequently the fastest way to return a horse to work; thus the manner of treatment may depend on the immediate athletic demands placed on the horse.

A broken-back hoof-pastern axis in the hind limbs is treated by trimming the toe, using radiography to assess the improvement. Frequently the solar margin of the distal phalanx is tilted by several degrees with the dorsal margin farther from the ground than the palmar processes. In my experience, it may not be initially possible to improve the angle of the solar margin of the distal phalanx beyond parallel to the ground. It frequently is ideal to allow the hind feet to go bare. When the foot must be shod, in contrast to the fore foot, I recommend setting the toe of a rim shoe in line with where the wall at the toe should meet the ground and provide no more coverage of the heels than is necessary.

Treatment of a broken-forward foot-pastern axis caused secondarily from pain or a flexural deformity, by decreasing the dorsal hoof wall angle may exacerbate the lameness. A broken-forward axis from pain must be addressed by treating the primary problem. Correction of a broken-forward foot-pastern axis associated with a flexural deformity is not always necessary, but when it is, it should be accompanied by desmotomy of the ALDDFT.

Compensation for a long pastern or a low foot-pastern axis when the weight-bearing surface of the foot is too far dorsal in relation to the limb may be achieved by extending the heel of the shoe.[81] This correction is directed at reducing the moment about the metacarpophalangeal joint by moving the palmar aspect of the foot/shoe farther palmarly, usually by using an egg bar shoe, but any heel extension that is not likely to result in the shoe being pulled by the hind foot will work. Compensation for an upright conformation is not readily feasible and fortunately seldom necessary.

HORSESHOES AND SHOEING

• Andrew Parks

An equine veterinarian must be able to assess the way a horse is shod in relation to the current use of the horse and make recommendations for shoeing to improve the function of the distal limb. This necessitates an understanding of the basic construction and fit of a shoe and its use. Determining how a shoe affects the horse's performance requires an understanding of how the elements of a shoe function. To understand how to change the function of the distal limb, it is necessary to know which modifications to form and fit of a shoe can achieve the desired result. It is more important to consider how a basic shoe may be modified to achieve a given result than list a variety of different shoes for specific conditions. Farriery developed as an art guided by individual and collective experience and has recently been supplemented by scientific studies. Some guidelines are derived empirically and others have a scientific basis, but the skill of the individual is a vital third element.

HORSESHOES

Foot Preparation

Shoeing cannot be considered in isolation from foot trimming. The foot is trimmed to remove the excess length of wall that accrues because the distal wall is protected from wear by the shoe. After the foot has been cleaned, the exfoliating sole and ragged margins of the frog are debrided with a hoof knife. The wall is trimmed with nippers and then leveled with a rasp.

In addition to maintaining optimal balance in a sound horse by trimming the foot to restore the length of the foot, several other modifications to the hoof capsule may be performed, usually with the intent of improving hoof capsule shape, and often in conjunction with specific shoeing practices. *Floating the hoof wall* refers to trimming part of the hoof wall short so that the hoof will not touch the shoe at that point. The shoe supports the wall on either side of the floated area dorsally and palmarly unless the heel is floated. Floating the hoof wall is used to relieve that section of the wall from weight bearing. This encourages faster growth at the coronary band, permits proximally displaced wall to descend, and relieves stress in the wall so that new wall growth may redirect itself. The heels are floated to treat under-run heels. This is most effective when the palmar aspect of the foot is given additional support (e.g., with a heart bar shoe).

Grooving of the hoof capsule is designed to mechanically dissociate the capsule on one side of the groove from the other. The groove is made through the full thickness of the stratum medium. The grooves may be created parallel or perpendicular to the horn tubules. The use of several grooves parallel to the horn tubules between the quarters and heel of the hoof capsule has been advocated to encourage expansion of the heels by increasing the flexibility of the wall but is of dubious value. Grooves perpendicular to the horn tubules usually are made around part of the circumference of the hoof capsule immediately distal to the coronary groove, typically at the toe or heels. These grooves relieve the pressure on the coronary band from the stresses in the weight-bearing wall. This increases the speed of new wall growth proximal to the groove and allows the new wall to grow independent of distracting forces in the distal wall.

Resection of the hoof capsule involves removal of the stratum medium, usually starting at the weight-bearing surface and extending a variable distance proximally, typically involving no more than 20% to 40% of the circumference of the hoof capsule. Because this creates instability of the hoof capsule, it is used only for treatment of laminitis, white line disease, and hoof wall avulsion injuries. Thinning the hoof wall at the heels so that partial thickness of the stratum medium is removed has been recommended to increase the flexibility of the wall and encourage expansion of the hoof capsule, but it is seldom performed.

The Horseshoe Form

In its most basic configuration a horseshoe is a curved steel bar, rectangular in cross section, that is shaped to conform to the contour of the ground surface of the hoof wall and wide enough to cover the ground surface of the hoof wall and the immediately adjacent sole. The shoe has four surfaces: the foot and ground surfaces and the inner and outer edges, called *rims*. The parts of the shoe are named after the corresponding section of the hoof, that is, the *toe*, *quarter*, and *heel*. Each shoe has two branches, medial and lateral, that extend from the center of the toe to the medial and lateral heels, respectively. The substance of the branches is called the *web*, which has a width and thickness. The shoe is punched with nail holes, three or four in each branch, three of which are usually used. This shoe is described as *flat* because the ground surface of the shoe is level, *stamped (punched)* because it has nail holes, and *open* because the bar of metal forming the shoe does not form a continuous loop between the heels.

The shoe should fit flush with the outer margin of the dorsal half of the hoof wall from one quarter to the other. From the quarter palmarly/plantarly the shoe should incrementally extend further abaxial to the wall until it extends approximately 0.3 cm abaxial to the wall at the heel to allow for expansion and contraction of the hoof capsule as the foot alternates between weight bearing and non–weight bearing. The shoe branches extend marginally palmar/plantar to the heels to allow for growth of the hoof capsule during the shoeing cycle. This basic shoe pattern and fit may suffice for many horses but frequently is altered to suit the exercise performed by a horse, the ground surface on which the horse is worked, and for therapeutic purposes.

Materials and Size

Horseshoes may be made of metal, synthetic polymers, or a composite of the two materials. Altering the material of a shoe alters the weight of a shoe for a given size, the durability of the shoe against wear and other damage, shock absorption, workability, and cost. Most horseshoes are made of steel for reasons of effectiveness, cost, wear, and workability. Aluminum also is used frequently because it is lighter and easier than steel to cold forge, but it wears faster than steel and is not as stiff. Shoes recently have been made from various synthetic polymers and composites of more than one material and are used in specialty situations, but shoe status is in constant flux as new products appear on the market and others disappear.

Metal shoes may be hand forged from bar stock or manufactured. Hand-forged shoes offer the advantage of being customized to the individual foot. However, manufactured shoes are used far more frequently than hand-forged shoes because they save time and a wide range of shoes is suitable for most feet. Bar stock is usually rectangular in cross section and is available in different sizes varying from 0.6 to 1.2 cm thick and 1.2 to 3.1 cm wide, although the most commonly used size is 0.8 × 1.9 cm. Concave stock is frequently used in Europe. Manufactured shoes, also called *keg shoes*, are sized. However, although sizing within and usually between product lines is consistent for a given manufacturer, there is no universal standard for sizing horseshoes. Manufactured shoes may be generically shaped to the general shape of a horse's foot or specifically designed for a fore or hind foot. The former requires more shaping but are cheaper and require less stock on hand. The dimensions of the stock of either manufactured or hand-forged shoes affect the weight of the shoe, stiffness, coverage of the

ground surface of the foot, height the shoe elevates the foot off the ground, and rate at which the shoe wears out.

Shoe weight influences the biomechanics of movement. The heavier the shoe, the more energy is expended accelerating and decelerating the limb at the beginning and end of each stride. Therefore the lightest shoe is used that is compatible with protecting the wall and adjacent sole and providing the stiffness and wear required. Shoes made from concave stock are lighter than shoes made from regular bar stock. The width and thickness of the shoe usually is uniform around the circumference of the shoe so that biomechanical influence of shoe weight and the stresses imposed are usually balanced about the axis of the limb. Occasionally a shoe may be unevenly weighted to alter the animation or balance of a gait. The increased weight may be at the toe, in one branch, or at one or both heels. Increasing the weight at the heels is done to increase animation but has not been scientifically tested. Increasing the weight of the toe has been used to encourage the horse to reach farther at the beginning of the stride. Toe weights do not increase stride length but do increase flexion in the limb of horses with poor limb flexion during protraction of the limb. They have no impact on horses that already have good limb flexion.[1]

Although the width of the web of a shoe is related to the thickness of the hoof and, at least in part, the size of the foot, it is common to increase the width of the web of the shoe to provide increased protection to the margins of the sole. The thickness of the shoe is related to the rate at which it is expected to wear and to a lesser extent the rigidity needed to prevent the shoe from bending out of shape. The height the shoe raises the foot off the ground also is influenced by the thickness of the shoe, but this is usually a secondary consideration to wear and rigidity.

Cross-Sectional Profile of Shoe Stock

The cross-sectional profile of the shoe may be modified by altering the ground surface, the solar surface, either rim of the shoe, or a combination, and may affect the whole shoe or part of the shoe, such as the toe, the branch, or a heel (Fig. 27-6).

Several common modifications are made to the ground surface of the whole shoe. Softening the 90° angles at the junction of the ground surface of the shoe and the inner and outer rims by beveling or rounding, called *rolling,* increases the ease of breakover. A shoe with a rounded outside rim is called a *roller motion shoe,* which improves the ease of breakover in any direction. A similar effect is achieved with a *half round shoe,* so called because it is made from half round stock that resembles a semi-circle in cross section. The toes of flat shoes frequently are rolled or beveled only at the toe to improve the ease of breakover (Fig. 27-7). A similar effect is achieved by rockering the toe, that is, bending the full thickness of the shoe proximally. Less commonly, a flat shoe may be asymmetrically beveled or rounded to improve the ease of breakover toward one side or other of the shoe to encourage a horse to breakover toward that side and direct the flight of the foot. Rounding the margin of a shoe to prevent interference is called *safing.*

There is little traction between smooth steel and the ground. Grooves in the ground surface of the shoe, called *fullering* or *creases,* increase traction. The fullering fills with dirt; the friction between dirt in the fullering and the dirt on the ground is greater than steel on dirt. In addition, the crease provides two additional edges that may bite into the ground. The full circumference of the shoe may be fullered, or it may be limited to the branches of the shoe and less frequently just the toe. Fullering a single branch of the shoe enhances traction uniaxially and delays breakover on that side of the foot. When the branches of the shoe are fullered, the nail holes are centered in the groove, which is formed to conform with the inside and outside of the nail heads.

Fig. 27-6 The cross-sectional profile of the shoe branch can be modified to vary traction and breakover. **A,** Half round; **B,** flat shoe incompletely creased or fullered; **C,** concave stock; **D,** fully creased rim shoe; **E,** incompletely creased rim shoe (Eventer, St. Croix Forge, Forest Lake, MN).

Fullering and modifying the shoe edges frequently are performed in conjunction with each other. Rim shoes are fully fullered, and the ground surface of the rims is beveled toward the fullering of the shoe. More specialized rim shoes have a higher inside or outside rim, hence the names *inside* or *outside rim shoes* (Fig. 27-8). A polo plate is a specialized form of inside rim shoe. Because the higher rim is on the inside, the horse is less likely to cause severe injury to another horse in competition yet still benefits from the additional traction of the rim. A barrel racing shoe is a form of outside rim shoe that provides greater traction than an inside rim shoe, although ease of breakover is sacrificed. A similarly modified profile of racing or training plates is termed *swedging.* A classic example of a shoe that uses all these techniques is a half round, half-swedge shoe worn on the hind feet by harness horses. The inner branch is half round in cross-sectional profile and the lateral branch of the shoe is swedged. Thus the medial branch, enhanced by the half round, breaks over rapidly, whereas the breakover of the lateral branch is delayed by the swedge.

The only common modification to the solar surface of the shoe is gentle beveling of the inner half of the web toward the inside, called *seating out* or *concaved inner surface.* Horses with flat soles are shod with seated-out or concaved shoes to decrease pressure on the sole adjacent to the wall. Less frequently the heels of the shoe are beveled to the outside margin of the shoe to encourage heel expansion, that is, abaxial movement of the wall during weight bearing. This practice is of questionable benefit, and if the shoe is beveled severely, it causes undue stress in the white line. Beveling the part of the heel of the shoe that extends abaxial to the quarters and heels, called *boxing,* decreases the likelihood of the shoe catching on another object or being trod on by another foot and pulled off.

Extensions

An *extension* is any projection of the shoe that extends outward from the normal outline of the shoe in the horizontal plane (i.e., away from the center of the sole). Extensions may be

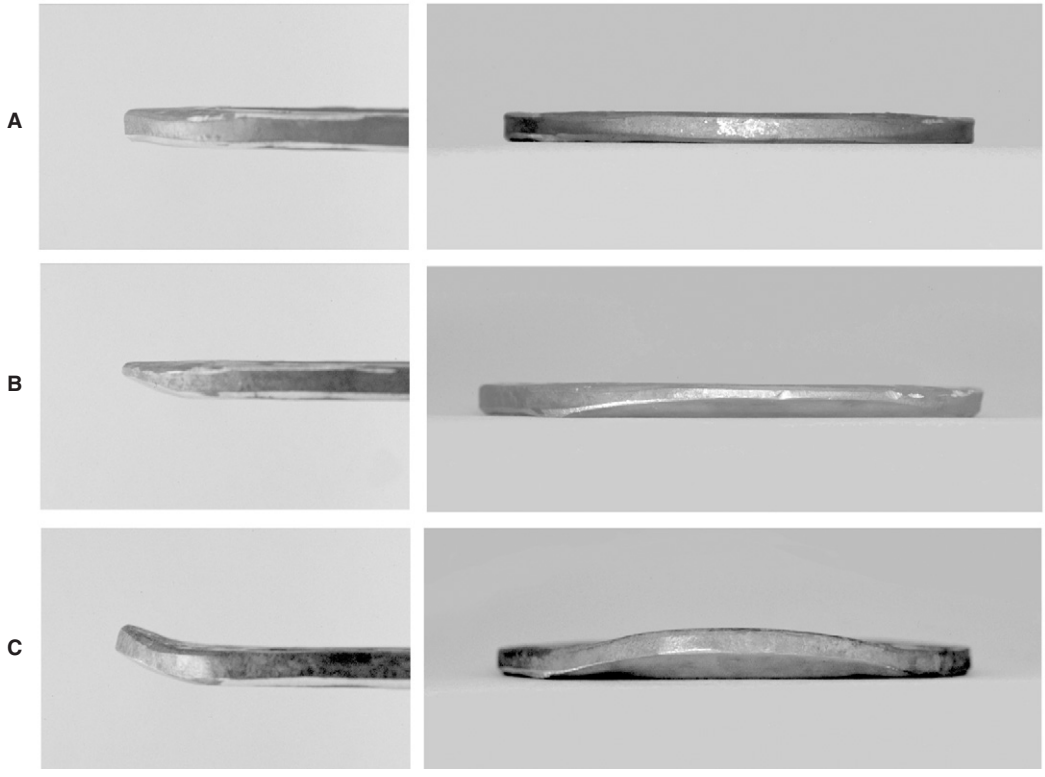

Fig. 27-7 The toe of a shoe frequently is modified to move the point of breakover palmarly compared with a flat shoe. **A,** Flat shoe; **B,** rolled-toe shoe; **C,** rocker toe shoe.

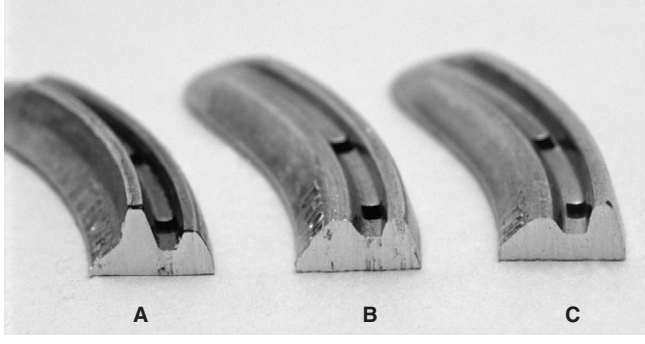

Fig. 27-8 Cross-section of the branch of three shoes. **A,** A high inside rim; **B,** rims of equal height; **C,** a high outside rim.

positioned anywhere around the circumference of the foot. An extension can be forged with the shoe at the time of manufacture or welded onto the outside rim of the shoe. A similar effect is obtained by using an oversized shoe positioned either forward or backward or by setting one branch of the shoe wide. Every extension has the potential to cause the shoe to act as a lever, and this lever action may be either static, when the animal is stationary and the foot bearing weight, or dynamic, particularly during the landing and breakover phases of the stride. When force is exerted on the extension by the ground, the stresses are increased in the adjacent wall and decreased in the opposite wall as the point of action of the GRF shifts. Because the digit is approximately symmetrical in the sagittal plane, the effect of medial or lateral extensions is similar. However, the absence of dorsopalmar symmetry means that dorsal and palmar/plantar extensions function differently. In addition to acting as levers, extensions increase the surface area available for ground contact, which decreases the amount the shoe descends into soft footing at that point in the circumference of the foot. If the surface area of one part of the shoe is altered, it causes the foot to be supported by a soft ground surface more than the opposite side so the interaction between shoe and ground becomes more complex because the foot is tilted.

Abaxial extensions may be used to force either the opposite wall of the hoof capsule to the ground or support the wall adjacent to the extension. In doing so, the lever decreases the compression in the opposite wall and increases the compression in the ipsiaxial wall, which imposes a moment in the frontal plane. This effect is used in foals with angular deformities. The extension is placed on the opposite side of the limb to the side of the deviation to increase the load in the side of the limb with the extension, slow growth, and apply an angular force across the mid-sagittal plane of the limb.

Toe extensions usually are applied to foals with a flexural deformity of the distal interphalangeal joint. The toe extension increases the moment about the distal interphalangeal joint at breakover, as the point of action of the GRF moves dorsally, and during weight bearing if the heels are off the ground. This increases tension in the DDFT and muscle. Therefore the toe extension acts to stretch the musculotendonous unit of the DDF. Success depends on the severity of the flexural deformity. In more severely affected animals the pain generated by the increased tension in the DDFT, with or without increased compression at the toe, becomes counterproductive. The change in location of the GRF places the wall at the toe under greater compression and it is prone to deform.

Heel extensions frequently are used uniaxially or biaxially. In performance horses, extensions frequently take the form of short continuations of the heel that are called *trailers*. Trailers are used almost exclusively on the lateral branch of hind

shoes. Front shoes with trailers are likely to be removed by interference from a hind foot. Egg bar shoes project palmar/plantar to the heels of the hoof capsule and act as heel extensions. They are most commonly used on the front feet, where they are less likely to be removed by interference than shoes with trailers. Force on a biaxial heel extension decreases the moment about the distal interphalangeal joint and the tension in the DDFT. Therefore horses convalescing from a DDFT injury benefit from heel extensions, frequently used in conjunction with heel elevation. Horses with navicular disease appear to benefit from egg bar shoes, theoretically because the navicular bone is under less compression from the DDFT,[2] but this has not been substantiated.[3] The consequence of this benefit is that the heels are under greater compressive stress.

Heel extensions alter the way the foot strikes the ground. If, as happens frequently, the heels are closer to the ground at impact, the extension contacts the ground first. A lateral uniaxial extension, either in line with or diverging up to 45° from the mid-sagittal plane of the foot, is used to force the foot to pivot toward the side of the trailer as the foot lands. The toe of the foot is directed laterally after impact and breakover is redirected.

Bars

A *bar* is any part of a shoe that extends from one branch of a shoe toward the other. A *complete bar* extends from one branch to the other; a *partial bar* extends part of the way across the shoe. Most bars extend from one heel to the other to form a closed shoe. A bar may extend from one quarter to the other, or even diagonally across the shoe. There are several patterns of complete bar shoe in common usage including the straight bar, egg bar, heart bar, and heart bar–egg bar (or full-support shoe). Bar shoes offer several benefits: increased stability and ground contact surface area, local protection, and recruitment of additional weight-bearing area of the foot.

Closing the shoe is considered to make the shoe more stable by decreasing movement between the branches of the shoe and is frequently used, often in conjunction with other shoeing techniques, for instability within either the hoof capsule or distal phalanx. Bars that extend palmar/plantar to the normal position of the heel of the shoe act as a palmar/plantar extension. Bars that set under the ground surface of the foot can be adjusted to protect that part of the foot from ground contact, apply pressure to that part of the foot, or recruit that part of the foot for weight bearing. A straight bar shoe may decrease pressure on the palmar/plantar third of the frog and protect the underlying navicular bone. The heart bar shoe is used to recruit or increase the role of the frog in weight bearing, particularly in the treatment of laminitis. However, heart bar shoes also may be used to support the palmar/plantar aspect of the foot to reduce the stress in the adjacent wall and permit floating of the heels.

An incomplete bar extends part of the way across the ground surface of the foot, most commonly from one heel onto the frog, which supports or reduces weight bearing on a single heel. Alternatively, a full bar across the full width of the foot may be used in conjunction with an incomplete shoe so that the bar covers both heels, but the shoe is incomplete between one quarter and heel. The bar of a Z bar shoe is shaped with two 90° bends that are incorporated into a three-quarter shoe, so that one leg of the Z is attached to the heel of one branch and the other is attached to the quarter of the opposite branch. This shoe also relieves one heel from weight bearing.

Calks, Grabs, and Other Devices Added to the Ground Surface of the Shoe

Various devices are added to the ground surface of a shoe to increase traction. They also influence the speed and direction of landing and breakover. Calks are projections of almost any size and shape, although most are round, square, or rectangular, on the ground surface of a shoe (Fig. 27-9). The terminology to describe the different types is confusing and at times inconsistent. Different types are called *blocks, stickers,* and *studs.* They are made of steel or steel with a tungsten carbide core. Toe grabs and bars welded to the shoe are, in essence, greatly elongated calks. Borium, tungsten carbide crystals in a flux, is welded onto the surface of a shoe in an incremental manner so that any shape or sized projection can be formed. Some calks are permanent, whereas others are temporary. Permanent calks are forged with the shoe, molded in the case of aluminum shoes, at the time of manufacture, or welded or brazed onto the shoe at the time of fitting. Drive calks are semi-permanent and are driven into a hole drilled into the shoe. Temporary calks, also called *screw-in calks* or *studs,* are screwed into tapped holes so they can be attached and removed as needed. Cotton wool is used to plug the hole when not in use. The size and shape of the studs may be changed with the ground conditions.

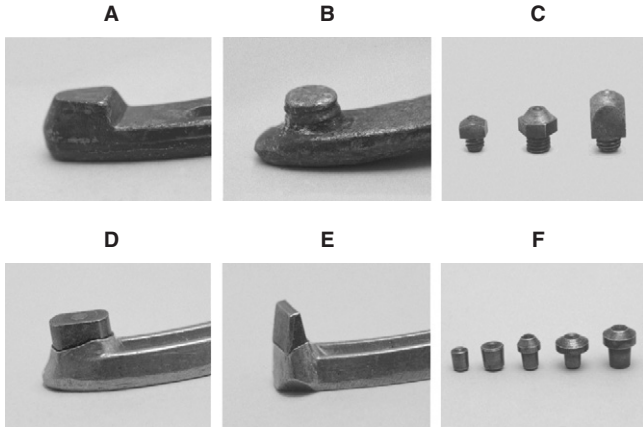

Fig. 27-9 Calks may be forged with the shoe at the time of manufacture or added later. **A,** Calk of a "heeled" shoe formed at the time of manufacture; **B,** calk formed by addition of borium; **C,** various sizes of screw in calks; **D,** a block inserted into an aluminum shoe at the time of manufacture; **E,** a sticker inserted into an aluminum shoe at the time of manufacture; **F,** drive-in calks.

Calks may be positioned at any point around the circumference of the shoe. The choice of whether to use calks, what type of calks to use, and where to position the calks follows no dogmatic guidelines, but usually is based on the preference of the farrier. However, although square and round calks probably offer equal resistance to both mediolateral and dorsopalmar motion, rectangular calks offer greater resistance to motion against movement perpendicular to the long axis. Bilateral heel calks typically are used on jumpers and event horses. Racehorse shoes may be equipped with toe grabs, with or without one or two heel calks (blocks or stickers). Draft animals usually have shoes with biaxial heel calks and, less frequently, a large toe calk.

Projections from the surface of the shoe, in addition to providing traction, inevitably alter the balance of the foot by altering the way the foot contacts the ground. The harder the ground surface, the greater the effect. The taller the calk, the greater the effect. A single calk at either the heel or toe alters mediolateral and dorsopalmar balance. Two heel calks of equal height alter dorsopalmar balance. The addition of a toe calk of equal height restores dorsopalmar balance. The addition of calks to the shoe concentrates stress in the wall immediately proximal to the calk. Therefore the lowest broadest calk compatible with adequate traction is recommended.

The effect of calks on breakover and landing is a secondary consideration, because other methods usually are applied to

achieve the same objective. A single heel calk acts in much the same way as an extension, causing the foot to turn toward the side with the calk as the foot lands. Symmetrical placement of two pairs of calks, one pair on either side of the toe and one pair at the heels, encourages the foot to break over in the center of the toe.

Pads

A pad is a layer of material inserted between the hoof capsule and the shoe (Fig. 27-10). Pads may provide protection, diminish concussion, and alter the effective angle, length, or both of the foot and shoe. Traditionally they have been divided by form into full and rim pads, and by composition into leather and synthetic. However, in the last two decades an imaginative range of products has become available, a range too great for comprehensive discussion. Pads may be riveted to the shoe, which is then nailed to the foot. However, shoes are available that are manufactured with a rim pad bonded to the shoe. Full pads are fitted between the foot and the shoe and cover the entire ground surface of the foot. The cavity between a full pad and the sole usually is filled with pine tar and oakum, or a synthetic equivalent such as silicone, to prevent the cavity filling with dirt. In contrast to full pads, rim pads are fitted to the contour of the shoe so that the sole is not covered.

Pads that cover the sole protect the ground surface from direct trauma. However, efficacy has been questioned because the pad and packing effectively lower the contact point with the ground. Pressure on the pad can then be transmitted to the sole, although in a more diffuse pattern. Any pad interposed between the shoe and the wall has the potential to diminish concussion on the wall. However, products vary greatly.[4] Wedge pads, either full pads or bar wedges, change the angulation of the hoof capsule to the ground. Wedge pads most commonly are used to raise the heels. Wedge pads also are used to raise either the medial or lateral wall to improve the mediolateral balance when this is not feasible by trimming. This can be achieved with a full pad, but it is more common to use a uniaxial wedged shim.

More novel pad designs include extension of the ground surface of the pad between the branches of the shoe to fill part or all of the cavity between the ground and the sole to form a flexible heart bar, or to recruit more weight-bearing surface area and support the ground surface of the foot. Similarly, silicone putty and pour-in polyurethane can be applied to form a pad in situ after the horse has been shod. Once set, these materials can be trimmed to selectively apply or relieve pressure.

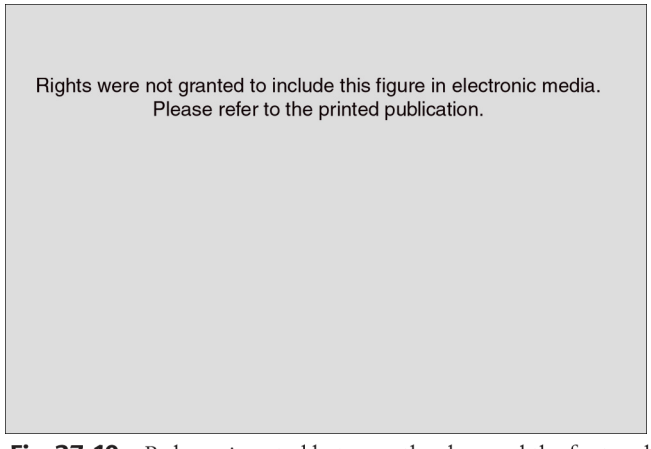

Fig. 27-10 Pads are inserted between the shoe and the foot and take various forms. **A,** Full leather pad; **B,** full plastic pad; **C,** oval plastic rim pad; **D,** full wedge pad; **E,** a bar wedge pad; **F,** a full plastic pad formed with a molded heart bar (Cushion Frog Pad; Castle Plastics, Leominster, MA).

Pads have several disadvantages. All pads compress, which causes the nails to loosen sooner than they otherwise would. Full pads trap moisture against the sole and frog. The underlying sole and frog are softer, and the horse is predisposed to developing thrush.

Miscellaneous Changes in Shoe Form or Fit

A shoe shape is not limited to covering the entire ground surface of the wall. Partial shoes cover part of the circumference of the hoof wall. Tips that cover just the toe are used to prevent wear at the toe in young horses. A three-quarter shoe extends from one heel to the opposite quarter and limits weight bearing in the uncovered heel. A shoe may be reversed so that it is open at the toe but closed at the heels. This functions as an egg bar shoe palmarly with a shortened breakover at the toe.

Hot Versus Cold Shoeing

In cold shoeing a previously manufactured shoe is shaped cold and applied to the trimmed foot. In hot shoeing a newly forged shoe or a manufactured shoe is heated in the forge and applied to the ground surface of the foot while the shoe is still hot. The heat sears and levels the trimmed surface of the foot. It should cause no discomfort to the horse. Cold shoeing is quicker and requires less equipment and less skill. Hot shoes are easier to shape than cold shoes because the steel is softer. Hot shoeing produces a better fit, because the searing levels any minor irregularities in the trim and highlights any overtly unleveled areas. This is no substitute for correct trimming of the foot beforehand. The searing also aids seating of clips. It is also considered to seal the ends of the horn tubules.

Attachment of the Shoe to the Hoof

The large majority of horseshoes are attached to the hoof capsule with nails. Horseshoe nails are available in a variety of styles and sizes, but all share a similar pattern. Each has a head, a shank (blade), and a point beveled at the tip. There are several types of head that vary in size and the angle of bevel. Heads with less bevel, such as European head nails, are suited for thicker webbed shoes. Other nails with thinner or narrower shanks, such as race and slim blade nails, minimize damage to the wall. The size and style of nail is chosen based on experience to provided secure attachment of the shoe to the hoof capsule, without unnecessarily damaging the hoof capsule. The shape of the crease and nail hole should be stamped to fit the shape of the nail head, which provides the greatest support to the nail. The heel nail is located at the bend in the quarter, the toe nail at the junction of the toe and quarter, and the quarter nail(s) evenly spaced in between. In North America, three nails are usually used in each branch of the shoe. In the United Kingdom, three nails are usually used in the medial branch and four nails in the lateral branch.

The nail should be driven into the ground surface of the foot at the outside of the white line and exit the wall approximately 1.9 cm proximally. The bevel at the point of the nail is always directed toward the sole to limit the likelihood of the nail entering the underlying sensitive structures. Once the nail is driven, only the flat head of the nail should extend distal to the shoe. Because there is some variability in thickness of hoof wall for a given sized foot, the position of the nail hole in relation to the thickness of the web should be adjusted so that it is immediately distal to the white line. When the nail holes are positioned more toward the inner rim than normal, the shoe is coarse punched; when they are toward the outer rim, the shoe is fine punched. Because the slope and thickness of the wall changes between the toe and quarter, the angle at which the nail is driven decreases from toe to heel. This should be reflected in the stamping of the nail holes. These adjustments to the position, shape, and angle of nail holes are easier to accommodate on hand-forged shoes, although modern manu-

factured shoes are available in sufficient variety and made to stringent specifications that most situations can be addressed satisfactorily. The number of nails, size of the nails, the congruency of the nail holes to the shoe, and the skill with which they are applied determine the security of attachment of the shoe to the hoof. Small nails may not adequately attach the shoe to the foot. Large nails may split the hoof capsule.

Recently the use of various adhesives to attach shoes has become more popular. The shoe can be affixed with an adhesive by either tabs or cuffs that are attached to the circumference of the shoe and extend proximally. The cuffs are made of semi-rigid plastic or synthetic cloth. Alternatively, the adhesive may be directly interposed between an aluminum shoe and the ground surface of the wall and immediately adjacent to the sole. Attachment of the shoe with adhesives offers several advantages over nailing in the following circumstances: (1) when nailing is too painful; (2) when there is insufficient wall for nailing the shoe; and (3) depending on the specific application, it permits greater expansion of the foot. However, there are disadvantages. The glue-on shoes or the adhesive are more expensive, and application of some adhesives to the side of the wall decreases the quality of the underlying wall over time. There is a also perception that glued-on shoes do not stay on as well as nailed-on shoes, but this impression is in part the result of poor case selection or poor application.

Clips are triangular-shaped projections that extend proximally from the periphery of the solar surface of the shoe. Clips may be forged from the shoe at the time of fitting, or shoes with preformed clips are purchased. When a shoe is fitted, the outer surface of the clip is congruent with the surface of the hoof wall. They reduce movement between the shoe and the hoof capsule, which decreases the shear stress on the hoof nails. A single clip usually is used in the center of the toe of fore shoes, and two clips are placed near the toe quarter junction of hind shoes. A toe clip is not used on hind feet in case it should injure the fore foot, but there is no reason why side clips should not be used on fore feet. For additional stability of the hoof capsule, clips may be positioned elsewhere around the periphery of the shoe to constrain expansion of the hoof capsule. Optimally, two or more clips should be located at 180° to each other around the circumference of the shoe so that the flat surface of the clips are aligned perpendicular to the direction of expansion.

Horseshoe Functions

The principal objective of shoeing a horse is to provide protection to the hoof wall from excessive wear. More far-reaching goals include improving balance, providing traction, modifying breakover, increasing animation, providing support or stabilization, and limiting interference.

Balance

Mediolateral and dorsopalmar balance are discussed elsewhere (see pages 252 to 253).

Protection

Shoes and accessories can provide protection from excessive wear, trauma, and excessive concussion. Protection from excessive wear is primarily required for the ground surface of the wall and is provided by any shoe that is interposed between the foot and the ground around the full circumference of the hoof wall and the adjacent sole. Protection of the rest of the ground surface of the foot, namely, the sole and the frog, may be achieved by interposing a layer between the ground and the ground surface of the foot. If a specific area needs protection, frequently this can be provided by modifying the shoe. For example, a seated-out wide web shoe protects more of the sole adjacent to the wall than a shoe with a narrower web. A bar added to the shoe protects the underlying sole or frog. For more extensive protection to the ground surface of the foot or alleviation of concussion, a pad may be inserted between the shoe and the foot (see page 266). Some shoes are manufactured with a composite of a metal backbone to provide rigidity and synthetic polymers to provide protection against concussion.[4]

Traction

Traction is required to facilitate optimal, confident movement of a horse over the ground as the limb decelerates at the beginning of the stride, as the horse propels itself forward and around turns, and as the foot breaks over. There is an indirect inverse relationship between traction and ease of breakover. Many modifications to a shoe that increase traction delay breakover and vice versa. The amount of traction required depends on the horse, type of exercise, and the ground surface.

Increased traction is provided by decreasing the ground surface area of the shoe, creasing or fullering the shoe, adding ridges to the cross-sectional profile of the shoe, or using calks, grabs, and nail heads that project below the surface of the shoe. Increasing the ground surface area of the shoe or rounding the outer rim or both rims of the shoe reduces traction.

Breakover Modification

The speed of breakover is related to the moment created about the distal interphalangeal joint by the dorsal hoof wall at the end of the stride. This is determined by the anatomical relationship between the center of rotation of the distal interphalangeal joint and the dorsal-most point of ground contact, termed the *breakover point*, and the shoe resistance to being elevated off the ground. The moment about the distal interphalangeal joint is dictated by the direct distance between the center of rotation of the joint and the breakover point and the angle this line forms with the ground. These are in turn influenced by the length and angle of the dorsal hoof wall. Breakover can be enhanced by shortening the toe, moving the breakover point palmarly and increasing the angle of the dorsal hoof wall. Breakover is delayed by lengthening the toe[5] and decreasing the angle of the dorsal hoof wall.[6] Shortening the toe is accomplished by trimming the foot and is limited by the underlying sensitive structures. Toe length can be increased by letting it grow out or addition of pads or a thicker webbed shoe. The breakover point can be moved palmarly by trimming a barefooted horse or rolling or rockering the toe of the shoe, squaring the toe of the shoe, or setting the shoe back. However, the use of rolled or rockered toes did not influence the timing of breakover.[7,8] The angle of the dorsal hoof wall may be increased by elevating the heels with wedge pads or using shoes with wedged heels. These practices are both preferable to leaving the heels long. The degree to which the shoe adheres to the ground is indirectly related to modifications made to the shoe to enhance traction.

The direction and the point on the circumference of the hoof at which breakover occurs are related to the conformation of the limb, namely, the presence of angular or rotational deformities. To change the breakover point, either the orientation of the shoe on the ground before breakover or the ease of breakover between the two branches can be changed. The direction the foot is oriented on the ground is influenced by the way it lands, and the way it lands is influenced by the path of the foot during the flight phase of the stride, which is in turn influenced by the way the foot breaks over to complete the full phase cycle. Uniaxial trailers and heel extensions turn the foot ipsilaterally at landing, which directs breakover toward the opposite side of the toe at the end of the stride.

Breakover may be redirected by changing the relative ease with which the branches leave the ground, changing the relative length of the lever arm, adherence of the two branches of the shoe to the ground, or a combination of these factors. Adherence is increased by use of traction devices or decreased by using a non-fullered branch. The length of the lever arm of a shoe branch may be increased by setting it more dorsal to create a small extension between the center of the toe and the

toe/quarter junction or decreased by setting it back. In essence, this is what happens when the toe is squared. Increasing the ease with which one branch lifts off the ground, while decreasing the ease the other branch lifts off, shifts the breakover point toward the side with slower breakover. Any maneuver to change the direction of breakover is accompanied by increased torsional stress in the limb.

Animation

Gait animation indicates increased range of joint movement with exaggerated temporal characteristics. Animation is primarily a cosmetic change created because such characteristics are considered esthetically desirable in certain equestrian disciplines. It may be improved by shoeing.[9] Increased animation of gait is achieved by increasing the weight of the foot and shoe and increasing the length of the foot, shoe, or both.[5] These manipulations delay breakover, which is then followed by an exaggerated response both in distance moved and joint angulation. Animation obtained by increasing the length of the foot creates imbalance and increases stresses associated with moments about the distal interphalangeal joint. Animation obtained through increased weight of the foot is accompanied by greater energy expenditure by the horse, fatigue, and a greater chance of injury. Interestingly, egg bar shoes decrease animation compared with flat shoes.[3]

Support

Support is a term widely used, seldom defined, and often ambiguous. Support usually means to hold a structure up or prevent it from collapsing. This can be interpreted in at least two ways. First, it can refer to the relationship between the foot and the ground. Second, it can refer to supporting a structure within the foot. On occasion, support may fit both of these circumstances. Specifically, supporting the foot in relation to the ground implies keeping the whole or part of the foot from descending into a ground surface that gives, or keeping the foot level. Increasing the ground surface area of the shoe at any juncture around the periphery of the foot will support that area. Typically, the palmar aspect of the foot is most likely to be supported by the use of a straight bar or an egg bar shoe.

Support as a concept applied to structures within the foot is not always straightforward. Collapse of the hoof wall under excessive compressive strain is a simple example. However, in horses with laminitis or rupture of the DDFT, the distal phalanx displaces from its normal position; however, the concepts behind providing support are quite different. In a horse with a ruptured DDFT the relationship between the distal phalanx and the hoof capsule is intact, whereas in a horse with laminitis, it is disrupted.

An injured tissue may require stress relief. The clinician should determine whether the tissue is stressed under tension (tendons, ligaments, lamellae) or compression (bone, hoof wall), at what point in the stride the stress is greatest, and whether the stress is associated with weight bearing, moments about the distal interphalangeal joint, or a combination of these two factors. The stresses that are greatest during the weight-bearing phase of the stride are redirected by altering the balance of the limb by trimming the foot, applying wedges, using shoe extensions as levers, or recruiting additional parts of the ground surface of the foot to bear weight. For example, in a horse with laminitis with uniaxial damage to the lamellae, the distal phalanx displaces distally on one side of the foot only and the distal interphalangeal joint becomes correspondingly asymmetrical. Support of the distal interphalangeal joint requires an extension to the side of the displacement, but this would further increase the strain in the damaged lamellae and cause further displacement. To protect the lamellae, contralateral extension, used with other measures to support a laminitic foot, would load the contra-axial lamellae and protect the damaged lamellae by reducing the load. An ipsilateral extension would be appropriate to treat a strain of the collateral ligament. However, redistributing the stress from one structure inevitably increases the stress on others.

Decreasing the moment about the joint reduces stresses that are greatest during extension of the distal interphalangeal joint. For example, in a horse with acute laminitis, the already damaged lamellae have a greater propensity to separate with the stress associated with breakover. To reduce this stress, shortening the toe decreases the length of the lever arm and elevating the heels decreases the tension in the DDFT.

A strain of the insertion of the DDFT is under stress during both weight bearing and breakover. A heel extension with elevation decreases the stress during weight bearing by moving the point of action of the GRF palmarly. Moving the breakover point palmarly decreases the tension in the DDFT at breakover by decreasing the torque about the distal interphalangeal joint. If the DDFT were severely strained, a heel elevation and extension would prevent the toe of the foot from lifting off the ground and subluxation of the distal interphalangeal joint.

Importantly, the practitioner needs to understand which tissue to support, how to achieve it, and anticipate the side effects. In addition to the immediate benefits of the support provided, the clinician must contend with the changes within the hoof capsule and changes in the relationship between the hoof capsule and the distal phalanx from movement between the epidermal and dermal lamellae, the viscoleasticity of the hoof capsule, and the altered pattern of growth of the hoof.

Prevention of Interference Injury

Interference occurs when the foot of one limb contacts another limb during the stride cycle, which frequently results in injury. Interference can be divided into two types. *Brushing* occurs when a forelimb or hindlimb interferes with the contralateral limb between the coronary band and the carpus or hock. When a limb interferes with the ipsilateral limb, the hindlimb strikes the forelimb (forging, overreaching) or, less frequently, the forelimb strikes the hindlimb (scalping, speedy cutting). *Cross firing* occurs when a forelimb and contralateral hindlimb interfere. The causes of interference include poor balance, poor conformation, fatigue, and lameness. When poor balance, or lameness, is identified as the cause, correction of these problems should resolve the interference. Increasing the fitness of the horse or using a lighter shoe may reduce interference from fatigue in unfit horses. However, the conformation of a horse cannot be changed. For example, a horse that is toed out will wing in during the flight phase of the stride, increasing the likelihood of interference with a contralateral limb. A horse with a short back in relation to the length of its limbs has an increased tendency for interference between a forelimb and a hindlimb. Treatment of interference that cannot be eliminated by removing the cause is directed at preventing interference by influencing the flight pattern of the feet and reducing the severity of injury when interference does occur.

Contact between ipsilateral limbs occurs as the forelimb is breaking over and the hindlimb is landing. Traditionally, prevention has been aimed at encouraging the forelimb to break over faster so that it moves out of the way of the hindlimb and delaying breakover of the hindlimb so that it lands later. Forelimb breakover has been discussed previously. Delaying breakover in the hindlimbs has been accomplished by lowering the heels of the hoof or thinning the branches of the shoe at the heel. However, although this does delay breakover, limb coordination is restored during the swing phase of the stride.[10] It also creates a dorsoplantar imbalance, which may cause other problems.

Contact between contralateral forelimbs occurs because the path of the limb in the swing phase is too close to the

position of the weight-bearing limb, which is most likely to occur in base-narrow, toed-out horses. Prevention aims to redirect breakover laterally away from the medial toe so that the phalanges do not diverge as far medially from the mid-sagittal plane of the limb as the metacarpophalangeal joint flexes.

Contact between a hind foot and the contralateral forelimb in pacers occurs between strides as the horse is suspended. Prevention of cross firing is aimed at encouraging the hindlimb to stay further lateral so that it does not contact the forelimb. This is accomplished by encouraging the foot to move laterally as it lands, adding a trailer to the lateral branch of the shoe, and encouraging the foot to break over toward the outside of the foot by using a half round–half swedge shoe.

To decrease the severity of injury when impact between the limbs is unavoidable, the clinician should reduce the likelihood of the shoe itself, particularly sharp edges, from contact of the limb likely to be injured and directly protect the injured limb. To limit injury caused by sharp edges at the periphery of the shoe, the margin of the shoe can be safed in the area of contact, or a shoe with a curved contour, such as a half round shoe, can be used. To limit contact between the shoe and the injured limb, the shoe can be fitted so that it is set back from the margin of the hoof wall by moving the toe of the shoe back or by moving the medial branch axially. Alternatively, the shoe is forged so that that part of the shoe making contact is set back from the wall. Boots can be worn during exercise to directly protect the part of the limb likely to be injured.

THE PRACTICE OF SHOEING

Effects of Shoeing on Foot Function

A horseshoe is not simply an extension of the hoof capsule. By interposing a shoe that has markedly different physical characteristics from the hoof capsule between the foot and the ground, a single interface is replaced by two interfaces, that between the foot and the shoe and that between the shoe and the ground. This inevitably has consequences for foot function.

A flat shoe nailed onto the hoof decreases movement of the hoof during the impact phase of the stride,[11] though the heels are still able to expand.[12] It increases the maximum deceleration of the foot,[4] increases the frequency of vibrations within the foot as it strikes the ground,[13] and maximizes vertical GRF.[14] This influence of shoeing on the shock caused by foot impact decreases proximally to the point where the influence is minimal at the metacarpophalangeal joint.[14] Shoeing does not change the principal compressive forces within the hoof wall, although it does cause slight reorientation and decreases the variability of the stresses within the wall.[15] In addition, shoeing increases the pressure on the navicular bone by the DDFT[3] and accentuates the decrease in tissue pressure within the digital cushion that occurs soon after impact.[13] Shoeing increases stride duration, but not stride length, in young horses shod for the first time.[9] Shoeing and the addition of weight to a shod foot increase the animation of the gait.[5,9] Shoeing has minimal effect on the point of force during the stride.[16] However a horse shod with flat steel shoes is likely to slide farther after impact on a firm, flat surface, such as macadam or concrete, than would a barefooted horse.[17] It has been suggested that the rigidity of the shoe alters the way the hoof capsule accommodates to irregularities on the ground surface.[17] A rigid shoe causes the whole foot to tilt or twist, whereas the viscoelastic hoof capsule might permit local distortion of the hoof capsule with less displacement of the whole foot. Finally, shod horses do not wear the feet naturally. Although virtually no wear of the distal hoof wall occurs between the toe and the middle of the quarter, because there is no movement of the hoof wall against the shoe, the heels do wear against the shoe as they expand and contract.[17] Therefore during the course of a shoeing cycle, the angle of the dorsal hoof wall decreases.

It is my impression that shoeing over a prolonged period results in a thinner hoof wall. The quality of the wall adjacent to the shoe is not as good as that of the same horse barefoot. It is also my impression that the distal phalanx may change shape as the result of certain shoeing practices and imbalance. Mediolateral imbalance may change the shape of the distal phalanx.[18] Of greater importance is the effect of shoeing on the development of the feet of young horses. The feet finish growing when a horse is between 4 and 6 years of age. If abaxial movement of the hoof is restricted by shoes before that age, it may affect the growth of the hoof and potentially the shape and size of the distal phalanx. I prefer to allow young horses to go barefoot until they are mature if the intended use of the horse permits.

The deleterious effects of shoeing have led to a resurgence of interest in maintaining horses barefoot with routine trimming as necessary. Although there are unquestionable benefits to keeping a horse barefoot, maintaining a horse under modern management conditions so that its feet are in a condition to withstand the demands of work without becoming lame can be challenging.

Shoeing Sound Horses for Performance

Routine shoeing is directed at maintaining optimal balance and foot function and then addressing any specific needs that are related to the nature of work the horse performs. Balance is discussed elsewhere (see pages 252 and 253). The specific needs of a horse for a given type of work often have an established tradition. Observation of how other horses competing in the same discipline are trimmed and shod is a good starting point. Specialized farriers who shoe horses competing at high levels are a valuable resource. Fads are as much a part of the present history of shoeing as they are of many other disciplines and should be viewed with circumspection. However, although most fads disappear, a few become part of the standard armamentarium. In addition to traditional guidelines, there are rules regulating certain trimming and shoeing practices set by the governing bodies of different branches of equine sports and competitions. These frequently regulate the type of traction devices, weight of shoe, or length of toe that may be used. These rules generally are aimed at limiting excessive injury to the horses. For example, the use of toe grabs is prohibited in racehorses in certain states in the United States because of the established association between use and severe musculoskeletal injuries. Polo ponies are allowed to compete with inside rim shoes on the fore feet but not outside rim shoes.

Corrective Shoeing

Modification of a shoe in the pursuit of one objective almost inevitably has other consequences, which may be untoward. For example, to alter the mediolateral imbalance of a foot by decreasing the thickness of the web of one branch, either the width of the web can be maintained with loss of weight or the weight of the web can be maintained but the width must be increased. Changing the weight of the web alters the inertia about the distal limb. Changing the width of the web potentially changes the traction between the ground and the shoe and the depth the shoe sinks into the ground surface.

Corrective shoeing is directed at preventing lameness in a horse with poor conformation or balance (see pages 253 to 259) or treating a horse that has become lame. Therapeutic shoeing of lame horses requires knowledge of the cause of the problem and how to treat it. Lameness usually is related to pain that is often the response to inflammation after

low-grade repetitive injury, insult from stresses within tissues, or at the interface between tissues. These stresses may be compressive, tensile, bending, torsional, shearing, or a combination of these. For example, compressive strains within the sole result in bruising and in some horses, osteitis of the distal phalanx. Bending or shearing stresses in the wall may result in hoof cracks. Long-toe, low-heel conformation increases tension in the DDFT, compression of the navicular bone, and tension within the dorsal lamellae.

Accuracy of the diagnosis may be the first impediment. Sometimes pain causing lameness can be isolated to a specific tissue with a combination of physical examination, local analgesia, radiography, and scintigraphy, but frequently the pain can only be isolated to part of the foot, and sometimes simply to the foot. The precipitating factor may not be within the tissue or structure exhibiting pain but may be a conformational change elsewhere. The more accurate the diagnosis, the more closely localized the source of pain and the more knowledge of any underlying stresses, the more appropriate treatment is likely to be and the greater the chance of success.

The less specific the diagnosis, the more symptomatic the therapy. This is most likely to be directed at the balance of the foot and conformation of the limb, not necessarily an easy task. However, if lameness and pain persist after optimal balance is restored, the pain is most likely to be related, directly or indirectly, to the concussive forces associated with impact and weight bearing or flexion and extension of the distal limb. The ground surface of the foot can be protected from direct impact with the ground, and the maximal deceleration and frequency of vibrations within the structures between the ground surface of the foot and the metacarpophalangeal joint can be decreased. Extension of the distal interphalangeal joint can be decreased by reducing the extent that the heels sink into a soft ground surface and the moment about the distal interphalangeal joint at breakover. Torsional stresses within the distal limb may be reduced by encouraging the foot to break over in the most natural position.

Lameness Associated with Shoeing

Although the incidence of lameness associated with shoeing is unknown, poor trimming, shoe selection, and shoe attachment are well-recognized causes of lameness. Trimming that leaves a hoof too long or imbalanced, either mediolateral or dorsopalmar, predisposes the distal limb to abnormal stresses and lameness. Similarly, trimming the wall and adjacent sole too short causes undue pressure on the sole, bruising, and lameness.

Shoe selection includes size, weight, and traction devices. If the shoe is too small or short for the foot, the heels are unlikely to have adequate coverage. Pressure is concentrated in the wall and adjacent sole, which leads to bruising, hoof cracks, and underrun heels. Shoes that are too long or wide are at greater risk of being pulled off. If the ends of long branches are redirected axially to prevent the shoe from being pulled off, the angle of the sole may bruise. If the web of the shoe is narrow, the adjacent sole is unprotected. Conversely, a wide web shoe may impinge on a dropped sole.[19] Shoe size influences its weight. A heavy shoe may cause fatigue, decreased agility, and predispose to interference.[19] The size of a shoe also affects the effective surface of the foot. Too small a ground surface area concentrates the stresses of weight bearing.

Inappropriate use of traction devices predisposes to injury. The use of calks and toe grabs alters the balance of the limb and concentrates stress wherever they are applied. Too much traction may cause shearing within the limb as the horse places the limb on the ground because the limb decelerates too rapidly. Traction devices that anchor the limb in the ground once the foot is planted may cause fractures of McIII or the proximal and middle phalanges as a horse pivots on the limb. An inside rim shoe provides a good compromise among traction, ability to pivot, and ease of breakover. Too little traction at least decreases a horse's confidence as it works and at worst may cause a horse to slip and injure itself.

If a shoe is unintentionally set eccentrically, so that one branch extends further abaxial than the other, greater stresses occurs in the wall proximal to that branch. If the shoe is unintentionally rotated, the coverage of the heels is uneven and the heel with the least coverage responds as if the foot is shod short on that branch. If the shoe is to be rotated intentionally, a larger sized shoe should be used.

Inappropriate attachment of the shoe to the foot may cause direct injury to the underlying sensitive tissues, damage the hoof capsule, and impair expansion. The use of larger nails than needed displaces more tissue as they are driven and therefore is more likely to fracture the hoof wall or impinge on the underlying sensitive structures. Nails that directly injure the sensitive tissues when driven, called *nail prick*, cause an instantly recognizable problem that is immediately corrected. More insidiously, a nail that is close to, but not within the sensitive structures, called *nail bind*, applies pressure to the lamellae or may cause the inner hoof wall to fracture toward the lamellae. This creates a tract through which infection may become established. Nail prick and nail bind may occur because the nail was driven too high or was started too far axially. The angle at which the nail holes are punched and the location in the web of the shoe may contribute to the problem. Nails set behind the middle of the quarter adversely affect the expansion of the foot and should be avoided.

NATURAL BALANCE TRIMMING AND SHOEING

• Gene Ovnicek

The feet of wild or domestic horses have the same anatomy, function similarly, and require stimulation to develop and perform optimally. The equine foot is a product of its environment, and the foot modifies and changes so that the basic requirements for health, function, and soundness can be met. This works well when the horse is roaming free in an area that is large enough for optimal foot maintenance, or if used aggressively barefooted. The sole, bars, and frog become callused and durable, with the wall chipping and wearing so that the wall at the toe is worn to the same level as at the sole. Feet managed in this self-maintaining manner are of the highest quality and generally are trouble free and healthy.

APPEARANCE OF A SELF-MAINTAINED FOOT

The wall of a self-maintained foot is worn down to the level of the sole callus in the toe region. The quarters are broken away at the widest part of the foot in horses that live in soft and sandy areas. This allows dirt to compact only in the palmar region of the foot, in the area of the bars. The heels grow beyond the height of the frog, which helps to form a trap for the dirt. The wall is worn to the level of the sole dorsal to the frog apex. The frog apex is generally in contact with the ground when the foot is loaded and is often enlarged and callused as a result of its use. Radiography shows that this area is in the center of the distal phalanx. Support for the distal phalanx is provided by the dorsal wall and sole callus, frog apex and frog buttress, bars, heels, and dirt compaction.

Fig. 27-11 This imprinted feral foot shows the wall is worn to the same level as the sole at the toe. This is typical of self-maintained feet of both feral and domestic horses.

Horses that are ridden or live in more abrasive areas, such as pavement or dry gravel, frequently wear the heels shorter than the level of the frog. The wall is always worn equal in height to the sole in the front part of the foot (Fig. 27-11). The thickness of the live sole callus (recognized as the functional epidermal sole tissue that extends beyond the dorsal distal border of the distal phalanx) at the toe, and the thickness of the live sole at the heel are a consistent distance from the distal border of the distal phalanx.[1] Therefore the sole is a reliable reference for mediolateral balance. The wall can be trimmed or rasped to the same distance from the live sole on each side of the foot so that the distal aspect of the distal phalanx is level, parallel with the sole.

The quality of the frog and digital cushion play a major role in dorsopalmar balance of the foot. The natural, healthy frog is designed to hold dirt between the bars and frog, and dirt seldom exceeds the level of the frog. The frog, along with the dirt compaction, is partially responsible for the alignment of the distal phalanx and the pastern. The frog, bars, and sole are all important in weight bearing.

The hoof wall breaks away while the sole and frog become callused and durable for the horse to walk on. With shod feet there is little control of the hoof wall trimming by wear and chipping. If the wall of a shod hoof is not prepared to an equal depth to the live sole plane medially and laterally, the coronary band distorts and quarter cracks and toe cracks may develop. Horses that break and crush the heels and those that develop toe cracks and quarter cracks all experience a natural but crude, deliberate way of trimming the foot so that the distal phalanx maintains a parallel medial/lateral orientation to the ground. Breaking and cracking of the wall allows the frog, bars, and sole to contact the ground to fulfill the natural function.

To maintain a horse barefooted without availability of a large, free roaming area, owners should try to keep the horse's living area and exercising area the same. If a horse is kept in a soft, sandy pasture or large, sandy paddock, then it should be ridden daily in that same type of sandy terrain. The same is true for horses kept in dry, rocky pastures. In addition to a consistent environment, regular activity also is required with exercise for 5 to 25 miles daily.

Most horses are housed in small, confined stalls or paddocks that are often soft, wet, and non-abrasive. The feet do not wear at all and adapt to that environment. These horses are reluctant to work barefoot on a more abrasive surface. Some horses have poor-quality, sub-standard feet that need some type of protection for any form of work.

NATURAL BALANCE TRIMMING FOR A BAREFOOTED HORSE

Natural balance trimming is maintaining the feet of domestic horses consistent with self-maintained feet. These instructions are for *domestic horses that are left barefoot*.

The majority of horses' feet can be separated into four types: (1) normal feet, (2) feet with underrun heels and long toes, (3) clubbed or upright feet, and (4) unusually flat feet. In all types the sole callus, the apex of the frog, and the callused portion of the frog buttress are the support structures of the foot (Fig. 27-12).

Fig. 27-12 Important support structures of the equine digit. *A*, Sole callus; *B*, apex of the frog; *C*, Callused portion of the frog buttress.

Normal Feet

The following trimming sequence is used for horses that have normal feet and are left barefooted without suitable activity to wear the feet to the natural hoof shape. After removal of dirt, the clinician should identify the sole callus in the toe area. This is the functional epidermal tissue that extends beyond the dorsal, distal border of the distal phalanx and is seen as the raised area just inside the hoof wall. The sole callus maintains its relationship with the distal phalanx at the 10-o'clock and 2-o'clock positions and adapts quickly to changes in the environment to best offer protection and support to the distal phalanx. The *live sole* is the functional epidermal sole tissue that extends beyond the distal border of the distal phalanx and has a waxy surface appearance. The clinician should remove only enough of the loose, flaky chalky sole material so that the live sole and the sole callus are clearly seen. Most horses left barefooted have little or no sole that needs to be exfoliated or removed.

If an imaginary line is drawn across the toe at the back edge of the sole callus, this is the place where natural breakover occurs in the self-maintained foot. With a normal foot the wall in this region is firmly attached to the sole callus at ground level. The sole callus on most normal bare feet is narrow and well defined, but not in flat or clubbed feet, because in these horses the toe of the distal phalanx is closer to the ground. The hoof wall should be conservatively rasped or nipped to the back edge of the sole callus. The rocker or roll should not exceed 10° to 15° from the flat plane of the sole (i.e., what is normally found on a well-worn shoe). Next, the wall is rasped or nipped down to the level of the sole callus on each side of the toe, behind the rockered portion. The hoof wall should be trimmed so the height of the sole callus and wall are equal. The length of that flattened area depends on the size and type of the foot and sole callus (2.5 to 3.5 cm).

The wall behind the toe callus is trimmed to the level of the live sole through the quarters. The heel that remains is flattened so that the heels are equal in height to each other and at the same level as the frog buttress or slightly shorter. This generally means that the quarters at the widest part of the foot are floated.

Only the cleft of the central sulcus of the frog is routinely trimmed to lessen the chance of bacterial colonization in less active horses. The rest of the frog should not be trimmed at all, unless parts are hanging by a small attachment from the live frog structure. The bars are trimmed only if they start to turn, roll over and become flat to the sole, or if cracked or diseased. If flares exist on the outer hoof wall, the clinician should find the most prominent growth ring near the middle of the dorsal hoof wall and remove only the amount necessary to make the wall straight from top to bottom. Rasping should not extend beyond the white line. Finally, the outer rim of the hoof wall that is closest to the ground is rounded (the rim is chamfered).

Flat Feet

Horses with flat, sensitive feet that are used for trail riding and multi-terrain activities often are unsuitable to leave barefoot. Many horses with flat feet have a thin sole that separates from the wall at ground level, causing laminar tearing at the distal aspect of the distal phalanx. With the sole callus used for weight bearing, the outer wall is removed in a dubbed, vertical manner to lessen the pull on the wall. The wall is brought back very close to the edge of the sole on the ground side so that no dirt will pack under the wall next to the sole. The sole of the foot is never touched with the knife or rasp. Feet of this type never need exfoliating. They need more sole thickness below the distal phalanx, which may develop if the wall is reattached closer to the ground surface of the sole. When the distal 3 to 4 cm of the wall is left to full thickness, the distal phalanx is supported proximally by stable wall. The sole callus may become more durable and develop dense protective tissue once the laminae are not torn by the wall pulling away from the sole.

The heels are rasped back to a solid horn structure and the frog is left untouched. The clinician should not rocker the toe until the wall attaches more normally to the sole at ground level. With repeated trimming the gap between the sole and wall disappears and eventually the callus at the toe quarters bonds tightly with the wall, and the solar surface may become concave.

Clubfeet

An upright or clubfoot often is smaller. The practitioner should not try to change it but treat it separately, using the same guidelines as for a normal foot. The sole callus at the toe is located to determine the point for breakover. The live sole in the heel region is used as a guide for trimming the heels, leaving the sole full thickness to protect the distal border of the distal phalanx. In my opinion, the most fragile part of the horse's foot is the distal border of the distal phalanx; in an upright foot, it may be more susceptible to trauma. However, if the heel is lowered excessively while the toe is left to

improve the digital alignment, damage to the distal border of the distal phalanx is more likely.

A normal foot has an even curve to the outer hoof wall at the heel buttress and an even arch to the bars with the heel buttress terminating slightly ahead of the back of the frog. The heel buttress (end of heel) of an upright foot has an abrupt curve with bars that are quite straight. The heel ends close to the back of the frog. Excessive removal of the heel of a clubfoot does not allow the horse to land heel first and increases the chances of distal phalanx trauma from landing toe first.

The sole callus on a clubfoot is slightly different from that of normal feet. There is usually a broad, raised formation to the sole, seen just ahead of the frog apex. The callus on each side of the frog apex is more prominent and extends well behind the tip of the frog. The natural place for breakover is closer to the frog apex because of the position of the sole callus. Therefore the wall is rockered ahead of the sole callus just as in a normal foot. The live sole in the back part of the foot is deeper. The hoof wall at the heel should not be trimmed equal to the live sole. The sole callus continues palmarly to the widest part of the foot and beyond, giving the appearance of a flat, thick sole from heel to heel. If the dorsal hoof wall is severely flared and resembles a foot with chronic laminitis, the flare should be removed.

Feet with Long Toes and Underrun Heels

Underrun heels grow forward under the foot with a sharp curve in the heel. The underrun heel ends ahead of the frog buttress with bars that are curved similarly. The frog apex is often elongated. This heel conformation is abnormal and often is painful. Natural balance trimming helps to restore the foot to a near natural shape, with alleviation of pain. The sole callus is broad and looks more like a small mound around the sole ahead of the frog apex. If the horse can be kept in a dry, soft area for 1 to 2 weeks, the toe can be aggressively rockered ahead of the callus, leaving the sole callus and medial and lateral walls to walk on. The heels need to be trimmed back below the level of the frog if the bars and heels are severely curled and appear to end in front of the back of the frog. However, the heel should never be trimmed down past the live sole at the heel or any other part of the foot. The wall is finished normally. This aggressive trimming rapidly starts to repair the deformed feet and can be done quickly and successfully as long as the bottom of the foot is hardened and protected with hoof and sole hardeners. Alternatively, more wall can be left at the medial and lateral sole callus to not overload the sole callus. The foot will respond well with each trimming.

NATURAL BALANCE SHOEING

When preparing the sole surface for a shoe, the frog, bars, and sole are prepared conservatively, similar to feet that are left bare. Feet that are shod do not exfoliate effectively, and sole material that is showing cracks in the sole and is chalky and crumbles when it is cut with a knife should be removed. When the sole and frog material changes from a chalky, crumbly state to a waxy-appearing surface, the live or functional sole and frog has been reached, and absolutely no more cutting should be done. The live, functional sole at the toe quarters (where the sole callus is) and the live sole at the heel quarters (behind the widest part of the foot) are references to the distal border of the distal phalanx. Trimming the wall to these live, functional structures offers the best guide to attain accurate medial/lateral and dorsopalmar balance.

The bottom surface of the foot is finished flat when the foot is prepared for shoeing (not relieved in the quarters as when trimmed to be left barefoot) and is hot seated if possible. Vigorous hot seating helps to dehydrate and strengthen the sole callus. It also pulls the sole proximally from the ground level to eliminate sole pressure.

Fig. 27-13 The aluminum Natural Balance Shoe is designed to be applied 0.3 to 0.9 cm (depending on foot size) from the frog apex to the inside edge of the shoe at the toe. This placement closely meets breakover requirements with respect to the sole callus. The seated-out reverse arch on the inside border of the shoe at the toe helps to protect the distal border of the distal phalanx from sole pressure.

Shoe Placement and Application

Shoe selection is important, and wide-web rim type shoes work best for easy modification. The outer rim is normally tapered-in to the nail groove, which is helpful and some what mimics the way the bare foot naturally wears. That same feature is equally helpful at the toe when the shoe is squared somewhat and positioned on the foot so the breakover point of the shoe fits directly over the back edge of the sole callus at the center of the toe. The heel of the shoe should extend to the full length of the frog. A good reference for that position is the back of the crease in the central sulcus. Radiographs can be used to determine the natural position for breakover.

When pre-made aluminum (Thoro'Bred Race Plate Company, Inc.; Anahaeim, CA) or steel (Malaysian Horseshoe Company; Malaysia) Natural Balance Shoes are used, the same criteria of shoe placement for breakover and heel length should be followed. A wide-web rim shoe is broadened at the toe and tapered from the inner rim to the toe between the toe quarters. The shoe is placed on the foot so that the inner rim (part of breakover) is over the inside edge of the sole callus. The Natural Balance Shoe is positioned a variable distance from the frog apex to the inside edge of the shoe for placement (Fig. 27-13). That distance is regulated with the heel position. If a line is drawn across the widest part of the foot where the bars end, one third of the foot mass is ahead of this line to the point of breakover.

HOOF RECONSTRUCTION MATERIALS AND GLUE-ON SHOES

• Robert Sigafoos

Advancements in adhesive technology have substantially improved the dependability of adhesive-bonded shoes. The ability to control plasticizer migration in adhesives has allowed the use of plasticizers in industrial adhesives, increasing adhesive flexibility and impact resistance without inhibiting adhesive strength at the bond line interface.

ADHESIVE TYPES

Most adhesives used to bond hoof wear to hooves evolved from use in hoof reconstruction.[1] Important features include impact resistance, the type of adhesive joint loads, speed of polymerization, heat production, surface sensitivity, and environmental compatibility.

Impact resistance is particularly important because of factors such as horse's weight, speed, and high level of cyclic loading of the feet. Adhesives that remain flexible once polymerization is complete (elastomeric adhesives) perform better than rigid adhesives with similar tensile strength characteristics. When the bonding is applied directly to the hoof wall (as opposed to bonding individual components of a shoe together), at least one surface (the hoof) is always flexible. The primary load will be in peel, for which elastomeric adhesives are preferable.

Speed of polymerization is critical because the horse needs to bear weight and ambulate immediately after shoeing. The cure profile of an adhesive involves a "green" phase when the adhesive has solidified, but not reached full strength. Challenging the bond in the early portion of the green phase can cause irreversible bond line failure. However, very fast polymerization may be at the expense of reduced impact strength.

The polymerization reaction produces heat that increases with the speed of the reaction. It is surface area dependent for a given volume of polymer. In concentrated volumes that are not allowed sufficient surface area to dissipate heat, temperatures can exceed 120° C in volumes typically used for hoof reconstruction or bonded shoes. Spreading the adhesive to provide increased surface area relative to volume allows dissipation of heat. Some adhesive manufacturers add fillers to very fast systems to dissipate heat, resulting in a temperature reduction as much as 25%. Submural temperatures underlying reacting exothermic resins vary depending on the hoof wall thickness but generally do not achieve dangerous levels. However, dermal layers underlying thin hoof walls (such as those found at the quarters, or in foals) may be at risk to substantial thermal trauma.

Surface sensitivity affects the ability of an adhesive to bond to a contaminated surface. Adhesives that solvate surface contaminants into the bond line are preferable. The adhesive must be resistant to moisture and microbial degradation. The adhesives commonly used for hoof reconstruction and bonded shoes are polymethyl/cyclohexyl methacrylate, cyanoacrylate, polyurethane, and, to a far lesser extent, epoxy resins. Each has distinct advantages.

Polymethyl/cyclohexyl methacrylate (PM/CHMA) systems are commonly referred to as *acrylic* adhesives. The newest elastomeric acrylic adhesives offer good impact resistance, rapid cure, minimal surface sensitivity, and excellent wetting characteristics for hoof wall and other substrates commonly used with hoof care applications. However, they have an intense odor, relatively high exothermic temperatures, and a high vapor pressure that limits shelf life in opened containers. As with all elastomeric adhesives subjected to high peel loads, the acrylic adhesives should be used with a thick bond line.

Polyurethane adhesives produce low-modulus adhesive joints. These joints exhibit excellent impact strength and perform remarkably well under high cyclic loads. Polyurethane has the best abrasion resistance and shock attenuation of all the adhesives commonly used. However, these adhesives require extensive substrate cleaning and preparation to ensure good bonds, which is often beyond the scope of practical field applications. These adhesives also do not form effective bonds with many of the plastics commonly used with hoof care, including acrylonitrile butadrene styrene (ABS), polyvinyl chloride (PVC), and acrylic/PVC copolymers.

Thermoplastic adhesives are principally dependent on mechanical bonding for adhesion, limiting structural use in horses.

Cyanoacrylate adhesives are thermoplastic, single-component systems that are cure inhibited through acid stabilization. Ambient surface moisture increases constituent pH and allows the polymerization process to begin. The principal advantage of these adhesives is the ability to form bonds with substrates that are difficult to bond for most adhesives. Cyanoacrylates are the only adhesive for many types of glue-on shoes that have polyurethane as a structural bonding substrate. They have excellent strength when loaded in sheer but poor peel and impact strength. Cyanoacrylate adhesives also are highly susceptible to post-cure, moisture degradation. Because cyanoacrylates become rigid after curing, the bond line rapidly develops a "mosaic" fracture pattern when exposed to impact. This allows capillary intrusion of water into the bond line, further subjecting the bond to environmental degradation. They also have limited gap-filling characteristics. The ideal surface for successful cyanoacrylate bonding is a virtually polished surface. The bond line must be very thin.

Epoxy resins offer excellent environmental resistance, very good sheer characteristics, and are the adhesive of choice when assembling shoe components that involve engineered fabric lay-ups and when an extended or elevated temperature are curing is acceptable. These systems are not useful when bonding directly to the hoof wall, because the hardeners that are commonly used markedly increase the rigidity of the cured polymer.

Polyester resins have some value in cosmetic repair of hoof wall, but they lack tensile strength and environmental resistance and have limited use.

Shoe Types

Currently four principal types of glue-on shoes are available. These include the "direct glue" method using PM/CHMA adhesive, the molded polyurethane "tab type" shoes that use a cyanoacrylate adhesive, the flocked-lined plastic cuff that used an epoxy adhesive, and the fabric cuff that uses a PM/CHMA adhesive.

Two techniques have been used for direct-glue shoes. The first method involves the use of a PM/CHMA adhesive without fillers, with the bond line between the distal aspect of the hoof wall and the shoe.[2] The hoof side of the shoe is cleaned and sanded. The hoof is prepared by cleaning the dirt and loose debris from the wall and sole. The adhesive then is applied directly to the shoe and hoof, and the shoe is positioned on the hoof so that the bond line is continuous from heel to heel and incorporates an increasing percentage of the sole toward the heels. The hoof must be held non–weight bearing through the green phase of the adhesive cure cycle, approximately 3 to 5 minutes depending on ambient temperature. Given the extended cure profile of this type of adhesive, the bond should be challenged as little as possible for 12 hours. A modification of this system has been developed using

staple fiberglass fibers as a filler for the adhesive.[3] The primary disadvantages are the need to keep the hoof non–weight bearing until the adhesive has green cycled and the need to bond the heels securely to the shoe.

Polyurethane "tab type" shoes use a cyanoacrylate adhesive to bond a component of the shoe (the polyurethane tab) to the hoof wall. These shoes require careful substrate preparation, including solvent cleaning and finish sanding with extremely fine sand paper. Because cyanoacrylates have limited gap-filling properties, the prepared hoof wall must match the profile of the tab precisely. Since these adhesives have limited moisture and impact resistance, shoe retention for competitive animals may prove difficult.

Plastic flock-line cuffs (Dalric Glue on Shoes, Advance Equine, Versailles, KY) are not actually shoes, but they act as a conjoining device to attach shoes to the dorsal aspect of the hoof wall. These devices use an epoxy (or a PM/CHMA adhesive) to attach the shoe to the hoof wall through a mechanical lock of the adhesive to the flock lining and rivets to attach the shoe to the cuff. This system is considerably more robust than the polyurethane tab system described previously. However, fitting the cuff to oddly configured hooves can be difficult.

The fabric cuff (Sigafoos Series Adhesive Bonded Shoes, Sound Horse Technologies; Unionville, PA) system uses a PM/CHMA adhesive to bond a braided fabric cuff that is an integral part of the shoe to the dorsal aspect of the hoof wall. This system comes as a fully assembled shoe (Series One) or a modular system (Series Two) that allows the farrier to assemble any type of pattern configuration desired. The primary disadvantage of this system is the limited choice of types of shoes currently available in the Series One system.

Glue-on shoes offer distinct advantages over mechanically attached shoes because of the non-invasive and non-destructive nature of the attachment. They are expensive, but this cost usually is recouped if the actual cost of lost shoes and the resultant hoof loss is considered. If the widespread acceptance of adhesives in other industries is any reflection on the potential for its use in the farrier industry, adhesives will become the dominant method of attachment of shoes for horses in the foreseeable future.

CHAPTER • 28

Trauma to the Sole and Wall

Robin M. Dabareiner, William Moyer, and G. Kent Carter

PROBLEMS ASSOCIATED WITH HORSESHOE NAILS

Nail Bind

History and Clinical Signs A *close nail* or *nail bind* refers to placement of a horseshoe nail not necessarily in the sensitive structures of the hoof but close enough such that the nail exerts pressure on these structures to cause discomfort. The horseshoe nail is designed to be driven obliquely through the hoof wall. When the nail is driven, the tip is placed at the inner edge of the white line with the bevel of the nail tip facing inward. When driven, the bevel contacts the hard hoof wall and curves outward and exits 1 to 2 cm above the level of the shoe. The tip of the nail is removed and the remainder is bent over to form a clinch to hold the shoe firmly to the hoof. Correct nail placement is important because if the nail is placed too shallow (superficial), the hoof wall will weaken and possibly split; if is it placed in too far, the sensitive structures of the hoof may be entered (pricked) (Fig. 28-1). Overzealous clinching of the nails causes inward bending of the nail that can result in pressure on sensitive tissues, which may result in immediate or delayed pain and lameness. Slight displacement of a shoe also can result in nail pressure on sensitive tissues.

Diagnosis Diagnosis of nail bind is difficult and often determined by eliminating other causes of foot pain. Lameness varies from subtle to severe. Sometimes a horse exhibits a change or lack in performance. The problem may not arise until several days after shoeing. Sometimes a horse is sound when trotted in a straight line, but it shows lameness when pulled in a tight circle or when making a turn. It is important to realize that nail bind is not always associated with poor farriery. A good nail can become a problem nail days or weeks after shoeing if the shoe shifts, causing abnormal nail pressure, or if the horse had a poor quality hoof wall and hoof wall loss occurs. This is a common problem in Thoroughbred (TB) racehorses and usually involves

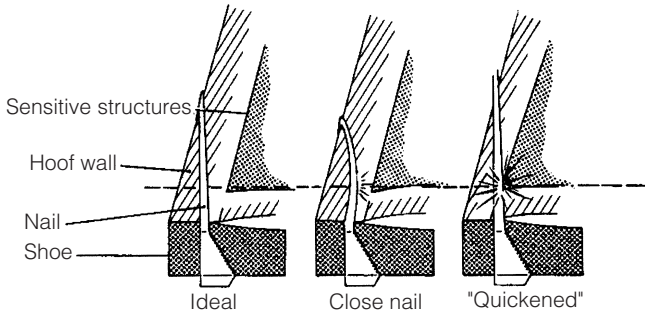

Fig. 28-1 Schematic of ideal, close, and pricked (quickened) horseshoe nail placement.

staple fiberglass fibers as a filler for the adhesive.[3] The primary disadvantages are the need to keep the hoof non–weight bearing until the adhesive has green cycled and the need to bond the heels securely to the shoe.

Polyurethane "tab type" shoes use a cyanoacrylate adhesive to bond a component of the shoe (the polyurethane tab) to the hoof wall. These shoes require careful substrate preparation, including solvent cleaning and finish sanding with extremely fine sand paper. Because cyanoacrylates have limited gap-filling properties, the prepared hoof wall must match the profile of the tab precisely. Since these adhesives have limited moisture and impact resistance, shoe retention for competitive animals may prove difficult.

Plastic flock-line cuffs (Dalric Glue on Shoes, Advance Equine, Versailles, KY) are not actually shoes, but they act as a conjoining device to attach shoes to the dorsal aspect of the hoof wall. These devices use an epoxy (or a PM/CHMA adhesive) to attach the shoe to the hoof wall through a mechanical lock of the adhesive to the flock lining and rivets to attach the shoe to the cuff. This system is considerably more robust than the polyurethane tab system described previously. However, fitting the cuff to oddly configured hooves can be difficult.

The fabric cuff (Sigafoos Series Adhesive Bonded Shoes, Sound Horse Technologies; Unionville, PA) system uses a PM/CHMA adhesive to bond a braided fabric cuff that is an integral part of the shoe to the dorsal aspect of the hoof wall. This system comes as a fully assembled shoe (Series One) or a modular system (Series Two) that allows the farrier to assemble any type of pattern configuration desired. The primary disadvantage of this system is the limited choice of types of shoes currently available in the Series One system.

Glue-on shoes offer distinct advantages over mechanically attached shoes because of the non-invasive and non-destructive nature of the attachment. They are expensive, but this cost usually is recouped if the actual cost of lost shoes and the resultant hoof loss is considered. If the widespread acceptance of adhesives in other industries is any reflection on the potential for its use in the farrier industry, adhesives will become the dominant method of attachment of shoes for horses in the foreseeable future.

Slight displacement of a shoe also can result in nail pressure on sensitive tissues.

Diagnosis Diagnosis of nail bind is difficult and often determined by eliminating other causes of foot pain. Lameness varies from subtle to severe. Sometimes a horse exhibits a change or lack in performance. The problem may not arise until several days after shoeing. Sometimes a horse is sound when trotted in a straight line, but it shows lameness when pulled in a tight circle or when making a turn. It is important to realize that nail bind is not always associated with poor farriery. A good nail can become a problem nail days or weeks after shoeing if the shoe shifts, causing abnormal nail pressure, or if the horse had a poor quality hoof wall and hoof wall loss occurs. This is a common problem in Thoroughbred (TB) racehorses and usually involves

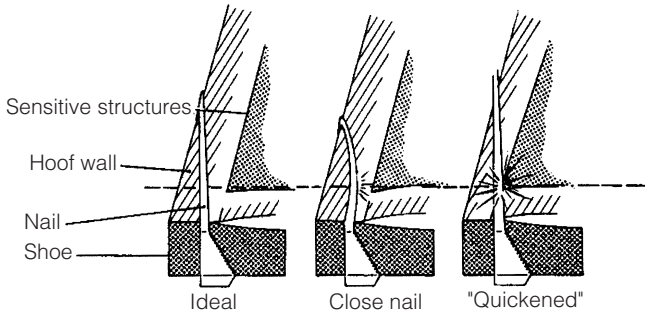

Fig. 28-1 Schematic of ideal, close, and pricked (quickened) horseshoe nail placement.

the inside heel nail (the inside quarter and heel wall usually is the thinnest aspect of the hoof wall). Hoof tester evaluation using both pressure and percussion may cause a painful response over the offending nail. Heat and increased digital pulse amplitudes may not be present, depending on the duration of the close nail. Often diagnosis is determined by pulling single nails one by one from the shoe and evaluating the lameness after each nail is removed. Paradoxically, lameness is sometimes transiently accentuated after removal of the offending nail.

Treatment and Prognosis The treatment of nail bind is removal of the offending nail; usually lameness resolves within a few days. No additional treatment is usually needed. Prognosis is good once the nail is removed provided infection does not ensue.

Nail Prick

History and Clinical Signs *Nail prick* or *quicking* refers to penetration of the sensitive hoof structures, usually the sensitive laminae, by a driven horseshoe nail (see Fig. 28-1). The horse usually reacts as the farrier drives or clinches the nail by jerking the foot from the farrier.[1] Sometimes blood appears on the nail or leaks from the nail hole. Nail pricks occur for many reasons and are not always caused by a misdirected nail. Poorly made shoes, misdirected nails, selection of a nail that is too large, poorly placed nail holes, and faulty nails can result in a nail prick. Horses with poor hoof quality, thin hoof walls, or flaring hoof walls can be very difficult to nail and thus are at greatest risk. Fractious horses and young horses that have not been previously shod may lean on the farrier or repeatedly pull the foot from the farrier, making driving a nail difficult. A rushed farrier predisposes to nail pricking, but it can also happen to the best of farriers. Damage from an improperly driven nail can vary from minimal to serious infection.

Diagnosis Diagnosis of a misdirected nail warrants great diplomacy from the veterinarian, because many owners become unjustifiably upset with the farrier. Some horses repeatedly stomp the affected foot or paw the ground immediately after shoeing. Others point the affected limb after shoeing. Lameness may not be apparent immediately but may occur days after shoeing when the nail hole becomes infected and the trapped pus begins to exert pressure. The horse usually becomes acutely lame and the lameness worsens over time unless it is treated. An infection may migrate up the lamellae (white line) and create an abscess or soft spot at the hairline of the coronary band. The abscess is directly aligned with the hoof wall tubules leading to the infected nail hole, which is an important diagnostic aid. Hoof tester examination, using both pressure and percussion over each nail, is essential to locate the offending nail. Increased digital pulse amplitudes and heat may be present.

Treatment Pricks from nails can be potentially serious and require immediate treatment. If the nail prick is discovered by the farrier at the time of shoeing, the nail is removed. The nail should be examined for moisture or blood. The nail hole can be irrigated with dimethyl sulfoxide, povidone-iodine solution, or hydrogen peroxide. The nail hole is packed with iodine-soaked cotton and left open. Often the nail is redirected and no further treatment is needed. Tetanus prophylaxis is essential for an unvaccinated horse.

If the offending nail cannot be localized or the nail hole is infected, the shoe is removed. Hoof testers then are used to localize the painful nail hole. Many times the pressure from the hoof testers cause black, malodorous liquid pus to exit from the hole. This may not be obvious immediately, but if the foot is replaced to the ground and the horse walks a few steps, pus may become obvious. The basis of treatment is to establish drainage. The infected nail hole often requires enlargement with a loop hoof knife or curette. Ideally a cone-shaped hole is made with the larger opening at the bottom of the hoof. The hole is irrigated or the entire foot is soaked in an Epsom salt and povidone-iodine foot bath for 20 to 30 minutes twice daily until the infection is resolved. It is important to protect the foot from the environment (mud, dirt) by keeping the foot bandaged between foot soaks. Alternatively, a poultice can be applied to the foot for several days. Additional medications usually are not necessary unless infection is widespread. Anti-inflammatory medication may be beneficial to decrease pain. Once the infection has cleared, the shoe is replaced. The affected nail hole can be packed with iodine-soaked cotton and the horse re-shod with a plastic pad covering the sole. Alternately, a hole can be drilled into the shoe over the affected nail hole and the shoe can be replaced, leaving access to the infected area for daily irrigation and povidone-iodine packing.

Prognosis Prognosis after nail prick usually is good, provided that minimal damage occurs to vital structures of the foot. Establishing drainage for infection is important to avoid potential complications, such as infectious osteitis of the distal phalanx or infection of the distal interphalangeal joint.

Solar Bruising

History and Etiology A *bruise* is a contusion or impact injury that causes focal or generalized damage with subsequent hemorrhage of the solar corium. Sole bruising occurs commonly in all types and breeds of horses, especially in racing TBs and Standardbreds (STBs).[2] The degree and severity of lameness varies from acute, severe lameness to chronic mild or intermittent pain, depending on location and degree of damage. It is important to determine the cause of the bruise, because this dictates proper treatment and prevention. The general cause is abnormal focal weight bearing on the solar surface of the foot. The location of the bruise is helpful in determining the cause of the injury. The most common location is the junction between the bars and the walls of the heel, termed a *corn*.[3] Corns occur most frequently on the medial side of the front feet. Heel bruising may be the result of improper shoeing or trimming. Some farriers bend the medial branch of the shoe toward the frog to prevent the horse from stepping on and pulling the shoe. This shoe position causes direct pressure to the sole at the heel angle, instead of the heel wall, resulting in continued concussion and bruising. A shoe that is too small or does not extend far enough back under the heels can lead to heel bruising.[4] The ends of the shoe should extend to the widest aspect of the frog for proper heel protection. Horses with long-toe–low-heel hoof conformation are susceptible to heel bruising. Toe bruising can be caused by excessive impact or weight bearing on the toe region secondary to another cause such as heel pain. An improperly positioned horseshoe that rests on the sole instead of the hoof wall also causes toe bruising. Horses with long toes and those shod with toe grabs concentrate impact at the toe region.[4] Sole bruising occurs often in horses with flat feet because the sole repeatedly strikes the ground surface. A flat foot can be congenital or created by trimming the hoof wall too short or excessive quarter wall breakage. Thin-soled horses or excessive trimming of the sole reduces the sole protection and predisposes to sole bruising. Loose shoes can shift position, and improperly balanced feet cause excessive impact forces to specific regions of the foot and cause bruising.[4] Riding on hard and rocky ground can result in stone bruises. A shod foot that has overgrown to the point where the shoe is riding on the sole is at risk of bruising.[4]

Clinical Signs The degree of lameness from sole bruising can change daily and lameness varies between horses. Removal of the shoe usually increases the degree of lameness. The bruising can be acute or chronic depending on the cause. Digital pulse amplitudes are increased after exercise, and careful hoof tester evaluation often reveals a focal painful response.

Discoloration is common, but if the bruise is chronic, deep, or if the horse's sole is pigmented, it may be difficult to identify. Bruising often affects several feet. In most horses, lameness will improve after perineural analgesia of the palmar digital nerves. Radiographic changes are rare but may reveal a serum pocket (fluid line) between the distal phalanx and external sole. Persistent, chronic bruising may lead to osteolytic lesions or solar margin fractures of the distal phalanx.

Treatment Initial treatment with phenylbutazone (2.2 mg/kg bid) and soaking the feet in Epsom salts help decrease inflammation. Corrective or proper shoeing is imperative to shift the weight-bearing forces away from the damaged area of the foot. Sole paint consisting of a combination of equal parts of phenol, iodine, and formalin can be applied to toughen the solar surface. Hoof balance problems and shoeing causes, such as heel calks, toe grabs or tucked heels, should be eliminated. One of many different shoeing techniques then is used to decrease impact and protect the bruised area. One method is use of a rim pad that is cut out over the bruised area so that the affected heel or quarter is floated and thus receives minimal weight-bearing forces. Another method is application of a bar shoe with a deeply concaved solar surface to stabilize the foot and alleviate any sole pressure from the shoe itself. A wide web shoe may provide relief by covering and providing protection over a larger surface. It is important that this shoe be properly positioned on the hoof wall so that it does not increase sole pressure. Application of full pads packed with silicone or oakum may provide temporary relief by distributing weight-bearing forces over a wider area but often leads to a weakened and softer sole, causing recurrent problems.[5]

Prognosis The prognosis is good if the inciting cause of the bruising can be corrected. Corrections may be difficult in horses with flat feet or long-toe–low-heel conformation, and such horses often have recurrent solar bruising.

Thrush

Thrush is a bacterial infection characterized by an accumulation of black, malodorous, necrotic material, usually originating within the central or collateral sulci of the frog of the hoof. This degenerative condition may spread to involve deeper structures of the foot, such as the digital cushion, hoof wall, and heel bulb region, causing inflammation and breakdown of these structures.[6] Many keratolytic organisms may be present, but *Fusobacterium necrophorum* is often isolated. Thrush is most often caused by poor environmental conditions; horses standing in soiled stalls, deep mud, swampy land, or wet pastures are at risk, especially if the feet are not cleaned daily.[7] Poor hoof conformation also predisposes to thrush. Saddlebreds, Tennessee Walkers and other gaited horses, and some Warmblood breeds have long feet with naturally deep frog sulci and are at risk of thrush.[7] Horses with sheared heels or acquired frog deformity also are predisposed. Horses shod with full pads may develop thrush secondary to moisture and dirt collection under the pad. Other well-kept, clean horses can develop thrush for no apparent reason.

Clinical Signs and Diagnosis Lameness often is not apparent, but if present, the severity can vary. With severe thrush lameness can be obvious, but in most horses thrush is an additional finding and the primary source of pain is elsewhere. Diagnosis is based on the presence of black, malodorous discharge located most commonly within the frog sulci. The central frog sulcus often is malformed and very deep. A painful response may occur when the affected sulci are cleaned, because the degenerative process may extend to sensitive structures of the foot. If structural damage has occurred, the heels may move independently of each other, causing pain on manipulation.

Treatment The predisposing cause should be identified and, if possible, removed. The horse should be moved to a clean, dry environment and the feet should be cleaned daily. Any necrotic debris and undermined tissue are carefully debrided and cleaned using a hoof knife. Foot bandages may be necessary if the debridement is extensive. Systemic antibiotics may be necessary if deep or more proximal tissues are affected, but infection is usually managed by topical medication. Several caustic materials have been recommended, including a combination of phenol, tincture of iodine, and 10% formalin, Kopertox solution (Fort Dodge, Fort Dodge, IA), or methylene blue. Others have recommended foot soaks in chlorine bleach (30 ml of bleach in 5 L of water). Corrective trimming and farriery may be necessary. If heel instability is present, a bar shoe may be necessary to stabilize the palmar aspect of the foot. Exercise is important to strengthen the palmar aspect of the foot and will naturally clean the feet.[7] The best treatment for thrush involves prevention by educating the client on proper hoof hygiene.

Prognosis The prognosis for horses with thrush is favorable if the cause can be identified and eliminated and if the condition is treated before extensive hoof damage has occurred.

Sheared Heels

History and Clinical Signs *Sheared heels* refers to instability between the medial and lateral bulbs of the heel. Mediolateral foot imbalance may be a predisposing cause. It is frequently but not invariably associated with distortion of the hoof capsule. The medial bulb of heel often is displaced proximally, with a steep medial wall and flaring of the lateral wall (see Fig. 6-3). However, instability between the bulbs of the heel can also occur in a more normally conformed foot, and distortion of the hoof capsule as previously described is not synonymous with sheared heels. It is also important to recognize that sheared heels can be present without causing lameness, although sheared heels may be a cause of lameness.

Sheared heels may be present in one or multiple feet and may be associated with mild to moderate lameness. Lameness is usually worst on firm footing. There may be distortion of the coronary band, which usually is higher medially. There may be a deep cleft dissecting between the medial and lateral bulbs of the heel. Sheared heels may predispose to thrush.

Diagnosis Instability of the bulbs of the heel is detected by grasping each bulb of the heel with the left and right hands and twisting each bulb in opposite directions in a shearing motion. In a normal horse the bulbs of the heel cannot be moved independently. Considerable independent motion can be associated with pain causing lameness. However, if the lameness is severe, another co-existing cause of lameness should be considered. Lameness associated with sheared heels is removed by perineural analgesia of the palmar digital nerves.

Treatment and Prognosis Any mediolateral or dorsopalmar foot imbalance should be corrected. The affected foot should be shod with a bar shoe to provide stability to the heel region. This may need to be continued for many months, and occasionally indefinitely, until some physical attachment between the heel bulbs has become established. If the hoof capsule is distorted in shape as previously described, the medial branch of the shoe should be set slightly wide to encourage the medial wall to grow down to it and prevent it from collapsing laterally. Any excess flare on the lateral wall should be removed. The prognosis is generally good.

Hoof Wall Separation (White Line Disease, Seedy Toe)

History and Clinical Signs The white line, visible at the sole, is created by the junction of the insensitive laminae of the hoof wall and the horn of the sole. *White line disease* has historically been a term to describe the separation of the hoof wall from its laminar attachments. A crack or opening occurs

within the white line, allowing a bacterial or fungal infection to invade the stratum medium, with proximity to the laminae causing cavities to develop between the laminae and outer hoof wall.[8] Environmental conditions of either too much moisture (continuous wet pastures) or drought conditions producing excessively dry feet predispose to development of a crack or opening in the white line. Horses with poor-quality hoof walls that split or crack or those with chronic laminitis and a thickened or stretched white line in the toe region may develop white line disease. The term *seedy toe* has been used differently in North America and Europe. In North America it is used to describe thickened or stretched white line at the toe in horses with chronic laminitis, whereas in Europe it is used to describe separation at the white line, filled with crumbly material, that is not associated with laminitis. The hoof wall separation usually is a chronic condition beginning weeks or months before veterinary advice is sought, since there usually is no associated lameness. Hard ground may exacerbate any lameness seen.

Diagnosis The degree of lameness varies, but if severe, white line disease can cause clinical signs of pain. However, the clinician should resist the temptation to incriminate this disease as the primary source of lameness until a thorough lameness examination is completed. Because lameness is abolished after palmar digital analgesia or a dorsally directed ring block, this disease can easily be confused with the many other conditions of the foot. Visual examination of the white line, assisted by a probing instrument, reveals a cavity with separation of outer hoof wall from the laminae. Radiographic evaluation determines the full extent of hoof wall separation. Often the cavity is either dry or filled with necrotic debris, which may involve a bacterial or fungal infection. The cavity is usually not painful to probing.

Treatment The separated outer hoof wall is removed using hoof nippers, hoof knife, and motorized tools. The aim is to remove cracks or crevices that could harbor bacteria. A Dremel tool burr (Dremel, Racine, WI) is useful to smooth any cracks in the insensitive laminae that are exposed after hoof wall removal. Large defects in the hoof wall require protection. A heart bar shoe redistributes weight-bearing forces to the frog and palmar region of the foot and away from damaged and weakened areas. The hoof wall defects prevent normal nailing procedures; therefore clips can help secure the shoe to the hoof. After hoof wall removal the exposed laminae may still have an active infectious component. The horse should be kept in a clean, dry stall and the exposed laminae are treated topically with iodine or merthiolate daily for 10 days or until they are dry. The horse may then be a candidate for prosthetic hoof wall repair using a product such as Equilox (Equilox International, Pine Island, MN). The plastic acrylic is trimmed and shaped to the horse's natural hoof wall at the next shoeing. The hoof to which the acrylic was applied should be kept dry to avoid losing the acrylic patch. The horse may return to normal activity once the prosthetic patch is in place.

Prognosis Prognosis depends on response to treatment and cause of the original problem. Horses with poor hoof quality or primary laminitis often have recurrence. If the horse responds to original treatment and environmental conditions improve, prognosis is good.

Poor Hoof Wall Quality

Poor hoof quality plagues many horses. Many factors determine hoof quality, including the environment, farrier management, hoof conformation, and use of the horse. Drought conditions may result in dry, brittle hooves that are prone to hoof wall splitting and cracking. Excessive moisture creates a weakened hoof wall that may flatten or collapse under normal weight-bearing forces. Improper trimming and shoeing methods can cause substantial hoof wall damage. Horseshoe nails that are placed too far outward in the hoof wall or exit too low in the hoof wall weaken the hoof wall and cause splitting and cracking. Many TB horses with long-toe–low-heel hoof conformation often have collapsing heels and thin, weak hoof walls that make proper nail placement and farrier management difficult. The most common cause of weak, poor-quality feet is lack of exercise and stall housing.

Diagnosis Diagnosis is somewhat subjective as poor hoof quality is usually in the eye of the beholder. There are no objective criteria for determining hoof quality. Diagnosis is usually made by visual examination of the foot. Communication with the farrier is imperative for the diagnosis and future treatment plan. Horses with poor hoof wall quality often have palmar heel pain or are prone to sole and heel bruising. They are prone to losing shoes, which can accentuate the problem.

Treatment If possible, the cause of the poor hoof wall quality should be corrected if identified. In drought conditions, painting the entire hoof and coronary band daily with a lanolin-based hoof dressing is sometimes beneficial. In an excessively wet environment, confining the horse to a stall and avoiding standing water or wet pastures may improve hoof wall quality. Poor farriery can be addressed, but in many horses poor hoof conformation and poor environment are more difficult to manage. Long-toe–low-heel hoof conformation should be balanced as much as possible with proper trimming of the heels back to the widest portion of the frog. The toe of the foot is shortened as much as possible and a rockered, round, or squared-toed shoe is used to further decrease toe length and ease breakover. Egg bar shoes are used if more palmar heel support is needed. Access to the outdoors and being able to move about are helpful but often difficult to achieve.

Hoof quality also is a function of proper diet and exercise. The horse's nutrition should be evaluated, paying particular attention to protein quantity. Biotin supplements may be beneficial.

Prognosis Poor hoof quality usually is not corrected but managed. Prognosis is generally unfavorable unless a specific cause can be identified and eliminated.

PENETRATING INJURIES OF THE SOLE

Sub-Solar Abscess

History and Clinical Signs Sub-solar abscess (gravel) is one of the most common causes of acute lameness in all horses. Sub-solar abscesses may originate from a penetrating wound in the white line, nail hole, or deep sub-solar bruise. A cause may not be identified. Lameness is usually acute and severe (grade 3 to 4 of 5) and may worsen over time until drainage is established. Lameness that develops during work or when a horse is turned out may falsely lead to the suspicion of a traumatic injury. The horse often points and may not bear full weight on the affected limb. Distal limb swelling often accompanies a sub-solar abscess that has not drained, leading the owner to suspect tendon injury. Systemic signs of infection (fever, lethargy) may be present if deeper structures are involved. The infected tract may migrate and open at the coronary band. Before breaking open, a soft, painful area can be located by digital palpation of the coronary band.

Diagnosis Digital pulse amplitudes are usually increased and the hoof capsule may have heat. A focal painful area can usually, but not always, be located with careful hoof tester examination. Careful paring of the sole and frog may be helpful in locating the abscess, but the clinician must be careful *not* to damage good, healthy tissue while looking for the infection site. Unnecessary, aggressive paring may lead to

large painful areas that take months to heal. Foot poultices and hot water foot baths with Epsom salts help to eventually localize the affected area, especially in horses with hard horn. Grey or black, malodorous liquid leaks from the infected tract. Firm digital palpation of the surrounding area can help to determine the extent to which adjacent tissues are underrun. Similar clinical signs can also be seen in weak-footed TB horses, especially in the palmar aspect of the foot, associated with frank sub-solar hemorrhage. Radiography sometimes is useful to identify a gas or fluid pocket.

Treatment Treatment is aimed at establishing adequate drainage. If the tract is open at the sole surface, it should be enlarged just enough for good irrigation and drainage. This may require sedation or perineural analgesia of the foot. If pink tissue or blood is encountered, debridement should be discontinued. Large holes should not be used to avoid solar corium protrusion, which can be a painful sequela to overzealous hoof paring. If drainage occurs at the level of the coronary band and solar surface, through-and-through lavage is beneficial. Debridement at the coronary band level should be minimal to prevent iatrogenic distal interphalangeal joint contamination. Once drainage is established, the foot is protected from the environment and re-contamination with a foot bandage or poultice. Continued foot soaks in warm water povidone-iodine and Epsom salt foot baths should be continued until infection and inflammation are eliminated. The shoe is replaced when the affected area is dry and cornified. Large areas may require a plastic pad under the shoe for solar protection. Antibiotics and non-steroidal anti-inflammatory drugs (NSAIDs) are rarely needed, unless infection is severe or deeper structures have been penetrated. Many practitioners consider antibiotics contraindicated because administration may prolong clinical signs. However, if swelling and infection of the coronary band and subcutaneous tissues of the pastern region occur, antibiotic therapy is indicated. Because lameness can be severe in horses with this type of disseminated infection, involvement of the distal interphalangeal joint is often suspected but usually not present. Tetanus prophylaxis is mandatory.

Prognosis Prognosis in horses with simple sub-solar abscess is excellent but decreases if complications develop in which deeper structures of the foot are involved.

Fig. 28-2 Oblique radiographic view of a foot; radiopaque contrast material has been injected into a hole through the sole, the result of a penetrating injury. The contrast medium extends proximally. A lateromedial view is also required to define better which structures may be involved.

Deep Penetrating Injuries to the Sole

History and Clinical Signs A horse's environment is filled with sharp objects that can penetrate the sole, causing severe damage to structures deep within the hoof capsule. All puncture wounds should be considered potentially serious, but those in the solar white line or palmar frog area require special attention because of the potential for navicular bursa, digital flexor tendon sheath (DFTS), deep digital flexor tendon (DDFT), or distal phalanx involvement.

The clinical signs vary with anatomical structure involved and chronicity of the injury. Lameness may be mild at the time of injury but moderate to severe once inflammation and infection occur. Penetrating wounds of the navicular bursa or DDFT result in severe lameness and a reluctance to bear weight on the heel.

Diagnosis If a foreign body is found in the bottom of the foot, the owner should usually be instructed to leave the object in the foot, unless there is danger of further penetration. Radiography is performed immediately to determine depth of penetration and orientation. In many horses, little superficial evidence of penetrating injury is present. Digital pulse amplitudes are increased and the foot is usually warm to touch. Hoof testers are useful to determine a focal point of pain, but often the entire surface of the foot is reactive. If necessary, the horse should be sedated and the foot desensitized to facilitate further examination. Light paring of the sole and frog areas with a hoof knife may reveal a black spot indicating the penetration site. Often, however, the entry is not discovered because the elastic nature of the hoof structures collapse the site of penetration. If an entry wound is discovered, the foot is scrubbed thoroughly before inserting a sterile, flexible probe. Care must be used so that inadvertent force and horse movement do not cause the probe to penetrate previously unaffected structures. A less invasive and preferred method is to place a sterile teat cannula into the hole and inject sterile radiopaque material to determine the affected structures (Fig. 28-2). It is important to obtain a true lateromedial radiographic view to determine the dorsal spread of the contrast medium.

If infection of the navicular bursa, distal interphalangeal joint, or DFTS is suspected, paracentesis, synovial fluid cytological studies, and culture and microbial sensitivity tests should be performed. Comprehensive radiographic examination should be performed to assess the distal phalanx and the navicular bone. Initial radiographs may appear normal, but lysis or new bone formation may become apparent within 10 to 14 days.

Treatment If penetration of deep hoof structures is suspected, broad-spectrum systemic antibiotics, NSAIDs, and tetanus prophylaxis should be administered. Antibiotic therapy usually should be continued for 2 weeks after resolution of clinical signs of infection. Establishing drainage, copious lavage with sterile ionic fluid, and debridement of all necrotic tissue is indicated. Management of infection of the navicular bursa is discussed in Chapter 24.

If the DDFT is involved (infectious tendonitis), debridement and removal of frayed and infected tendon fibers may be performed in a standing, sedated horse using a tourniquet and perineural analgesia, or with the horse under general anesthesia depending on horse temperament and owner financial constraints. After debridement, use of a 4- to 8-degree wedge shoe decreases forces on the DDFT and provides some pain relief. The wedge shoe angle is gradually decreased over several months as the DDF tendon begins to heal and strengthen. The bottom of the foot requires protection with a bandage or hospital plate until the surgical site granulates in and cornifies.

Infectious Osteitis of the Distal Phalanx

Deep penetrating wounds to the sole, especially the solar–white line junction, can result in infectious osteitis of the distal phalanx. Usually a chronic, recurrent draining tract is located at the coronary band or solar surface of the foot, associated with variable lameness. Infection of the distal phalanx also can result from undetected soft tissue infection, dissection of sub-solar abscesses, or as a sequela to laminitis secondary to recurrent abscessation and ischemia at the toe. As the bone infection progresses, blood supply to the area is compromised and the area of avascular bone separates from the parent bone forming a sequestrum.[9] Radiographic abnormalities may not be detectable for weeks after a penetrating injury.[9] Radiography reveals a radiolucent area in the margin of the distal phalanx, with or without sequestrum formation (Fig. 28-3). Debridement and curettage of all soft and necrotic bone often can be performed in a standing, sedated horse, but general anesthesia may be required. The foot is desensitized using perineural analgesia, cleaned with a hoof knife and steel brush, and prepared for aseptic surgery. Hemostasis is achieved by wrapping a roll of elastic bandage firmly around the fetlock joint to compress and occlude the palmar digital arteries. The infected bone is accessed by removal of sequential layers of the sole using either a motorized Dremel tool or a Galt trephine (Miltex, Bethlage, NY) with a retractable pilot bit.[10] The infected bone usually is discolored and soft and should be curetted to healthy bone margins. Culture of the infected bone and microbial sensitivity testing should be performed. A post-operative radiograph should be obtained to ensure complete debridement. After surgery the surgical site is packed with sterile gauze sponges soaked in antiseptic or antimicrobial solutions and then the foot is bandaged. Disposable diapers and duct tape are inexpensive materials used to make a waterproof foot bandage. The bandage is changed at 1- to 2-day intervals for the initial few weeks. A bar shoe and hospital plate provide solar protection. A plastic pad secured with duct tape also works well. The bolts and metal plate are removed from the hospital plate and the surgery site can be cleaned and treated; the plate then is bolted back in place. After surgery the horse is confined to a small area until the hole granulates and cornifies, which usually requires 4 to 6 weeks. If granulation tissue becomes excessive at the surgery site, application of 2% tincture of iodine speeds healing. If severe infection is present, the surgery site can be packed lightly with antibiotic-impregnated beads for continued antibiotic release at the infected site. Regional limb perfusion with antibiotics may also be beneficial.

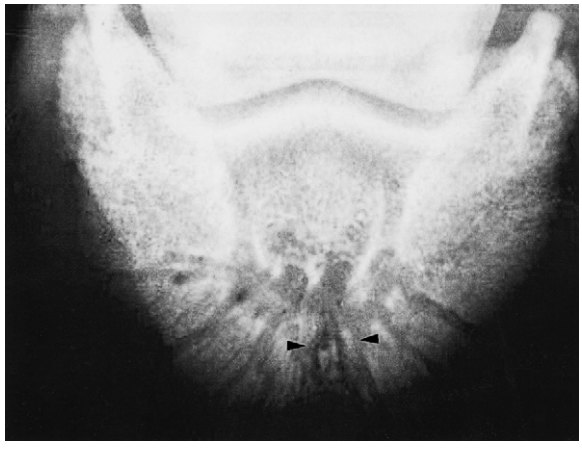

Fig. 28-3 Dorsoproximal-palmarodistal oblique radiographic view of the distal phalanx demonstrating infectious osteitis with a sequestrum *(arrowheads)*.

Prognosis Prognosis depends on whether the infection is severe and chronic. Horses with acute penetrating wounds that receive immediate and aggressive treatment have a good chance of returning to athletic use. Horses with penetration injuries that have an established infection involving the navicular bursa,[11] DFTS, or distal interphalangeal joint have a poorer prognosis. Prognosis for horses with infectious osteitis of the distal phalanx is good if the cause of infection is not laminitis. In one study, up to 24% of the distal phalanx was removed with successful results.[12]

Hoof Wall Cracks

History and Clinical Signs Hoof wall cracks occur from improper foot balance; coronary band defects; excessive hoof growth; and thin, dry, or wet hoof walls. The horny hoof wall often fails internally before being visible on the external hoof surface.[13] Central toe cracks usually are associated with distal phalanx rotation and club feet. Hoof cracks are characterized by location (toe, quarter, heel or bar), length (complete or incomplete), depth (superficial or deep), site of origin (ground surface or coronary band), and whether hemorrhage or infection is present.[13] Hoof cracks are usually obvious by visual examination of the foot, except those originating at the hairline, which may be only 1 to 2 cm long and difficult to see. Lameness may be present, depending on whether the hoof crack involves the sensitive laminae and if infection is present.

Diagnosis Hoof wall cracks are diagnosed by visual assessment of the hoof capsule. The depth of the hoof crack, pain, and associated instability surrounding the crack are determined by careful hoof tester examination. Pain associated with a hoof crack is usually determined by digital pressure and hoof tester manipulation over the crack. Purulent material may exude during hoof tester pressure. Radiography is useful to evaluate rotation of the distal phalanx in horses with central toe cracks. Bleeding from a hoof crack after exercise indicates that the sensitive laminae are involved.

Treatment Treatment varies with hoof crack location, depth, horse use, and presence of exposed sensitive laminae and infection. Superficial hoof cracks do not extend into laminar tissue and therefore are not painful. These may be the result of improper foot balance or basic neglect regarding trimming. Treatment involves balancing the foot and providing stability by application of a full bar shoe. If the horse is shod correctly and restricted from strenuous activity, most hoof cracks will resolve.[14]

Treatment of deeper hoof cracks varies somewhat with location of the crack. If lameness exists, diagnostic analgesia should be performed to confirm that the hoof crack is the source of pain. Careful observation of the affected foot as the horse walks slowly often shows that the defect is unstable and actually closes and pinches the underlying sensitive laminae as the foot strikes the ground, causing pain. The hoof crack is explored and debrided with a hoof knife or motorized burr (Dremel tool) to remove all necrotic and infected tissue. Any undermined hoof wall is also removed. The area is treated for 24 to 48 hours with an antiseptic such as merthiolate

(Thermisol; Eli Lilly, Chicago, IL) or tincture of iodine, until the crack is dry and free of infection. The hoof wall must be stabilized so that it can regrow. Previous recommendations have suggested grooving or burring the proximal extent of the crack, but this is rarely successful.[13] Many techniques for hoof wall stabilization use a combination of frog support with a heart bar shoe and clips combined with either a fiberglass patch,[14] drill and lace,[13] or metal plate technique. The heart bar shoe is essential to oppose the forces causing collapse of the crack during weight bearing. The toe must be trimmed short and squared before application of the shoe. The drill and lace technique is used if the deep crack does not extend to the coronary band, and the metal plate technique is used if it does. Using the metal plate technique, two drill holes are placed 1 to 2 cm on either side of the trough directly opposite each other. Care is needed to ensure that drilling too deep does not affect deeper hoof structures. The foot should *not* be desensitized to avoid iatrogenic penetration of deeper tissues with the screws. One or two plates are cut that are longer than the exposed hoof crack and about 0.6 cm wide. With the foot held in a non–weight-bearing position, the metal plate is drilled and bolted in place to stabilize the crack. The hoof wall adjacent to the toe crack is trimmed shorter than the remaining hoof wall to minimize weight-bearing forces on the damaged area and decrease potential bending forces on the plate. The crack is treated for several days with Thermisol or tincture of iodine until the sensitive structures begin to cornify and infection has resolved. The hoof crack can then be filled with an acrylic material (e.g., Equilox; Equilox International, Pine Island, MN). Adhesion of the acrylic to the hoof wall is enhanced by sanding the hoof wall, applying acetone to dry the area, and using a hair dryer at the external hoof surface before acrylic application.

Quarter and heel hoof cracks often are incomplete and may be predisposed by low-heel–long-toe conformation with underslung heels.[13] After the crack is debrided and infection eliminated, the foot is balanced and a heart bar shoe applied. Two holes are drilled using a 0.24-cm drill bit approximately 1 to 2 cm apart on either side of and parallel to the crack. The holes begin at the ground surface and extend up the hoof wall. A shoelace or synthetic multifiber suture is laced in a far-near–near-far suture pattern to stabilize the crack.[13] After the crack is dry and free of sensitive tissue and infection, it is filled with acrylic material. Readers are also referred to Chapter 27.

Prognosis The prognosis for horses with both superficial and deep hoof cracks is good and lameness usually resolves as soon as the hoof is stabilized, but recurrence is common. Success is improved if the mechanical cause of the hoof crack can be identified and eliminated.

Coronary Band and Hoof Wall Lacerations

History and Clinical Signs The hoof wall is thicker and stronger at the toe region and becomes thinner through the quarters and heel, where the younger hoof has a greater moisture content.[14] The quarter and heel regions of the foot are susceptible to traumatic injuries. Coronary band and hoof wall lacerations usually occur from the horse catching a segment of hoof on an object as it steps down or kicking or stepping on a sharp object. Hoof avulsion injuries also can occur when the foot is entrapped between fence boards or in a cattle guard. Continued hoof imbalance, improper shoe removal, and repetitive trauma to the coronary band region result in a chronic hoof avulsion or spur—a fibrous bed of scar tissue beneath a displaced segment of hoof wall. Horses that overreach are predisposed to coronary band spurring or heel avulsion injuries. Steeplechase horses and horses racing on grass often slip and lacerate the heel region of a front foot.

Hoof avulsions are described as acute (lacerations) or chronic (repetitive trauma and spur formation) injuries. Avulsions can be complete, with total tissue loss, or incomplete in that a border of hoof remains intact. Hoof wall, coronary band, sole, distal phalanx, laminae, and the distal interphalangeal joint may be involved in deep lacerations. The degree of lameness varies with duration, depth, and location of the injury. Horses with acute, superficial injuries may show mild lameness, and horses with deeper structure involvement may be non–weight bearing. If degree of lameness does not seem appropriate for severity of the laceration, the integrity of the palmar digital vein, artery, and nerve should be investigated.

Diagnosis Diagnosis is straightforward, but involvement of deeper structures can be difficult to identify. Careful manipulation of the foot causes a painful reaction if deep structures are involved and provides valuable information regarding the integrity of the supporting hoof structures. Instability of the distal interphalangeal joint may indicate collateral ligament damage. If manipulation produces a sucking noise, the distal interphalangeal joint or DFTS may be involved. Before further evaluation the coronary band hair should be clipped, the outer hoof wall rasped, and sole trimmed to eliminate any superficial contamination. The area should be scrubbed with antiseptic solution and lavage performed. The wound then is digitally explored by the veterinarian using sterile gloves. Radiography is recommended for all deep lacerations, because fractures of the distal or middle phalanges may be present. Contrast radiographic studies may be necessary to identify openings in synovial structures. Ultrasonographic examination may help to determine the extent of soft tissue damage.

Treatment The equine foot heals primarily by epithelialization and reformation of the corium.[15] Decreasing motion at the affected site and hoof stabilization are essential for a successful outcome. Treatment varies with duration, severity, and type of injury. Incomplete, superficial hoof wall lacerations without coronary band involvement are treated by excision of the separated hoof wall and bar shoe application until healing occurs. The goal of shoeing is to eliminate weight-bearing forces at the damaged site and provide hoof stability.

Incomplete, clean, acute hoof avulsions involving the coronary band can be treated by cleaning and debriding the displaced flap of tissue and suturing it back in place. This generally requires general anesthesia. Interrupted vertical mattress sutures with No. 1 or No. 2 monofilament suture are recommended.[14,15] Any undermined or contaminated hoof wall is removed. Immobilization is essential and is provided by applying a foot cast. The cast is usually left in place for 2 to 3 weeks. When applying the foot cast, the clinician should ensure that the proximal extent of the cast is located at midpastern level and does not impinge on the fetlock joint during movement. Administration of systemic antibiotics and NSAIDs may be necessary if contamination is suspected. If deeper structures are involved, cast application should be delayed until infection is eliminated. Open synovial structures can be lavaged daily, and the foot is protected with a sterile foot bandage. Antibiotic-impregnated beads and regional limb perfusion with antibiotics may be necessary with severe contamination.

Horses with compete avulsion injuries that appear stable during movement are treated by daily cleaning and bandaging until healing occurs. Bar shoe application is required if the hoof is unstable and contaminated. A foot cast can be used if infection is not a problem.

Repair of a chronic avulsion injury, or spur, usually requires surgical excision with the horse under general anesthesia. The hoof is rasped and prepared for aseptic surgery. The hoof wall distal to the avulsed segment should be thinned with a rasp to allow placement of the sutures through the hoof wall. The excessive cornified tissue growing from the displaced coronary band is trimmed to a level just distal to the coronary band. The fibrous tissue under the avulsed segment, which lies in

the bed of the defect created by the hoof avulsion, is resected. This provides a vascularized area and room for replacement of the avulsed segment back to its original location. The displaced coronary band and hoof wall are replaced and sutured in the correct anatomical position using No. 2 monofilament suture in a simple interrupted or vertical mattress suture pattern. The surgery sites are covered with a light bandage and the foot immobilized in a foot cast for 2 weeks.

Prognosis Treatment is usually prolonged and often takes 3 to 5 months for complete healing, which can be costly to the owner.[15] Incomplete superficial avulsion injuries or injuries that can be sutured usually heal by first intention, with a good functional, and sometimes cosmetic, end result. A roughened or thickened hoof wall distal to the defect often occurs at the site of avulsion, but it usually does not create a clinical problem. Prognosis decreases if deeper structures or synovial structures are involved. Complications such as infectious arthritis, fractures, and potential osteoarthritis can occur often with a guarded prognosis.

CHAPTER • 29

Functional Anatomy of the Palmar Aspect of the Foot

Robert Bowker

The palmar portion of the foot consists of several important structures functioning to support the foot and the limb of the horse, as well as being an integral part of the energy dissipation mechanisms present within each limb. These palmar foot structures include the cartilages of the foot (also called the *lateral collateral* or *ungual* cartilages), the digital cushion, and an extensive vascular network. Although each of these structures is present in every foot, morphological features and tissue composition vary widely among horses, which may be responsible for differing efficiencies in ability to dissipate energy. Furthermore, such differences may in part account for differences between the feet of a sound horse compared with feet of a horse with chronic lameness associated with the foot. Awareness of how these tissues interact and relate to each other during foot impact is important for understanding how the foot dissipates energy and how potential problems may arise to produce lameness, when energy dissipation is not efficient and the concussive forces are transmitted to the bones and other connective tissues. The domestic horse spends considerable time standing, so the structure of the palmar aspect of the foot is important for support to minimize the weight of the horse being shifted dorsally toward the connective tissues at the toe of the foot.

The medial and lateral cartilages of the foot extend from the palmar surface of the distal phalanx to the bulbs of the heel as large vertical sheets, whereas the digital cushion lies between the medial and lateral cartilage and extends dorsally toward the solar surface of the distal phalanx ventral to the deep digital flexor tendon (DDFT). Associated with each cartilage of the foot is a venous network that connects with the venous vessels under the distal phalanx and the vessels associated with the dermis of the hoof wall. This venous microvasculature forms a hydraulic system that is hypothesized to form the mechanism for how the ground impact energies are dissipated, before these forces are transmitted to and damage the bone and other connective tissues within the foot. Those horses with good to excellent hydraulic systems should be more efficient in dissipating the impact energy compared with horses with feet with less well-developed hydraulic networks.

Functional Anatomy of the Palmar Aspect of the Foot

Robert Bowker

The palmar portion of the foot consists of several important structures functioning to support the foot and the limb of the horse, as well as being an integral part of the energy dissipation mechanisms present within each limb. These palmar foot structures include the cartilages of the foot (also called the *lateral collateral* or *ungual* cartilages), the digital cushion, and an extensive vascular network. Although each of these structures is present in every foot, morphological features and tissue composition vary widely among horses, which may be responsible for differing efficiencies in ability to dissipate energy. Furthermore, such differences may in part account for differences between the feet of a sound horse compared with feet of a horse with chronic lameness associated with the foot. Awareness of how these tissues interact and relate to each other during foot impact is important for understanding how the foot dissipates energy and how potential problems may arise to produce lameness, when energy dissipation is not efficient and the concussive forces are transmitted to the bones and other connective tissues. The domestic horse spends considerable time standing, so the structure of the palmar aspect of the foot is important for support to minimize the weight of the horse being shifted dorsally toward the connective tissues at the toe of the foot.

The medial and lateral cartilages of the foot extend from the palmar surface of the distal phalanx to the bulbs of the heel as large vertical sheets, whereas the digital cushion lies between the medial and lateral cartilage and extends dorsally toward the solar surface of the distal phalanx ventral to the deep digital flexor tendon (DDFT). Associated with each cartilage of the foot is a venous network that connects with the venous vessels under the distal phalanx and the vessels associated with the dermis of the hoof wall. This venous microvasculature forms a hydraulic system that is hypothesized to form the mechanism for how the ground impact energies are dissipated, before these forces are transmitted to and damage the bone and other connective tissues within the foot. Those horses with good to excellent hydraulic systems should be more efficient in dissipating the impact energy compared with horses with feet with less well-developed hydraulic networks.

CARTILAGES OF THE FOOT

The cartilages of the foot lie beneath the skin and dermis and the coronary venous plexus and have previously been described as rhomboid-shaped, with a convex surface abaxially and a concave surface axially. Several ligaments secure the cartilages of the foot to the digital bones.[1-4] However, these descriptions are over-simplistic and appear to have been obtained from horses with underdeveloped structures in the palmar aspect of the foot. The morphological features of the cartilages of the foot vary greatly with a range of shapes and thickness, the presence of an axial projection from its distal edge, and the extent of vascularity.[5] The structure of the cartilages of the foot is best determined by viewing the foot in frontal and transverse sections (Figs. 29-1 and 29-2). In frontal sections cut perpendicular to the ground, beginning at the bulbs of the heels, the cartilages of the foot have a C- to L-shaped configuration. Both the upright and the base parts of the L-shaped cartilage vary in thickness among horses. The mean thickness of the upright part at the level of the navicular bone ranges from 0.5 to 2.0 cm in an adult horse (450 to 550 kg body weight). The base part or axial projection of the L-shaped cartilage varies in its thickness and the distance that it extends toward the midline of the foot overlying the bars and the frog. The cartilages of the foot are thinnest in the heel region (0.45 to 1.3 cm) but become thicker closer to the distal phalanx (0.6 to 1.5cm) and thin slightly as they attach onto the distal phalanx (0.5 to 1.0 cm). The cartilages of the foot are thicker in forelimbs than hindlimbs.

Overlying the abaxial surface of the cartilages of the foot are a venous plexus, the laminar dermis, and the hoof. Loose connective tissue extends from each cartilage to the DDFT. On the axial surface the axial projection of the cartilage extends toward the midline of the foot. In most feet, this axial projection extends from the dorsal half of the cartilage; the palmar half of the cartilage has virtually no, or very small, extension into the substance of the digital cushion. However, in some feet it extends the entire dorsal-palmar extent of the cartilages of the foot. This axial projection extends to overlie the epidermal ridges of the bars, with many finger-like projections extending into the substance of the digital cushion, and may extend across the midline of the palmar foot under the digital cushion to fuse with that of the opposite side of the foot. These white bundles of fibrous and fibrocartilaginous tissues are easily discerned from the surrounding yellow elastic, adipose, and collagen fibers of the digital cushion. The relative thickness of the axial projection in a distal-proximal orientation varies. In horses younger than 4 to 5 years of age the axial projection usually is not fully developed along the entire length of the cartilage, and in young foals there is only a thin sheet of fibrous tissue.

The cartilages of the foot contain primarily hyaline cartilage, but in many horses from 4 to 5 years of age the medial border of the cartilage develops fibrocartilage. A fibrocartilaginous ligament of variable thickness develops between the cartilage and the DDFT; this is consistently larger in forelimbs than hindlimbs. In some horses the cartilages of the foot can ossify. This may be genetically controlled, but stress on the foot, such as that produced with certain shoe types improving traction, may promote ossification.

Several ligamentous attachments connect the cartilages of the foot to the distal and middle phalanges, as well as to the navicular bone.[3,4] The chondroungular ligaments attach the cartilage to the distal phalanx along the palmar process, whereas the medial and lateral chondrocoronal ligaments attach the cartilage to the distal end of the middle phalanx. The medial and lateral ligaments of the cartilages of the foot (collateral chondroungular ligaments) attach the cartilage to the angle of the distal phalanx. The paired chondrosesamoidean ligaments attach the axial surface of the cartilage to the navicular bone. A pair of elastic ligaments extends between the proximal phalanx and the proximal surface of the cartilages of the foot and are most prominent in larger horses, such as draft breeds. Cruciate ligaments of the cartilages of the foot (cruciate chondroungular ligaments) connect the axial surface of the cartilage to the palmar process on the opposite side of the foot. Within the digital cushion are fiber tracts radiating from the connective tissue ventral to the attachment of the DDFT (digital torus), through the digital cushion, to the axial surface of the cartilages of the foot.

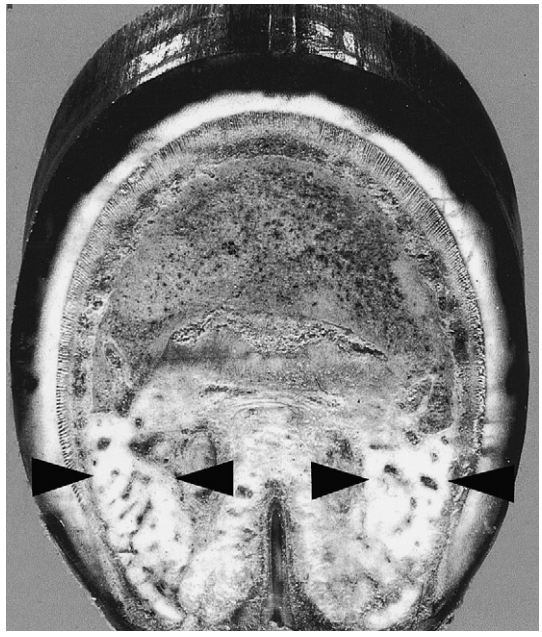

Fig. 29-1 Transverse section through the distal foot of a Quarter Horse 25 years of age, with no history of foot problems. *Arrows* show the thick cartilages of the foot. An axial projection composed of fibrocartilage extends between each cartilage of the foot.

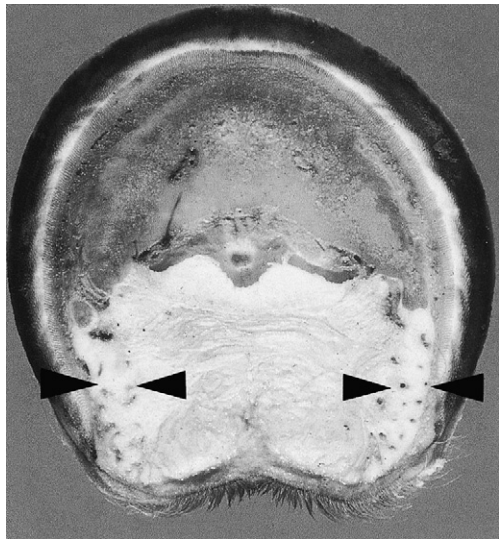

Fig. 29-2 Transverse section of the foot of a horse with chronic foot pain with thin cartilages of the foot *(arrows)*. The digital cushion is primarily composed of fat and elastic tissue, with little fibrocartilage.

Each hoof cartilage is perforated by numerous vascular foramina, the number of which varies depending on the thickness of the cartilages of the foot. Within the vascular channels is a large central vein, with a rich network of microvessels termed *veno-venoanastomoses*.[5-7] These microvessels exit the large central vein and, after a variable course within the vascular channels, re-enter the same vein. More of the vascular channels are present at the distal level of the cartilages of the foot, but in feet with relatively thicker collateral cartilages, there are more vascular channels proximally compared with feet with much thinner cartilages. The veins coalesce proximal to the cartilage into a venous plexus before uniting to form the medial and lateral palmar digital veins.[7,8]

DIGITAL CUSHION

The digital cushion consists of a meshwork of collagen and elastic fiber bundles, with small areas of adipose tissue, and lies between the cartilages of the foot, extending dorsally as a wedge-shaped tissue attached to the DDFT and the solar surface of the distal phalanx, near the distal attachment of the DDFT.[1-4] It overlies the frog and its dermis and the axial projection from the cartilages of the foot. Proximally and dorsally the digital cushion fuses with the distal digital annular ligament and bulges into the bulbs of the heel, that are separated superficially by a central shallow groove. Some horses have areas of fibrocartilage in the digital cushion and if present, these extend between the cartilages of the foot and the DDFT. The digital cushion has two arteries that pass through the digital cushion to the area distal to the digital cushion, but proximal to the axial projection of the cartilages of the foot, and then branch extensively to supply the frog.[2-6] Only a few vessels ramify through the digital cushion from these two arteries.

ENERGY DISSIPATION

The function of the digital cushion is controversial. The structural organization of the cartilages of the foot, the digital cushion, and the vasculature suggests a role in energy dissipation.[5] The pressure theory suggests that at ground contact the frog stay is pushed upward into the digital cushion, forcing the cartilages of the foot outward. The depression theory emphasizes a downward movement of the pastern into the digital cushion during ground impact, forcing the cartilages of the foot to move outward. However, neither theory is consistent with measurement of negative pressure within the digital cushion during stance and locomotion.[9] The hemodynamic hypothesis provides a hydraulic mechanism during ground contact, so that impact energy is transmitted to the fluid within the blood vessels.[5] During ground impact the outward expansion of the cartilages of the foot probably occurs through the bars contacting the axial projections and the downward movement of the bony column within the hoof capsule. This creates a negative pressure within the digital cushion. At this brief moment of impact the venous blood within the vessels of the palmar aspect of the foot is forced into the microvenous vasculature within the vascular channels of the cartilages of the foot. Hydraulic resistance to flow through the microvasculature dissipates the high-frequency energy waves, which are potentially deleterious to bone and other tissues. Negative pressure in the foot enables refilling of the vasculature before the next footfall. In feet with thick cartilages of the foot, enclosing more microvessels within the vascular channels, more energy is dissipated on ground contact compared with feet with thin cartilages of the foot. The fibrocartilage content of the digital cushion also is crucial to energy dissipation, because the fibrocartilage has its own energy-absorbing mechanisms. The elastic tissue acts only like a spring and absorbs little energy on ground contact, serving to return the foot to its original position as the foot leaves the ground.

The shape of the foot appears to influence the development of the cartilages of the foot and the structure of the digital cushion. In well-balanced feet, with the frog on the ground along with the bars, cartilages of the foot tend to be thick with fibrocartilage in the digital cushion.[5] In feet with a low heel and long toe, the site of ground contact of the hoof wall at the angle of the wall and the bars usually is beneath the bony part of the distal phalanx, rather than underneath the cartilages of the foot. Therefore more of the energy of impact is transferred to the bone and hoof wall laminae, as the cartilages of the foot and the digital cushion are in essence by-passed during ground impact.

NAVICULAR SUSPENSORY APPARATUS

The navicular suspensory apparatus consists of several ligaments functioning to suspend the distal sesamoid bone or navicular bone on the palmar surface of the distal interphalangeal joint.[1-4] Proximally, paired collateral suspensory ligaments of the navicular bone (or the collateral sesamoidean ligament) arise from the distal surface of the proximal phalanx and pass in a distopalmar direction, attaching along the abaxial surface of the middle phalanx,[10] to insert on the extremities of the navicular bone. In addition, small branches attach to the axial surface of the cartilages of the foot and the distal phalanx. The attachment along the middle phalanx is important biomechanically during forward movement of the limb, because high loads are created on the joint surfaces between the navicular bone and the middle phalanx and between the navicular bone and the distal phalanx.[11] These ligaments are composed of collagen fibers with an abundance of elastic tissue fibers. Distally the distal sesamoidean impar ligament extends from the distal border of the navicular bone to the entire flexor surface of the distal phalanx adjacent to the insertion of the DDFT.[1-4] At its insertion the distal sesamoidean impar ligament contains an extensive network of microvessels containing arteriovenous complexes and nerves fibers within loose connective tissue septae.[10] The arteriovenous complexes are innervated by many peptidergic nerve fibers, including substance P, neurokinin A, and calcitonin gene-related peptide, which are present in the many sensory fibers innervating the foot.[12] The peptide nerves substance P and neurokinin A also have pharmacological receptors, located on the small isolated microvessels and the arteriovenous complexes within the distal sesamoidean impar ligament, to control blood flow through this intricate vascular network. When these peptides are released from the sensory nerve fibers in the foot, they promote an active vasodilatation of these small vessels, presumably through a nitric oxide pathway. The locations of these arteriovenous complexes suggest that they may have two possible functions, including a protective mechanism for detection of high-pressure differences within the region during movement, and maintaining the hydration status of the distal sesamoidean impar ligament and other nearby connective tissues for optimal function.

The distal border of the navicular bone has a narrow, elongated facet for articulation with the distal phalanx. Between this and the attachment of the distal sesamoidean ligament is a fossa containing foramina for blood vessels. The proximal border also has several small foramina. The dorsal articular surface of the navicular bone and the articulation between the navicular bone and the distal phalanx create a substantial palmar extension of the articular surface of the distal interphalangeal joint. During extension of the distal interpha-

langeal joint, with fixation of the foot on the ground and the movement of the body over the distal limb, the middle phalanx contacts the dorsal articular surface of the navicular bone, and the navicular bone becomes a weight-bearing structure. Loads transmitted through the navicular bone are supported by the proximal and distal suspensory ligaments. The role of the DDFT is discussed further in Chapter 33.

DISTAL INTERPHALANGEAL JOINT

The distal articular surface of the middle phalanx, the articular surface of the distal phalanx and the articular surfaces of the navicular bone form the distal interphalangeal joint. The relatively short medial and lateral collateral ligaments of the distal interphalangeal joint arise from the distal ends of the middle phalanx to insert on the distal phalanx and the dorsal part of the cartilages of the foot. The joint capsule has a small dorsal pouch and an extensive palmar pouch, and blend with the collateral ligaments and common digital extensor tendon. The palmar pouch of the distal interphalangeal joint is greatly expandable (25 to 30 ml in volume) and is subdivided into a proximal palmar pouch and a small distal palmar pouch extending between the navicular bone and the distal phalanx. In the midline the palmar pouch extends proximally beyond the two small secondary tendons of the DDFT, which attach to the distal end of the middle phalanx. The proximal palmar pouch almost surrounds the collateral sesamoidean ligaments.[13,14] The distal interphalangeal joint cavity also has several small abaxial, dorsal projecting outpouchings that are in close proximity to the sensory nerves of the medial and lateral palmar digital nerves. The distal interphalangeal joint capsule therefore has a large surface area through which local anesthetic solution may diffuse. The comma-shaped navicular bursa is much smaller (approximately 3 ml in volume). Proximally it can extend over the proximal border of the navicular bone to protrude dorsally.

INNERVATION

The innervation of the equine distal forelimb is via the medial and lateral palmar nerves and the medial and lateral palmar metacarpal nerves.[1-4] The distal continuation of the palmar nerves course parallel to the accompanying artery and then obliquely across the abaxial surface of the ligament of the ergot to supply most tissues of the palmar half to third of the foot (see Chapter 10). The Editors point out that given their clinical experience and current research results, diagnostic analgesia of the digital nerves result in analgesia of most of the foot, including the solar surface. Several small nerves branch from the medial palmar digital nerve, to course with the artery of the digital cushion, to supply the palmar foot, including the dermis of the overlying skin and frog, parts of the digital cushion, laminae of the bulbs of the heel, cartilages of the foot, and portions of the quarters. A small branch of the lateral palmar nerve may supply the ligament of the ergot. The dorsal branches of the palmar nerve continue with the palmar digital vein to innervate the dorsal aspects of the foot, including the distal interphalangeal joint, laminar and solar dermis, and the dorsal part of the cartilages of the foot. An intermediate branch from this nerve occurs in approximately a third of horses. In some horses a branch of the medial palmar metacarpal nerve supplies the coronary band. No communication occurs between the palmar metacarpal nerves and the dorsal branches of the palmar digital nerves. Variable branches occur, including one from the lateral palmar nerve in the proximal metacarpal region extending obliquely to the coronary band, and one from the medial palmar digital nerve to the navicular bursa. In the hindlimbs an additional nerve supplies the coronary and laminar dermis of the dorsal foot, provided by the medial and lateral dorsal metatarsal nerves (terminal branches of the deep fibular nerve). Rarely branches from the plantar metatarsal nerves course under the distal ends of the second and fourth metatarsal bones to supply the dermis of the periople and coronet. The widespread distribution of these nerves provides a broad sensory and sympathetic autonomic innervation pattern to the tissues and vasculature of the foot.

The sensory nerves have many diverse functions in addition to conveying consciously perceived sensations, including touch, proprioception, and pain. The palmar digital nerves are composed of both small, unmyelinated nerves and larger myelinated nerves in a ratio of nearly 4:1. Approximately 25% of the unmyelinated fibers are sympathetic nerves and 75% are afferent fibers. Much of the sensory information from the foot and the activity of the sympathetic autonomic nerves is conveyed to the spinal cord through the unmyelinated fibers, which are the more slowly conducting nerve fibers. Many neurochemicals are present within the nerves including noradrenaline and adrenaline, substance P, neurokinin A, calcitonin gene-related peptide, neuropeptide Y, peptide histidine isoleucine, vasoactive intestinal peptide, and the enkephalins. These are released locally from the peripheral processes of the sensory nerves, and the effect on surrounding tissues depends on which neurochemical(s) is emitted.

Most of these peptides have been identified in the foot, usually in close association with blood vessels and other microvasculature. Within the dorsal hoof wall the sympathetic fibers containing noradrenaline and neuropeptide Y are present along the small arterioles within the dermal laminae and form dense plexuses around the arteriovenous anastomoses.[15] The same neurotransmitters are present in the navicular region, including the arteriovenous complexes.[13] Noradrenaline and neuropeptide Y promote vasoconstriction, whereas vasoactive intestinal peptide is a prominent dilator of the smooth muscle of the microvessels.[16] The other peptides, such as substance P, calcitonin gene-related peptide, and peptide histidine isoleucine, are present in the sensory nerve fibers of the dorsal hoof wall and the distal aspect of the distal sesamoidean impar ligament[10,12] and also promote vasodilation by means of an endothelial-dependent mechanism and the activation of a nitric oxide pathway.[17,18] Activation of these sensory nerves either directly, or indirectly through pain mechanisms, produces a measurable increase in the concentration of these peptides in joints and tissues as they interact with tissue elements, such as inflammatory cells and macrophages, and controls edema formation.[19]

Other sensations, such as touch and proprioception, are mediated to the spinal cord through the larger myelinated fibers. The receptors of these nerve fibers are present in the bulbs of the heel and in association with the collateral ligaments of the navicular bone.[20-22] The locations of these lamellated receptors appear to be critical for the perception of proprioceptive stimuli by the horse during movement when heel-first landing occurs. Activation of these receptors at ground impact and the rapid conduction to the spinal cord through these thickly myelinated fibers enable this sensory information to become incorporated into the spinal cord reflex mechanisms controlling locomotion. During toe-first or flat-footed landings, activation of these sensory receptors is presumably less. If a horse is shod with a pad, it may shorten its stride because the pacinian receptors are not adequately stimulated. If a little, finger-sized piece of rubber is attached temporarily to the pad, within one or two steps the stride extends forward maximally, as the horse "realizes" the importance of this area of the foot, by activation of the sensory receptors. If the rubber is removed after several days, the gait does not revert. Together the unmyelinated and the myelinated nerves

enable the horse to smoothly negotiate the varying surfaces of the terrain during locomotion and provide a means for monitoring changes in the peripheral tissues and controlling the physiological and pathological environment within the foot.

CHAPTER • 30

Navicular Disease and Other Soft Tissue Causes of Palmar Foot Pain

Sue J. Dyson

PATHOPHYSIOLOGY OF NAVICULAR DISEASE

Navicular disease is a chronic forelimb lameness associated with pain arising from the distal sesamoid or navicular bone and closely related structures, including the collateral ligaments of the navicular bone, the distal sesamoidean impar ligament, the navicular bursa, and the deep digital flexor tendon (DDFT), but does not include primary DDF tendonitis. Although historically considered to be a single disease, given its variety of clinical manifestations it is likely that there are probably a number of different clinical conditions, of different origins, that give rise to pain. It is difficult to conceive of a single disease that can result in an insidious-onset, slowly progressive bilateral forelimb lameness, or an acute-onset, relatively severe unilateral forelimb lameness, each with a variety of different radiological manifestations and with some horses never developing radiological changes. It is curious that sometimes clinical signs become apparent in young horses just

commencing work, whereas more typically lameness is seen in mature riding horses. It is also seen in horses with vastly different distal limb conformation. It is a common condition in Quarter Horses, which tend to have narrow, upright, boxy feet, small relative to the body size, as well as in European Warmblood horses, many of which have relatively tall narrow feet. It is also common in Thoroughbred horses, which frequently have rather flat feet, with low collapsed heels, often associated with dorsopalmar foot imbalance. Recent evidence has suggested a heritable tendency toward the development of navicular disease in the Dutch Warmblood.[1,2]

Navicular disease has not been reproduced experimentally; therefore, all proposed causes remain speculative. Earlier theories suggesting a vascular etiology with arteriosclerosis,[3] or thrombosis, resulting in ischemia within the navicular bone,[4] have largely been rejected because of failure to identify ischemic bone or thrombosis, failure to reproduce clinical signs or pathological changes by occluding blood supply to the bone, and increasing evidence demonstrating increased bone modeling.[5-8] Post-mortem studies to date have focused principally on horses with long-term, chronic lameness, generally with advanced radiographic abnormalities, reflecting the end stage of a disease complex. However, studies of aging changes in the navicular bone of normal horses and comparison with those with navicular disease have given valuable evidence that there is a degenerative aging process that may be accelerated in horses with navicular disease.[7-9] Non-physiological biomechanical factors may promote this degenerative disease.[7,10] The explanation for pain and lameness in horses with no detectable radiological change has been poorly investigated by post-mortem studies.

The navicular apparatus comprises the navicular bone, the collateral ligaments of the navicular bone, the distal sesamoidean impar ligament (DSIL), the navicular bursa, the DDFT, and the distal digital annular ligament. The navicular bone or distal sesamoid bone, which articulates with the middle and distal phalanges, provides a constant angle of insertion, and maintains the mechanical advantage of the DDFT, which exerts major compressive forces on the distal one third of the bone. Contact studies between the phalanges in isolated limbs have demonstrated that the greatest forces are applied in the propulsion phase of the stride, during extension of the distal interphalangeal joint, with increased tension of the DDFT on the palmar aspect of the navicular bone, increased contact between the navicular bone and the middle phalanx, and increased tension in the collateral ligaments.[11,12] Tension in the DDFT and the distal digital annular ligament promotes stability of the distal interphalangeal joint. Forces may be altered by foot conformation: in a horse with weak heels, there is less flexion of the distal interphalangeal joint compared with a horse with strong heels, which results in increased pressure concentrated on the distal aspect of the navicular bone.[13]

Compressive forces and stress on the navicular bone have been compared in clinically sound horses and horses with navicular disease.[10] Although the mean peak force and stress were similar, the force and stress in the horses with navicular disease were approximately double early in the stance phase of the stride. This early peak stress resulted in a much higher loading rate in the group with navicular disease. The difference in loading patterns was associated with an increased force in the DDFT in the early and mid-stance phases, probably as a result of increased contraction of the DDF muscle. This contraction of the DDF muscle may result in toe-first ground contact seen in some horses with navicular disease. It is suggested that pain associated with the navicular bone may result in a positive feedback by increasing the force in the DDFT and hence increasing the compressive force on the navicular bone. This hypothesis is supported by reduction in peak forces on the navicular bone throughout the stance phase in horses with navicular disease after perineural analgesia of the palmar digital nerves.[14]

The shape of the navicular bone may be determined at birth, and this may influence the biomechanical forces subsequently applied to the bone and hence influence the risk of development of navicular disease[1,15] (Fig. 30-1). Finnhorses and Friesian horses tend to have a straight or convex contour of the proximal articular border of the navicular bone and rarely develop navicular disease. The incidence of navicular disease is much higher in the Dutch Warmblood, and horses in which the proximal articular margin is concave or undulating appear to be at highest risk of development of the disease.[2,14]

Aging results in degenerative change in the fibrocartilage on the palmar aspect of the navicular bone.[7,8] Physiological forces result in adaptive remodeling of the subchondral bone with cortical thickening. Non-physiological forces result in subchondral sclerosis associated with thickening of the trabeculae with focal areas of lysis (Fig. 30-2). There is edema, congestion, and fibrosis of the marrow stroma within the

The subchondral bone has an increased area and porosity in **A** compared with **B** and **C;** the trabecular area is decreased, but the trabeculae are thickened. (From Wright IM, Kidd L, Thorp BH: Gross, histological and histomorphometric features of the navicular bone and related structures in the horse, *Equine Vet J* 30:220, 1998.)

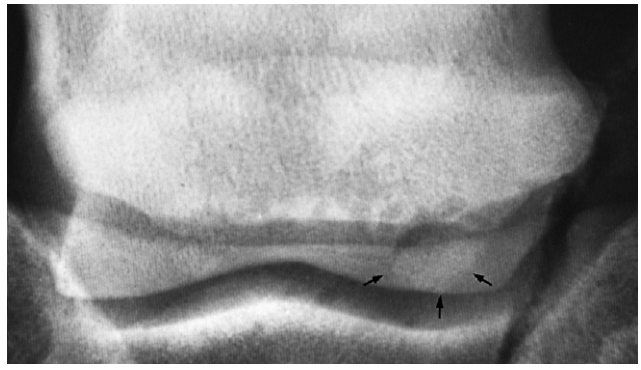

Fig. 30-3 Dorsoproximal-palmarodistal oblique radiographic view of a navicular bone showing a large discrete mineralized fragment on the distal lateral aspect of the bone *(arrows)*, an abnormal concave contour of the adjacent distal border of the bone, and the lucent zones along the distal border of the bone. The horse had bilateral forelimb lameness associated with distal border fragments in both front feet.

medullary bone, which may result in cyst-like formation. Enlarged synovial invaginations are the result of recruitment and activation of osteoclasts following the course of the nutrient vessels into the spongiosa. Concurrently there may be fibrillation of the dorsal surface of the DDFT, which may predispose to adhesion formation between the DDFT and regions of partially or fully eroded fibrocartilage on the palmar aspect of the navicular bone. Whether lesions in the DDFT are primary or secondary to pre-existing damage of the fibrocartilage currently remains open to debate.

Aging changes also have been recognized in the articular cartilage of the navicular bone and the opposing face of the distal phalanx.[12] There is loss of proteoglycan and tidemark advancement, which is thought to reflect excessive shear stress in the zone between the mineralized and non-calcified articular cartilage. A greater number of tidemarks were seen in horses with clinical signs of navicular disease than normal horses of similar age.

To date, active lesions of the collateral ligaments have not been well recognized, whereas the presence of entheseous new bone on the proximal border of the navicular bone, reflecting previous insertional desmopathy, is well documented in both normal horses and horses with navicular disease.[7,8,16] Its significance remains uncertain, although more extensive new bone tends to be associated with other signs of navicular disease.[16] Mineralized and osseous fragments in the distal sesamoidean impar ligament also have been recognized in both normal horses and in horses with navicular disease, and the clinical significance remains difficult to determine. Fragments associated with a defect in the distal margin of the navicular bone were more common in horses with navicular disease than in age-matched controls[8] (Fig. 30-3). Although other gross and histological abnormalities of the distal sesamoidean impar ligament have not been well documented, inflammation has recently been recognized histologically at the intersection of the distal sesamoidean impar ligament and DDFT in horses with clinical signs of navicular syndrome.[17] This region is rich in sensory nerve endings, with many arteriovenous complexes that are damaged in horses with navicular disease.[18] Aging changes have been seen in the region of insertion of the distal sesamoidean impar ligament and the DDFT, with a change in fibroblast shape and an increase in proteoglycans.[12] The functional significance of this is not yet known.

The incidence and cause of primary bursitis of the navicular bursa is not known, nor is its relationship to the development of navicular disease. Villous hypertrophy, hyperplasia of synovial lining cells, and venous congestion have been described in association with navicular disease, whereas the synovial membrane appeared uniform in six normal horses of undetermined age.[19] However, in anther study comparing immature horses, horses with navicular disease, and age-matched controls, 3 of 25 age-matched controls had evidence of asymptomatic chronic synovitis. In both the navicular disease group and the age-matched controls, mild hyperplasia and hypertrophy was seen compared with immature horses up to 3 years of age.[8]

Pain associated with navicular disease may be due to venous distention following venous hypertension. Dilated venules and sinusoids entrapped in fibrous marrow have been identified only in horses with navicular disease.[7] Raised intraosseous pressure has been measured in horses with navicular disease.[20,21] The contribution of other causes or sources of pain remains open to speculation, although many sensory nerve endings also have been identified in the collateral ligaments of the navicular bone and the distal sesamoidean impar ligament.[22]

DIAGNOSTIC CONSIDERATIONS

History

Most horses present with a history of an insidious onset of loss of performance, shortening of stride, or intermittent shifting bilateral forelimb lameness that usually is worst on firm ground. The complaint from the owner may be loss of action, stiffness, unwillingness to jump, especially drop fences, and inability to lengthen stride. Less commonly a horse may have acute-onset, moderate to severe, usually unilateral but sometimes bilateral, forelimb lameness. The condition is rare in ponies compared with horses and, although hindlimb lameness associated with navicular navicular disease is unusual, it does occasionally occur in both ponies and horses.[23,24]

Clinical signs often are first apparent when the horse is approximately 7 to 9 years of age, although the disease can occur in young horses of 3 to 4 years of age, which may have fairly advanced radiographic abnormalities. Lameness may first become apparent after a period of enforced rest because of some other unrelated problem or after a change in management. Development of lameness soon after change of ownership, associated with a change in trimming and shoeing,

different work patterns, and altered periods of turn-out is not uncommon.

The incidence of navicular disease varies among breeds. The Quarter Horse,[25] Warmblood horses,[26] and Thoroughbred cross horses[27] have a relatively high incidence, whereas the incidence, recognition, or both in some breeds such as the Finnhorse, the Arab,[28] and the Frisian is relatively low. The incidence in higher level competition horses appears to be lower than in horses subject to lesser athletic demands.[8,24]

Clinical Signs

Pain when the horse is standing at rest may be a feature of navicular disease; however, this is a variable finding and some clinically normal horses habitually point one or both front feet. A horse that has resting pain associated with navicular disease may stand pointing one front foot, sometimes alternating between feet. Alternatively, an affected horse may pack bedding under its heels or have a tendency to sit on a manger to relieve pressure on the palmar aspect of the foot. Navicular disease is recognized in horses with a wide variety of foot shapes: narrow, boxy upright feet of the Quarter Horse and low, collapsed heels typical of many Thoroughbreds. Navicular disease often is seen in association with poor mediolateral or dorsopalmar foot balance. If lameness is consistently worse on one forelimb, the feet may become asymmetrical in shape, with the lamer foot being narrower with a taller heel.

The digital vessels sometimes are palpably enlarged, but this is an inconsistent, non-specific finding. The response to hoof testers applied to the frog region is often negative,[5,24,29] although other authors[30] have described a positive response as a fairly consistent feature of navicular disease. Pain may be elicited at the toe if the horse has been repeatedly overloading the toe, resulting in sub-solar bruising. Differences in clinical signs observed by different clinicians may reflect genuine differences in horse populations in different geographical locations. Distention of the distal interphalangeal joint capsule is sometimes seen in association with navicular disease, but not invariably so. Raised intra-articular pressure (>40 mm Hg) is said to be associated with navicular disease,[31] although in my experience there is considerable variability in the degree of distal interphalangeal joint distention and pressure in both normal and lame horses.

Lameness is sometimes apparent when the horse is moving on a hard surface in straight lines. It may fluctuate in degree within an examination period or between examinations performed on different days. The horse may show a tendency to stumble associated with an altered foot placement. Overt unilateral lameness may be evident, but in some horses there is only marginal shortening of stride and reduced lift to the stride, which may be difficult to detect if the horse was not previously known to the observer. The horse may move better on a soft surface, even in circles. No clinical signs are detectable in some horses when examined moving in hand on a hard surface. Lameness generally is accentuated if the horse moves in circles on a hard surface, especially with the lame limb on the inside of the circle. In some horses, lameness is apparent only under these circumstances. Less commonly lameness is accentuated when the lame limb is on the outside of a circle. Sometimes lameness cannot be detected unless the horse is ridden, when it may move in a slightly stiff, "flat," and restricted fashion. Recognition of this requires prior knowledge of the horse, knowledge of the expected quality of movement of a horse of that type, or respecting the opinion of the rider that the horse has "lost some action." A vast difference may be detected by desensitizing both front feet. This may be easier to appreciate when riding the horse than watching it.

The response to distal limb flexion is extremely variable. Many horses with navicular disease show a transient, mild increase in lameness.[5,24,29] Resistance to flexion or marked accentuation of lameness after flexion is unlikely to reflect navicular bone pain. Elevation of the toe of the foot on a wedge or wooden board, with the contralateral limb picked up, resulting in extension of the distal interphalangeal joint, may increase lameness, but this response is neither consistent nor pathognomonic for navicular disease.

If the horse's foot conformation is poor and the feet are not trimmed and shod optimally, it is worthwhile improving the trimming and shoeing and re-assessing the lameness after several weeks. If the lameness has markedly improved, it is unlikely to reflect navicular disease.

Response to Local Analgesic Techniques

Perineural analgesia of the palmar digital nerves, using 1.5 to 2 ml of mepivacaine hydrochloride (2%) per site, performed immediately axial to the cartilages of the foot usually results in improvement in lameness. However, lameness often is not alleviated fully.[29,32] Occasionally there is no response. Lameness is generally alleviated completely after perineural analgesia of the palmar nerves, performed at the base of the proximal sesamoid bones, unless there is another concurrent source of pain. Horses should always be re-evaluated in both straight lines and circles to determine if lameness becomes apparent or is accentuated on the contralateral limb.

Intra-articular analgesia of the distal interphalangeal joint using 6 ml of mepivacaine can alleviate or improve pain associated with the navicular bone within 5 minutes of injection.[28,32,33] A negative response does not preclude navicular pain, because approximately 20% of horses have a negative response to intra-articular analgesia of the distal interphalangeal joint and a positive response to intra-thecal analgesia of the navicular bursa[32]; this has correlated with both radiographic and post-mortem abnormalities of the navicular bone. A positive response to intra-articular analgesia of the distal interphalangeal joint is a non-specific result (Figs. 30-4 and 30-5), since this technique can alleviate solar pain[34] and pain associated with the palmar processes of the distal phalanx, the distal sesamoidean impar ligament, the DDFT, and the joint itself.[32,33,35] Misleading positive results are more likely to occur with larger volumes of local anesthetic solution and evaluation of the response more than 10 minutes after injection.[36]

A positive response to analgesia of the navicular bursa (3 to 4 ml of mepivacaine) usually reflects primary navicular bone pain or primary bursal pain. For accurate injection into the navicular bursa the needle should be sited in the middle of the flexor surface of the navicular bone. Placement of a needle into the navicular bursa is best performed under radiographic control or should be followed by injection of a radiographic contrast agent to check its position. If the needle is positioned too far proximally, there is danger of injection into the proximal palmar outpouching of the distal interphalangeal joint or the digital flexor tendon sheath. If the needle is too far distal, it may enter the distal palmar outpouching of the distal interphalangeal joint. If synovial fluid appears spontaneously in the needle hub, it is unlikely that the needle is positioned correctly. Improvement in lameness is usually appreciated within 5 minutes of injection of local anesthetic solution. A negative response to analgesia of both the distal interphalangeal joint and the navicular bursa makes it unlikely that the horse has navicular disease.

Radiographic Examination

Radiographic examination of the navicular bone should be performed after removal of the shoes and appropriate preparation of the feet, and should include lateromedial (LM), dorsoproximal-palmarodistal oblique (DPr-PaDiO), and palmaroproximal–palmarodistal oblique (PaPr-PaDiO) views. Flexed oblique views of the distal interphalangeal joint

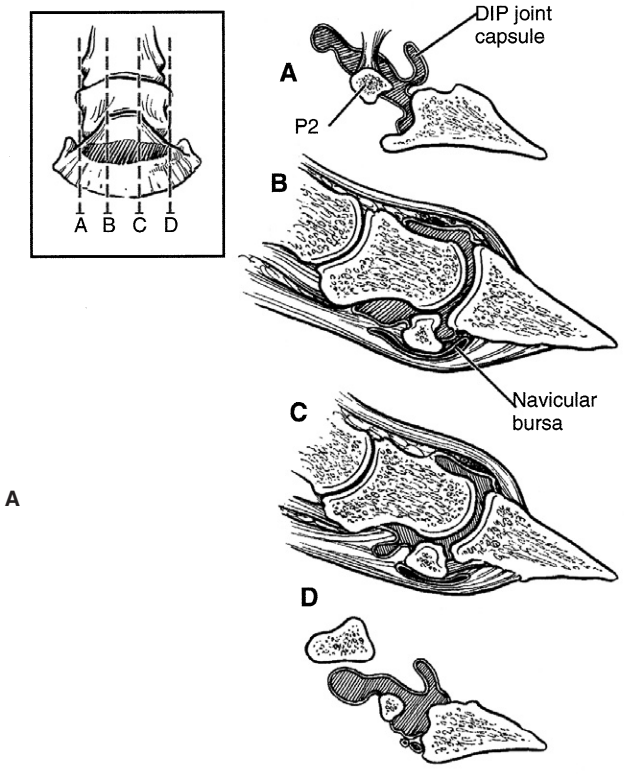

Fig. 30-4 **A,** Diagram of the relationship between the distal interphalangeal joint *(DIP)* capsule, the collateral ligaments of the navicular bone, and the distal sesamoidean impar ligament. The four sagittal sections through the foot are denoted with lines *A, B, C,* and *D.* **B,** Lateromedial radiographic view of a foot. Three milliliters of radiopaque contrast medium has been injected into the navicular bursa to show its proximodistal extent. *P2,* Middle phalanx.

also are useful for evaluation of its articular margins. Appropriate positioning of the feet is critical for high-quality images. Correct angulation of the x-ray beam for PaPr-PaDiO views is crucial for diagnostic images. Artifacts can be created unless the x-ray beam is tangential to the palmar surface of the navicular bone.[37] The correct angle can vary between 35° and 50° depending on the shape of the foot.

The proximal border of the navicular bone has two margins: the flexor surface, which is always convex in a DPr-PaDiO view, and the articular margin, which is variable in shape. It can be categorized as concave, undulating, straight, or convex. In the Dutch Warmblood an enhanced risk of the development of navicular disease has been suggested if the articular margin is concave or undulating, rather than convex.[2]

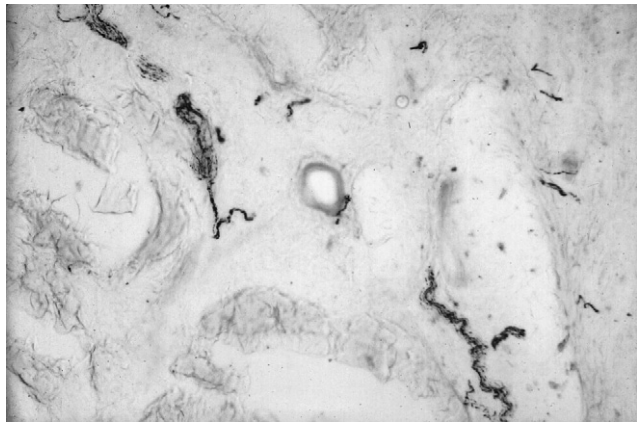

Fig. 30-5 Histological sample stained to show substance P, a small peptide, within thinly myelinated sensory nerves in the collateral ligaments of the navicular bone, appearing to innervate microvessels and pass toward the navicular bone. (Courtesy Dr. R. Bowker.)

The following features should be evaluated in all views[37] (Figs. 30-6 through 30-11): the presence, number, shape, size, and location of radiolucent zones along the distal borders of the navicular bone; the presence of lucent zones along the proximal border of the navicular bone; lucent zones within the medulla of the bone; trabecular pattern within the medulla; entheseophyte formation on the proximal or distal aspects of the bone; presence of mineralization within a collateral ligament of the navicular bone; presence of articular osteophytes; thickness of the flexor cortex; regularity of outline of the flexor cortex; lucent areas in the flexor cortex; new bone formation on the flexor surface; corticomedullary definition; and presence of mineralized fragments distal to the navicular bone.

A grading system for evaluation of the navicular bone in LM and DPr-PaDiO views was devised by Dik.[38] An adapted version is presented in Box 30-1. The degree of lameness and the degree of radiological abnormality often are poorly correlated. Some horses with navicular bone pain have no detectable radiological change. Some horses, especially young horses, have relatively advanced radiographic changes when lameness is first recognized. In many horses with suspected navicular disease the radiological abnormalities are equivocal. The ability to document the progression of radiological change over time (years) is relatively unusual. The appearance of the navicular bone varies in normal horses,[39,40] which may in part be related to breed and conformation and thus biomechanical forces placed on the navicular apparatus. Horses with very upright conformation tend to have a thinner flexor cortex compared with horses with lower heels.[24]

Some changes are more likely to be seen in older athletes than in immature horses and reflect the biomechanical stresses placed on the bone and its supporting structures. Older horses are more likely to have entheseophyte formation on the proximal border of the bone, especially laterally, compared with immature athletes. The presence of new bone on the proximal border is not always associated with lameness.[41] The flexor cortex generally increases in thickness with age as an adaptive remodeling process in athletic horses. The number, shape, and size of radiolucent zones along the distal border of the navicular bone may vary between breeds. Mineralized fragments on the distal border of the navicular bone may be seen as an incidental radiological abnormality, although there was a higher incidence (39%) in horses with navicular disease at postmortem examination compared with age-matched controls

Fig. 30-6 **A,** Lateromedial view of a normal navicular bone. **B,** Dorsoproximal-palmarodistal oblique view of a normal navicular bone. **C,** Palmar 45° proximal-palmarodistal oblique view of a normal navicular bone with a well-defined, crescent-shaped lucent zone in the central eminence of the flexor cortex. **D,** Palmar 50° proximal-palmarodistal oblique view of a normal navicular bone in a horse with upright foot conformation. The flexor cortex is flatter compared with **C.**

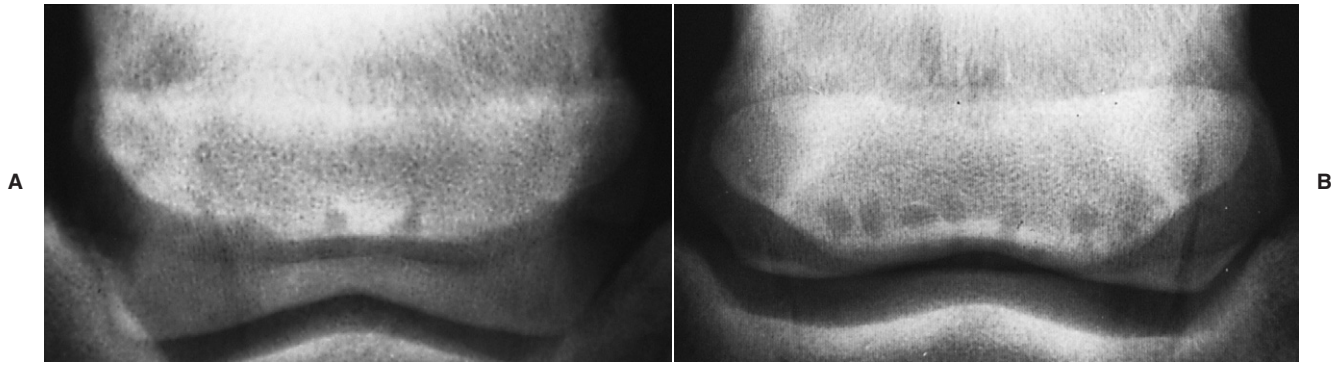

Fig. 30-7 **A,** Dorsoproximal-palmarodistal oblique view of a navicular bone of a normal horse. There are several small lucent zones along the distal border of the bone. **B,** Dorsoproximal-palmarodistal oblique view of a navicular bone of a horse with clinical signs of navicular disease. Note the variable shape, size, and position of the lucent zones along the distal borders of the bone.

(4%).[8] In some of the horses with clinical evidence of navicular disease, mineralized fragments occurred in the absence of other pathological changes. Mineralized fragments were found in 3% of 1111 sound horses examined radiographically, whereas a 28% incidence was seen radiographically in 118 horses with navicular disease.[16]

A high-quality PaPr-PaDiO view is the most sensitive projection for detection of subtle, but significant radiological changes, including medullary sclerosis (see Fig. 30-11), reduced corticomedullary demarcation, change in contour of the flexor cortex resulting from either erosions (see Fig. 30-10, *A* to C) or new bone formation (Fig. 30-10, *D*), and lucent zones in the flexor cortex. Radiographic abnormalities may not be detectable in other views. Small, crescent-shaped lucent zones within the flexor cortex at the sagittal ridge are probably an aging change reflecting adaptive remodeling of the subchondral bone.[42]

Generally the larger number of radiological changes that are present in all radiographic projections, the more likely it is that the horse has clinical navicular disease. The most significant radiological changes likely to reflect navicular disease include cyst-like lesions within the medulla (see

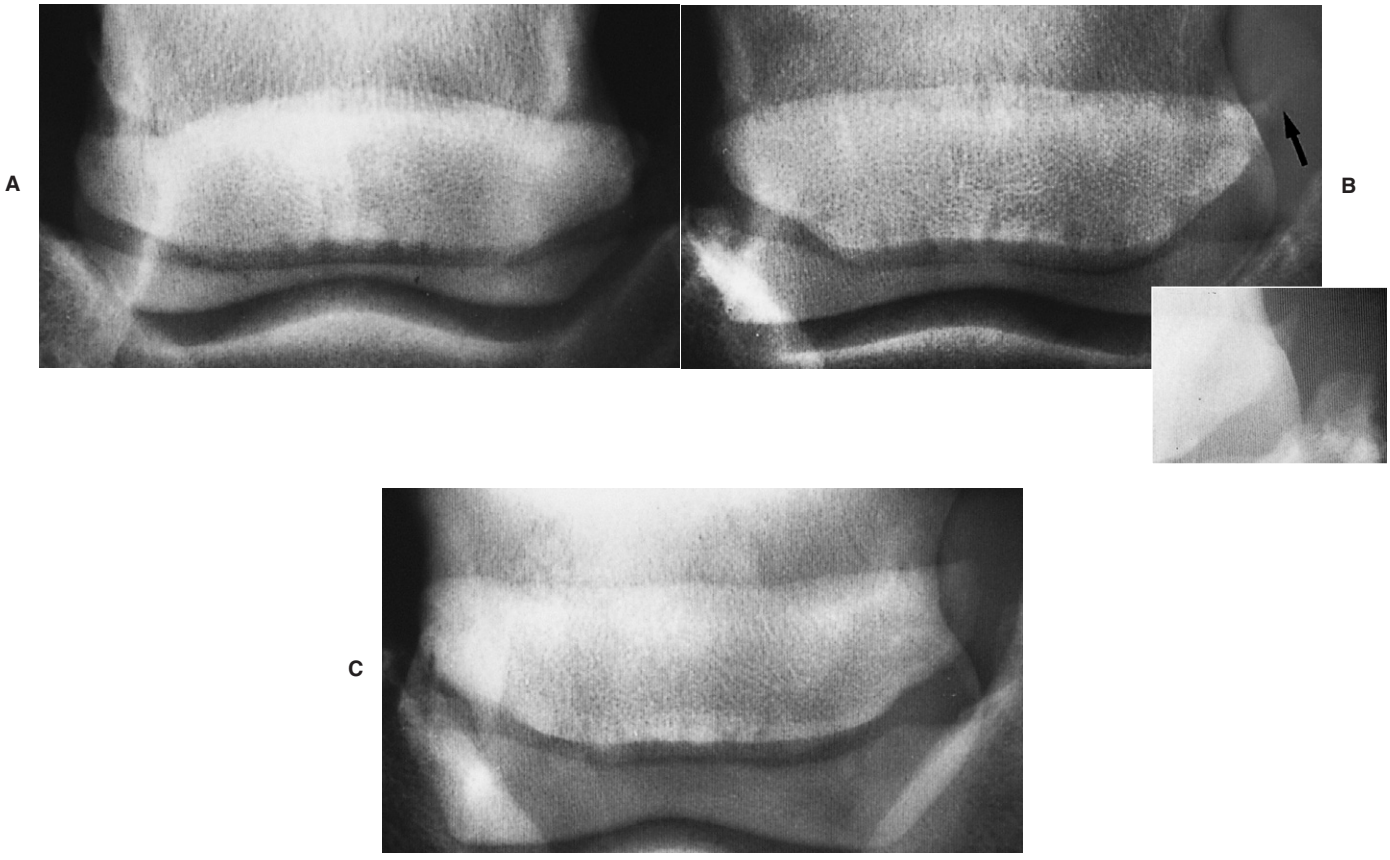

Fig. 30-8 **A,** Dorsoproximal-palmarodistal oblique view of a navicular bone of a normal horse. The asymmetry of the medial and lateral aspects of the bone is the result of mild entheseophyte formation. **B,** Dorsoproximal-palmarodistal oblique view of a navicular bone of a horse with clinical signs of navicular disease. There is a prominent entheseophyte on the proximolateral aspect of the bone *(arrow)*. Note also the lucent zones along the distal aspect of the bone. The *inset* shows detail of the entheseophyate. **C,** Dorsoproximal-palmarodistal oblique view of the navicular bone of a horse with clinical signs of navicular disease. Lateral is to the right. The modeling of the proximal border and lateral margin of the bone is the result of entheseophyte formation.

Fig. 30-9, *A*) that are discrete from distal border lucencies, medullary sclerosis, reduced corticomedullary demarcation, new bone on the flexor surface, and erosions of the flexor cortex of the bone (see Fig. 30-9, *B* and *C*).

In some horses, concurrent degenerative changes of the distal interphalangeal joint are also seen, with modeling* of the proximal dorsal articular margin of the navicular bone, the dorsal and palmar articular margins of the middle phalanx, and the extensor process of the distal phalanx.

In some horses the development of advanced radiological changes precedes the recognition of clinical signs. However, the absence of radiological abnormalities of the navicular bone does not preclude the presence of pain associated with the navicular bone and scintigraphic evidence of increased bone modeling.

*There is confusion between the histological and radiographic usage of the terms *remodeling* and *modeling.* Histologically, *remodeling* refers to resorption and formation of bone that is coupled and occurs in basic multicellular units. This regulates the microstructure of bone without altering its shape and is a continuous process, replacing damaged bone with new bone. Thus it cannot be appreciated on radiographs. The term has been used with regard to radiographs to describe the reshaping of bone to match form and function (e.g., after fracture repair), but strictly speaking, the term *modeling* should be used.

Histologically, *modeling* refers to resorption and formation of bone that is not coupled and occurs at anatomically different sites (bone drift). It is a continuous process that regulates the macroscopic appearance of bone according to Wolff's law. In terms of radiography, *modeling* has been used to describe the formation of bone relative to the cartilage model that is being replaced (i.e., the normal formation of bone). Thus the two definitions do not agree; to avoid confusion, strictly speaking the term *modeling* should be applied to describe the change in shape of a bone as it adapts to the stresses applied to it.

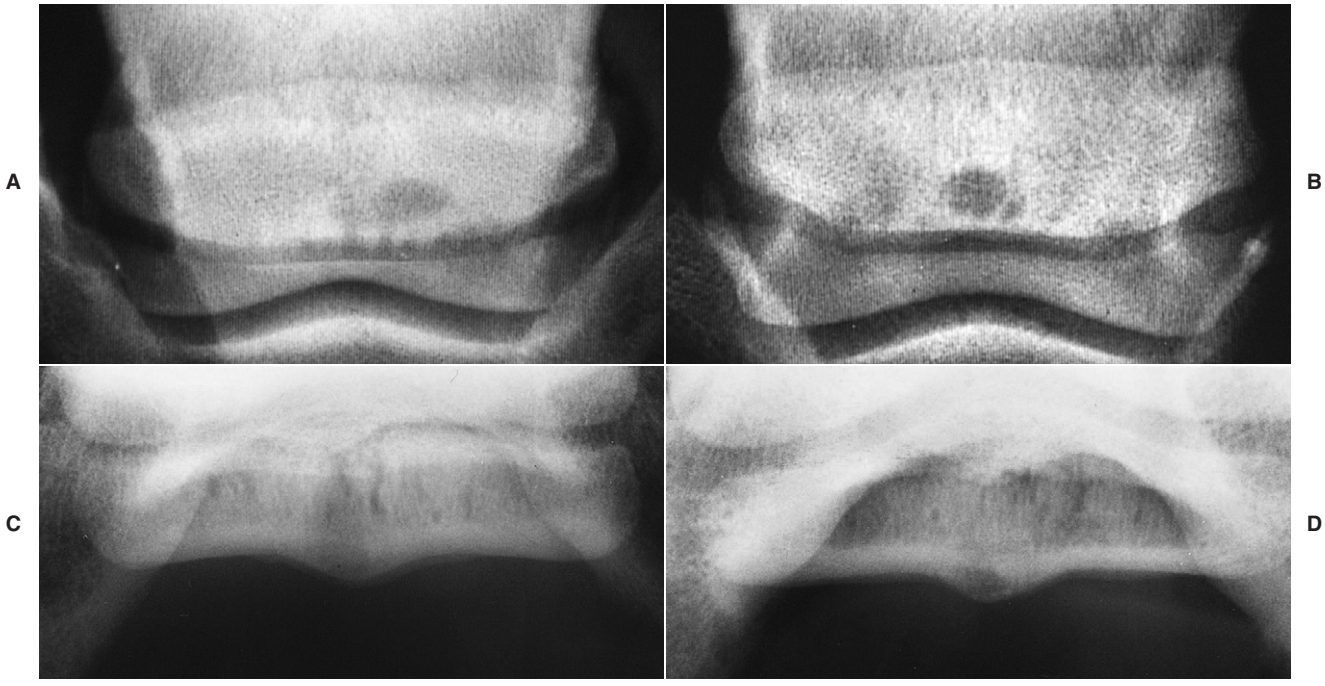

Fig. 30-9 **A,** Dorsoproximal-palmarodistal oblique view of a navicular bone with a large cyst-like lesion within the medulla of the navicular bone. This lesion did not penetrate the flexor cortex of the bone. The horse had a bilateral forelimb lameness, which was improved by analgesia of the distal interphalangeal joint or navicular bursa. **B,** Dorsoproximal-palmarodistal oblique view of a navicular bone with a large cyst-like lesion within the medulla of the bone, which did penetrate the flexor cortex of the bone (see **C**).The horse had a bilateral forelimb lameness that was worse on soft ground with the lamer limb on the outside of a circle. Lameness was improved by palmar (abaxial sesamoid) nerve blocks. **C,** Palmaroproximal-palmarodistal oblique view of the same navicular bone as in **B,** with a large lucent area penetrating the flexor cortex of the bone. **D,** Palmaroproximal-palmarodistal oblique view of a navicular bone of a 7-year-old event horse that had been rested because of a tendon injury and developed left forelimb lameness soon after resuming work. Lameness was alleviated by analgesia of the navicular bursa. There is a well-defined lucent zone in the flexor cortex in the medial aspect of the sagittal ridge of the navicular bone (compare with Fig. 30-6, C). Radiographic abnormalities were detectable only in this projection.

Box • 30-1

Radiographic Findings of the Navicular Bone in Normal and Diseased Horses

Grade	*Condition*	*Radiographic Findings*
0	Excellent	Good corticomedullary demarcation; fine trabecular pattern. Flexor cortex of uniform thickness and opacity. No lucent zones along the distal border of the bone, or several (fewer than six) narrow conical lucent zones along the horizontal distal border. Right and left navicular bones symmetrical in shape.
1	Good	As above, but lucent zones on the distal border of the navicular bone are more variable in shape.
2	Fair	Slightly poor definition between the palmar cortex and the medulla as a result of subcortical sclerosis. Crescent-shaped lucent zone in the central eminence of the flexor cortex of the bone. Several (fewer than eight) lucent zones of variable shape along the distal horizontal border of the navicular bone. Mild entheseophyte formation on the proximal border of the navicular bone. Navicular bones asymmetrical in shape.
3	Poor	Poor corticomedullary definition as a result of medullary sclerosis. Thickening of the dorsal and flexor cortices. Irregular opacity of the flexor cortex of the bone. Many (more than seven) radiolucent zones along the distal horizontal or sloping borders of the navicular bone. Lucent zones along the proximal border of the bone. Large entheseophyte formation on the proximal border of the bone. Discrete mineralization within a collateral ligament of the navicular bone. Radiopaque fragment on the distal border of the navicular bone.
4	Bad	Large cyst-like lesion within the medulla of the navicular bone. Lucent region in the flexor cortex of the navicular bone. New bone on the flexor cortex of the navicular bone.

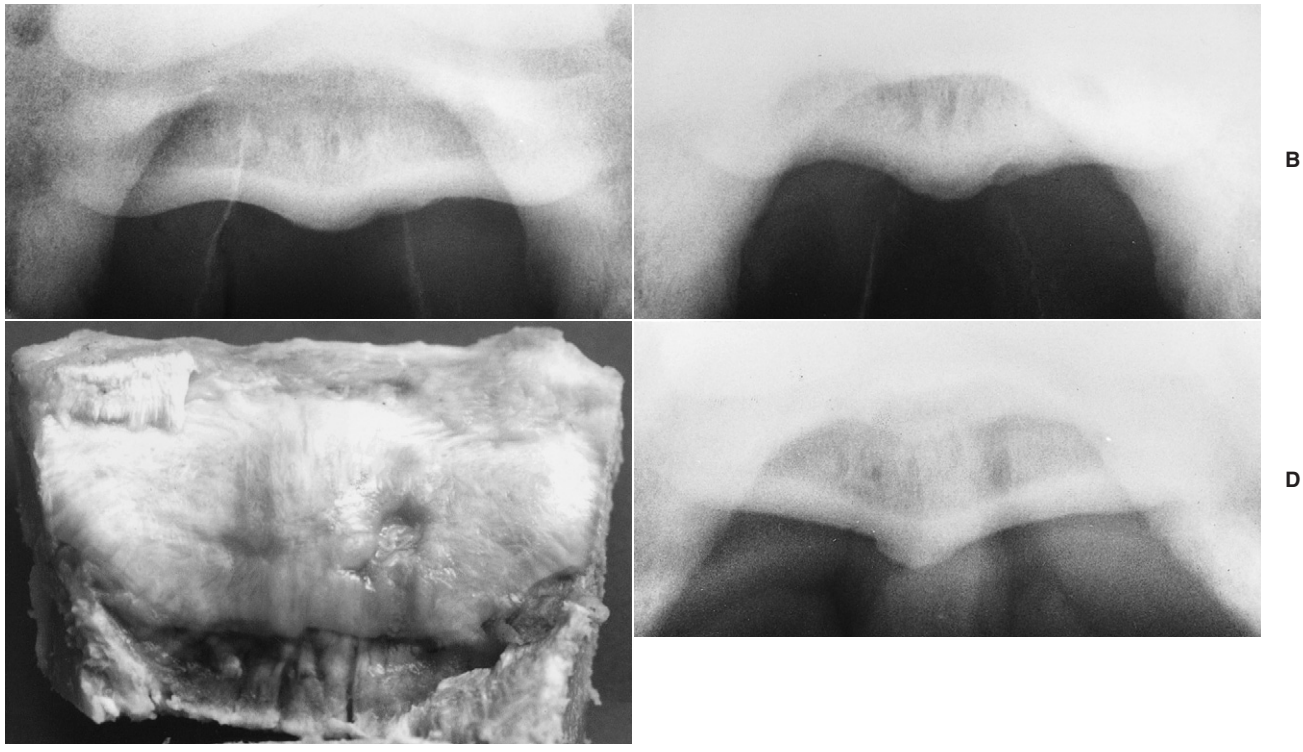

Fig. 30-10 **A,** Palmar 45° proximal-palmarodistal oblique view of a navicular bone with an irregular contour of the lateral aspect of the flexor cortex. Lateral is to the right. The horse had a bilateral forelimb lameness, which was improved by intra-articular analgesia of the distal interphalangeal joint or analgesia of the navicular bursa. **B,** Palmar 35° proximal-palmarodistal oblique view of the same navicular bone as in **A.** The irregularity of the flexor cortex is more obvious. Apparent reduction in corticomedullary demarcation is an artifact, the result of the angle of projection. Lateral is to the right. **C,** The same horse as in **A.** The gross pathological specimen has a defect in the flexor surface, lateral to the sagittal ridge. Lateral is to the right. **D,** Palmaroproximal-palmarodistal oblique view of a navicular bone of a horse with unilateral forelimb lameness improved by analgesia of the navicular bursa. There is new bone on the flexor cortex of the navicular bone. Radiological abnormalities were detectable only in this projection.

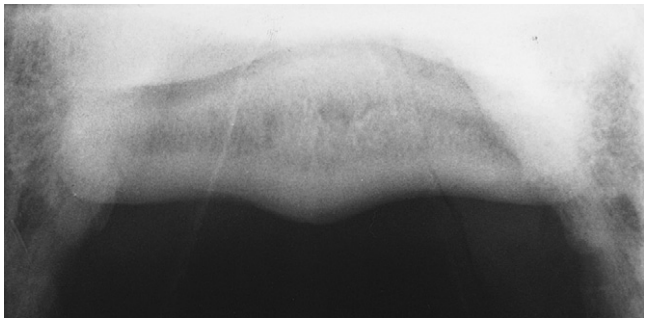

Fig. 30-11 Palmaroproximal-palmarodistal oblique view of a navicular bone of a 6-year-old riding horse with acute-onset right forelimb lameness that was improved by perineural analgesia of the palmar digital nerves or intra-articular analgesia of the distal interphalangeal joint. There is increased cortical thickness, medullary sclerosis, and reduced corticomedullary demarcation (compare with Figs. 30-6, C and *D*). The left front navicular bone appeared normal. The lameness persisted.

Contrast Radiography of the Navicular Bursa

Contrast radiography of the navicular bursa may reveal a number of abnormalities not detectable on plain radiographs, including thinning or erosion of the flexor fibrocartilage of the navicular bone, loss of the dye column thought to be caused by adhesion formation between the DDFT and the navicular fibrocartilage, and filling defects on the palmar aspect of the bursa perhaps associated with surface fibrillation of the DDFT.[24,43] The clinical significance of these findings is currently questionable, because it has been well recognized that thinning of the flexor fibrocartilage is a normal aging change, and the significance of surface fibrillation of the DDFT is still open to debate.

Nuclear Scintigraphy

Tetracycline labeling of bone has revealed increased bone turnover in the navicular bone in navicular disease.[5,6] Nuclear scintigraphy offers a sensitive method of detecting increased bone turnover; however, this is not necessarily synonymous with either pathological change or pain.

Lateral pool- (soft tissue) and lateral and palmar (solar) bone–phase images of the front feet are required for accurate diagnosis of navicular disease.[44-46] In solar views of normal horses, uptake of the radiopharmaceutical in the navicular bone and the distal phalanx is approximately similar (Fig. 30-12, *A*). However, uneven uptake in various regions of the distal phalanx can complicate interpretation. Care must be taken when interpreting lateral views not to confuse uptake in the cartilages of the foot with uptake in the navicular bone. In solar views, uptake associated with the proximal interphalangeal joint can potentially be superimposed over the navi-

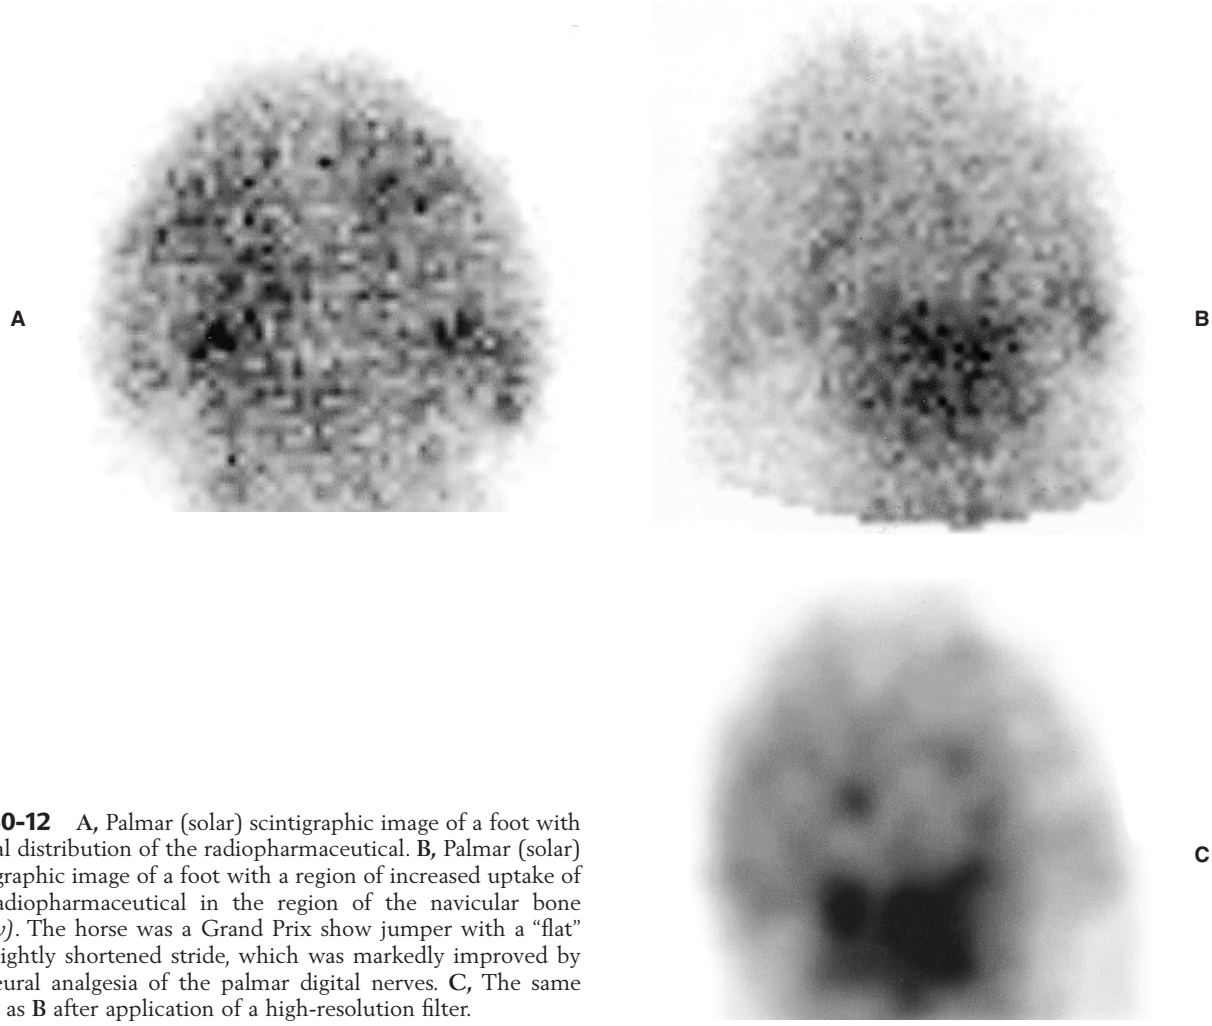

Fig. 30-12 **A,** Palmar (solar) scintigraphic image of a foot with normal distribution of the radiopharmaceutical. **B,** Palmar (solar) scintigraphic image of a foot with a region of increased uptake of the radiopharmaceutical in the region of the navicular bone *(arrow)*. The horse was a Grand Prix show jumper with a "flat" and slightly shortened stride, which was markedly improved by perineural analgesia of the palmar digital nerves. **C,** The same image as **B** after application of a high-resolution filter.

cular bone, unless the foot is well extended during image acquisition and the pastern region is masked with a lead shield. Interpretation can also be difficult, because some horses with unilateral lameness have a region of increased uptake of the radiopharmaceutical in both the left and right front navicular bones while apparently experiencing pain in only one limb.

Various patterns of uptake of the radiopharmaceutical have been identified in association with horses with palmar foot pain: focal or generalized increased radiopharmaceutical uptake (IRU) in the navicular bone (Fig. 30-12, *B*),[44-47] IRU in the navicular bone and the distal phalanx in the region of insertion of the DDFT,[24,48] IRU in both the navicular bone and the palmar processes of the distal phalanx,[44] IRU in one or both palmar processes of the distal phalanx,[24,44] and IRU in the distal phalanx at the sites of insertion of the DDFT.[48] The close proximity of the regions of insertion of the DDFT and the distal sesamoidean impar ligament makes accurate differentiation of insertional injuries difficult. It also may be difficult to differentiate IRU in the subchondral bone of the distal interphalangeal joint.

IRU in the navicular bone, with or without IRU at the region of insertion of the DDFT, has correlated well with a positive response to intra-thecal analgesia of the navicular bursa.[48] False-positive results can be found in clinically normal horses, although a relatively high percentage have subsequently developed lameness associated with palmar foot pain.[48,49]

There is a relatively high incidence of horses with clinical signs compatible with navicular disease and a positive response to intra-articular analgesia of the distal interphalangeal joint or intra-thecal analgesia of the navicular bursa, which have no detectable radiological abnormalities of the navicular bone but have IRU of radiopharmaceutical associated with the navicular bone.[48] Thus nuclear scintigraphy offers a sensitive method of diagnosis of navicular disease, although specificity is probably less good.

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT; see Chapter 20) and magnetic resonance imaging (MRI; see Chapter 21) are potentially more sensitive than radiography in determining structural lesions of the navicular bone[50-53] (Fig. 30-13) and identifying degenerative changes in the articular cartilage of the distal interphalangeal joint and primary lesions in the DDFT, the distal sesamoidean impar ligament, and the collateral ligaments of the navicular bone. An abnormal amount of fluid within the distal interphalangeal joint or the navicular bursa and synovial proliferation may be identified by MRI (Figs. 30-14 and 30-15). MRI permits detection of pathophysiological changes within the navicular bone, such as bone edema. However, both CT and MRI require the horse to be under general anesthesia. These techniques may permit clinicians to develop further understanding of the pathological processes earlier in the course of navicular disease.

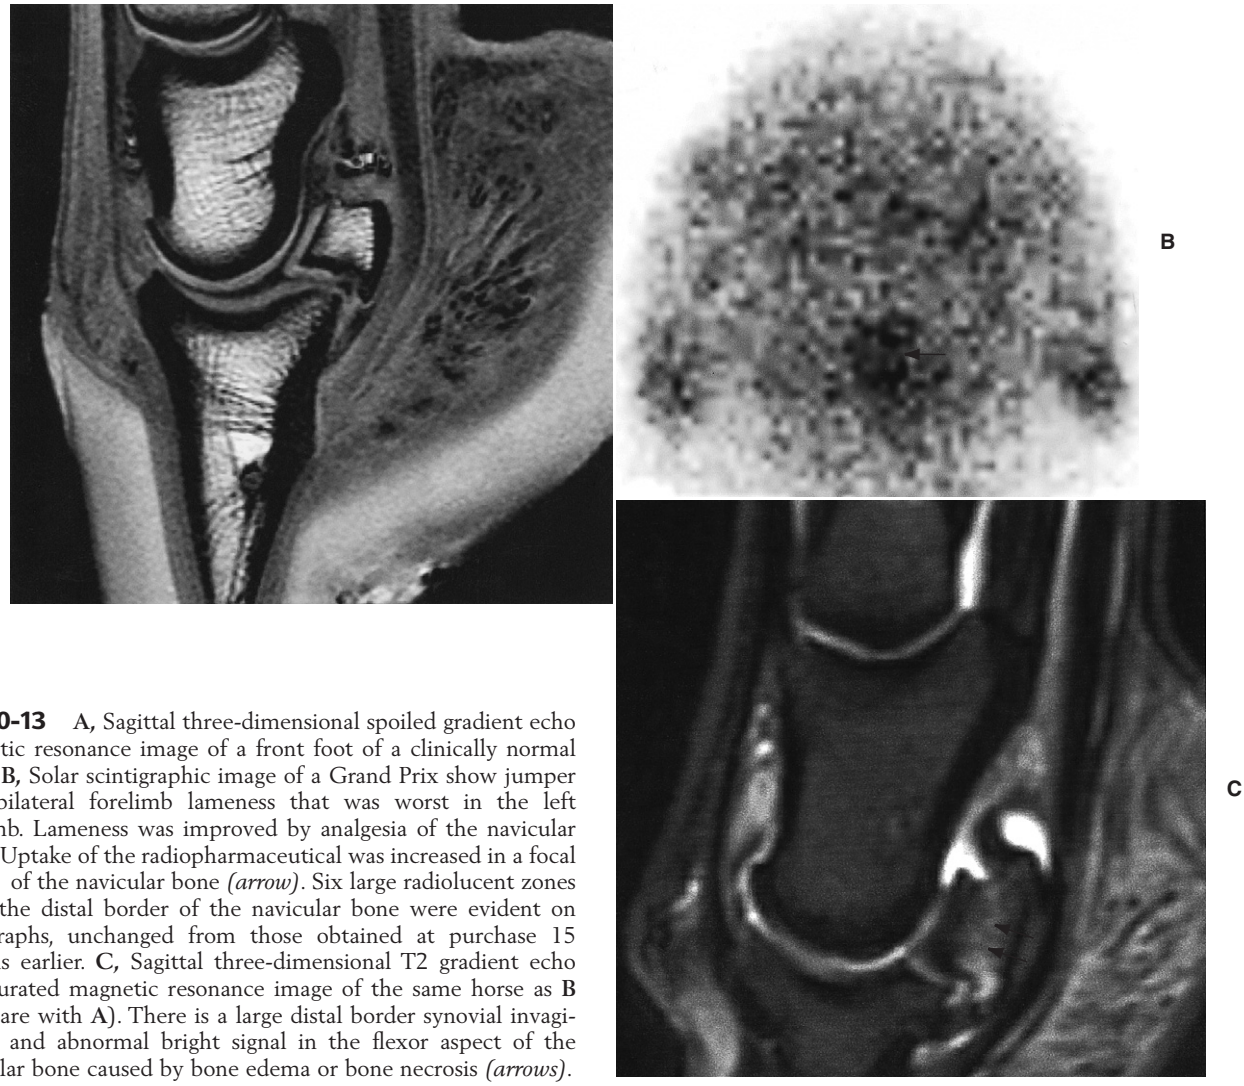

Fig. 30-13 **A,** Sagittal three-dimensional spoiled gradient echo magnetic resonance image of a front foot of a clinically normal horse. **B,** Solar scintigraphic image of a Grand Prix show jumper with bilateral forelimb lameness that was worst in the left forelimb. Lameness was improved by analgesia of the navicular bursa. Uptake of the radiopharmaceutical was increased in a focal region of the navicular bone *(arrow)*. Six large radiolucent zones along the distal border of the navicular bone were evident on radiographs, unchanged from those obtained at purchase 15 months earlier. **C,** Sagittal three-dimensional T2 gradient echo fat-saturated magnetic resonance image of the same horse as **B** (compare with **A**). There is a large distal border synovial invagination and abnormal bright signal in the flexor aspect of the navicular bone caused by bone edema or bone necrosis *(arrows)*.

Fig. 30-14 Sagittal three-dimensional T2* gradient echo magnetic resonance image of a Grand Prix show jumper with lameness improved by analgesia of the navicular bursa. There is an increased amount of fluid in the navicular bursa *(small arrow)* reflecting synovitis (compare with Fig. 30-13, *A)* and an abnormal amount of fluid within the distal interphalangeal joint *(large arrow)*.

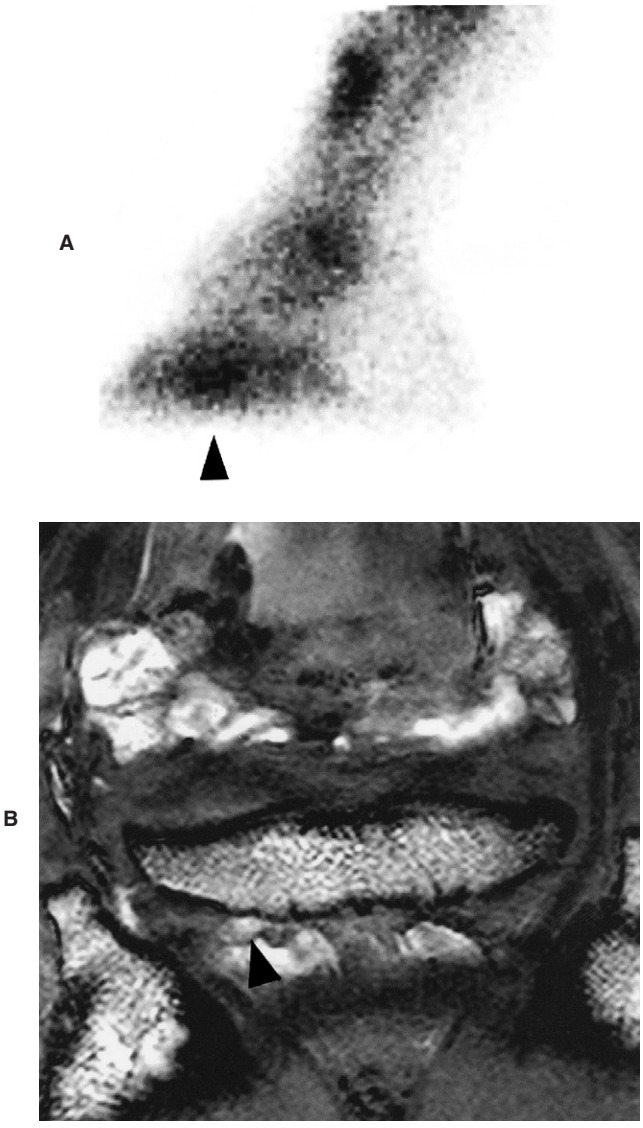

Fig. 30-15 **A,** Lateral scintigraphic image of the left front foot of a 9-year-old event horse with unilateral lameness that was improved by analgesia of the distal interphalangeal joint or navicular bursa. Uptake of the radiopharmaceutical is increased on the solar aspect of the distal phalanx in the region of insertion of the deep digital flexor tendon and distal sesamoidean impar ligament (DSIL). No significant abnormality was detectable radiographically. **B,** Dorsal three-dimensional T2* gradient echo magnetic resonance image of the same horse as in **A** shows an osseous fragment in the DSIL *(arrow)* and an abnormal signal in the DSIL lateral to it. Lateral is to the right.

Endoscopic Evaluation of the Navicular Bursa

Endoscopic examination of the navicular bursa (see Chapter 24) permits evaluation of the fibrocartilage on the flexor surface of the navicular bone, the navicular bursa itself, the overlying dorsal surface of the DDFT, and a limited view of the distal sesamoidean impar ligament.[24,54] Thus it is possible to definitively identify adhesions between the DDFT and the palmar aspect of the navicular bone, thinning or full-thickness erosion of the flexor fibrocartilage of the bone, fibrillation of the dorsal aspect of the DDFT, and synovitis of the bursa. Tears in the distal sesamoidean impar ligament have also been identified,[24] but these are thought to be of traumatic origin rather than part of the navicular disease complex. It is important to differentiate between age-related changes and pathological abnormalities.

OTHER SOFT TISSUE CAUSES OF PALMAR HEEL PAIN

Our understanding of soft tissue pain associated with the palmar aspect of the foot has been limited until recently to identification of pain seen in association with poor foot balance, poor shoeing, or both factors that responded to corrective trimming and shoeing (see Chapter 27). Horses that respond satisfactorily to trimming and shoeing alone are unlikely to have chronic navicular disease and although navicular bone pain may be present, the precise source of pain cannot be determined. A hemodynamic function for the cartilages of the foot and associated vascular system may contribute to force dissipation.[55] Peptidergic sensory nerve endings also have been identified in the vascular channels of the cartilages of the foot, close to pacinian-like corpuscles, indicating that this part of the foot may respond to sensory and proprioceptive stimuli. In horses with long toes and underrun heels the cartilages of the foot and associated vasculature are less well developed than in a better conformed foot. This may result in less effective force distribution, predisposing to the development of palmar foot pain. In addition, tissue morphological differences have been identified in the digital cushions between "healthy" and "weak" feet, so the digital cushion also may be involved in force dissipation.

Relatively recently other soft tissue causes of palmar heel pain have been confirmed. These horses usually have no detectable radiological abnormalities. Primary lesions of the DDFT are discussed in detail in Chapter 33. Other injuries that should be considered include the following:

- Desmitis of the distal sesamoidean impar ligament
- Desmitis of the collateral (suspensory) ligaments of the navicular bone
- Navicular bursitis
- Synovitis of the palmar pouch of the distal interphalangeal joint
- Combination injuries

Definitive diagnosis of most of these conditions requires MRI, and to date, only small numbers of horses have undergone imaging.[56] Therefore clinical manifestations must be restricted to case examples that may prove unrepresentative in the future. Desmitis of the lateral aspect of the distal sesamoidean impar ligament has been seen in conjunction with a focal tear in the articular cartilage of the distal interphalangeal joint on the ipsilateral side and an abnormal amount of fluid within the navicular bursa. Lameness had been acute in onset and had persisted despite rest. Lameness was alleviated by perineural analgesia of the palmar digital nerves and was improved by intra-articular analgesia of the distal interphalangeal joint. Scintigraphic examination revealed IRU in both pool- and bone-phase lateral images in the palmar aspect of the distal phalanx in the region of insertion of the DDFT and distal sesamoidean impar ligament.

A focal tear in the distal sesamoidean impar ligament also has been identified by endoscopic examination of the navicular bursa in an event horse with acute-onset severe lameness that improved after perineural analgesia of the palmar digital nerves or intra-articular analgesia of the distal interphalangeal joint[57] (Fig. 30-16).

Ectopic mineralization within a collateral ligament of the navicular bone has been seen in conjunction with other radiological abnormalities of the navicular bone compatible with navicular disease. Primary desmitis has not yet been recognized.

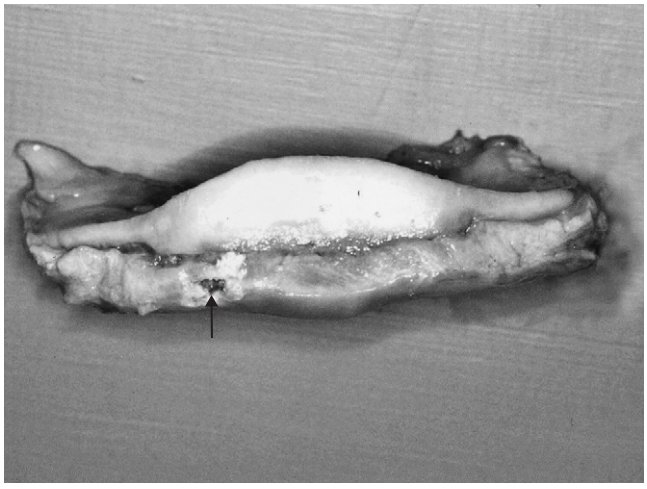

Fig. 30-16 Gross post-mortem specimen of the distal aspect of the navicular bone and the and distal sesamoidean impar ligament (DSIL). There is a focal tear in the DSIL *(arrow)*, which had been identified by arthroscopic evaluation of the navicular bursa. Surface fibrillation of the deep digital flexor tendon had also been seen.

Lameness alleviated by analgesia of the navicular bursa, but unassociated with any radiological sign of navicular disease, has previously been attributed to navicular bursitis, but further evidence for primary bursitis has been lacking. These horses frequently have scintigraphic evidence of abnormal modeling of the navicular bone[58] and respond only transiently to medication of the navicular bursa with either corticosteroids or hyaluronan. It therefore seems unlikely that these horses have a primary bursitis. MRI has demonstrated distention of the navicular bursa and the distal interphalangeal joint capsule in a horse with bilateral forelimb lameness that was substantially improved by analgesia of the navicular bursa. There was scintigraphic evidence of increased modeling of the navicular bones, but other than enlarged synovial invaginations on the distal border of the bones, no structural abnormality could be identified using MRI. The response to treatment of the bursae was only transient. MRI also has demonstrated synovial proliferation and distention of the bursa in association with desmitis of the distal sesamoidean impar ligament.

Treatment and Prognosis of Horses with Navicular Disease

John B. Madison and Sue J. Dyson

NAVICULAR DISEASE

For the purposes of this chapter, *navicular disease* is defined as pain believed to originate from the navicular bone based on clinical signs, response to local analgesic techniques, and presence of substantial radiological abnormalities of one or both navicular bones (see Box 30-1) or scintigraphic evidence of increased modeling of the navicular bone(s). If the clinical signs are not suggestive of navicular disease, especially in horses with unilateral lameness, the possibility of a soft tissue injury should be considered. In these horses rest may be indicated.

In navicular disease the problem is managed because there currently is no cure for the condition. Rest is not a useful

CHAPTER • 31

Treatment and Prognosis of Horses with Navicular Disease

John B. Madison and Sue J. Dyson

NAVICULAR DISEASE

For the purposes of this chapter, *navicular disease* is defined as pain believed to originate from the navicular bone based on clinical signs, response to local analgesic techniques, and presence of substantial radiological abnormalities of one or both navicular bones (see Box 30-1) or scintigraphic evidence of increased modeling of the navicular bone(s). If the clinical signs are not suggestive of navicular disease, especially in horses with unilateral lameness, the possibility of a soft tissue injury should be considered. In these horses rest may be indicated.

In navicular disease the problem is managed because there currently is no cure for the condition. Rest is not a useful

strategy in the management of most horses with pain in the navicular region, because although lameness improves somewhat in most horses after a period of rest, it often returns shortly after the horse resumes exercise. A period of rest for some other cause often precedes the onset of clinical signs of navicular disease.

The recent work of Wilson et al.[1] suggests that relief of pain is vitally important to alleviate a potentially vicious circle. The horse should be encouraged to land normally, rather than toe first, to avoid increased forces on the navicular bone from the deep digital flexor tendon (DDFT).

In horses with early navicular disease without major radiological abnormalities, medical management using non-steroidal anti-inflammatory drugs (NSAIDs), isoxsuprine, and careful trimming and shoeing may be effective, but obviously these drugs cannot be used if the horse will compete. The aim of medical management is to attempt to return the horse to regular work as soon as possible, starting initially with work predominantly in straight lines. Horses should be exercised as much as possible daily, combining ridden exercise with either turnout or walking on a horse walker. In some horses, use of corrective trimming and shoeing combined with isoxsuprine is sufficient, whereas in others additional analgesia is required using a NSAID. In horses with marked medullary sclerosis, lesions involving the flexor surface of the navicular bone, or central osseous cyst-like lesions, the response to medical management often is unsatisfactory and surgical treatment may be indicated.

MANAGEMENT STRATEGIES

Trimming and Shoeing

Successful management depends on a good relationship with an accomplished, reliable farrier. There is an art and science to farriery, and finding the right combination of the method of trimming and the selection of an appropriate shoe for a given horse often requires some trial and error. Each foot and each horse must be examined individually with regard to the distal limb and foot conformation, limb flight, foot placement, and the intended use of the horse. Both the farrier and the veterinarian must agree, and both must also agree to alter the initial approach if it does not work. Some degree of compromise is always involved. However, some principles apply for all horses with navicular disease. The degree to which lameness can be improved by trimming and shoeing alone is dependent on the horse's hoof-pastern angle and the previous suitability of trimming and shoeing. If the horse already had a well-conformed foot, little will be achieved in most horses with navicular disease.

Care must be taken either to correct or preserve dorsopalmar and lateromedial foot balance whenever possible. This depends to some extent on the natural shape of the horse's foot and its distal limb conformation. Ideally, the hoof-pastern axis should be straight, but whether this can be achieved depends on the horse's conformation. Radical changes in foot trimming may temporarily result in increased lameness; therefore it may be necessary to achieve correct foot balance in stages. The foot should be trimmed to maintain heel mass and shorten the toe to facilitate breakover. Sufficient shortening of the toes usually requires trimming the horn from the solar and dorsal aspects of the foot. The use of the so-called four-point or natural balance trim has recently been favored in some quarters, but the same principles of breakover can probably be achieved with more traditional trimming, provided that the toe is shortened sufficiently (see Chapter 27). Although the four-point trim results in clinical improvement in some horses, in others lameness has been increased, possibly caused by excessive trimming, resulting in altered hoof wall strain,[2] or by excessive sole pressure.

Elevation of the heel may relieve pressure from the DDFT on the palmar aspect of the navicular bone, with subsequent pain relief. In a study of normal Dutch Warmblood horses, elevation of the heel using a 6° wedge reduced the maximal force on the navicular bone by 24% compared with flat shoes.[3] However, not all horses with heel pain need to have the heel elevated and in many, the response is only temporary. One of us (J.B.M.) strives for a hoof angle between 50° and 55° and establishment of a straight foot-pastern axis. However, many horses with low, collapsed heels have a natural angle of no more than 35° and it is impractical to achieve an angle of 50° to 55°. Lateromedial radiographic views may be helpful to demonstrate to a less skilled farrier whether a horse needs more or less heel. If the horse's lameness is worsened after elevating the toe using the wedge test, some degree of heel elevation may be beneficial. Elevation of the heel can be achieved by using a wedge heel shoe or a rim or complete wedge pad.

A variety of shoes have been used successfully in the management of navicular disease, including egg bar, egg bar–heart bar, straight bar shoes, and the so-called Tennessee shoe, which moves the point of breakover to just in front of the apex of the frog by placing rails on the palmar aspect of the branches of the shoe. Success has also been achieved in some horses using the natural balance shoe.

The strategy of using shoes that move the weight-bearing axis in a palmar direction in horses with low, collapsed, and underrun heels is quite successful. However, a recent study has shown that using egg bar shoes in clinically normal Dutch Warmblood horses with well-conformed feet did not reduce force on the navicular bone compared with flat shoes.[3] The forelimb gait was also described as less animated with egg bar shoes compared with flat shoes. However, these findings cannot necessarily be translated to lame horses with less than ideal foot conformation. Many top-level show jumpers and dressage horses have been shod with egg bar shoes with no apparent detriment to the quality of the gaits. Egg bar shoes provide a greater surface area through which forces are transmitted and clinically seem to help reduce pain associated with either navicular bone pain or distal interphalangeal joint pain. Of 55 horses with clinically diagnosed navicular disease, 53% had permanent relief of lameness after application of egg bar shoes in a follow-up period of 12 to 40 months.[4] In some horses, clinical improvement took many weeks. Resolution of lameness was seen despite the persistence of low, collapsed heels, which is also our experience. In another study, treated horses showed histomorphometric evidence of altered navicular bone modeling compared with untreated controls.[5] The shoes should be made to measure and of sufficient size and length to provide adequate support to the heel region (Fig. 31-1).

Fitting an egg bar shoe is not necessarily easy and depends on the shape of the horse's foot. If the quarters are very wide it can be difficult to "pick up" the heels. In such horses a traditional open shoe fitted long and wide at the heels or a straight bar shoe may be more appropriate. The correctly fitted egg bar shoe should project beyond the ground-bearing surface of the foot. It is more likely to be pulled off than a standard shoe, and the use of over-reach boots should always be considered, at least when the horse is worked or turned out. These shoes are not suitable for a horse that is going to work in deep mud, since they are readily sucked off.

In summary, the following principles may aid in the selection of a shoe: correction and then maintenance of dorsopalmar and lateromedial balance, ease of breakover achieved by rolling the toe of the shoe, maintenance of foot (and especially heel) mass, and protection of the palmar aspect of the foot from concussion.

Screw-in studs are used in many competition horses to enhance traction. Some riders just use studs in the lateral

Fig. 31-1 **A,** Lateral; **B,** palmar, and **C,** solar views of a correctly fitted egg bar shoe. The shoe projects beyond the ground bearing surface of the foot to cover the bulbs of the heel.

branch of the shoe to avoid the risks of tread injuries created by a medial stud in the contralateral limb. This inevitably creates mediolateral imbalance, and therefore care should be taken either to use studs in both branches or to avoid the use of studs. The studs should be positioned as far palmarly as possible to avoid shortening the effective length of the shoe. When the ground is hard, small, pointed studs are preferable to large, square-shaped studs.

Non-Steroidal Anti-Inflammatory Medication

A wide variety of NSAIDs are used in horses. In general, these drugs should be administered at the lowest dose necessary to achieve the desired effect. There are anecdotal reports that certain NSAIDs are better for horses with foot pain (e.g., meclofenamic acid [Arquel]), but there are no controlled studies to support these claims. Phenylbutazone is widely used, and many, but not all, horses with navicular pain respond to this drug. To determine the lowest effective dose of phenylbutazone, the horse is given a dose of 4 mg/kg twice daily for 3 days and the dose is then gradually decreased until the lameness returns. Depending on lameness severity, NSAID treatment may only be necessary when the horse is being used. It should be borne in mind that it has been demonstrated that phenylbutazone may influence bone turnover.[6] After bone biopsy of the tibia, mineral apposition rate was significantly decreased in horses treated with phenylbutazone (4.4. mg/kg BID) compared with untreated, control horses. The clinical significance of this finding in the management of navicular disease is unknown. For horses that are intolerant of phenylbutazone, carprofen ([Rimadyl] 1.0 to 1.5 mg/kg SID) has been a useful alternative in one author's (J.B.M.) practice.

Isoxsuprine

Isoxsuprine is a β-agonist that causes peripheral vasodilation in people. Its mode of action in the treatment of navicular disease is unknown. It has been suggested that there are no

measurable cardiovascular effects of isoxsuprine given orally in the horse.[7,8] However, orally administered slow-release isoxsuprine resin was absorbed and resulted in thermographic evidence of increased skin temperature of the distal forelimbs for about 8 hours after administration.[9] Isoxsuprine also binds strongly to α-adrenoreceptors[10] and therefore may be active despite insignificant measurable levels in plasma.[9] The drug also may have some anti-inflammatory or hemorheologic properties that could explain why some horses with navicular disease appear to respond to isoxsuprine therapy. A double-blind clinical trial evaluating the response to isoxsuprine in the treatment of navicular disease demonstrated a decrease in lameness in the treated horses.[11]

If the horse responds to a trial dose of 0.6 mg/kg twice a day for 30 days, then continued treatment at the same dose given once or twice a day indefinitely may be indicated. In one author's (S.J.D.) experience, some horses have been treated for 12 weeks and responded satisfactorily and have then shown remission of clinical signs for up to 9 months without treatment. If no response is seen within 30 days, it is unlikely that further treatment will be beneficial. However, some horses that did not respond a dose of 0.6 mg/kg twice daily did respond satisfactorily to 0.9 mg/kg twice daily. If lameness is moderate to severe, then treatment should be combined with a NSAID for the first 3 to 4 weeks of treatment. The response to treatment in horses with major radiological abnormalities is generally very poor.

Intra-Articular Medication

Although lameness associated with navicular disease may be improved by intra-articular analgesia of the distal interphalangeal joint, the intra-articular administration of hyaluronan with or without corticosteroids (e.g., triamcinolone, 10 mg) does not usually result in a similar degree of improvement, unless there is concurrent synovitis of the distal interphalangeal joint. Intra-thecal injection of corticosteroids into the navicular bursa may provide transient relief of clinical signs for up to 2 to 3 months.[12] In one author's (S.J.D.) experience, this treatment is effective only in horses with low-grade radiographic abnormalities but can result in very substantial although temporary improvement.

Other Drugs

Warfarin previously was used to treat horses with navicular disease, and in one series an 80% success rate was claimed.[13] However, these were predominantly pleasure horses and low-level competition horses. Experience in higher level competition horses produced disappointing results.[14] Warfarin therapy requires careful adjustment of the dose guided by monitoring of prothrombin time at least at monthly intervals. This, combined with the drug's limited efficacy, has largely resulted in the abandonment of this treatment.

Pentoxyfylline and propentofylline are hemorheologic drugs that alter the deformability of the red blood cell membrane and inhibit platelet aggregation.[8,15] These drugs are advocated by some clinicians for the treatment of navicular disease, although clinical efficacy to date is largely unknown. No measurable effect on digital and laminar blood flow was seen in healthy horses after oral administration of pentoxifylline.[8] A small clinical study using propentofylline resulted in improvement, but not alleviation of lameness associated with navicular disease, during a 6-week treatment period.[15] A long-term clinical trial using metrenperone found similar efficacy to isoxsuprine; only 27% of horses had long-term resolution of lameness.[16]

The pathological similarities between navicular disease and osteoarthritis have prompted the use of drugs used for the management of osteoarthritis. Systemic administration of a polysulfated glycosaminoglycans (PSGAG [Adequan], 500 mg IM every 4 days for 7 treatments] resulted in clinical improvement in lameness in treated horses compared with controls during the treatment period.[17] In one author's (S.J.D.) experience, PSGAG treatment has not had any long-lasting benefit on lameness associated with navicular disease.

Chemical "Neurectomy": Cryoneurectomy

Temporary resolution of palmar foot pain can be achieved by chemical ablation of sensory fibers in the palmar digital nerves. Several products are capable of causing a temporary loss of sensation when injected over the nerves. These include Sarapin (a plant alkaloid that is thought to alter transmission in type C fibers), P block, and cobra venom. The product usually is injected over, or directly into, the nerve with a corticosteroid. Injection of absolute alcohol into the perineurium may also be used. Any of these products may result in localized perineural fibrosis, which makes subsequent surgical neurectomy more complicated. Alternatively, the digital nerves may be frozen percutaneously using liquid nitrogen. Both methods result in 2 to 3 months of clinical improvement when successfully applied. In our experience, these methods work well on occasion but are unreliable. Return of sensation in most horses is accompanied by a return of the lameness.

Desmotomy of the Collateral (Suspensory) Ligaments of the Navicular Bone

Navicular suspensory desmotomy has been described as a treatment for navicular disease.[18,19] In an initial report from the United Kingdom, 13 of 16 horses treated with this technique were able to work without lameness,[18] and in a subsequent report, 76% of 118 horses were sound at 6 months, but only 43% remained sound 3 years later.[20] Diehl[19] from Germany reported clinical improvement in 50% of 57 horses. In a study from New Zealand, 12 of 17 horses were sound at least 6 months post-operatively.[21] In our experience, navicular suspensory desmotomy often results in short-term (6 to 12 months) improvement in lameness. One author (J.B.M.) has never seen complete resolution of lameness, whereas the other (S.J.D.) has. The difference in response may relate to post-operative management. One author (S.J.D.) starts walking exercise from the first post-operative day, with a rapidly ascending exercise program after suture removal, whereas the other (J.B.M.) starts light exercise 3 weeks post-operatively with a return to full work after 3 months. It was originally suggested that this surgical procedure resulted in alteration of the biomechanical forces on the navicular bone, but clinical improvement may also be the result of sectioning the sensory nerve fibers that run in the suspensory ligaments. The original surgical technique described transecting the ligaments near the origin through oblique skin incisions, but the proximal interphalangeal joint capsule can be penetrated by this approach. Better results have been achieved via vertical skin incisions further distally, centered over the collateral ligaments of the navicular bone.

Desmotomy of the Accessory Ligament of the Deep Digital Flexor Tendon

Desmotomy of the accessory ligament of the deep digital flexor tendon has been described as a treatment for navicular disease in horses with a markedly upright foot conformation.[22] Long-term follow-up results are not available.

Periarterial "Sympathectomy"

Litzke et al.[23] described a technique for cutting the sympathetic nerve supply to the lateral and medial digital arteries, either alone or with palmar digital neurectomy. This technique is still practiced in Germany, but the results have not been well documented.

Palmar Digital Neurectomy

If lameness associated with navicular disease is completely eliminated by perineural analgesia of the palmar digital nerves, then palmar digital neurectomy may be considered as a treatment of last resort.[24] The technique has been associated with a significant number of complications, including failure to alleviate lameness, recurrence of lameness, complete or partial rupture of the DDFT, and subluxation or luxation of the distal interphalangeal joint, neuroma formation, and failure to recognize either sub-solar infection or penetrating injuries of the palmar aspect of the foot. Case selection is very important. Horses with pre-existing pathology of the DDFT are probably at highest risk of subsequent rupture of the DDFT. If there is radiological evidence of a substantial defect in the flexor surface of the navicular bone, DDFT lesions are likely and these horses should not be treated by neurectomy.

A variety of techniques of palmar digital neurectomy have been described. Recent work suggests that the simple guillotine technique results in the longest period of desensitization and less neuroma formation compared with epineural capping and carbon dioxide laser division.[25] Surgery should be delayed for at least 7 days after perineural analgesia. We both prefer to use two long (3- to 4-cm) incisions just dorsal to the medial and lateral edges of the superficial digital flexor tendon starting just below the base of the sesamoid. The nerve is gently stretched and transected using a scalpel blade as far distally and proximally as possible. Approximately 50% of horses have one or more (up to five) accessory branches that must be divided to achieve complete desensitization of the heel region. In most instances the accessory branches are located abaxial to the palmar digital nerve and run in a palmar direction and parallel to the ligament of the ergot. If an accessory branch is located at one surgical site, there are invariably accessory branches associated with the remaining palmar digital nerves. The incision is closed in a single layer, and the horse is confined to a box stall with hand walking only for a period of 30 days. Phenylbutazone (2.2 mg/kg BID) is administered for a period of 10 days. This limited exercise, combined with minimal handling of the nerve(s) intraoperatively, seems to reduce the risk of neuroma formation.

The horse is shod in the manner that was most successful before surgery. This procedure usually provides relief of clinical symptoms in approximately 65% to 70% of horses for approximately 12 to 18 months post-operatively.[26,27] Individual horses may have recurrence of lameness sooner.

With careful handling of the nerve intraoperatively, followed by conservative postoperative management, neuroma formation is uncommon. A painful neuroma, which may occur several months after surgery, may be successfully managed with perineural injections of Sarapin and triamcinolone. Occasionally a second neurectomy proximal to the neuroma is required.

If lameness occurs because of re-innervation, surgery may be repeated, assuming that perineural analgesia of the palmar digital nerves still results in relief of pain. However, re-innervation may be due to axons sprouting from the proximal nerve stump and anastomosing with other local nerves. Repeated surgery may therefore be less successful.

Surgical Drilling

A technique for drilling cyst-like lesions in the navicular bone through an arthroscopic approach has recently been described, but long-term follow-up results are not available.[28]

CHAPTER • 32

Fracture of the Navicular Bone

Sue J. Dyson

Fractures of the navicular bone occur in a variety of configurations. The most common is a slightly oblique sagittal fracture, medial or lateral to the midline. Y-shaped fractures and other comminuted fractures are less common. Distal border fragments are discussed elsewhere (see Chapter 30). Fractures occur more commonly in forelimbs than hindlimbs. In a series of 40 navicular bone fractures, 28 (70%) occurred in a forelimb.[1] Fractures usually are traumatic in origin, although it is not always possible to identify the cause. Fractures in hindlimbs have been the result of kicking a wall. Bipartite and tripartite navicular bones also have been described and should be differentiated from a fracture.[2] It has been suggested that many fractures are pathological secondary to severe navicular disease,[3] but this confusion probably arises because lucent zones adjacent to the fracture line and along the distal border of the navicular bone develop rapidly, within months of fracture occurrence.[4] Palmar (plantar) displacement of fracture fragment(s) may result in laceration of the deep digital flexor tendon.[5] Other fractures of the middle or distal phalanx occasionally occur concurrently.

HISTORY

Lameness is usually acute in onset and severe. However, sometimes a horse may develop less severe lameness and radiographic examination reveals evidence of an old fracture, which presumably healed by fibrous union but has recently become unstable.

CLINICAL EXAMINATION AND DIAGNOSIS

The horse may be reluctant to bear full weight on the limb. Digital pulse amplitudes may be increased, and in some horses, pain can be elicited by application of hoof testers to the heel or frog regions. Percussion of the frog may be resented. Lameness usually is severe with an acute fracture and may be accentuated as a horse turns. Lameness is usually substantially improved by perineural analgesia of the palmar digital nerves, although it sometimes is unaffected. Diagnosis is dependent on radiographic identification of the fracture(s). Most fractures are best identified in a dorsoproximal-palmarodistal oblique view (or an "upright pedal" plantarodorsal view in a hindlimb) (Fig. 32-1). It is important that frog cleft artifacts not be confused as a fracture. The clinician should examine any lucent line carefully to see whether it extends beyond the bone margins, or if it changes position relative to the medial and lateral margins of the bone if the x-ray beam is reoriented 5° medially or laterally. The frog clefts should be well packed with a moldable compound (e.g., PlayDoh; Hasbro, Pawtucket, RI) and if necessary re-packed. If doubt persists, a weight-bearing dorsopalmar view and a palmaroproximal-palmarodistal oblique view of the navicular bone should determine whether a fracture is present. The palmaro-

proximal-palmarodistal oblique view is also useful for determining the presence of comminution or displacement. The presence of lucent zones along the fracture line indicates that it is not of recent origin but is likely to have been present for at least several months (Fig. 32-2).

Treatment

Lameness associated with a simple sagittal fracture usually improves progressively with rest, but the prognosis for complete resolution of lameness or return to full athletic function is guarded. Some horses do become sound enough for light hacking, but lameness may be recurrent.[3,6] Better results have been described in a limited number of horses by trimming the foot to establish a normal hoof-pastern axis followed by application of four 3° wedge pads and a flat shoe to reduce the weight-bearing function of the navicular bone.[7] The horse is confined to box rest for 60 days and then starts walking exercise for an additional 2 months. The shoe is refitted every 4 weeks with 3° less elevation at each shoeing. However, healing probably is only by fibrous union. Treatment by palmar digital neurectomy may provide symptomatic relief in some horses, but a substantial proportion develop osteoarthritis of the distal or proximal interphalangeal joints and associated lameness.[6] Internal fixation using a lag screw technique with a specially designed limb jig and radiographic control offers the best prognosis for simple, oblique sagittal fractures.[1,8] Twenty-three (68%) of 40 horses resumed work. The prognosis was significantly better for fractures of less than 4 weeks' duration than for older fractures. Potential complications included splitting the fragment, inability to reduce the fracture resulting in a step deformity, and poor stabilization of the fracture. The prognosis for more complicated fractures is guarded.

CHAPTER • 33

Primary Lesions of the Deep Digital Flexor Tendon within the Hoof Capsule

Sue J. Dyson

ANATOMY

Within the hoof capsule the deep digital flexor tendon (DDFT) is molded to the palmar (plantar) surface of the navicular bone and separated from it by the navicular bursa. The distal recess of the navicular bursa separates the DDFT and the distal sesamoidean impar ligament. The DDFT has a terminal fan-like expansion containing cartilage that occupies the entire space between the medial and lateral palmar processes of the distal phalanx. It inserts on the facies flexoria and semilunar crest of the distal phalanx. The dorsal portion of the DDFT joins with the distal sesamoidean impar ligament immediately before insertion on the facies flexoria of the distal phalanx. There are parallel fibers of dense connective tissue, separated by loose connective tissue, within which are many sensory nerves and numerous blood vessels.[1] A prominent line (tidemark) indicates the transition from nonmineralized tendon and ligament to mineralized regions of the DDFT and distal sesamoidean impar ligament before attachment to the distal phalanx.[2]

Within the digit the DDFT induces axial compression of the articular surfaces of the proximal and distal interphalangeal joints.[2,3] It has an important role in stabilizing the distal interphalangeal joint. The anatomical arrangement of the collateral ligaments of the navicular bone facilitates compression of the articular surfaces of the navicular bone into those of the middle and distal phalanges.[2] The DDFT has a dorsal fibrocartilaginous pad that supports pressure of the tuberositas flexoria, the transverse prominence on the proximopalmar aspect of the middle phalanx.[3]

The relationship of the DDFT to the navicular bone varies with the phase of the stride. During the full weight-bearing stance of the stride the DDFT is only in contact with the distal aspect of the bone, whereas in the propulsion phase the DDFT bends over the distal scutum (the fibrocartilaginous insertion of the straight sesamoidean ligament on the middle phalanx) and comes into full contact with the navicular bone. Tension in the DDFT is maximal, and active muscle contraction and the elasticity in the tendon and in its accessory ligament result in extension of the distal interphalangeal joint.[3] At the beginning of the swing phase of the stride the tension in the DDFT contributes passively to induce flexion of the interphalangeal joints. During extension of the distal interphalangeal joint, which is maximum at the propulsion phase of the stride, pull on the DDFT creates a shear force between the DDFT and the distal sesamoidean impar ligament.[2]

proximal-palmarodistal oblique view is also useful for determining the presence of comminution or displacement. The presence of lucent zones along the fracture line indicates that it is not of recent origin but is likely to have been present for at least several months (Fig. 32-2).

CHAPTER • 33

Primary Lesions of the Deep Digital Flexor Tendon within the Hoof Capsule

Sue J. Dyson

ANATOMY

Within the hoof capsule the deep digital flexor tendon (DDFT) is molded to the palmar (plantar) surface of the navicular bone and separated from it by the navicular bursa. The distal recess of the navicular bursa separates the DDFT and the distal sesamoidean impar ligament. The DDFT has a terminal fan-like expansion containing cartilage that occupies the entire space between the medial and lateral palmar processes of the distal phalanx. It inserts on the facies flexoria and semilunar crest of the distal phalanx. The dorsal portion of the DDFT joins with the distal sesamoidean impar ligament immediately before insertion on the facies flexoria of the distal phalanx. There are parallel fibers of dense connective tissue, separated by loose connective tissue, within which are many sensory nerves and numerous blood vessels.[1] A prominent line (tidemark) indicates the transition from nonmineralized tendon and ligament to mineralized regions of the DDFT and distal sesamoidean impar ligament before attachment to the distal phalanx.[2]

Within the digit the DDFT induces axial compression of the articular surfaces of the proximal and distal interphalangeal joints.[2,3] It has an important role in stabilizing the distal interphalangeal joint. The anatomical arrangement of the collateral ligaments of the navicular bone facilitates compression of the articular surfaces of the navicular bone into those of the middle and distal phalanges.[2] The DDFT has a dorsal fibrocartilaginous pad that supports pressure of the tuberositas flexoria, the transverse prominence on the proximopalmar aspect of the middle phalanx.[3]

The relationship of the DDFT to the navicular bone varies with the phase of the stride. During the full weight-bearing stance of the stride the DDFT is only in contact with the distal aspect of the bone, whereas in the propulsion phase the DDFT bends over the distal scutum (the fibrocartilaginous insertion of the straight sesamoidean ligament on the middle phalanx) and comes into full contact with the navicular bone. Tension in the DDFT is maximal, and active muscle contraction and the elasticity in the tendon and in its accessory ligament result in extension of the distal interphalangeal joint.[3] At the beginning of the swing phase of the stride the tension in the DDFT contributes passively to induce flexion of the interphalangeal joints. During extension of the distal interphalangeal joint, which is maximum at the propulsion phase of the stride, pull on the DDFT creates a shear force between the DDFT and the distal sesamoidean impar ligament.[2]

PATHOPHYSIOLOGY

Primary lesions of the DDFT have only recently been recognized clinically, and only limited information concerning pathophysiology is available. Currently it is not known whether degenerative aging changes that are common to many other tendons and ligaments may predispose to injury. A progressive increase in proteoglycans with age has been seen in the distal aspects of the DDFT and distal sesamoidean impar ligament, which may be an adaptation to stress.[2] It was suggested that horses with low, weak heels may be more susceptible to these changes. Similar but more extensive changes were seen in two horses with navicular disease. Lesions within the DDFT within the foot were identified in less than 10% of horses with unknown history in a post-mortem study of SDFT and DDFT lesions in the metacarpal region and digit.[4]

In a post-mortem study of 38 horses with suspected navicular disease, 1 horse had a core lesion of the DDFT with no associated pathological condition of the navicular bone[5]; 4 additional horses had histological evidence of focal regions of necrosis within the tendon concurrent with other pathological conditions of the navicular bone. Surface fibrillation was a common finding in horses with navicular disease but not in age-matched controls. No lesions of the DDFT were described in the age-matched controls. Pool et al.[6] considered lesions in the DDFT to be secondary to navicular disease. Inflammation at the intersection of the DDFT and distal sesamoidean impar ligament was recognized in the Quarter Horse in association with other signs compatible with navicular disease.[7] It was considered that these lesions may be involved with the pathogenesis of navicular disease.

Ectopic mineralization within the DDFT has been identified radiographically, at the level of the navicular bone and immediately proximal to it, but its clinical significance has been speculative.[8] Entheseous new bone at the site of insertion of the DDFT on the facies flexoria and semilunar crest of the distal phalanx has been described associated with lameness, unassociated with navicular disease.[9] Nuclear scintigraphic examination of horses with palmar foot pain has revealed horses with focal regions of increased uptake of the radiopharmaceutical in the region of insertion of the DDFT,[10] either alone or in association with a region of increased uptake in the navicular bone. Many of these horses had no detectable radiographic abnormality.

Primary DDF tendonitis may be the result of repetitive overstress or an acute-onset traumatic tear. Lesions identified in association with navicular disease have been identified in the region where the tendon passes over the palmar aspect of the navicular bone, whereas primary tendonitis has been identified not only in this region but also further proximally and distally, with some lesions confined to the actual insertion into the distal phalanx.[11]

Rupture of the DDFT secondary to previous neurectomy of the palmar digital nerves is considered a separate condition; however, it is likely that a pre-existing, unrecognized pathological condition of the DDFT predisposes to rupture.

HISTORY AND CLINICAL SIGNS

Lameness associated with primary DDF tendonitis within the hoof capsule has been identified most commonly in horses that jump,[1-13] but it has also been seen in general-purpose riding horses. Lameness usually is unilateral, acute in onset, and moderate to severe in intensity. In horses with severe lameness the horse may point the affected limb at rest. In mild to moderate injuries, lameness may resolve with rest but recur with work and progressively worsen.

There are generally no substantial palpable abnormalities of the limb, unless the lesion extends proximally into the pastern region. There is also no response to pressure applied to the foot with hoof testers. Lameness often is worse on a soft surface, especially on a circle, and in some horses is apparent only under these circumstances. The response to distal limb flexion is variable. Extension of the distal interphalangeal joint using the board or wedge test may accentuate the lameness.

LOCAL ANALGESIA

Perineural analgesia of the palmar digital nerves immediately proximal to the cartilages of the foot usually but not invariably improves lameness but rarely is lameness fully alleviated. Perineural analgesia of the palmar nerves at the level of the base of the proximal sesamoid bones usually relieves the lameness. Intra-articular analgesia of the distal interphalangeal joint results in rapid improvement in lameness in some horses, but in others lameness persists unchanged. There has been no correlation between the analgesic response and the proximodistal site of the lesion.[11] Analgesia of the navicular bursa often results in improvement in lameness but rarely alleviates it fully.

DIAGNOSTIC IMAGING

Radiography

In some lateromedial radiographic projections of the foot a faint outline of the DDFT can be seen; the significance of this finding is unknown. Occasionally a focus of mineralization is seen within the DDFT, at the level of or proximal to the navicular bone, but to date this has not been correlated with primary tendonitis of the DDFT. In a well-positioned, high-detail lateromedial projection, entheseous new bone or a radiolucent focus may be identified on the facies flexoria of the distal phalanx. This finding has been seen more commonly in heavier Warmblood breeds[9] than in Thoroughbred and cross-bred horses[11] and has been correlated with increased bone activity identified by nuclear scintigraphy.

Ultrasonography

Diagnostic ultrasonographic imaging of the DDFT within the hoof capsule is not easy because of the horny hoof capsule and the difficulties in orientating the ultrasound transducer perpendicular to the line of the tendon fibers. Thus it is easy to create artifacts. The proximal part of the DDFT may be imaged using a 6.5-MHz transducer positioned between the bulbs of the heel, unless the heel is very contracted. The region of the DDFT overlying the navicular bone and close to its insertion is potentially seen by a solar approach, placing the transducer (7.5-MHz) on the frog. The frog must be sufficiently soft; this generally is achieved by soaking the foot by bandaging a water-soaked sponge on the foot for several hours. If the horn is exceptionally hard, soaking may have to be continued for several days. The horn must also be pared to provide a relatively flat site for placement of the ultrasound transducer. This is difficult to achieve if the horse has a very narrow foot with a deep frog cleft and sulci. Only the region of the DDFT in the mid-sagittal plane can be successfully imaged. Orientation is achieved most easily in longitudinal images.

A normal DDFT has linear, parallel echoes and its margins are well defined.[14] An anechoic region representing fluid in the navicular bursa is interposed between the DDFT and the echoic line of the palmar aspect of the navicular bone. There are limited reports of correlation of postulated lesions within the DDFT and either post-mortem studies or

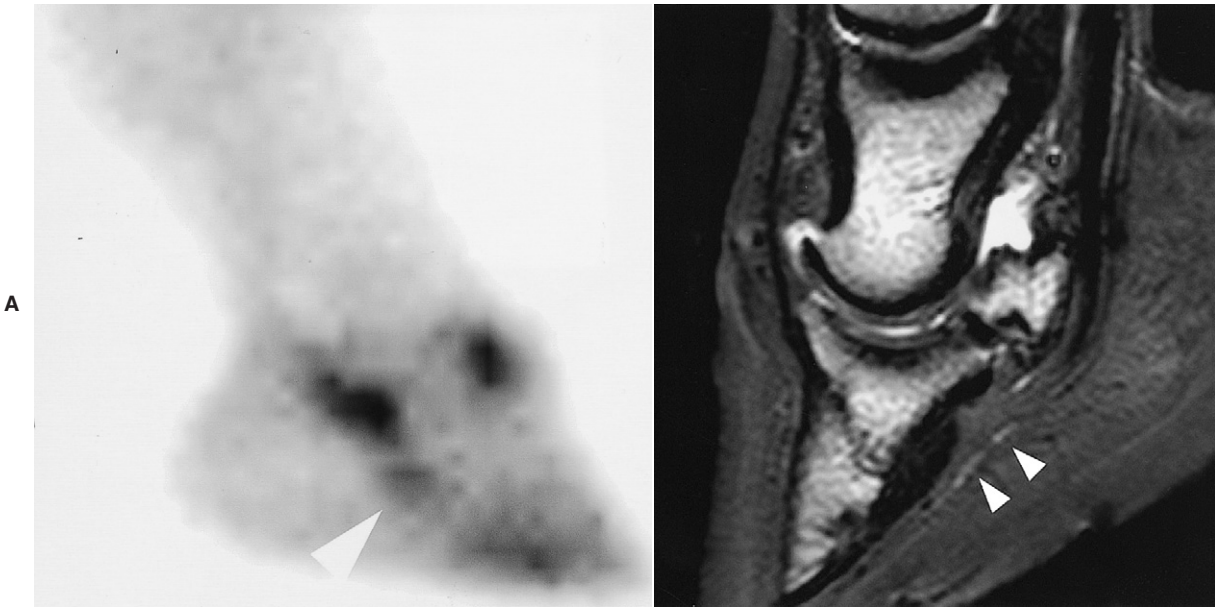

Fig. 33-1 **A,** Lateral pool-phase scintigraphic image of the right front foot of a 9-year-old event horse with a history of acute-onset severe lameness after competing. Lameness had persisted despite rest. Lameness was improved by perineural analgesia of the palmar digital nerves or intra-articular analgesia of the distal interphalangeal joint, but it was not affected by analgesia of the navicular bursa. There is a region of increased uptake of the radiopharmaceutical *(arrow)*. Superimposition of a lateromedial radiograph demonstrated that this was at the site of insertion of the deep digital flexor tendon (DDFT) on the distal phalanx. Magnetic resonance imaging demonstrated an abnormal signal at the insertion of the DDFT. **B,** Sagittal three-dimensional T2-weighted gradient echo magnetic resonance image of the same foot in **A.** There is an unusual bright signal immediately distal to the DDFT *(arrows)*, the significance of which is currently unknown. The increased signal in the DDFT distally is due to its structural composition and the magic angle effect. There is also a large amount of fluid in the distal interphalangeal joint.

confirmation of the presence of a lesion using alternative means[15]; thus the sensitivity and specificity of the technique are currently unknown.

Nuclear scintigraphy

Pool- and bone-phase nuclear scintigraphic lateral and solar images of the foot have been used to identify a region of increased uptake of ^{99m}Tc either at the site of insertion of the DDFT on the facies flexoria of the distal phalanx or further proximally within the DDFT[9,16] (Figs. 33-1 and 33-2). Superimposition of a lateromedial radiographic image and a lateral scintigraphic image helps to accurately locate the site of increased uptake in the lateral view.[17] Pool-phase images have been more sensitive than bone-phase images in identifying lesions of the DDFT proximal to its insertion. Although the bone-phase solar (palmar) view may be more sensitive for identification of abnormal modelling associated with insertional stress, there is a relatively high incidence of false-positive results.[16]

The results from pool-phase lateral images have correlated well with findings using magnetic resonance imaging, arthroscopic evaluation of the DDFT through the navicular bursa, and post mortem studies.[17] However, the close proximity of the insertion of the distal sesamoidean impar ligament to that of the DDFT makes differentiation of insertional injuries potentially difficult.

Computed tomography

Computed tomography (CT) can only be performed with the horse under general anesthesia, but has the potential to give information about the size, shape, and internal architecture of the DDFT within the hoof capsule. It is therefore an accurate method of diagnosis of primary DDFT lesions. Lesions have been identified in one or both of the two lobes of the DDFT and were seen as enlargement of the DDFT with an increase or decrease in density[13,18] (Fig. 33-3). Thirteen of 78 horses

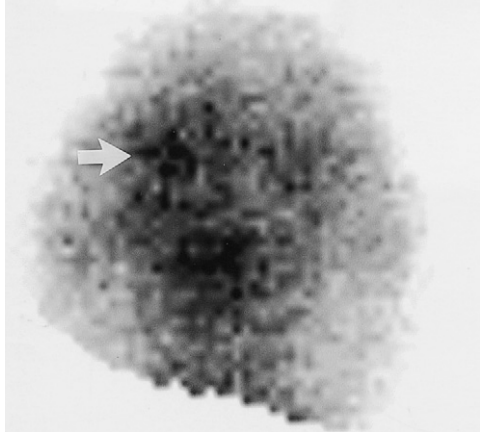

Fig. 33-2 Solar (palmar) bone-phase scintigraphic image of the left front foot of a 7-year-old show jumper with acute-onset, chronic left forelimb lameness that was alleviated by perineural analgesia of the palmar digital nerves. There is a focal region of increased uptake of the radiopharmaceutical *(arrow)*. Post-mortem examination revealed focal bone necrosis and reactive bone at this site associated with the insertion of the deep digital flexor tendon.

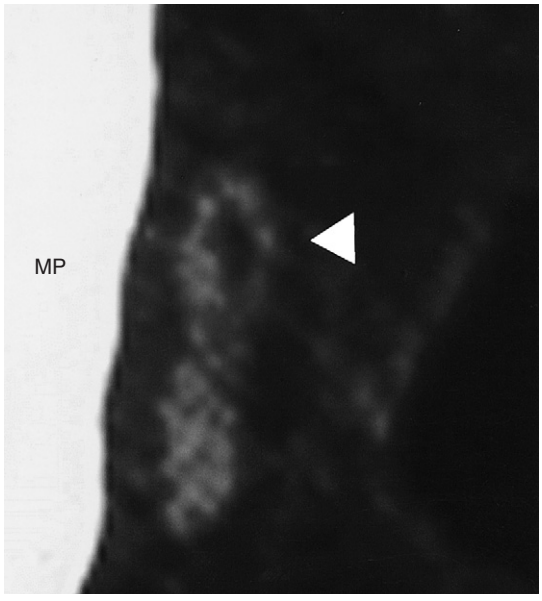

Fig. 33-3 Transverse computed tomographic image at the level of the middle phalanx (MP). Dorsal is to the left. The medial lobe of the deep digital flexor tendon has a focal decrease in signal density *(arrow)*.

examined using CT had abnormalities of the DDFT within the hoof.[13] To date, the results of clinical cases have not been correlated with post mortem examination and thus the clinical significance of the lesions remains speculative. However, correlation of an abnormal CT scan result with abnormalities verified at post mortem examination has been described without clinical details.[18]

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) can only be performed with the horse under general anesthesia, but it potentially offers the optimal method of diagnosis of primary DDFT lesions[12] (Fig. 33-4). Experience is still required to determine the clinical significance of relatively subtle changes in signal intensity. Three-dimensional T2*-weighted gradient echo sequences, with slice thickness of 1 to 1.5 mm, provide the best image quality.[19] Lesions are seen best in sagittal and transverse planes. Fat-suppressed two-dimensional fast spin echo or three-dimensional gradient echo sequences also are useful for detection of bone pathology at the insertion.

Most primary DDFT lesions have been identified proximal to the navicular bone, extending from the middle phalanx a variable distance distally. A small number of lesions have been identified at the insertion of the DDFT. Lesions usually are restricted to either the medial or the lateral lobe, but occasionally they occur in both lobes. Core lesions or dorsal fiber disruption are most common, sometimes with herniation of fibers and granulation tissue into the navicular bursa. Focal, full thickness, sagittal plane splits have also been seen at the level of the navicular bone, in association with abnormal signal in the palmar cortex of the bone. Seven of 18 horses with palmar foot pain of previously undetermined cause had primary DDFT injuries diagnosed using MRI.[20]

Correlation of the results of MRI examination of cadaver specimens from horses with clinically suspected DDFT lesions and post mortem examination has been good[17,21] (Fig. 33-5). Collagen necrosis and chondroid metaplasia within the DDFT have been seen in regions of increased signal intensity.[17,21] Care must be taken in the interpretation of sagittal plane images in the region of insertion of the DDFT,

Fig. 33-4 **A,** Sagittal magnetic resonance image of a normal foot obtained using a three dimensional T2-weighted gradient echo sequence. There is a uniform signal throughout the deep digital flexor tendon (DDFT). **B,** Sagittal three-dimensional T2-weighted, fat-saturated, gradient echo magnetic resonance image of a normal foot. There is increased signal in the distal aspect of the DDFT *(arrow)*.

because there is an increased signal intensity in normal horses (see Figs. 33-1, *B,* and 33-4, *B*). This is related in part to the composition of the tendon, but also to the magic angle effect. This is due to orientation of fibers at approximately 55° to the main magnetic field.

SURGICAL EXPLORATION

Endoscopic examination of the digital flexor tendon sheath and the navicular bursa allows visual evaluation of the surface of the DDFT and assessment of its integrity by probing (see Chapter 24). Core lesions of the DDFT frequently have been

Fig. 33-5 Sagittal magnetic resonance image of the right front foot of an advanced event horse with acute-onset severe lameness that was alleviated by perineural analgesia of the palmar digital nerves and improved by intra-articular analgesia of the distal interphalangeal joint. The deep digital flexor tendon is enlarged and has increased signal intensity proximal to the navicular bone *(arrow)*. This correlated with an extensive core lesion at postmortem examination.

associated with extensive surface fibrillation of the tendon and inflammation of the synovial lining of the navicular bursa with villous proliferation.[11] However, this technique is both invasive and provides only limited information about the internal architecture of the tendon.

TREATMENT

Although Ueltschi[10] has reported a favorable outcome for horses with scintigraphic, radiographic, or both types of evidence of insertional lesions of the DDFT following prolonged rest,[10] in my experience with both these lesions, or those located further proximally, lameness frequently has persisted over the long term. These lesions have been confirmed at postmortem examination. Lesions have been identified within the DDFT immediately proximal and distal to the navicular bone, or localized to the insertion of the DDFT, with focal bone necrosis at that site.[17]

CHAPTER • 34

The Distal Phalanx and Distal Interphalangeal Joint

PRIMARY PAIN ASSOCIATED WITH THE DISTAL INTERPHALANGEAL JOINT

• Sue J. Dyson

FUNCTIONAL ANATOMY

The distal interphalangeal joint is a complex structure comprising not only the articulation between the middle and distal phalanges, with supporting collateral ligaments, but also the articulation with the navicular bone. It therefore forms a close relationship with the distal sesamoidean impar ligament, the collateral ligaments of the navicular bone, and the navicular bursa.

The distal interphalangeal joint can move in three planes with flexion and extension movements in the sagittal plane, lateromedial movements in the frontal plane, and rotation and sliding in the transverse plane.[1,2] During normal load bearing and propulsion on a flat, level surface, distal interphalangeal joint movement is principally flexion and extension. On an uneven surface and a circle, or if the foot is unbalanced, passive movements result in the distal phalanx sliding and twisting relative to the middle phalanx. Movement is restricted by the collateral ligaments of the distal interphalangeal joint, the deep digital flexor tendon (DDFT), the distal digital annular ligament, and the distal sesamoidean impar ligament and collateral ligaments of the navicular bone. The degree of sliding and axial rotation within the distal interphalangeal joint[3] may predispose the horse to distal interphalangeal joint injury and may explain why lameness associated with the distal interphalangeal joint frequently is accentuated on a circle.

HISTORY

Lameness associated with the distal interphalangeal joint may be acute or insidious in onset and unilateral or bilateral. It is more common in forelimbs than in hindlimbs but does occur in both. Lameness in horses with unilateral disease tends to be sudden in onset, but those with bilateral lameness may be evaluated because of poor performance (e.g., shortened stride, unwillingness to jump drop fences, or unwillingness to land with one forelimb leading).

CLINICAL SIGNS

The distal interphalangeal joint capsule often is distended unilaterally or bilaterally. Distention of the joint capsule also can occur in clinically sound horses; therefore this finding is not pathognomonic for distal interphalangeal joint pain. However, chronic distention does reflect synovitis and treatment may reduce the risk of future problems. The dorsal proximal outpouching of the joint capsule can be palpated on the distal dorsal aspect of the pastern. Distention may result in obvious swelling, but it may be difficult to appreciate unless the horse has a fine hair coat. When distention of the joint capsule is present, ballottement of fluid from medial to lateral of the dorsal midline should be possible. The degree of distention may vary according to the recent work history.

Pain may be present on flexion or rotation of the distal limb joints. However, a marked reaction to distal limb flexion more likely reflects metacarpophalangeal joint pain. Mediolateral, dorsopalmar, or both types of foot imbalance are frequent findings and are considered important predisposing factors for the development of distal interphalangeal joint pain. The degree of lameness varies depending on the nature of the underlying pathological change, recent work history, and whether lameness is unilateral or bilateral. With bilateral distal interphalangeal joint pain the horse may move just a bit "flat" with a slightly shorter than normal stride. Severe lameness may reflect trauma to one of the supporting soft tissue structures of the joint. Lameness may be accentuated by distal limb flexion or rotation of the distal limb joints, but the response is variable. Lameness often is worse on a circle, especially on a hard surface, either with the lamest limb on the inside or outside of the circle.

DIAGNOSIS

Local Analgesia

Pain associated with the distal interphalangeal joint often improves after perineural analgesia of the palmar digital nerves and sometimes is alleviated fully. However, in some horses perineural analgesia of the palmar nerves at the level of the proximal sesamoid bones is required to completely eliminate lameness.

Intra-articular analgesia of the distal interphalangeal joint is not specific for pain that affects the joint itself. The potential exists for relief of pain from the navicular bone, insertions of the distal sesamoidean impar ligament and the DDFT on the distal phalanx, the palmar processes of the distal phalanx[4] and the sole, even at the toe.[5,6] A standard approach is suggested to aid in interpretation of the response. A maximum volume of 6 ml of local anaesthetic solution should be used. After injection through a dorsal midline approach the horse should stand still until re-assessment 5 minutes after injection. The clinician should ascertain whether sensation remains around the coronary band and whether any response to hoof testers has been eliminated to determine the specificity of the block. Lameness caused by primary distal interphalangeal joint pain usually improves rapidly and substantially after intra-articular analgesia. If the lameness persists, the veterinarian should re-assess the horse after an additional 5 minutes. If lameness is still apparent, the distal interphalangeal joint is not a likely primary source of pain. However, after this time the block still could result in further improvement in lameness as the local anesthetic solution diffuses to adjacent structures, thereby potentially confounding the response to any other block performed at this stage.[4,7] Intra-articular analgesia of the distal interphalangeal joint can substantially improve lameness associated with navicular disease within 5 minutes of injection,[8,9] although 20 % of horses with navicular bone

pain had a negative response to intra-articular analgesia of the distal interphalangeal joint.[8] Therefore the result of intra-articular analgesia of the distal interphalangeal joint is best interpreted in comparison with the response to analgesia of the navicular bursa.[7,8]

A slight or negative response to intra-articular analgesia of the distal interphalangeal joint does not eliminate completely a response to treatment of the joint, especially if the joint capsule is distended. For example, medication of the joint with hyaluronan and triamcinolone (10 mg) sometimes may resolve lameness that was not altered by intra-articular analgesia.

Retrieval of synovial fluid from the distal interphalangeal joint depends on the synovial fluid pressure within the joint and position of the needle. Using a dorsal approach to the joint and a 20-gauge needle, synovial fluid usually appears spontaneously in the needle hub and, if the joint capsule is distended, may flow out under pressure. Relief of this pressure may help to resolve lameness. However, not all horses with considerable pressure within the distal interphalangeal joint respond to intra-articular analgesia or medication of the joint. The pressure within the distal interphalangeal joint also increases if the contralateral limb is picked up; therefore if the contralateral limb is picked up to aid restraint of the horse for injection of the distal interphalangeal joint of the ipsilateral limb, a tendency for backflow through the needle puncture site may occur until the contralateral limb is placed on the ground.

Imaging Techniques

Radiography

Comprehensive radiographic examination of the distal interphalangeal joint should include weight-bearing dorsopalmar, lateromedial, dorsoproximal-palmarodistal oblique, and flexed oblique views of the interphalangeal joints.[10] Because intra-articular analgesia may influence pain associated with the palmar processes of the distal phalanx and the navicular bone, these structures also should be evaluated carefully.

The shape of the extensor process of the distal phalanx varies considerably among horses on lateromedial views (Fig. 34-1), but the shape usually is bilaterally symmetrical.[10] Modeling changes of the extensor process can be present without associated lameness. Care should be taken in interpretation of the bony prominences on the distal medial and lateral aspects of the middle phalanx, which always appear larger in bigger-boned horses. The distal interphalangeal joint should be inspected carefully for recognition of small osteophytes on the distal palmar aspect of the middle phalanx and the dorsoproximal aspect of the navicular bone. Joint space congruity and the shape of the proximal articular surface of the distal phalanx should be assessed carefully. A smoothly outlined depression sometimes is seen in the middle of the proximal articular surface of the distal phalanx in clinically normal horses.

The flexed oblique views—dorsal 60° lateral-palmaromedial oblique and dorsal 60° medial-palmarolateral oblique—enhance detection of periarticular new bone (Fig. 34-2) and modeling of the distal aspect of the middle phalanx. Care is

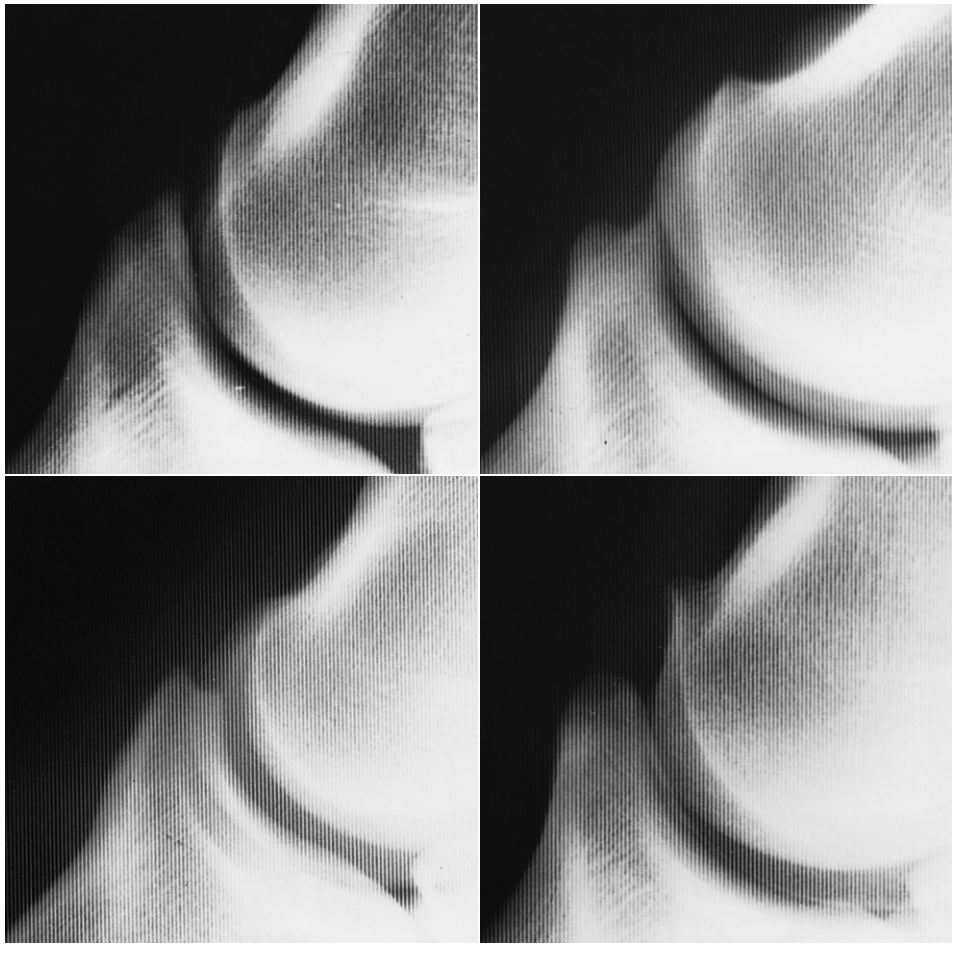

Fig. 34-1 Lateromedial radiographic views of the extensor process of normal distal phalanges. Note the variability in shape.

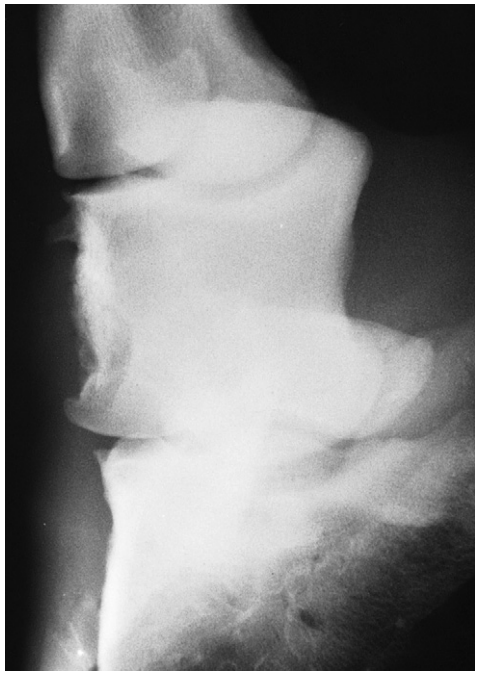

Fig. 34-2 Flexed dorsal 60° lateral-palmaromedial oblique view of the distal interphalangeal joint. There are modeling changes of the articular margins of both the the distal interphalangeal joint and proximal interphalangeal joints.

needed to differentiate between periarticular osteophytes and entheseous new bone at the insertion of the digital extensor tendon. Evaluation of the integrity and thickness of the subchondral bone plate of the middle and distal phalanges is important. Discontinuity of the subchondral bone plate may be the first radiological sign of the development of an osseous cyst–like lesion. Increased thickness of the subchondral bone plate may occur with osteoarthritis.

New bone also may develop on the dorsal aspect of the diaphysis of the middle phalanx. Smoothly outlined new bone usually is subsynovial and insignificant, whereas active-appearing, pallisading new bone usually is associated with lameness. Palisading is one of the earliest radiographic signs but often is missed. The dorsal cortex of the middle phalanx may become sclerotic (thicker), and early proliferative new bone may be seen.

Small, well-rounded mineralized opacities on the dorsoproximal aspect of the distal phalanx are not uncommon and may be present unassociated with clinical signs. Large mobile pieces are more likely to be associated with lameness.

The distal border of the navicular bone also should be evaluated carefully, because the lucent zones along the distal border represent synovial invaginations from the distal interphalangeal joint. An increase in size and number of these lucent zones has been observed with chronic synovitis of the distal interphalangeal joint.

Ultrasonography

Diagnostic ultrasonography with a 7.5-MHz transducer and a stand off is invaluable for assessment of the dorsal pouch of the distal interphalangeal joint, the amount of fluid within the joint, and the presence of synovial proliferation. Assessment of the palmar pouch is much more difficult, and evaluation of the articular cartilage is extremely limited. The structure of the collateral ligaments of the distal interphalangeal joint proximal to the hoof capsule can be assessed[11,12] and the chondrocompedal, chondrocoronal, and distal digital annular ligaments.[13]

Fig. 34-3 Dorsal three-dimensional T2* gradient echo magnetic resonance imaging of the left hind foot of a riding horse with lameness of 3 months' duration. The lameness was completely resolved by intra-articular analgesia. Radiographic examination was negative; scintigraphy revealed focal increased radiopharmaceutical uptake in the proximal aspect of the distal phalanx. A focal lesion is present in the subchondral bone plate of the distal phalanx *(arrow)*.

Nuclear Scintigraphy

Nuclear scintigraphy has been useful in the identification of horses with distal interphalangeal joint capsule and subchondral bone trauma. It appears to be rather insensitive to the identification of osteoarthritis unless the disease is advanced.[14] Abnormal uptake of the radiopharmaceutical is best detected in lateral images.

Diagnostic Arthroscopy

The dorsal and palmar pouches of the distal interphalangeal joint may be inspected arthroscopically; however, the view of joint surfaces is very limited and complete assessment of the integrity of the articular cartilage is not possible. Access may be enhanced after joint trauma with resultant instability of the joint. Affected horses usually develop long-term lameness problems. Lavage of the joint may be beneficial therapeutically in some horses with chronic distal interphalangeal joint pain without joint instability. A limited view of the distal sesamoidean impar ligament can be seen through the navicular bursa.

Magnetic Resonance Imaging

Sagittal, frontal, and transverse magnetic resonance images of the distal interphalangeal joint permit excellent evaluation of the articular cartilage and subchondral bone of the joint and the dorsal and palmar pouches of the distal interphalangeal joint capsule (Fig. 34-3). The distal sesamoidean impar ligament, DDFT, collateral ligaments of the navicular bone, and the navicular bone and bursa also may be assessed. Magnetic resonance imaging (MRI) is the imaging modality of choice for horses with chronic distal interphalangeal joint pain that does not respond adequately to medical treatment.

DIFFERENTIAL DIAGNOSIS OF PRIMARY DISTAL INTERPHALANGEAL JOINT PAIN

Synovitis

The most common cause of distal interphalangeal joint pain is synovitis, which may occur unilaterally or bilaterally. Lameness is mild to moderate in degree and palpable distention of the distal interphalangeal joint capsule usually is present. Intra-articular analgesia generally resolves the lame-

ness. Treatment should be directed to identification of any predisposing causes. Corrective trimming to restore correct foot balance and appropriate shoeing is essential for successful management. Horses with collapsed heels usually benefit substantially from properly fitted egg bar shoes (see Fig. 31-1). The timing of trimming and shoeing can be crucial: if the feet are allowed to get too long, soreness may return.

In my experience, systemic administration of hyaluronan is generally of limited benefit in the initial treatment of horses with acute or chronic lameness, but it may have a role in longer-term management. Intra-articular medication using hyaluronan, with or without short-acting corticosteroids (e.g., triamcinolone) or polysulfated glycosaminoglycans (PSGAG) is the most effective treatment method. In horses with acute synovitis with only mild lameness a single treatment with hyaluronan alone may be sufficient, but if the lameness is more severe or chronic, better results may be achieved with a combination of triamcinolone and hyaluronan. Improvement usually is evident within 5 days of treatment. If lameness persists, better results may be achieved by two additional injections using hyaluronan alone at weekly intervals. Intra-articular treatment with PSGAG is contraindicated if acute inflammation is present, but in horses with more chronic lameness, good results have been achieved using serial (up to five) weekly treatments.[15,16] PSGAG used systemically may be useful for longer-term management. Treatment is followed by walking for 7 days and then a progressive resumption of work after the final treatment. In some horses, intra-articular therapy results in long-term resolution of the problem. Others require repeated treatments at intervals as needed.

Care is necessary during injection of the distal interphalangeal joint to avoid puncturing the large vessels on the distodorsal aspect of the pastern. Puncture tends to cause localized fibrosis and future injections are more difficult. With excellent technique the distal interphalangeal joint will tolerate well many injections, and the prognosis for future soundness is good.

Osteoarthritis

Osteoarthritis without Radiographic Abnormalities

Scintigraphy may be useful in the diagnosis of early subchondral lesions associated with osteoarthritis. The definitive diagnosis of osteoarthritis without radiographic abnormalities is possible pre-mortem only by MRI (Fig. 34-4). Horses may have signs similar to those of primary synovitis, but the degree of lameness may be more severe, especially if the horse is exerted maximally, and the response to intra-articular medication tends to be shorter and less complete. MRI may show a generalized loss of signal within the articular cartilage of the distal interphalangeal joint, in addition to irregularity in the cartilage surface, with or without concurrent abnormalities in the subchondral bone. The prognosis for sustained future soundness is guarded.

Osteoarthritis with Radiographic Abnormalities

Correlation is lacking between modeling in the region of the extensor process of the distal phalanx and lameness associated with the distal interphalangeal joint. Entheseophytes at the site of insertion of the common digital extensor tendon should be differentiated from osteophytes. Entheseophytes often are not associated with current lameness. However, the presence of periarticular osteophytes on the distodorsal and palmar aspects of the middle phalanx and the proximal articular surface of the navicular bone is more likely to be associated with lameness (Figs. 34-5 and 34-6). Radiographic evidence of osteoarthritis of the distal interphalangeal joint can be seen with other causes of lameness, such as navicular disease. Horses with primary osteoarthritis of the distal interphalangeal joint may respond better to serial treatments with PSGAG than treatment with hyaluronan and corticosteroids.[15,16] However, if concurrent severe synovitis is present, primary treatment with triamcinolone and hyaluronan, followed by intra-articular PSGAG, may yield the best results. In my experience, better results are achieved in horses that are sound after intra-articular analgesia compared with horses that show partial improvement in lameness. Prognosis usually is inversely related to the severity of the radiographic abnormalities.[7]

Fig. 34-4 Sagittal three-dimensional T2* gradient echo magnetic resonance image of the foot of a Grand Prix show jumper. There is loss of the normal homogenous signal in the cartilage of the distal interphalangeal joint and irregularities in the subchondral bone in the center of the distal phalanx *(arrow)*. Mild periarticular osteophyte formation was evident on radiographs. Scintigraphic examination was unremarkable.

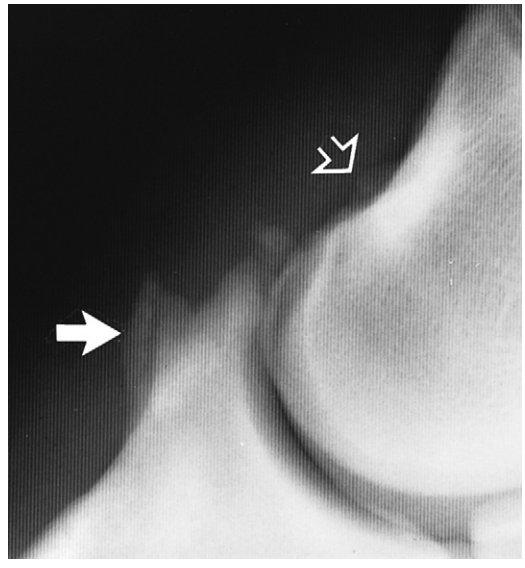

Fig. 34-5 Lateromedial radiographic view of the distal interphalangeal joint of a 7-year-old pleasure horse. Marked entheseophyte formation is present on the dorsoproximal aspect of the distal phalanx *(arrow)*. In addition, modeling of the extensor process of the distal phalanx and slight new bone formation on the distal dorsal aspect of the middle phalanx are seen *(open arrow)*.

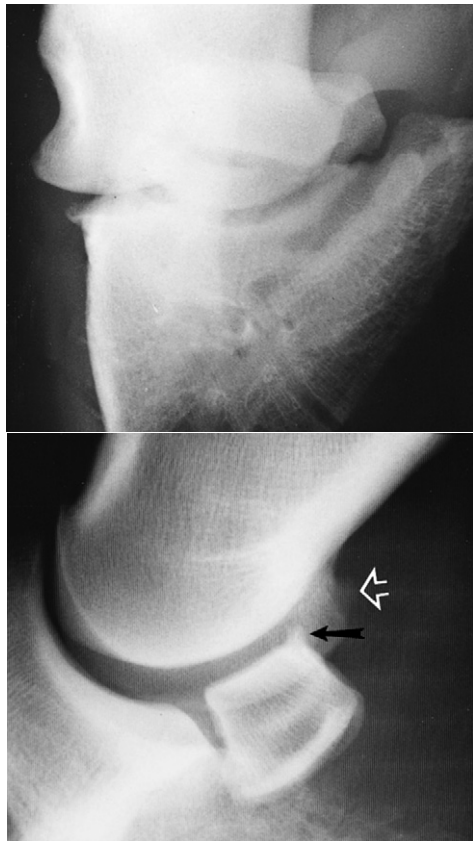

Fig. 34-6 **A,** Dorsolateral-palmaromedial oblique view of a flexed distal interphalangeal joint of an 8-year-old show jumper with bilateral forelimb lameness alleviated by intra-articular analgesia of the distal interphalangeal joints. Modeling of the proximal articular margin of the distal phalanx is seen, radiographic evidence of osteoarthritis (compare with Fig. 34-2). No radiographic abnormalities were seen in lateromedial or dorsopalmar views. **B,** Lateromedial radiographic view of the left front foot of a riding horse with lameness improved by intra-articular analgesia of the distal interphalangeal joint. An articular osteophyte is seen on the dorsoproximal aspect of the navicular bone *(arrow)*, and osteophyte formation is visible on the distal palmar aspect of the middle phalanx *(open arrow)*.

Traumatic Damage to Articular Cartilage

Sudden onset of unilateral lameness may be related to traumatic damage to the articular cartilage of the distal interphalangeal joint, with or without other concurrent soft tissue damage. Definitive diagnosis is possible only with MRI. Intra-articular medication may provide temporary relief of clinical signs but the long term prognosis is guarded.

Joint Capsule Trauma

Traumatic damage to the joint capsule, with or without subchondral bone trauma, usually results in sudden-onset, severe lameness that persists despite rest. Lameness may be accentuated markedly when the horse turns. In the acute stage, no abnormalities are detected on radiographic examination. However, periarticular new bone may develop after several weeks (Fig. 34-7). Nuclear scintigraphic examination may show generalized increased uptake of the radiopharmaceutical in the region of the distal interphalangeal joint (Fig. 34-8). Arthroscopic evaluation in these horses has been unrewarding. The response to intra-articular medication has been poor,

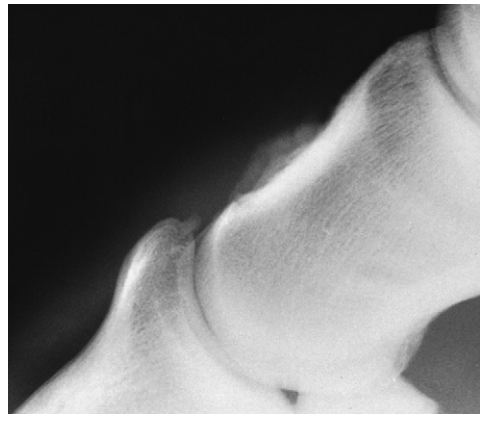

Fig. 34-7 Lateromedial radiographic view of the left front foot of a 3-year-old Thoroughbred filly with severe lameness that improved substantially after intra-articular analgesia of the distal interphalangeal joint. Entheseous new bone is seen on the dorsal aspect of the middle phalanx, in addition to the small fragment at the extensor process of the distal phalanx. Nuclear scintigraphic examination had revealed a similar pattern of uptake to that seen in Fig. 34-8.

and the prognosis for return to athletic function despite prolonged rest is guarded.

Subchondral Bone Trauma

Subchondral bone trauma may be focal or more generalized and usually is associated with unilateral lameness, which responds poorly to intra-articular medication and short periods of rest. No detectable radiological abnormalities may be apparent in the acute stage, although Ross[14] described subtle proliferative changes on the distal aspect of the middle phalanx and the proximal aspect of the distal phalanx and a variable degree of subchondral lucency in the proximal aspect of the distal phalanx. Nuclear scintigraphy is required for definitive diagnosis.[14] MRI has demonstrated a focal lesion in the proximal subchondral bone plate of the distal phalanx (see Fig. 34-3). Whether this finding may be a precursor to the development of an osseous cyst-like lesion is unknown.

Osseous Cyst-Like Lesions

Osseous cyst-like lesions occur most often in the center of the proximal aspect of the distal phalanx.[17,18] They vary in size and the presence of visible communication with the distal interphalangeal joint. Not all are detectable radiographically; some have been identified only at postmortem examination after a poor response to medical treatment of the distal interphalangeal joint.[16] Horses with large osseous cyst-like lesions may be asymptomatic but be lame at a later date. Lameness usually is unilateral, sudden in onset, and moderate to severe. Osseous cyst-like lesions may occur in young immature horses and mature athletes. Not all osseous cyst-like lesions that cause pain have active bone turnover; therefore nuclear scintigraphy may not be helpful in determining whether a long-standing osseous cyst-like lesion is the current cause of lameness. However, currently or recently developing osseous cyst-like lesions usually are associated with marked increased bone activity and may be evident on nuclear scintigraphic scans before radiographic evidence is evident. Conservative treatment may result in spontaneous resolution of the lameness, with or without resolution of the cyst, but in some horses lameness persists, with or without enlargement of the cyst. Arthroscopic access to a cyst usually

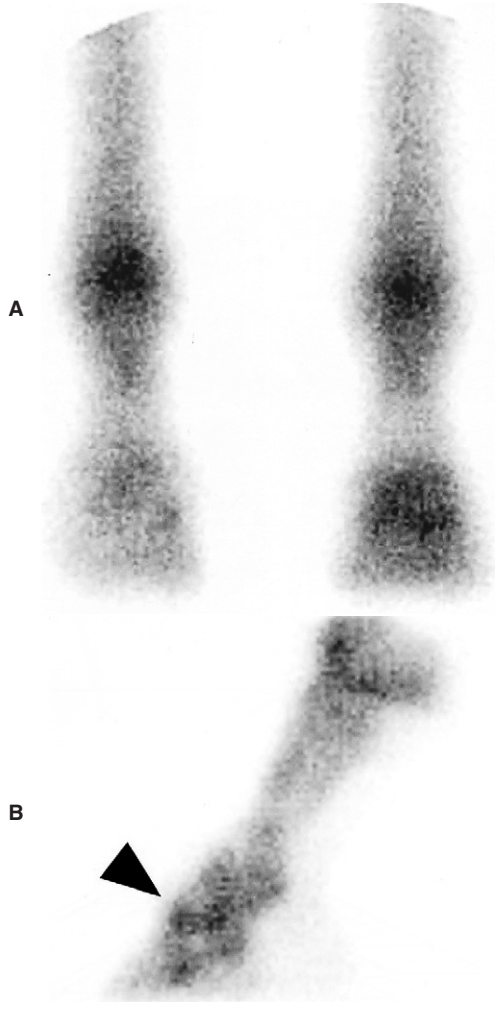

Fig. 34-8 **A,** Dorsal nuclear scintigraphic image of the front feet of a 6-year-old show jumper with sudden-onset, severe lameness markedly improved by intra-articular analgesia of the distal interphalangeal joint. The left forelimb is on the right. Radiopharmaceutical uptake is increased in the subchondral bone of the distal interphalangeal joint. **B,** Lateral scintigraphic image of the left front foot shows increased uptake of the radiopharmaceutical centered on the distal interphalangeal joint *(arrow)*. Slight periarticular new bone formation was evident radiographically. Arthroscopic evaluation revealed synovial proliferation. The horse remained lame.

is poor if it is in the central portion of the distal phalanx. Therefore surgical debridement of a well-defined osseous cyst-like lesion usually is performed through the hoof wall. Cysts located more dorsally can be debrided arthroscopically, however. Prognosis depends in part on the integrity of the overlying articular cartilage and, in some horses, lameness persists.[19,20]

Palisading New Bone on Dorsal Aspect of Middle Phalanx

Pain associated with the distal interphalangeal joint occasionally is associated with new bone formation on the dorsal aspect of the middle phalanx. The origin of this new bone is unknown. Arthroscopic evaluation of the joint may reveal crumbly bone, which is easily debrided, with resolution of lameness in some horses.[21]

Desmitis of Collateral Ligaments of Distal Interphalangeal Joint

Desmitis of the medial or lateral collateral ligament of the distal interphalangeal joint results in sudden-onset, severe unilateral lameness.[4,11,22] The desmitis is believed to be due to abnormal sliding and rotation of the joint (e.g., lateral sliding of the distal phalanx and medial rotation, which causes the medial collateral ligament to undergo great strain). Avulsion fractures also may accompany this injury. Damage to the body of the ligament results in obvious periligamentous soft tissue swelling and pain, but no palpable abnormality may exist with insertional injuries. Detection of joint instability may be possible with severe injury.[22]

Desmitis of the body of the medial or lateral collateral ligament is confirmed ultrasonographically[11,12] and is characterized by enlargement in cross-sectional area of the ligament and a diffuse reduction in echogenicity or a hypoechogenic core lesion. Modeling at the insertion on the middle phalanx may also be seen. In a few horses a well-defined radiolucent area has been identified in the distal phalanx at the site of insertion of a collateral ligament.[4,22]

Treatment is box rest for a minimum of 2 months followed by at least 4 months of walking exercise. When the medial collateral ligament is damaged, a shoe with a wide medial branch and narrow lateral branch is recommended. For lateral collateral desmitis a shoe with a wide lateral branch with a lateral extension and a narrow medial branch is preferred.[2]

The prognosis for return to athletic function is fair for horses with injuries that affect primarily the body of the ligament.[11] The prognosis for horses with avulsion injuries at the insertion of a collateral ligament on the distal phalanx, with joint instability and radiographic abnormalities, is much more guarded.[4,22]

Osseous Fragments on Dorsal Aspect of Distal Interphalangeal Joint

Small osseous fragments on the dorsoproximal aspect of the extensor process of the distal phalanx may be seen in clinically normal horses. Some are pointed proximally with a flat base and look like the tip of the extensor process, whereas others are well rounded. These fragments may represent separate centers of ossification or be a manifestation of osteochondrosis. If the fragments are seen in association with distal interphalangeal joint pain, the significance should be interpreted with care. Arthroscopic removal should be considered only if medical therapy of the joint fails.

Fracture of Extensor Process of Distal Phalanx

Fractures of the extensor process of the distal phalanx are discussed on page 316.

Articular Chip Fracture of Middle Phalanx

Articular chip fractures of the medial or lateral condyle of the middle phalanx occasionally cause acute-onset lameness.[16] Such fractures can be detected only by flexed oblique radiographic views of the distal interphalangeal joint. The prognosis after surgical removal is favorable provided joint stability has not been compromised. Surgical repair with arthroscopic guidance also is possible.

Damaged Distal Sesamoidean Impar Ligament

Focal tears in the distal sesamoidean impar ligament have been seen in association with sudden-onset, severe lameness that improves after intra-articular analgesia of the distal interphalangeal joint. In horses with acute lameness the synovial fluid may be hemorrhagic. Usually no radiological abnormalities are present. Definitive diagnosis is possible with MRI or arthroscopic evaluation of the navicular bursa.[4] The prognosis for athletic function is guarded.

FRACTURES AND FRAGMENTATION OF THE EXTENSOR PROCESS OF THE DISTAL PHALANX

• Gayle Trotter

HISTORY

Osteochondral fragments of the extensor process of the distal phalanx are classified as type IV fractures and exist as two clinical entities.[1-3] Small fragments variably are considered as traumatically induced or unusual manifestations of osteochondrosis. Large fragments are considered as traumatically induced or separate centers of ossification[2] or a variation of the traumatically induced, non-union fracture osseous bodies often observed in other locations on the distal phalanx in foals.[4]

Both types of fragments involve predominantly the front feet, and lameness may be present. Fragments can be seen as incidental radiological abnormalities. The fragments almost always are intra-articular, but they usually are non-displaced to minimally displaced.

CLINICAL AND IMAGING FINDINGS

Low-grade lameness may be present in horses with small fragments. Lameness alleviated by intra-articular analgesia of the distal interphalangeal joint was present in 16 of 21 horses with osteochondral fragments.[3] Lameness may not develop until the horse is in full work when the presence of the fragment induces synovitis. The fragment is seen readily on a lateromedial radiographic view. Many fragments are removed prophylactically.[3]

Lameness associated with large fragments may be delayed in onset; radiological abnormalities often appear chronic when lameness is first recognized. A strong fibrous union may maintain stability of the fragment until trauma causes minor fragment loosening. Lameness apparently is unrelated to fragment size.[1] I have observed large bilateral fragments in a horse with unilateral lameness, and surgery was performed to remove the smaller but clinically relevant fragment. Seven years later lameness related to the fragment developed in the opposite limb that also was corrected surgically. In some horses the hoof shape becomes triangular or pyramidal; this clinical appearance has been described as *pyramidal disease* or *buttress foot*.[2]

TREATMENT AND PROGNOSIS

Removal of small fragments under arthroscopic guidance is a well-accepted treatment with a highly favorable prognosis.[3] Lameness resolved in 14 or 16 horses with lameness associated with a small fragment, and 5 of 5 horses remained sound after the fragment was removed prophylactically.[3] Horses can return to work within 2 weeks of fragment removal if surgery is prophylactic and at 10 weeks later if preoperative lameness was present.

Guidelines for treatment of horses with large fragments are less clear. Full recovery after internal fixation of these fragments was reported for two horses in four reports (six horses).[1,3-5] At least one horse had an acute fracture.[5] Fragment removal by dorsal midline arthrotomy has been reported in 14 horses with a successful outcome in 8 (57%).[1] Of the 6 horses with unfavorable results, preoperative duration of lameness exceeded 2 years in 3 horses, suggesting more favorable results might be expected if preoperative lameness duration were shorter. Horses usually return to full work by 4 months after surgery.

OSSEOUS CYST-LIKE LESIONS IN THE DISTAL PHALANX

• Gayle Trotter and Sue J. Dyson

HISTORY

Osseous cyst-like lesions in the distal phalanx usually are unilateral, solitary, and range in location from the extensor process to deep within the weight-bearing surface. Debate continues on whether the lesions have a traumatic or developmental origin. When large bilateral lesions are present in a young horse, a developmental component is strongly suggested.[1-3]

CLINICAL AND IMAGING FINDINGS

Affected horses often are young but mature, and acute-onset, moderate to severe lameness frequently is present. Less commonly the history includes a low-grade, intermittent lameness. Occasionally osseous cyst-like lesions are identified as incidental radiological findings. Osseous cyst-like lesions sometimes are seen in older horses with pain localized to the foot. Such lesions may be clinically significant. Lameness may be exacerbated by distal limb flexion, but results of hoof tester examination usually are negative. Lesions are seen more commonly in the forelimbs, although the hindlimb was affected in 3 of 15 horses in one report.[1] Effusion of the distal interphalangeal joint occasionally is present, and large bilateral lesions sometimes are associated with a buttress foot appearance.

Lameness often is unaltered by perineural analgesia of the palmar digital nerves, but it is resolved by palmar (abaxial sesamoid) nerve blocks. Intra-articular analgesia of the distal interphalangeal joint improves lameness associated with osseous cyst-like lesions that communicate with the joint. Small articular lesions may not be detectable radiographically, but large osseous cyst-like lesions usually are readily identifiable on dorsoproximal-palmarodistal (upright pedal) views. Lesions involving the extensor process are seen readily on lateromedial projections. Smaller osseous cyst-like lesions located in a very medial or lateral location within the more weight-bearing aspect of the joint are best identified in weight-bearing dorsopalmar views. Nuclear scintigraphic examination may identify small osseous cyst-like lesions that are not identifiable radiographically. Osseous cyst-like lesions may be associated with increased uptake of radiopharmaceutical, depending on the stage of lesion development and activity of the surrounding bone. However, an osseous cyst-like lesion that is scintigraphically silent still may be a cause of lameness.

TREATMENT AND PROGNOSIS

Reports documenting results after either conservative or surgical treatment are limited. In one study, conservative treatment resulted in clinical improvement in approximately 30% of horses, but the prognosis for full recovery was guarded.[1] One report documented favorable results in a horse with bilateral extensor process fragmentation through what were presumed to be pre-existing cystic lesions in the extensor processes.[4] Anecdotally arthroscopic debridement of smaller extensor process lesions can be associated with full return to function.[5] Many lesions are not accessible by arthroscopy or arthrotomy through a dorsal approach. Debridement of distal phalanx lesions through the hoof wall has been described,[6] but this approach has not gained universal acceptance. However, good results have been achieved in a limited number of horses.[7] Intra-articular medication can be useful in the ongoing management of selected horses; occasionally conservative treatment results in a horse suitable for a limited amount of riding activity.

KERATOMAS, NEOPLASTIC, AND NON-NEOPLASTIC SPACE-OCCUPYING LESIONS IN THE HOOF

• Sue J. Dyson

Keratomas are classified as aberrant, possibly hyperplastic, keratin masses originating from epidermal horn producing cells of the coronary band.[1] They also have been defined as benign neoplasms originating from the coronary dermis.[2] As the abnormal horn tubules grow distally toward the toe, hoof wall deformation may occur with disruption of the white line, which may permit entry of infection. Expansion of the mass results in pressure necrosis of the adjacent distal phalanx. Keratomas occur most often in the dorsal half of the foot.[3] A keratoma is the most common space-occupying lesion in the hoof, but other neoplastic conditions occur occasionally and result in similar clinical signs, although they usually can be differentiated radiographically.[4-8] Other non-neoplastic space-occupying lesions, such as epidermal inclusion cysts, have been identified that can be differentiated from a keratoma only by histological examination.[9]

HISTORY

Often mild intermittent forelimb or hindlimb lameness exists, or more severe episodes of lameness associated with recurrent sub-solar abscessation may have occurred.[2,3,10-12] Neoplastic conditions may be associated with more severe lameness. Distortion of the hoof capsule may have been noted.

CLINICAL SIGNS AND DIAGNOSIS

The hoof capsule, the white line, or both may be distorted but not invariably. Pressure applied with hoof testers may elicit local pain. A variable degree of lameness is present that is alleviated by desensitization of the foot or unilateral palmar block on the side of the lesion. Radiographic examination may reveal a smoothly demarcated radiolucent defect in the margin of the distal phalanx (Fig. 34-9). This characteristic is typical of keratomas or other non-neoplastic space-occupying lesions, whereas neoplastic lesions tend to have more irregular margins and may be associated with new bone formation.[8] Infectious osteitis of the distal phalanx may have a similar appearance, although if the osteitis is chronic, marginal sclerosis with or without new bone formation may be present. The crena at the toe of the distal phalanx should not be confused with a space-occupying lesion. Lesions are best detected in dorsoproximal-palmarodistal oblique, dorsolateral-palmaromedial oblique, or dorsomedial-palmarolateral oblique views. A keratoma also may be present in the absence of radiological change with only distortion of the hoof capsule.[3] If the clinical significance of such a radiographic lesion is in doubt, nuclear scintigraphy may be helpful because such lesions usually are associated with focal increased uptake of radiopharmaceutical. Diagnostic ultrasonography also has been used to identify a keratoma at the coronary band.[13]

TREATMENT

Horses with keratomas and other benign space-occupying lesions respond well to surgical excision and have a good prognosis,[2,3,10-14] but those with neoplastic lesions have a more guarded prognosis. It is best to excise keratomas and other space-occupying lesions through a hoof wall rather than solar approach, if possible.

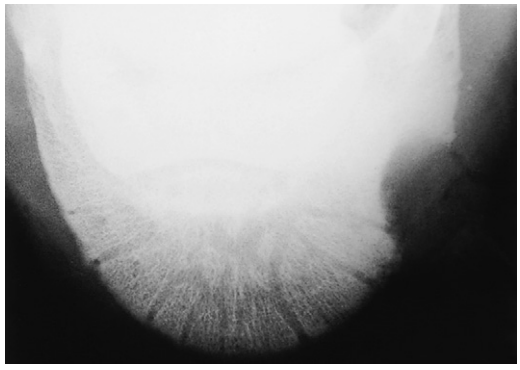

Fig. 34-9 Slightly oblique dorsoproximal-palmarodistal oblique view of a foot. A smoothly outlined semicircular defect is present in the lateral aspect of the distal phalanx, typical of a keratoma. Lateral is to the right.

FRACTURES OF THE DISTAL PHALANX

• Sue J. Dyson

Fractures of the distal phalanx are a relatively common cause of lameness in horses from all disciplines and often are the result of trauma, through a mis-step or high-speed impact, or kicking a fixed object. Fractures have been classified into six types,[1,2] but other configurations also occur. Fractures of the extensor process of the distal phalanx (type IV) are discussed elsewhere (see page 316). Fractures of the solar margin of the distal phalanx (type VI), which may occur in foals or adults, are considered separately from fractures of the body of the bone. The latter may be articular or non-articular and comprise sagittal (type III), oblique (extending from the midline to the lateral or medial solar margin) (type II), and comminuted fractures (type V), fracture of a palmar process (type I) and, less commonly, fractures of other configurations.

FRACTURE OF THE SOLAR MARGIN OF THE DISTAL PHALANX

Foals

Fractures of the palmar-most aspect of the palmar process of the distal phalanx occur commonly in foals.[3,4] These fractures originate at the incisure (which normally separates the proxi-

mal and distal palmar process angles), continue dorsally toward the toe for 1 to 3 cm and then extend to the solar margin. They are believed to be caused by shear forces generated by tension of the DDFT or by compression of the solar cortical surface and tension on the dorsal cortical surface during weight bearing. One hypothesis is that excessive trimming of the heel, thus increasing tension in the DDFT, or excessive trimming of the sole of the frog, thus increasing concussion on the distal phalanx and forces on the palmar processes, may be predisposing factors to these fractures, but this was not substantiated in a clinical study, perhaps because of the high overall incidence of fractures (34%).[5]

Clinical Signs and Diagnosis

Lameness usually is mild and extremely transitory, lasting only 1 to 2 days, and may precede radiographic identification of a fracture. No consistent response to pressure applied with hoof testers at the heel is present. Diagnosis is based on radiographic identification of a discrete osseous body at the palmar process. Fractures may be identified on lateromedial views, but dorsal 65° proximal-palmarodistal oblique views are more sensitive. Not all fractures are detectable radiographically.

Treatment and Prognosis

Even with normal management, lameness is only transitory and spontaneous healing occurs within 4 to 8 weeks with an excellent long term prognosis. Any type of shoe should be avoided, because shoe application in foals can quickly cause contracted feet.

Adult Horses

Fractures of the solar margin of the distal phalanx in adult horses occur from the quarters toward the more dorsal aspect of the distal phalanx; these fractures also are referred to as *cracking off*.[2,6] These fractures may heal, be resorbed, or persist without signs; therefore radiographic identification of solar margin fragmentation is not necessarily synonymous with identification of the source of pain causing lameness. Solar margin fractures occur almost exclusively in forelimbs. A geographical influence on the incidence of solar margin fractures is apparent, which may reflect the footing on which the horses work or other undefined factors. In the Editors' experience, these fractures are rare, whereas a study in California of distal phalanx fractures in 274 horses identified 132 (48%) horses with solar margin fractures. However, these fractures frequently occurred in association with radiographic evidence of laminitis or another potential cause of lameness, such as navicular disease.[6] Solar margin fractures as the sole potential cause of lameness were identified only in 25 horses. Irregularity and reduced opacity at the solar margin, with widening of the vascular channels, may be a predisposing factor.

Clinical Signs and Diagnosis

Horses with solar margin fractures often have a history of foot soreness. With an acute solar margin fracture, there may be increased sensitivity to hoof testers at the toe, provided that the sole is not excessively hard. Lameness is removed by perineural analgesia of the palmar nerves in the proximal pastern region or at the level of the proximal sesamoid bones. Diagnosis depends on radiographic identification of the fracture or fractures, which may be single or multiple and affect a variable extent of the solar margin. Primary solar margin fractures usually are single, whereas those that occur in association with laminitis or radiographic evidence of demineralization of the solar margin are more likely to be multiple, comminuted, or both. Fractures are identified readily in an appropriately exposed dorsoproximal-palmarodistal oblique radiographic view, but they are overlooked easily if the radiograph is over-exposed. The radiographs should be inspected carefully to detect evidence of any other potential cause of lameness that may influence treatment and prognosis.

Treatment

Horses with lameness associated with a solar margin fracture usually require prolonged rest, especially if radiographic evidence of pre-existing demineralization of the solar margin is present; healing is assessed by periodic radiographic examination. The use of a broad web shoe with a concave solar margin, with or without pads, is recommended. Limited documented long-term follow up information is available for horses with primary solar margin fractures, but the prognosis generally is favorable.

FRACTURES OF THE BODY OF THE DISTAL PHALANX

Fractures of the body of the distal phalanx occur more commonly in forelimbs than hindlimbs, but they are not uncommon in either limb.[1,2,7-9] A fracture of the distal phalanx usually results in acute-onset, severe lameness. If the fracture is articular the distal interphalangeal capsule may be distended. Pain usually occurs when pressure is applied with hoof testers, but this finding may not be a feature of a non-displaced fracture of a palmar process, especially if it has been present for more than several days. Articular fractures invariably result in continuous lameness, but a non-articular fracture of a palmar or plantar process of the distal phalanx may be associated with intermittent lameness, especially in a hindlimb. Clinical signs of an articular fracture usually reflect foot pain and thus regional analgesia often is not required, but with non-articular fractures the clinical signs may be less specific and perineural analgesia may be required to determine the source of pain. Some fractures heal only by fibrous union and not osseous union. The radiographic findings of such fractures, which do not have the appearance of a narrow, clearly defined line, should be interpreted with care because although such fractures may be unstable and therefore are a potential source of pain, the pain does not necessarily originate in the fracture.

Fractures of the distal phalanx are a common racehorse injury in North America. Fractures occur most often in the lateral aspect of the left front foot and the medial aspect of the right front foot in association with the counterclockwise direction of training and racing.

Diagnosis

Diagnosis is based on radiographic identification of a fracture (Figs. 34-10 and 34-11). A very recent non-displaced fracture may be difficult to identify radiographically unless the x-ray beam is completely parallel to the fracture line, and many oblique views may be required. The foot should be cleaned thoroughly before radiographic examination to avoid artifacts. The frog clefts may create confusing lucent lines across the distal phalanx; therefore the foot should be packed with a moldable modeling compound (e.g., PlayDoh; Hasbro, Inc., Pawtucket, RI). Many articular fractures are seen readily on dorsoproximal-palmarodistal oblique views, but fractures of the palmar processes and other less common configurations of fracture may not be apparent. A fracture of a palmar process may be evident on a lateromedial projection, but oblique views of the palmar process are required in many horses. Most of these fractures can be detected in dorsal 30° to 45° lateral (or medial)-palmarodistal oblique views with the foot either bearing weight or in the upright pedal position, but occasionally oblique views are required with the horse standing on the x-ray cassette (e.g., dorsal 45° proximal 45° lateral–palmarodistal medial oblique view). Separate centers of ossification at the palmar aspect of the palmar process should not be confused with a fracture.[10] Rarely a palmar process fracture is seen only in a palmaroproximal-palmarodistal oblique view.

Fig. 34-10 Dorsoproximal-palmarodistal oblique view of a left hind foot. The distal phalanx has a complete, articular, parasagittal fracture.

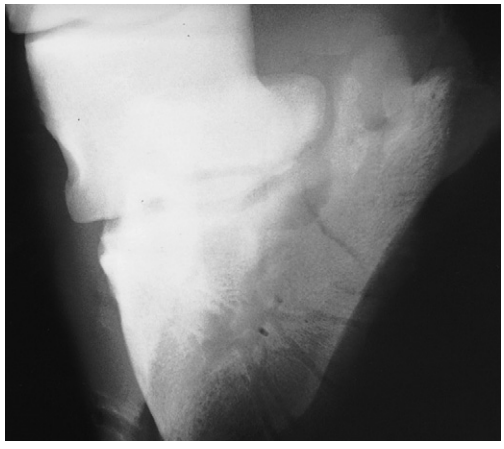

Fig. 34-11 Palmarolateral-dorsomedial oblique view of a left front foot. There is a complete, non-displaced, non-articular fracture of the medial palmar process of the distal phalanx.

Occasionally obscure incomplete, non-articular fractures of the body of the distal phalanx are identified in a palmaroproximal-palmarodistal oblique view.

Nuclear scintigraphic examination usually is unnecessary for the identification of most acute fractures, except those causing episodic lameness, but can be helpful in confirming the likely significance of older fractures.[11] Scintigraphy also is useful for identification of subchondral bone trauma unassociated with detectable radiographic abnormalities (see following text).

Treatment and Prognosis

Conservative treatment of horses with non-articular palmar process fractures, by box rest and use of a bar shoe with five clips or bar rim shoe, has a good prognosis. Complete healing of the fracture may not be evident radiographically for several months but most fractures eventually do heal. Horses with fractures extending into the medial or lateral extremity of the distal interphalangeal joint also have a good prognosis with conservative management. The horse should continue to be shod with a bar shoe when work is resumed to reduce the risks of re-injury. If a bar shoe is replaced by an open shoe, avoidance of maximum work intensity may be preferable until the hoof capsule and distal phalanx have had time to adapt to altered concussive forces. Although sagittal and oblique articular fractures of the distal phalanx often heal well if treated conservatively in horses younger than 3 years of age, the prognosis for adult horses is more guarded and internal fixation using a lag screw technique is recommended.[1,7,9,12] Prognosis depends on whether displacement at the articular margin exists; displacement inevitably results in osteoarthritis and associated lameness. Potential complications include postoperative infection and screw irritation or rejection. The use of a headless titanium Herbert cannulated screw (Zimmer Corp. Warsaw, IN) may result in fewer complications.[13] Complete fracture healing requires 6 to 12 months of convalescence with surgical management.

COMMINUTED FRACTURES

Comminuted fractures of the distal phalanx are not common[1,2,7] but do occur occasionally. Many radiographic views may be required to establish the precise configuration of the fractures and determine possible articular involvement, which results in a more guarded prognosis. The configuration of the fracture determines whether internal fixation is a viable option.[7,12]

FRACTURES OF THE DISTAL PHALANX ASSOCIATED WITH PENETRATING INJURY

A penetrating injury of the foot (see Chapter 28) may result in a fracture of the distal phalanx of any configuration. Treatment is dictated by the fracture configuration. The primary aim is to control infection. Removal of small bone fragments that otherwise may sequestrate may be preferable.

SUBCHONDRAL TRAUMA OF THE DISTAL PHALANX

Some horses have forelimb lameness, usually unilateral, associated with pain localized to the foot but no significant detectable radiological abnormality. Nuclear scintigraphic examination reveals a focal round or semi-circular area of increased uptake of the radiopharmaceutical, seen in a solar view, either medially or laterally, far removed from the distal interphalangeal joint or on a lateral view in the center of the bone in a similar location to fractures.[14] This lameness is believed to reflect subchondral bone trauma and is an injury that occurs particularly in racehorses in North America but also in other types of horses. Lameness usually is unaffected, or less commonly, only partially affected by intra-articular analgesia of the distal interphalangeal joint. In some horses, mediolateral foot balance may be a predisposing factor. Less commonly the onset of lameness is associated with trauma. The failure to identify a fracture radiographically may reflect the inherent limitations of radiography. Alternatively, such reactions may indicate that distal phalangeal fractures, especially in racehorses, may not be single-event episodes but the result of stress remodeling. Treatment comprises rest and correction of any mediolateral foot imbalance. Floating the heel of the affected side may be helpful. The prognosis is favorable given sufficient time, which is proportional to the duration of lameness before diagnosis and treatment. With acute lesions a period of 6 to 8 weeks of box rest and controlled walking exercise usually is sufficient, with a progressive increase in work intensity thereafter, but with more chronic lesions a longer period may be necessary and repeated scintigraphic evaluation may be helpful to determine when the lesion is no longer active.

PEDAL OSTEITIS: DOES IT EXIST?

• Sue J. Dyson

Pedal osteitis strictly means inflammation of the distal phalanx and has long been suggested as a cause of forelimb lameness. However, it is a poorly defined condition, previously diagnosed radiographically, characterized by focal or general demineralization around the solar margin of the distal phalanx and widening of the vascular channels, with or without abnormal lucent areas in the palmar processes. It is now recognized that considerable variation exists in the radiographic appearance of the distal phalanx in normal horses.[1-3] No good studies correlate foot conformation and the radiographic appearance of the distal phalanx. It is my impression that those horses with a particularly thin sole, especially in association with a horizontal orientation of the solar margin of the distal phalanx, seem prone to foot soreness if worked regularly on hard ground, but the source of pain has been poorly defined. Radiographic changes of the distal phalanx, once established, often persist over the long term and therefore are not synonymous with active inflammation. Radiographs represent a historical record of previous activity or injury. Scintigraphic examination of a large number of horses with foot pain occasionally has revealed evidence of abnormal bone turnover around the solar margins of the distal phalanx or confined to the palmar processes (see page 322).[4] In those horses with increased uptake of radiopharmaceutical around the solar margin of the distal phalanx in solar views, correlation with other clinical signs and radiographic findings frequently is poor unless the condition is localized to the toe, when it often reflects laminitis. The significance of this finding in the absence of localizing clinical signs remains open to question, since it also is seen in clinically normal horses. Pedal osteitis tends to have been used to describe a cause of lameness, when frequently the cause is actually undetermined.[5] The cause of pedal osteitis has not been defined, although abnormal concussion has been suggested.

Therefore I suggest that the term pedal osteitis is inappropriate and should not be used to describe a cause of lameness. Nonetheless, a variety of radiological changes of the margins of the distal phalanx can be identified, the causes of which are poorly defined. With our current state of knowledge, attribution of lameness to these radiological changes seems inappropriate unless localizing clinical signs, or concurrent evidence of ongoing inflammation with or without abnormal bone turnover, are documented scintigraphically.

Chronic laminitis may be associated with modeling of the toe of the distal phalanx and bone resorption with or without new bone on the dorsal aspect at the toe. Mineralization also has been identified on the dorsal aspects of the distal phalanx, midway between the coronary band and the solar margin; mineralization is seen best on lateromedial or slightly oblique views. This may represent mineralization in the dermal laminae or formation of new bone on the dorsal cortex of the distal phalanx. Extensive mineralization has been associated with lameness, but some roughening of the dorsal cortex in the region of the parietal sulci may be an incidental finding. Some horses with a club foot conformation develop focal loss of bone around the solar margin at the toe of the distal phalanx, and new bone on the dorsal aspect of the bone, associated with chronic lameness on hard ground. I suggest that in these conditions the radiological changes should be described and attributed to the primary cause, rather than labeled as pedal osteitis. Many horses with poor foot conformation suffer chronic lameness, probably associated with abnormal concussion to both the soft tissue and bony elements of the hoof. Identification of the primary cause of the problem and admission that the precise source or sources of pain cannot be defined is preferable to use of the term pedal osteitis, which implies a definitive diagnosis.

OSTEITIS OF THE PALMAR PROCESSES OF THE DISTAL PHALANX

• Sue J. Dyson

ANATOMY

The palmar processes or angles of the distal phalanx are prism-shaped masses that project backward on the medial and lateral aspects of the bone. Each is divided into upper and lower parts by a notch or is perforated by a foramen that leads to the dorsal groove of the distal phalanx. The cartilages of the foot attach to the proximal border of each palmar process. In a normal horse the solar and abaxial surfaces of the palmar processes are relatively smooth.

Osteitis of the palmar processes of the distal phalanx may be part of the pedal osteitis complex, related to the long toe–low heel syndrome. Its origin is poorly understood. It occurs almost exclusively in the forelimbs and may result in irregular roughening of the bone surface (Fig. 34-12, *A*).

HISTORY AND CLINICAL FINDINGS

Lameness often is bilateral, insidious in onset, and tends to be worst on hard ground, similar to navicular disease. Affected horses often have poor conformation of the feet, with low, collapsed heels. The sole may be very flat, thin, and readily compressible. If the sole is readily compressible, pressure applied with hoof testers may be resented, but this usually is not a localized response.

DIAGNOSIS

Diagnosis requires a combination of response to nerve blocks, radiography, and, ideally, nuclear scintigraphy.

Local Analgesia

Lameness is improved by perineural analgesia of the palmar digital nerves but generally is unchanged after intra-articular analgesia of the distal interphalangeal joint or analgesia of the navicular bursa.

Imaging Techniques

Radiography

The orientation of the distal phalanx should be assessed in a lateromedial view. In a normal horse the solar margin is smooth in outline and at a 5° to 10° angle to the sole, sloping proximally toward its palmar aspect.[1] In some affected horses the palmar processes are at the same level, or lower than the toe of the distal phalanx (Fig. 34-12, *B*). The solar aspect of the palmar processes may have a fluffy appearance. The shape may change with elongation of the palmar processes; this change also is seen in dorsal 60° lateral-palmaromedial oblique or dorsal 60° medial-palmarolateral oblique views (Fig. 34-13, *A*). In a dorsoproximal-palmarodistal oblique view, discrete circular lucent areas, 2 to 3 mm in diameter, may be visible in the palmar processes, or the trabecular pattern may be more obvious as a result of generalized demineralization (Fig. 34-12, *C*).

Inversion of the distal phalanx in hindlimbs, with the plantar processes lower than the toe, also has been seen in association with more proximal sites of pain causing hindlimb lameness, such as proximal suspensory desmitis.[2,3] I have not recognized this as a primary cause of hind foot pain.

Nuclear Scintigraphy

If the bony changes are active, nuclear scintigraphic evaluation may reveal increased uptake of the radiopharmaceutical in the affected palmar processes to substantiate the significance of the clinical and radiographic findings (Fig. 34-13, *B*). However, this is sometimes an incidental finding and its significance should be interpreted in light of other clinical observations.

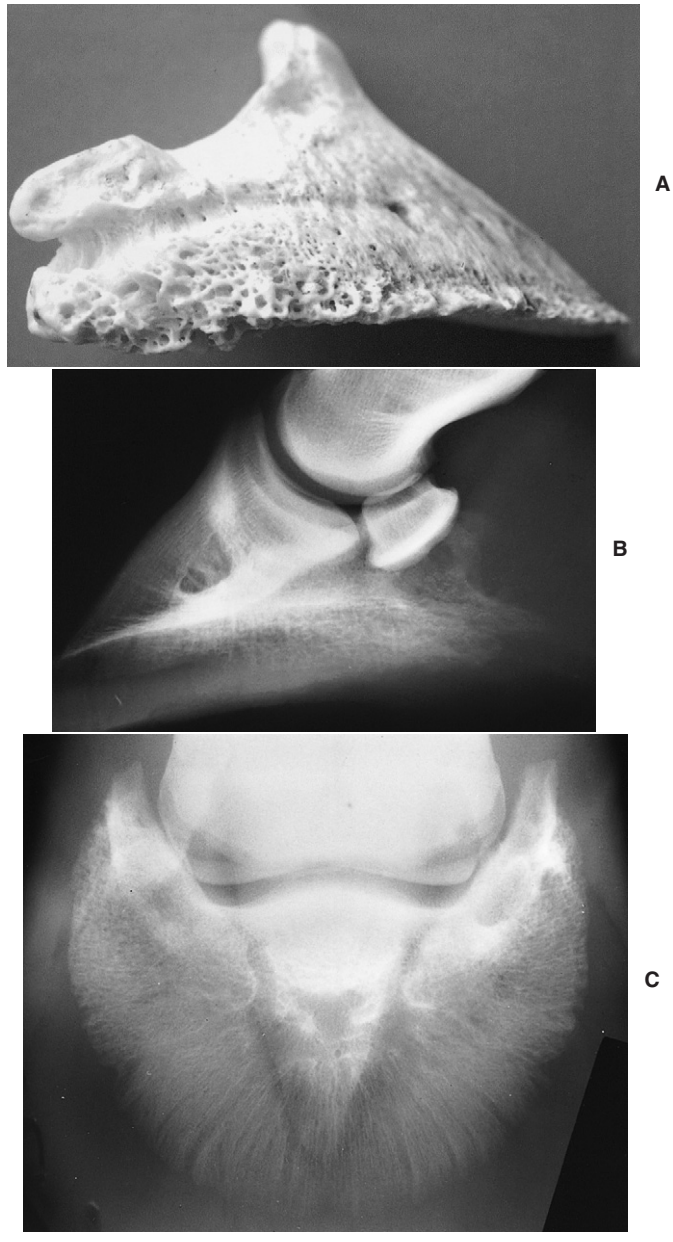

Fig. 34-12 **A,** The distal phalanx of a horse that had chronic heel pain. The palmar process has a roughened surface and new bone is evident on the solar surface. **B,** Lateromedial radiographic view of a foot of an 8-year-old Selle Francais with recurrent heel pain. Note the orientation of the solar surface of the distal phalanx: the palmar process is lower than the toe and the solar aspect of the palmar processes has an irregular contour. **C,** Dorsoproximal-palmarodistal oblique radiographic view of the same foot as shown in **B.** There is a very distinct trabecular pattern in the palmar processes, with many small lucent areas.

TREATMENT AND PROGNOSIS

Effective treatment depends on early recognition and corrective trimming and shoeing to try to restore more normal foot

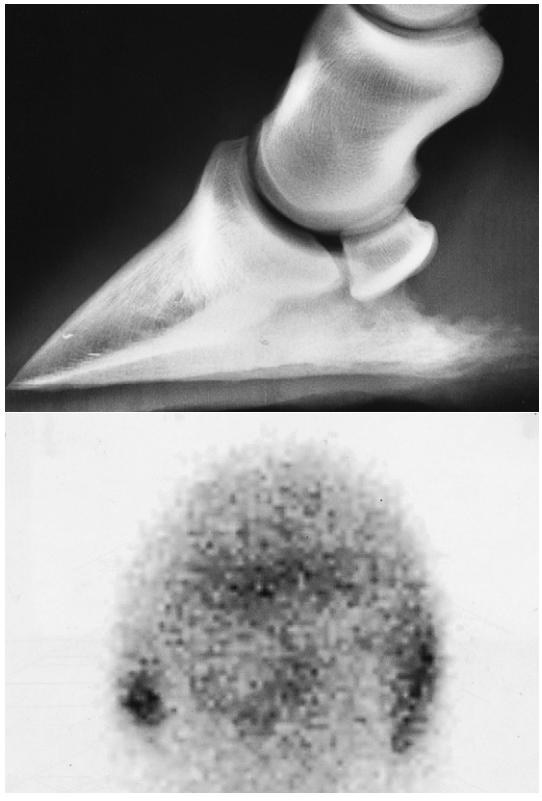

Fig. 34-13 **A,** Lateromedial radiographic view of a front foot of a 9-year-old Warmblood. Features include the abnormally elongated shape of the palmar processes, the horizontal orientation of the distal phalanx, and the thin sole. **B,** Solar scintigraphic image of the same foot in **A.** There is increased uptake of the radiopharmaceutical in the palmar processes of the distal phalanx.

conformation. The response to treatment often is slow, and during the convalescent period work on hard ground should be avoided. Horses with chronic lameness with a markedly distorted hoof capsule have a guarded prognosis. Some horses may benefit from removal of the shoes for 6 months and unrestricted exercise at pasture, provided that the hoof wall quality permits this approach and the ground is not excessively hard.

DISEASE OF THE CARTILAGES OF THE FOOT

• Sue J. Dyson

ANATOMY

The cartilages of the foot, also referred to as the *collateral cartilages of the distal phalanx*, *ungular (ungual) cartilages,* and *lateral cartilages,* originate as hyaline-type cartilage and become fibrocartilage in adults.[1] They attach to the proximal border of the palmar processes of the distal phalanx. The size and shape vary, as does the degree of ossification. The cartilages have axial extensions and they seem to provide an internal support structure for the back part of the foot.[2] An extensive network of venovenous anastomoses is present within the cartilages. Marked differences in the thickness and tissue composition exist in the front and hind feet. The cartilages of the foot tend to be thicker in forelimbs than in hindlimbs, perhaps reflecting the greater weight-bearing capacity of the forelimbs.[2] The digital cushion has more fibrous or cartilaginous tissue in forelimbs than in matched hind feet, which have more adipose and elastic tissues. There may also be breed differences. An extensive and complex relationship exists between the cartilages of the foot and the digital cushion. The combined role is thought to be energy dissipation, which is dependent on hemodynamic flow.[2]

Fig. 34-14 Dorsoproximal-palmaromedial oblique view of a foot of a mature riding horse. Lateral is to the right. Several centers of ossification of both the cartilages of the foot are present, more obvious laterally.

The cartilages of the foot are joined to adjacent structures by a variety of ligaments that vary in size and definition. The chondrocompedal ligament attaches the palmaroproximal aspect of the cartilage with the proximal phalanx, with a medial branch to the distal phalanx.[1] The chondrocoronal ligament connects the dorsal part of the cartilage with the middle phalanx.[1] Ossification of the lateral cartilage of the foot often is more extensive than the medial cartilage.[3] The term *sidebone* has been used to describe extensive ossification of one or both cartilages of the foot. Ossification may occur from more than one center of ossification. Radiolucent lines between separate centers of ossification may persist throughout life (Fig. 34-14).[4] The degree of ossification is greater in mature horses than in horses younger than 2 years of age.[3] Ossification tends to be more extensive in heavier breeds of horse than in lighter-weight horses. Among Finnhorses, ossification was more common and extensive in mares compared with male horses.[3] A correlation also was noted between the extent of ossification of the cartilages of the foot and the height of the heels of the foot.

CLINICAL SIGNS AND DIAGNOSIS

The proximal aspect of the cartilages of the foot can be palpated proximal to the coronary band. However, palpation is an unreliable indicator of both the size of the cartilages and

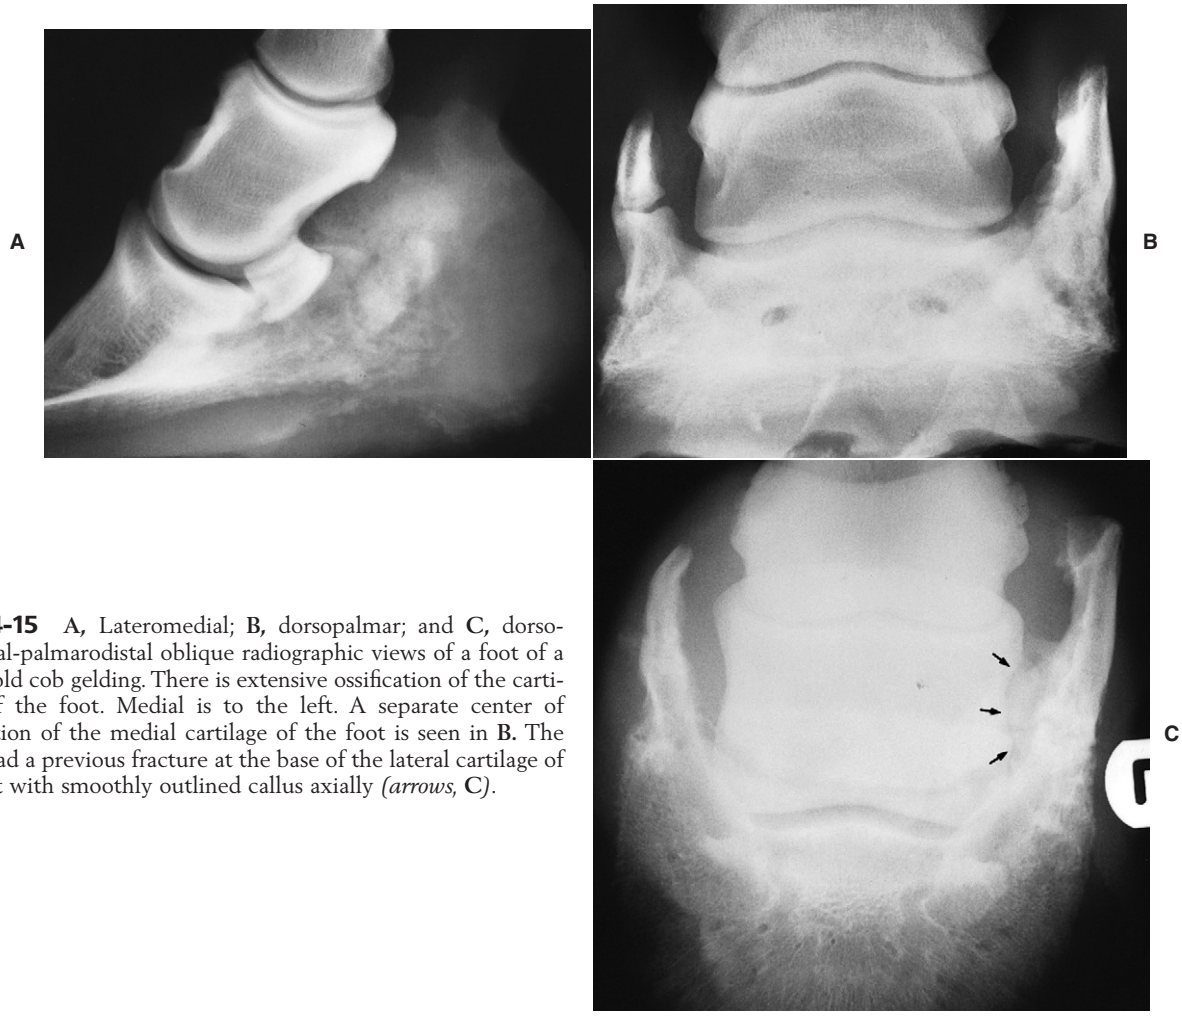

Fig. 34-15 **A,** Lateromedial; **B,** dorsopalmar; and **C,** dorsoproximal-palmarodistal oblique radiographic views of a foot of a 7-year-old cob gelding. There is extensive ossification of the cartilages of the foot. Medial is to the left. A separate center of ossification of the medial cartilage of the foot is seen in **B.** The horse had a previous fracture at the base of the lateral cartilage of the foot with smoothly outlined callus axially *(arrows,* **C***)*.

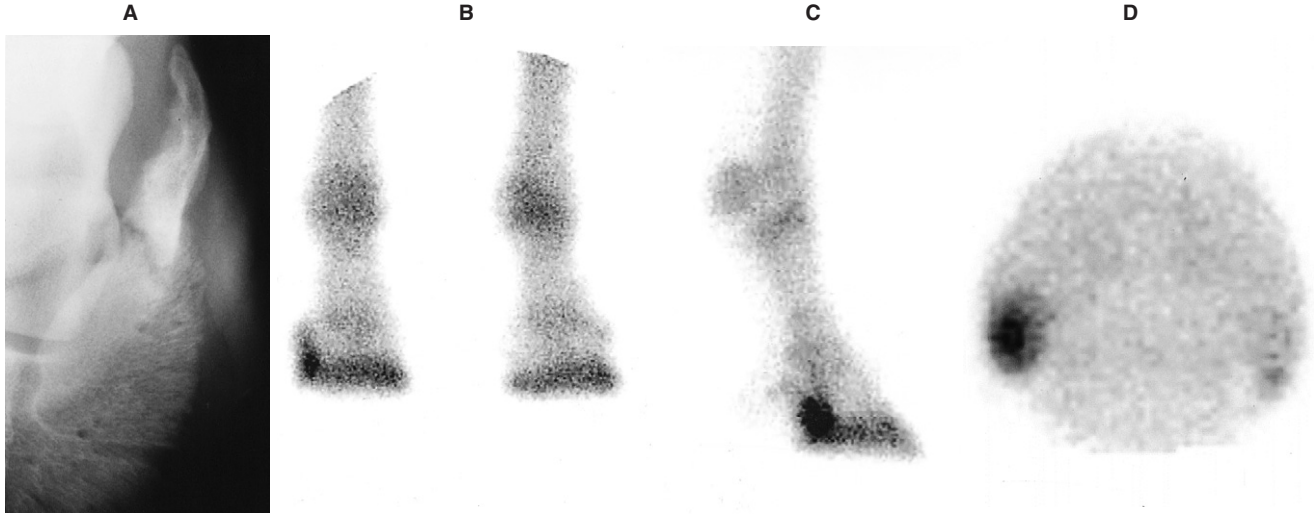

Fig. 34-16 **A,** Dorsoproximal-palmarodistal oblique radiographic view of the right front foot of a Warmblood mare with severe lameness that partially improved with perineural analgesia of the palmar nerves at the base of the proximal sesamoid bones. The lateral cartilage of the foot is fractured. **B,** Dorsal (the right front foot is on the left); **C,** lateral; and **D,** solar scintigraphic images of the same foot in **A.** There is increased uptake of the radiopharmaceutical in the lateral cartilage of the right front foot.

the degree of ossification. The degree of ossification can be established only by radiography. Lateromedial and weight-bearing dorsopalmar views are the most useful (Fig. 34-15).

Ossification of the cartilages of the foot rarely is directly associated with lameness. If ossification extends to the level of the proximal interphalangeal joint, it may be associated with a short-striding gait.

Occasionally a fracture of an ossified cartilage of the foot may be associated with lameness, but care should be taken not to confuse a radiolucent line between separate centers of ossification as a fracture. Nuclear scintigraphy may facilitate a definitive diagnosis (Fig. 34-16).

Desmitis of the chondrocompedal ligament and chondrocoronal ligaments occasionally has been recognized in association with lameness.[5] The clinical features have not been documented.

CHAPTER • 35

Laminitis

PATHOPHYSIOLOGY OF LAMINITIS

• Christopher C. Pollitt

A tough, flexible, connective tissue suspensory apparatus suspends the distal phalanx to the inside of the inner hoof wall. The surface of the inner hoof wall is folded into leaf-like lamellae (laminae) to increase the surface area of attachment between hoof and bone. A horse has laminitis when this attachment apparatus fails. Without the distal phalanx properly attached to the inside of the hoof, the weight of the horse and the forces of locomotion drive the bone down into the hoof capsule. Important arteries and veins are sheared and crushed, and the corium of the coronet and sole is damaged. Unrelenting pain in the feet and a characteristic lameness occur.

In acute laminitis the tissue suspending the distal phalanx from the inner hoof wall fails at the junction between the connective tissue of the dermis or corium (the bone side) and the basal cell layer of the epidermal lamellae (the hoof side). This junction, the basement membrane zone, appears to be the weak link in an otherwise robust and reliable structure. In acute laminitis, wholesale epidermal cell detachment from and lysis of the lamellar basement membrane occurs,[1,2] leading to failure of the lamellar anatomy and ultimately failure of the suspensory attachment between hoof and distal phalanx. A good correlation exists between the severity, as seen with the microscope (histopathology), and the degree of lameness (using the Obel [1948] grading system[3]) shown by the horse.[1] When a horse first starts to show laminitic pain, the anatomy of the hoof wall lamellae is being destroyed. The higher the lameness grade, the more severe the microscopic damage. Any activity that places stress on an already weakened lamellar attachment apparatus (such as forced exercise) causes further damage and is contraindicated. The use of nerve blocks to eliminate pain encourages locomotion and does more damage.

PATHOPHYSIOLOGY

The disintegration of the lamellar attachment apparatus is initiated during the developmental phase of laminitis. A normally tightly controlled, metabolic process is targeted, causing lamellar-specific pathological conditions during the laminitis developmental period. The continually proliferating hoof wall[4] moves past the stationary distal phalanx by a process of controlled enzymatic remodeling. New evidence suggests that the lamellar attachment apparatus is destroyed when these enzymes are activated out of control. These enzymes, metalloproteinase-2 and metalloproteinase-9 (MMP-2 and MMP-9), destroy key components of the lamellar attachment apparatus.[5]

MMP enzyme is a normal constituent of lamellar cells, and it responds to the stresses and strains of equine life and to constant growth. Sufficient MMP is manufactured locally to release epidermal cell to cell and cell to basement membrane attachment as required, maintaining the correct shape and orientation of the lamellae. From time to time injury to the basement membrane requires its lysis and reconstruction. The controlled release of MMPs and specific MMP inhibitors keeps the remodeling process in equilibrium. In horses without laminitis or those with mild disease the hoof lamellae slowly migrate distally past the stationary basement membrane that is firmly attached to the connective tissue covering the upper surface of the distal phalanx.[6]

HISTOLOGICAL GRADING

The sequences of microscopic events that initiate laminitis follow a consistent pattern, and the stages of histological laminitis can be identified by the degree of severity of these changes. Making the lamellar basement membrane clearly visible is important and requires staining lamellar tissues with periodic acid–Schiff (PAS) and periodic acid–silver methanamine

the degree of ossification. The degree of ossification can be established only by radiography. Lateromedial and weight-bearing dorsopalmar views are the most useful (Fig. 34-15).

CHAPTER • 35

Laminitis

PATHOPHYSIOLOGY OF LAMINITIS

• Christopher C. Pollitt

A tough, flexible, connective tissue suspensory apparatus suspends the distal phalanx to the inside of the inner hoof wall. The surface of the inner hoof wall is folded into leaf-like lamellae (laminae) to increase the surface area of attachment between hoof and bone. A horse has laminitis when this attachment apparatus fails. Without the distal phalanx properly attached to the inside of the hoof, the weight of the horse and the forces of locomotion drive the bone down into the hoof capsule. Important arteries and veins are sheared and crushed, and the corium of the coronet and sole is damaged. Unrelenting pain in the feet and a characteristic lameness occur.

In acute laminitis the tissue suspending the distal phalanx from the inner hoof wall fails at the junction between the connective tissue of the dermis or corium (the bone side) and the basal cell layer of the epidermal lamellae (the hoof side). This junction, the basement membrane zone, appears to be the weak link in an otherwise robust and reliable structure. In acute laminitis, wholesale epidermal cell detachment from and lysis of the lamellar basement membrane occurs,[1,2] leading to failure of the lamellar anatomy and ultimately failure of the suspensory attachment between hoof and distal phalanx. A good correlation exists between the severity, as seen with the microscope (histopathology), and the degree of lameness (using the Obel [1948] grading system[3]) shown by the horse.[1] When a horse first starts to show laminitic pain, the anatomy of the hoof wall lamellae is being destroyed. The higher the lameness grade, the more severe the microscopic damage. Any activity that places stress on an already weakened lamellar attachment apparatus (such as forced exercise) causes further damage and is contraindicated. The use of nerve blocks to eliminate pain encourages locomotion and does more damage.

PATHOPHYSIOLOGY

The disintegration of the lamellar attachment apparatus is initiated during the developmental phase of laminitis. A normally tightly controlled, metabolic process is targeted, causing lamellar-specific pathological conditions during the laminitis developmental period. The continually proliferating hoof wall[4] moves past the stationary distal phalanx by a process of controlled enzymatic remodeling. New evidence suggests that the lamellar attachment apparatus is destroyed when these enzymes are activated out of control. These enzymes, metalloproteinase-2 and metalloproteinase-9 (MMP-2 and MMP-9), destroy key components of the lamellar attachment apparatus.[5]

MMP enzyme is a normal constituent of lamellar cells, and it responds to the stresses and strains of equine life and to constant growth. Sufficient MMP is manufactured locally to release epidermal cell to cell and cell to basement membrane attachment as required, maintaining the correct shape and orientation of the lamellae. From time to time injury to the basement membrane requires its lysis and reconstruction. The controlled release of MMPs and specific MMP inhibitors keeps the remodeling process in equilibrium. In horses without laminitis or those with mild disease the hoof lamellae slowly migrate distally past the stationary basement membrane that is firmly attached to the connective tissue covering the upper surface of the distal phalanx.[6]

HISTOLOGICAL GRADING

The sequences of microscopic events that initiate laminitis follow a consistent pattern, and the stages of histological laminitis can be identified by the degree of severity of these changes. Making the lamellar basement membrane clearly visible is important and requires staining lamellar tissues with periodic acid–Schiff (PAS) and periodic acid–silver methanamine

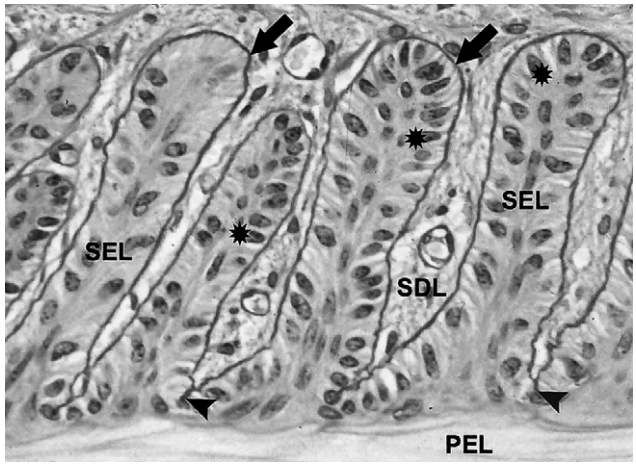

Fig. 35-1 Micrograph of normal hoof lamellae stained to highlight the basement membrane. The basement membrane (indicated by *arrows*) of each secondary epidermal lamella (*SEL*) shows as a dark line closely adhering to the secondary epidermal lamellae basal cells. Between the bases of each secondary epidermal lamellae the basement membrane penetrates deeply (*arrowheads*) and is close to the anuclear, keratinized, primary epidermal lamella (*PEL*). The secondary epidermal lamellae tips are rounded (club-shaped). The basal cell nuclei are oval (*stars*) and positioned away from the basement membrane at the apex of each cell. The long axis of each basal cell nucleus is at right angles to the long axis of the secondary epidermal lamellae. The secondary dermal lamellae (*SDL*) are filled with connective tissue even at their tips, between the secondary epidermal lamellae bases. These parameters of hoof lamellar anatomy form the basis of the histological grading system of laminitis histopathology. (Periodic acid–Schiff stain.)

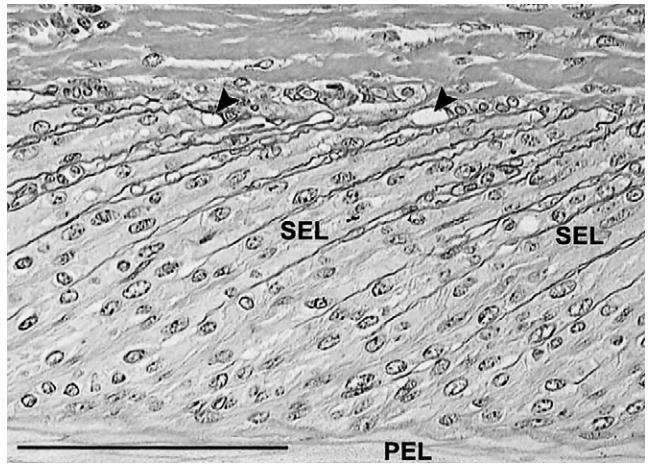

Fig. 35-2 Micrograph showing hoof lamellar tissues (stained to highlight the basement membrane) with histological grade 2 laminitis. The basement membrane is stained dark magenta. At the tips of the now pointed secondary epidermal lamellae (*SEL*s) the basement membrane has continued to lift from the underlying basal cells to form empty, teat-shaped caps (*arrowheads*). The basement membrane has disappeared from the crypts between the secondary epidermal lamellae bases. The lamellar basement membrane is no longer close to the primary epidermal lamella (*PEL*). A reduced amount of connective tissue exists between the secondary epidermal lamellae. Bar is 10 µm. (Periodic acid–Schiff stain.)

(PASM) stains or with immunohistochemical methods using basement membrane–specific antibodies.[1,2]

The normal anatomical characteristics assessed before allocating a laminitis grade to a section of lamellar hoof tissue are as follows:

- The tips of the secondary epidermal lamellae are always rounded (club-shaped) and never tapered or pointed.
- The basal cell nuclei are oval, with the long axis of the oval at a right angle to the long axis of the secondary epidermal lamellae.

These parameters can be satisfactorily assessed using routine hematoxylin and eosin staining of sections. The basement membrane penetrates deeply into the crypts between the secondary epidermal lamellae and outlines the wafer-thin, but connective tissue–filled, secondary dermal lamellae. The basement membrane tightly adheres to the basal cells of each secondary epidermal lamellae. The PAS and PASM stains show this best (Fig. 35-1).

Grade 1

As the developmental phase ends and the acute phase begins, loss of shape and normal arrangement of the lamellar basal and parabasal cells occurs. The basal cell nuclei become rounded instead of oval and take an abnormal position in the cytoplasm of the cell. The secondary epidermal lamellae become stretched, long, and thin, with tapering instead of club-shaped tips.

While the former takes place, the basement membrane of the secondary epidermal lamellae loses its attachment to the basal cells and is first noticeable at the tips of the secondary epidermal lamellae where teat-shaped bubbles of loose basement membrane form. The tissues should be stained with PAS or PASM stains to show this best.

Examination of laminitis tissues with the electron microscope confirms lysis and separation of the lamellar basement membrane. Importantly, the greater magnification shows widespread loss of basal cell hemidesmosomes and contraction of the basal cell cytoskeleton away from the inner cell surface. Electron microscopy shows why the basement membrane separates from the feet of the basal cells. The anchoring filaments that bridge the gap between the hemidesmosome and the lamina densa of the basement membrane are no longer present.[7]

Grade 2

Because the basement membrane is no longer tethered to the basal cells, it slips farther away with each cycle of weight bearing by the horse. The lamellar basement membrane begins to disappear initially at the bases of the secondary epidermal lamellae (Fig. 35-2). The basement membrane retracts from between the secondary epidermal lamellae and takes with it the connective tissue. The basement membrane–free epidermal cells appear not to be undergoing necrosis, at least initially, and clump together to form amorphous, basement membrane–free masses on either side of the lamellar axis.

Grade 3

In laminitis the worst-case scenario is a rapid and total basement membrane separation from all the epidermal lamellae. Sheets of basement membrane peel away to form aggregations of loose, isolated basement membrane in the connective tissue adjoining the lamellae. The epidermal lamellar cells are left as isolated columns with no connection whatsoever with the dermal connective tissue. The lamellar tips slide away from the basement membrane connective tissue attachments, at first microscopically, but as the degree of separation increases, the distance between hoof and distal phalanx becomes measurable in millimeters (Fig. 35-3). This manifests clinically as the sinker. Because the basement membrane is the key struc-

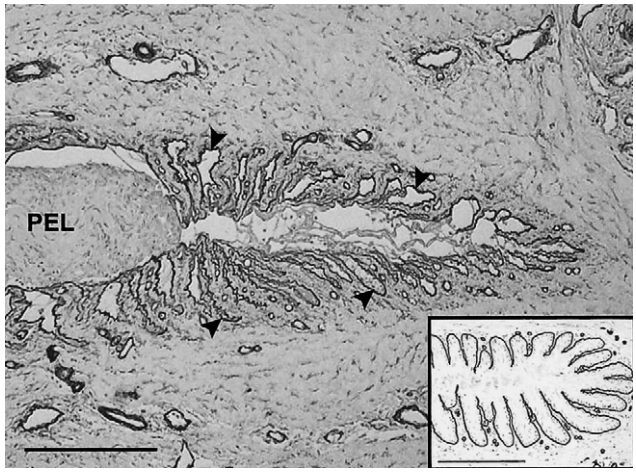

Fig. 35-3 Grade 3 histological laminitis (immunostain). The basement membrane of a lamellar tip is highlighted by type IV collagen immunostaining. The tip of the primary epidermal lamella (*PEL*) has completely detached from its basement membrane. The primary epidermal lamella basal cells are now an unattached, amorphous mass. Collapsed tubes of basement membrane, now empty of epidermal cells, are still attached to connective tissue (*arrowheads*). The primary epidermal lamella has already moved 0.03 mm from its dermal compartment and soon the distance will be measured, using a tape measure, on a radiograph. The inset shows a normal lamellar tip, immunostained the same way. Type IV collagen immunostain was used. Bars are 10 μm.

ture bridging the epidermis of the hoof to the connective tissue of the distal phalanx, wholesale loss and disorganization of the lamellar basement membrane follows and inexorably leads to the failure of hoof anatomy so characteristic of the chronic stage of laminitis.

The laminitis process also affects the lamellar capillaries. As the basement membrane and the connective tissue between the secondary epidermal lamellae disappear, so do the capillaries. They become obliterated, compressed against the edges of the primary dermal lamellae. Without capillaries in the lamellar circulation, blood bypasses the capillary bed through dilated arteriovenous shunts[8] and dramatically changes the nature of the foot circulation. A bounding pulse is detectable by finger palpation of the digital arteries. Furthermore, epidermal cell necrosis, intravascular coagulation, and edema are not present in sections made from tissues in the early stages of laminitis. The vessels in the primary dermal lamella, even the smallest, are predominantly open, without evidence of microvascular thrombi. The gross anatomical appearance of freshly dissected laminitis tissue is dryness. Sometimes the lamellae just peel apart.

ENZYMATIC THEORY OF LAMINITIS

The enzymatic theory of laminitis, based on the triggering of lamellar MMP activity, challenges the alternative view that laminitis develops because the flow of blood is impeded to cause ischemic necrosis of epidermal lamellae.[9]

How do the trigger factors of laminitis reach the lamellae? Strong evidence from three independent international laboratories now exists that the foot circulation during the developmental phase of laminitis is vasodilated.[10-12] Laminitis does not occur if the foot is in a state of vasoconstriction during the developmental phase, suggesting that the trigger factors only cause laminitis if they reach the lamellar tissues at a high enough concentration and over a long enough time.

What are the laminitis trigger factors? Because the carbohydrate overload model of laminitis is characterized by endotoxin production, a reasonable presumption seems to be that endotoxemia plays a key role in initiating laminitis. Tumor necrosis factor, along with other cytokines such as interleukin, is expressed by mononuclear phagocytes within minutes of exposure to endotoxin. The cytokine cascade originating from an inflamed leaky bowel is responsible for most of the pathological effects of endotoxemia. However, laminitis has never been triggered by the experimental administration of endotoxin into the bloodstream or the peritoneal cavity, and the actual trigger factors of laminitis remain unidentified. What appears certain in the light of recent research is that the lamellar disintegration of laminitis is mediated by the inappropriate release of excess activated MMP. But what triggers MMP release and activation?

NATURAL TRIGGER FACTORS

Many of the proposed laminitis trigger factors have been investigated using an in vitro laminitis model. Small explants of tissue were taken from the inner hoof wall of normal, freshly killed abattoir horses. After incubation for 48 hours in tissue culture medium, along with the laminitis trigger factor under investigation, each explant was subjected to tension. The force required to separate epidermal from dermal lamellae was recorded. When dermal-epidermal lamellar separation occurs readily (as occurs in field cases of laminitis), the tissue is deemed to have developed in vitro laminitis. Lamellar explants can be cultured for up to 7 days in normal medium and no lamellar separation occurs. Separating normal lamellar explants is virtually impossible. Normal explants can supports a mass of 900 g. When a non-physiological chemical, known to activate metalloproteinases (the organo-mercurial compound aminophenylmercuric acetate) was added to the explant tissue culture medium, the explants separate when only a small separating mass was applied.

Explant tissues were fixed in formalin and examined histologically for evidence of separation. Histological sections showed a clear zone of complete separation between the basement membrane and the basal cells of the epidermal lamellae. This separation is characteristic of in vitro laminitis and resembles the basement membrane lesion of natural in vivo laminitis. The presence or absence of MMP activation in the explant tissue culture medium is detected zymographically using gelatin polyacrylamide electrophoresis. Analysis of the culture medium from normal hoof explants shows that explants produce two MMPs (gelatinases) of molecular weight 92 and 72 kd. A small amount of the active forms of the MMP-2 is also present in normal horses. Incubation of normal hoof explants with aminophenylmercuric acetate results in the activation of MMP-9 and MMP-2.

Laminitis and Metalloproteinase Activity

Lamellar explants from horses with acute laminitis, cultured in medium under the same conditions, contained not only increased amounts of inactive MMP-2 and MMP-9 but also greatly increased amounts of activated MMPs. Furthermore the genes controlling hoof lamellar MMP-2 and MMP-9 activity are significantly up-regulated in tissues affected by acute laminitis. Together this provides firm circumstantial evidence that MMP activation is a pivotal event in the development of laminitis.

Metalloproteinase Inhibitors

The activity of tissue MMPs recently has been shown to correlate strongly with the degree of malignancy and invasiveness of lethal human tumors, such as malignant melanoma, breast

cancer, and colon cancer. Research in this field has generated a wide range of chemical agents capable of inhibiting MMP activity in vitro and in vivo. BB-94 (Batimastat; British Biotech, Oxford, England) blocks the activity of the laminitis MMPs in vitro and has the potential to be a useful tool in preventing and managing acute laminitis. Whether MMP inhibitors can prevent or ameliorate conditions in horses with naturally occurring laminitis has yet to be established.

Trigger Factors of Bacterial Origin

Equine lamellae, cultured in vitro, have tested resistant to virtually all known cytokines, tissue factors, and prostaglandins. Gram-negative bacterial endotoxin, extract of black walnut (*Juglans nigra*), and even anaerobic culture conditions fail to induce lamellar separation or significant MMP activation. Some notable exceptions occur, however. Factors present in the supernatant of cultures of *Streptococcus bovis* isolated from the equine cecum activate equine hoof MMP-2 and cause lamellar separation.

During grain overload *S. bovis* is the principal microorganism responsible for the rapid fermentation of carbohydrate to lactic acid in the equine hindgut.[13] In the presence of virtually unlimited substrate, the population of *S. bovis* increases exponentially. Possibly *S. bovis* and a number of other bacteria produce laminitis trigger factors[14] that cross the mucosal barrier of the hindgut and enter the circulation. These factors attach to basement membranes throughout the body, but they only cause significant damage to lamellar basement membranes because of the uniquely equine involvement in weight bearing.

Changes in Glucose Metabolism

Hoof lamellar explants kept in tissue culture medium consume glucose and readily separate when glucose is absent from the culture medium.[15] Apparently, after removal from the horse, hoof tissue relies on glucose for maintenance of adhesion between the epidermal lamellae and the basement membrane. The addition of compounds to the culture medium that block lamellar energy production from glucose also cause lamellar separation (in vitro laminitis). Ultrastructural studies of hoof lamellae undergoing glucose starvation in vitro show a specific lesion of the hemidesmosomes that bridge the dermo-epidermal junction. The longer the duration of glucose starvation, the more hemidesmosomes disappear, until lamellar separation occurs.[8] The glucose starvation lesion is quite unlike that induced by MMP activation.

The major feature of the acute metabolic stress that attends acute fulminating diseases such as colitis, metritis, and carbohydrate alimentary overload is the reduction of glucose consumption in many peripheral tissues. The purpose of this change is to maintain glucose, and therefore energy supplies, to the vital organs (heart, lung, and brain) at the expense of other tissues. Metabolic stress is regulated by the hormones insulin, glucagon, cortisol, and adrenaline. Insulin promotes glucose utilization; glucagon promotes glucose production, especially by the liver. Cortisol and adrenaline promote glucose production from other substrates and reduce glucose consumption in peripheral tissues such as skin and hoof. In vitro studies show that hoof tissues rely greatly on glucose, and the rapidly decreasing local concentrations of glucose that accompany severe physiological stress could mimic the in vitro situation and cause lamellar separation. Other epithelia may be similarly weakened, but gross separation would be manifest most readily in the hoof because of the large mechanical forces generated by weight bearing.

Evidence exists that the metabolic changes described previously do occur as a consequence of carbohydrate overload in horses developing laminitis. During the development of laminitis, an increase in blood cortisol, consistent with a metabolic change to conserve glucose, occurs. Failure of the lamellar basement membrane may be occurring via two mechanisms: lamellar MMP activation (because of arrival of bacterial laminitis trigger factors) and hemidesmosome dissolution (because of lamellar basal cell glucose uptake).

Equine Cushing's Disease

Equine Cushing's disease, caused by a pituitary adenoma, results in excess production of adrenocorticotropic hormone, producing a hormone imbalance that creates a tissue resistance to insulin, disturbing glucose uptake in hoof lamellae and causing an insidious, relentlessly developing chronic laminitis. Affected horses and ponies often have higher than normal serum concentrations of glucose, cortisone, and insulin. This laminitis is usually refractory to treatment. However, promising results have been obtained after administration of pergolide mesylate (Permax, Eli Lilly), a drug registered for human use.[16] Doses in the range of 1 to 2 mg/horse/day have been recommended. The drug reduces production in the pituitary gland of the adrenocorticotropic hormone, which controls cortisol production in the adrenal gland. With cortisol under control, insulin responsiveness in hoof lamellae returns and the laminitis stabilizes.

Exogenous Corticosteroids and Laminitis

Clinically an association has been observed between systemic or intra-articular administration of corticosteroids, including triamcinolone and methylprednisolone acetate, and the development of laminitis in otherwise apparently healthy horses.[17] However, a cause and effect has yet to be proved. Intra-muscular administration of 60 mg of triamcinolone daily for 7 days failed to induce laminitis in healthy horses. Nonetheless, clinicians must be aware of the risks associated with exogenously administered corticosteroids.

DIAGNOSIS OF LAMINITIS

• Sue J. Dyson

Laminitis is characterized by an acute onset lameness of variable severity involving one or more feet. Most often both front feet are affected, with or without the hind feet, but unilateral laminitis does occur, usually caused by excessive load bearing because of severe contralateral limb lameness. Occasionally the hind feet are affected, without involvement of the front feet. The horse may be extremely reluctant to move and, if persuaded to move, tends to land heel first, with a short, pottery gait, with the hindlimbs placed unusually far underneath the body. Lameness may be accentuated as the horse turns. Lameness is worse on hard ground than on soft ground. Although many horses show severe lameness, in those with milder lameness the lameness may be less typical, although suggestive of foot pain.

Usually, but not invariably, a significant increase in digital pulse amplitudes occurs, and in the acute phase the affected feet may be hot. Pressure or percussion applied to the feet, especially in the toe region, usually causes pain, but if the horn is excessively hard, the horse may not react. Careful palpation around the coronary band may reveal an unusual depression associated with sinking of the distal phalanx. An area of unusual softness may herald infection tracking proximally in association with laminitis complicated by sub-mural abscessation.

Clinical signs are usually diagnostic, except in less severely affected horses or those with involvement of only the hind feet, when the characteristics of the lameness may be suggestive of foot pain, but not necessarily pathognomonic for laminitis. The response to perineural analgesia varies and is not associated necessarily with the degree of pain and lameness. Apparent desensitization of the foot with palmar (abaxial sesamoid) nerve blocks may have absolutely no effect on the lameness in some horses, although in others some improvement may occur.

Because laminitis frequently develops secondarily to a primary disease process, it is critical to evaluate the entire horse and to identify any predisposing factors that require treatment, such as endotoxemia, septic metritis, or Cushing's disease.

Radiographic examination is critical for establishing a treatment protocol and prognosis. Although rotation of the distal phalanx often can be managed successfully, sinking warrants an extremely guarded prognosis. Lateromedial views help to determine whether the condition is acute or an exacerbation of a more chronic problem. Abnormal thickness of the dorsal hoof wall, with or without modeling of the toe of the distal phalanx, implies previous disease. Lateromedial views are also important to establish the baseline position of the distal phalanx within the hoof capsule. Dorsopalmar projections may be useful for assessing mediolateral balance in horses with chronic, unstable laminitis. If the foot is grossly misshapen, trimming it first is preferable; otherwise, a false impression of severe rotation of the distal phalanx, which merely reflects the abnormal hoof wall growth, may occur.

Standardizing the procedure (positioning, film-focus distance, and exposure factors) is essential to make meaningful comparisons between examinations. To enhance soft tissue detail, use soft exposures or radiographic film with a large grey scale. A grid is usually unnecessary. A horizontal x-ray beam should be perpendicular to the sagittal plane of the digit, centered between the toe and the heel, about 2 cm distal to the coronary band. Radiodense markers are placed on the dorsal aspect of the hoof wall and on the sole at the apex of the frog. The marker on the dorsal hoof wall should extend from the coronary band distally. This helps to establish the orientation of the distal phalanx and its position relative to the coronary band. Radiographic abnormalities include rotation or sinking of the distal phalanx, increased thickness of the dorsal hoof wall, and radiolucent lines in the dorsal hoof wall, reflecting necrotic tissue or gas caused by infection or hoof wall separation.

MEDICAL THERAPY OF LAMINITIS

• Christoper C. Pollitt

Laminitis often develops because disease is occurring in a body compartment other than the foot. Thus it is of paramount importance that the primary disease is treated urgently and effectively. If the duration and severity of the primary disease can be reduced by intensive therapy, a strong chance exists that the severity of lamellar pathology also may be reduced, thus improving the prognosis for the horse. Severe laminitis is sometimes the outcome despite the best of current therapy, but some horses can exhibit early, mild clinical signs of laminitis yet recover with no long-term ill effects.

Currently no therapeutic regime is able to arrest or block the triggering of laminitis, and damage is what influences the outcome.[1] An effective laminitis preventive may emerge when the mechanism behind the disintegration of the anatomy of the hoof wall lamellae is fully understood. The discovery that a class of enzymes appears to be involved in the lamellar failure of laminitis[2] offers hope that proteinase inhibitor therapy, specifically targeted at hoof wall matrix metalloproteinases, may arrest laminitis development. Horses that were able to keep the feet cool during the laminitis developmental period did not develop laminitis,[3] suggesting that cryotherapy may be a useful preventive, first-aid measure. Bacteria are a source of laminitis trigger factors,[4] so effective anti-microbial therapy is a treatment priority.

Horses diagnosed with toxemia during enteritis, colitis, strangulating colic, pleuropneumonia, retained placenta, infectious metritis, and grain overload are at high risk of developing laminitis, and ideally, medical therapy and mechanical support for the distal phalanx should be initiated before the clinical signs of foot pain appear. Addressing laminitis as soon as it appears in a sick horse should always be regarded as an emergency procedure. Even then treatment may be too late. Anti-endotoxin hyperimmune serum (Polymmune J, Veterinary Dynamics Inc., Templeton, CA) should be included in the intravenous fluid therapy for horses with, or at risk of developing, endotoxemia.

Non-steroidal anti-inflammatory drugs (NSAIDs) are required to reduce inflammation and foot pain. Flunixin

meglumine (0.25 mg/kg tid intravenously [IV] or 1.1 mg/kg bid IV) has a proven anti-endotoxin effect by reducing prostaglandin production via cyclooxygenase inhibition[5] and is valuable. Horses receiving flunixin meglumine that subsequently are given endotoxin had significantly lower blood prostaglandin and lactate concentrations and reduced clinical signs than control horses. However, the effectiveness of flunixin or any NSAID as an anti-laminitis agent has never been tested. A proven cause-and-effect link between endotoxemia and laminitis has never been established.[6]

Phenylbutazone (4.4 mg/kg IV or orally every 12 hours) appears to be a potent NSAID for the control of foot pain and is popular with most clinicians. Phenylbutazone and flunixin meglumine at the lower dose rate can be used concurrently; the former to control severe foot pain and the latter to control the effects of endotoxemia. Intravenously administered ketoprofen (2.2 mg/kg bid) can be used interchangeably with flunixin. Horses with acute laminitis usually require NSAID therapy for at least 2 weeks, and because of its low cost, phenylbutazone (2.2 mg/kg) is the best choice for maintenance therapy. Care must be taken not to over-dose small ponies.

However, NSAIDs have been administered to horses during experimental induction of laminitis without altering the outcome; laminitis still occurred.[7] In vitro studies of laminitis indicate that MMP activation is slightly potentiated when NSAIDs are present in the culture system. When the laminitis process is triggered, virtually nothing by way of drug therapy stops its progress. The administration of phenylbutazone during the developmental and acute stages reduces foot pain and creates a more comfortable-looking horse, but the disease continues unabated. This creates an ethical dilemma: balancing the need to alleviate pain and suffering against the realization that most of what is administered is only palliative. When NSAIDs are in use, the patient should be confined to a stall with deep bedding. Exercise is contraindicated while the horse is under the influence of analgesics.

CRYOTHERAPY

Distal limb cryotherapy to cool the foot and induce digital vasoconstriction may be a useful preventive strategy in the developmental phase of laminitis. Cold-induced, digital vasoconstriction during the laminitis developmental phase may limit exposure to circulating trigger factors and reduce the impact on lamellar anatomy.[3] Cryotherapy may bestow additional protection by slowing the kinetics of lamellar enzyme activity below a threshold that causes damage. Nuclear scintigraphic studies showed cold therapy significantly decreased perfusion of the soft tissues of a horse's foot within 30 minutes of the application of external cold.[8] Limited anecdotal evidence from practicing veterinarians suggests that cryotherapy does halt the development of the disease. An ice water footbath was used successfully to treat a pony in the developmental stage of acute laminitis after experimental cecal catheterization.[9] Cryotherapy for laminitis requires maintaining the limbs from the proximal metacarpal region and distad in a slurry of crushed ice or a circulating cold water (4° C) apparatus continuously for 24 hours or even longer if the period of septic shock, pyrexia, and digital vasodilation persists. Cryotherapy is safe, well tolerated, and economical. Unlike people, horses do not find cold therapy noxious. We have kept the forelimbs of normal horses in a slurry of ice and water continuously for 2 days, with no immediate or long-term ill effect. Initial experiments support the effectiveness of cryotherapy for halting laminitis onset.[7] Keeping a horse with its feet in ice boots requires an extraordinary amount of time and dedication but can be done and, if laminitis is prevented, is worth the effort.

DIGITAL BLOOD FLOW THERAPY

Vasodilatory therapy and hot water footbaths during the developmental phase of laminitis are contraindicated. Drugs with vasodilator action such as isoxsuprine hydrochloride, acepromazine, and glyceryl trinitrate (applied as patches to the pastern) may be beneficial after lamellar damage has occurred, when healing is required, but should be administered with caution during the developmental phase. However, neither orally administered isoxsuprine nor pentoxifylline produced significant improvement in digital or lamellar blood flow when tested under controlled conditions using ultrasound and laser Doppler flowmetry.[6,10,11] Intravenously administered acepromazine maleate, long held to be effective at increasing lamellar microcirculatory blood flow, had no significant effect when tested by laser flowmetry.[12] Glyceryl trinitrate tested in the same way, against a black walnut extract laminitis induction model, had no effect on lamellar blood flow.[13] The continued veterinary use of these drugs in the therapy of laminitis is questionable.

Exercise of an intensity that raises core temperature and local analgesia of the palmar or plantar nerves result in hoof wall heating (and by implication vasodilation) and are contraindicated during the developmental stage of laminitis. Local analgesia of the foot to reduce foot pain and encourage the horse to walk may result in greater lamellar damage than in a rested, confined horse. Forced exercise of any horse with acute laminitis is strongly contraindicated.

FREE RADICAL SCAVENGERS

Dimethylsulfoxide (DMSO) may be given intravenously for its free radical scavenging and anti-inflammatory effects. DMSO (90% solution) mixed with polyionic solutions and 5% dextrose is best administered slowly at about 8 L per hour. The concentration of DMSO must remain below 20% to avoid the risk of intravascular hemolysis. However, despite the potential of DMSO, its promise as an effective laminitis therapy has not been fulfilled. No evidence exists that ischemia, reperfusion injury, and the generation of free radicals are involved in the pathogenesis of most horses with laminitis.

RECOMMENDED TREATMENT STRATEGY

The list of pharmaceuticals that have been administered to horses with laminitis is long, and apart from the NSAIDs none have achieved particular prominence. I recommend aggressive treatment of the primary disease, using fluids and electrolytes, antibiotics and NSAIDs, and uterine lavage for horses with infectious metritis or retained placenta.

The administration of 4 L of mineral oil four times a day may be beneficial in laminitis developing from grain overload. Mineral oil has a laxative effect and is said to block the absorption of toxins in the large intestine.[14] Activated charcoal is an effective adsorbent of a range of toxins and may be useful in cases of grain overload if administered promptly. In Australia, doses of 1 to 5 g/kg/day have been used to treat plant toxicoses in large animals. The higher dose is indicated if a large quantity of grain has been consumed. However, activated charcoal has not been tested against alimentary laminitis, so its true effectiveness is unknown. The application of cold therapy to the front feet, strict confinement to a stall with a deep bedding of sand or shavings and mechanical support for the distal phalanx are also recommended.

Laminitis developing secondary to Cushing's disease is usually refractory to treatment unless treated using pergolide mesylate (1 to 2 mg/horse/day) to reduce adrenocorticotropic

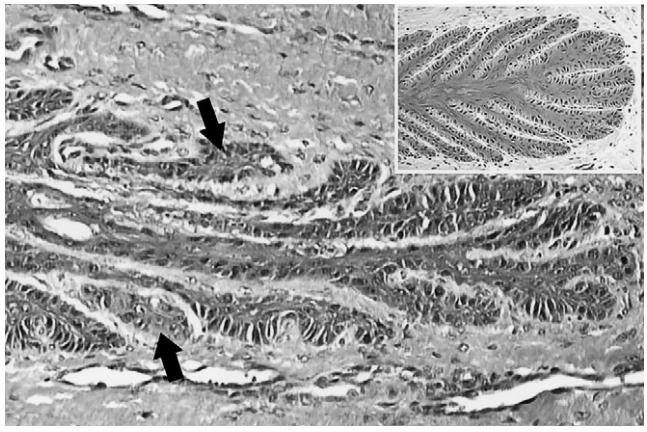

Fig. 35-4 Histopathological section of chronic laminitis in the lamellar tip. Despite an apparent clinical recovery by the horse, biopsies of hoof lamellae show that the normal architecture has not been restored. The lamellar tips are distorted and weak, and some secondary epidermal lamellae (*arrows*) are not connected to the primary epidermal lamella. The *inset* shows the tip of a normal lamella. (Hematoxylin-eosin stain.)

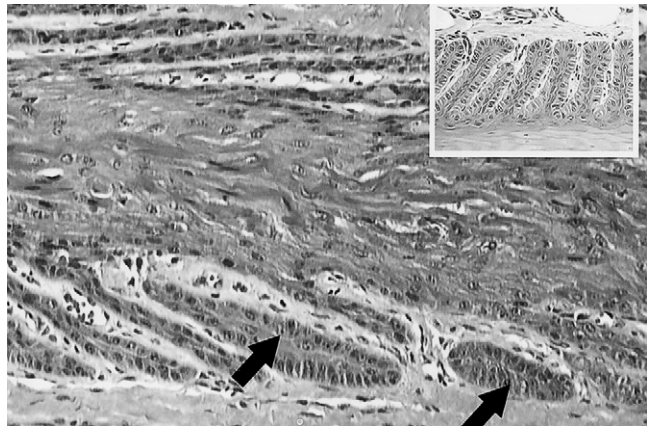

Fig. 35-5 Histopathological section of chronic laminitis in the mid-lamellar region. Some secondary epidermal lamellae (*arrows*) are not connected to the primary epidermal lamella. Laminitis has compromised the surface area of attachment, leaving the horse prone to recurrent bouts of the disease. The *inset* shows normal lamellae. (Hematoxylin-eosin stain.)

hormone production in the pituitary gland and thus reducing adrenal cortisol production.[15] This restores insulin responsiveness, permitting more normal glucose use by the hoof lamellae.

Some horses that show the clinical signs of acute laminitis recover completely if treated promptly using a combination of rational medical therapy and mechanical support. However, horses recovering from even the mildest laminitis should be allowed to rest and observed closely. If no radiographic evidence of palmar displacement of the distal phalanx within the hoof capsule is apparent, and the digital pulse amplitude is not palpably exaggerated 48 hours after treatment has ceased, the horse can be returned to its usual function with caution.

If radiographs do show displacement of the distal phalanx, then the prognosis must be more guarded. Horses with a mild increase in the distance between the distal phalanx and the dorsal hoof wall, with or without rotation of the distal phalanx, often make an apparent recovery and remain sound indefinitely. However, horses with marginally greater displacement and rotation of the distal phalanx make only partial recoveries and often have a history of intermittent lameness, especially after exercise. Histopathological examination of the hoof lamellae of partially recovered horses showed a reduction in the number of secondary epidermal lamellae. Many of the secondary epidermal lamellae had distorted, abnormal shapes even several years after the initial episode of laminitis. Some secondary epidermal lamellae become isolated from the attachment to the primary epidermal lamella and exist as isolated, unattached islands adrift in the lamellar connective tissue (Figs. 35-4 and 35-5). If the surface area of the lamellae of the inner hoof wall is reduced after laminitis, the effectiveness of the lamellar distal phalanx suspensory mechanism must also be reduced. Horses developing laminitis associated with significant initial lamellar destruction, as manifest by radiographic displacement of the distal phalanx, appear never to make a complete anatomical recovery and are prone to recurrent episodes of foot pain.

Ultimately the prognosis is directly proportional to the severity and extent of lamellar pathological condition. Horses with more than 15° of rotation, accompanied by downward displacement of the distal phalanx within the hoof capsule, within 4 to 6 weeks of the initial episode of laminitis have a poor prognosis. Prolapse of the distal phalanx through an already necrotic sole, accompanied by sub-solar and sub-lamellar infection, usually occurs. Pus discharges from the coronet and the heels. Osteitis and lysis of the distal margin of the distal phalanx develop. Such horses require months of expensive supportive care and surgery and although occasionally a horse does make a surprisingly good recovery, most suffer months of crippling foot pain and recumbency and eventually require euthanasia on humane grounds.

The road to recovery after a serious bout of laminitis is a rocky one. The extent of lamellar pathology lies hidden beneath the hoof wall, and we can only guess at what is really going on. Radiographs and the initial degree of pain expressed by the horse, often masked by analgesics such as phenylbutazone, give valuable clues. However, relentless sinking of the distal phalanx in the hoof capsule and involvement of all four feet make recovery unlikely.

HOOF CARE OF A LAMINITIC HORSE

• Frank A. Nickels

Hoof care in all phases of laminitis is extremely important. The goal is to reduce stress to the damaged lamellae by minimizing the distracting forces affecting the displacement of the distal phalanx (rotation or sinking). These distracting forces are the weight of the horse, the constant pull of the deep digital flexor tendon (DDFT), and the leverage on the toe of the hoof capsule. Nothing can be done about the horse's weight, but absolute stall rest can alter the increased stress associated with movement. Some of the weight of the horse can be partially redirected away from the hoof wall in the resting horse by removing the shoes. Recruiting other parts of the ground surface of the hoof to bear weight can also reduce stress on the hoof wall with the use of particular bedding or sole pads. Elevating the heel reduces the stress on the DDFT. In horses with rapid rotation or penetration through the corium of the sole, a tenotomy of the DDFT is recommended to eliminate any pull on the distal phalanx (see page 333). Finally, beveling (unweighting) the toe with a rasp helps increase ease of breakover, thereby decreasing the stress created by the leverage of the toe. Baseline radiography (see page 329) is important to establish the relationship between the distal phalanx and the hoof capsule. I place both front feet on two 8 × 13 × 18-cm wooden blocks in the surface of which are radiodense markers. I also place small spherical radiodense markers at the dorsal aspect of the coronary band and at the apex of the frog and a linear marker on the dorsal aspect of the hoof capsule (Fig. 35-6).

In the developmental phase the goal is to recognize the possibility of disease and be prepared if the disease occurs. The goal is to prevent and/or minimize distal displacement of the distal phalanx. This can be partially accomplished by transferring weight from the wall to the solar surface of the foot thereby reducing the pull of the DDFT. If the horse is shod, the shoes should be removed carefully by rasping off each nail clinch, then removing each nail separately with a creased nail puller. This helps to reduce mechanical trauma, pain, and discomfort associated with shoe removal. Then the toe of the hoof capsule should be unweighted by beveling it with a rasp back to a point 2.5 to 4 cm in front of the true apex of the frog depending on the size of the hoof. In a normal horse the frog can serve as a reference point for the tip of the distal phalanx, which is located approximately 1.9 to 2.5 cm dorsal to the apex of the frog.

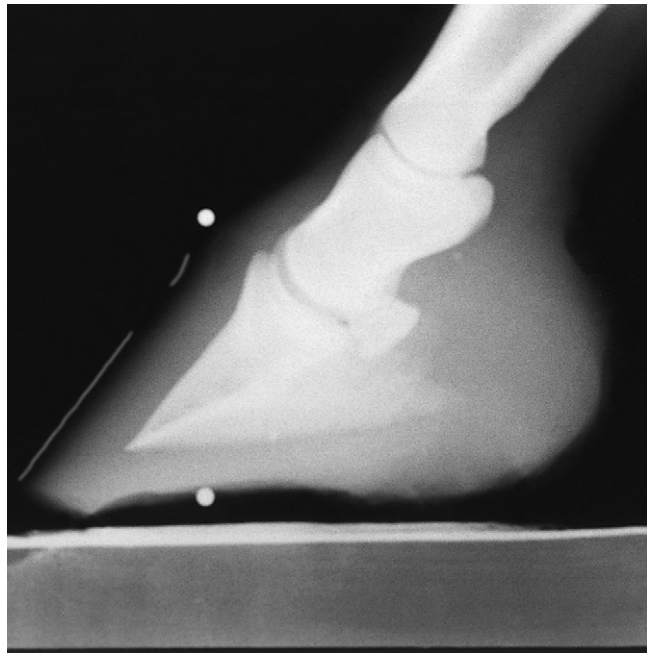

Fig. 35-6 Lateromedial radiographic view of a normal foot. There are circular radiodense markers at the coronary band and at the apex of the frog and a radiodense tape on the dorsal aspect of the hoof capsule. Radiodense wire is also embedded in the surface of the wooden block on which the foot is resting.

Soft bedding materials, such as sand or damp peat, provide good support and relief, but they may be difficult and expensive to maintain. Alternatively, frog or sole supports can be used. Frog supports using Lily pads (Kentucky Blacksmith, Shelbyville, KY) or roll gauze taped to the frog were commonly used in the past, but they are being replaced by pads that adapt to the entire solar surface, providing more support and comfort to the entire foot.

High-density foam is now one of the most practical and economical methods for providing solar support. Sheets of 5-cm extruded foam house insulation (Styrofoam scoreboard, Dow Chemical, Midland, MI) can be purchased at home centers or building supply companies. For foam application the clinician stands the horse on small precut rectangular blocks of the foam insulation, then cuts and shapes it to the foot using a serrated bread knife. The clinician then attaches the foot-formed pad with duct tape (Fig. 35-7). In the acute phase, two layers of foam are used to provide more comfort and to elevate the heel. One layer is applied and then removed within 24 hours when it becomes compressed. Ideally, this layer will compress evenly to approximately 2 cm. If the foam compresses more unevenly at the toe than the heel, the clinician should remove the excess from the ventral surface with a rasp to make it uniform. Removing the dorsal portion of this pad reduces the pressure over the most painful area of the sole. This trimmed pad and another foam layer are then attached to the foot with duct tape to raise the heel and provide more cushion to an area of the foot that can tolerate weight bearing (Fig. 35-8). The foam pads should be replaced every 4 to 5 days or as needed. A commercial wedge pad system (Redden Ultimate, Kentucky Blacksmith) using rubber impression material (Advanced Cushion Support, Kentucky Blacksmith) is available and works well in horses that are not getting adequate support from the foam insulation. These

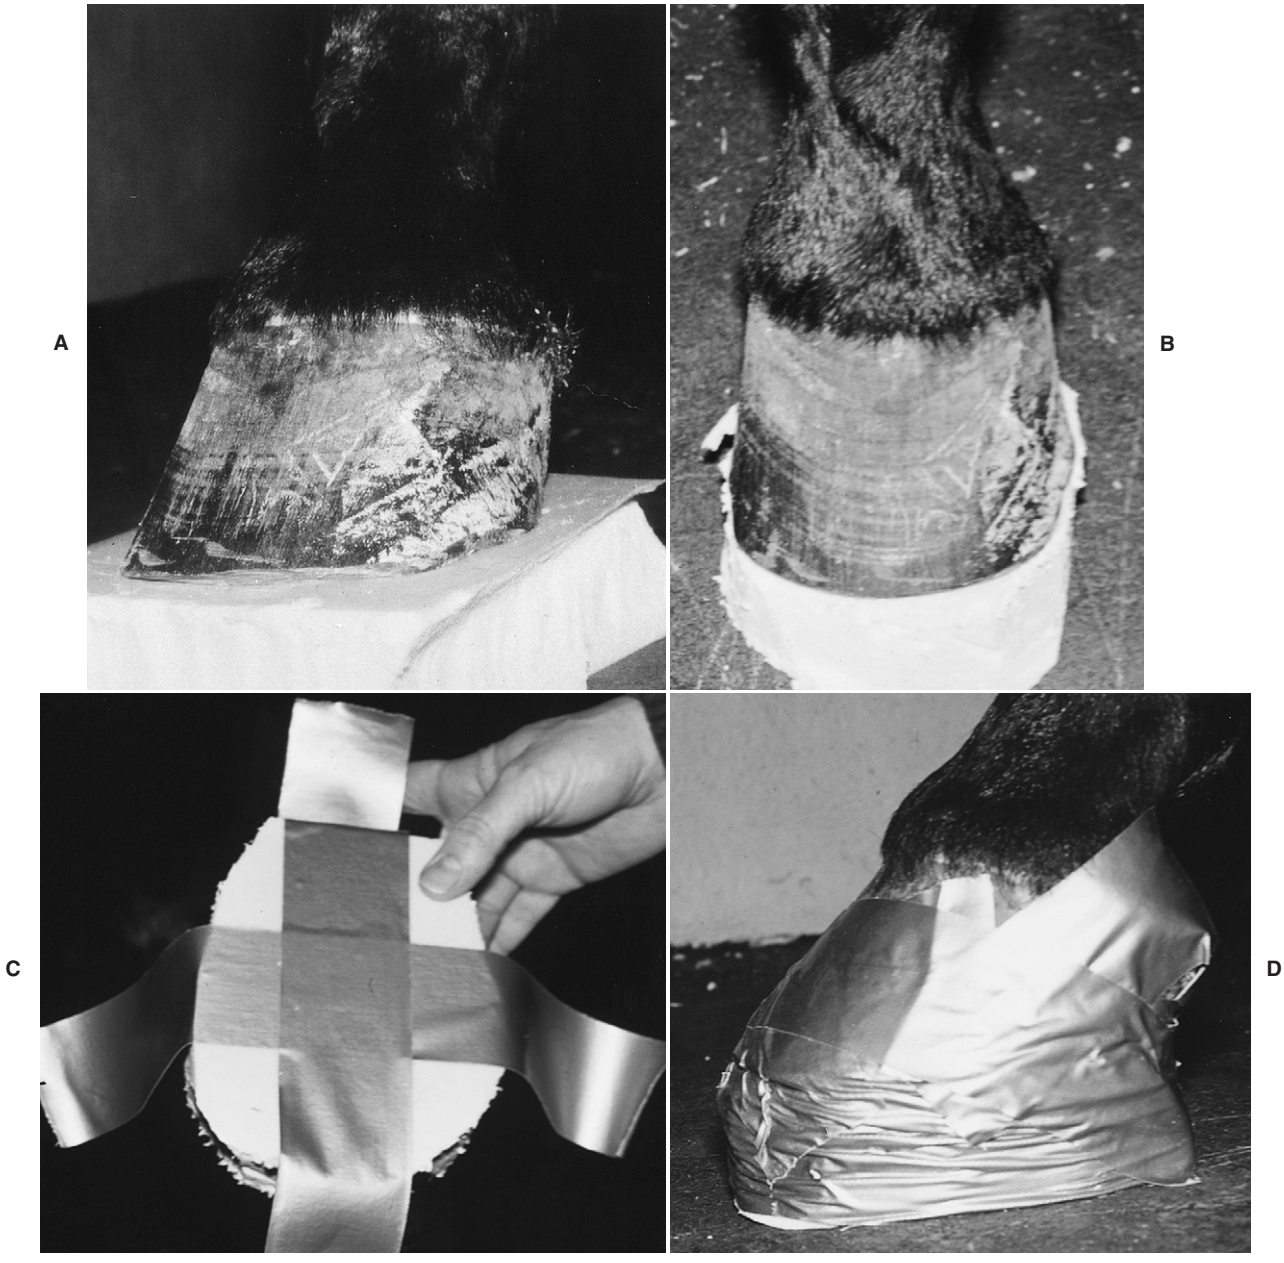

Fig. 35-7 The use of styrofoam insulation for making sole pads. With the horse standing on a precut block of foam **(A),** the foam pad is trimmed to the shape of the foot **(B),** duct tape applied to the bottom of the pad to help adhere it to the hoof **(C),** and the pad is completely secured to the hoof with duct tape **(D).**

commercial pads are taped or glued to the foot (Fig. 35-9). The system combines a cuff with two attached 5° wedge pads with a built-in dorsal to palmar breakover. The bottom wedge also has beveled edges for ease of medial to lateral breakover; this bottom wedge can be removed separately. The guidelines for the removal of the wedge pads are the absence of medication and pain for at least 10 days, indicating the treatment is progressing successfully. If these parameters remain unchanged, the first wedge should be removed. If no change occurs during the next 10 days, the last wedge is removed. It is important to remember that clinical improvement occurs before lamellar healing. Therefore if the lamellae become unduly stressed, re-injury to the lamellae will occur.

The goal of hoof care in the chronic phase is to minimize further rotation of the distal phalanx. The following principles should be followed when preparing the hoof and selecting a therapeutic horseshoe:

1. The palmar aspect of the hoof should be supported using all structures (sole, bars, and frog, including the central and lateral sulci).
2. The sole should be protected by not removing any portion of the sole.
3. The hoof wall should be trimmed from the quarters to the heel only, lowering the heel to reestablish the normal relationship between the solar surface of the distal phalanx and the sole.

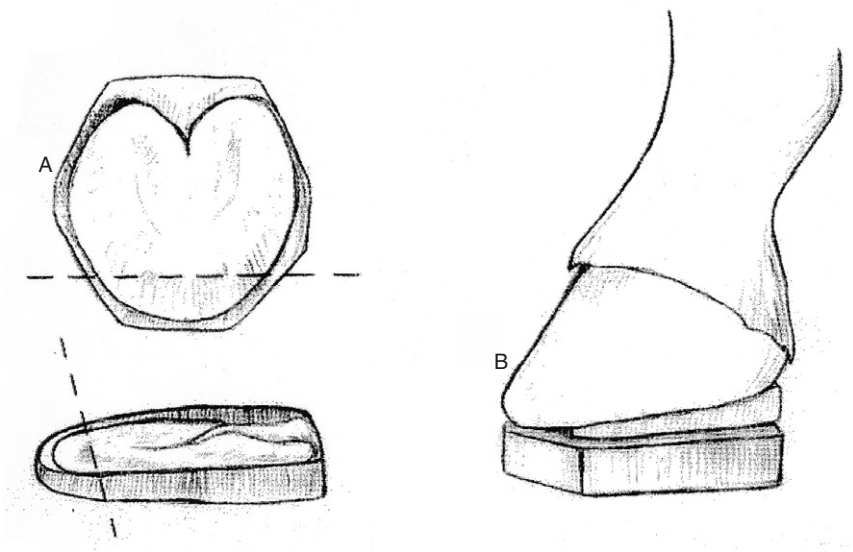

Fig. 35-8 Trimming *(dashed line)* of the previously used compressed foam pad **(A)** to be added to a new layer of foam **(B)** before attaching the two to the hoof with duct tape.

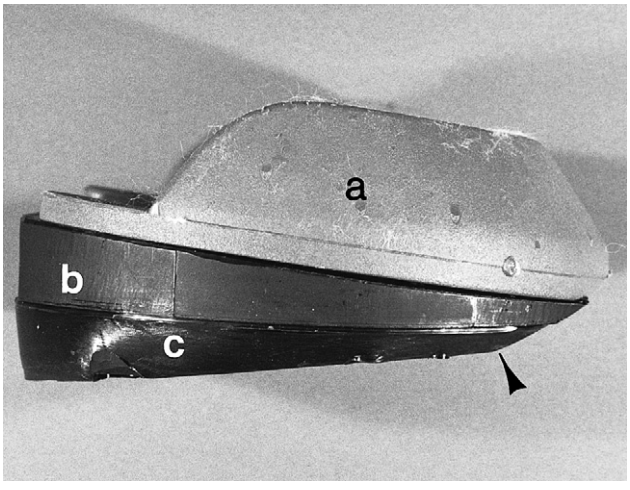

Fig. 35-9 The Redden Ultimate wedge system can be attached to the hoof by a cuff *(a)* with special glue or adhesive tape. There are two 5° wedge pads *(b* and *c)* attached to each other with screws. The bottom pad *(c)* has round edges for ease of lateral to medial breakover. The *arrow* depicts how the system eases the dorsal to palmar breakover.

4. The dorsal aspect of the hoof capsule should be protected by bringing the point of breakover back to between 2.5 and 4 cm (depending on hoof size) from the apex of the frog.
5. In some horses the heel should be raised to reduce tension of the DDFT on the distal phalanx.

Specific hoof care management in this phase depends on whether this chronic laminitic condition is stable or unstable. In horses maintaining a stable condition, trimming alone may be all that is necessary, carefully following the stipulated principles. Generally, the traditional therapeutic horseshoes (heart bar shoe, reverse shoe with a wedge, reverse shoe with frog support, and the egg bar shoe with a treatment plate) advocated for chronic laminitis are beneficial if the condition is reasonably stable (see page 338).

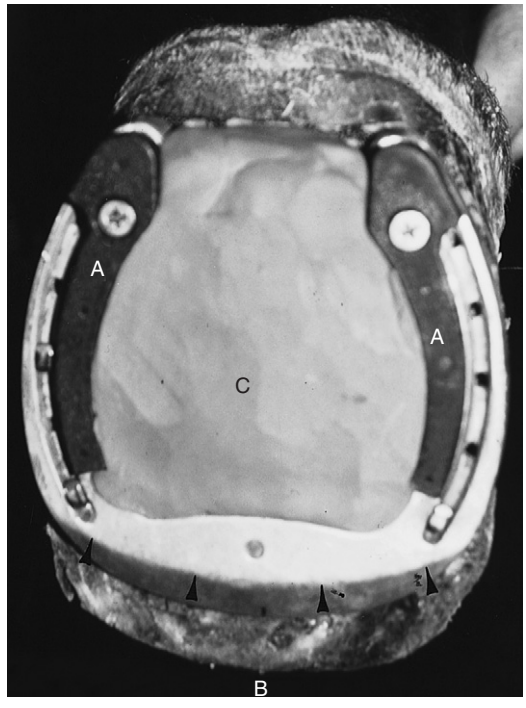

Fig. 35-10 The Ovnicek aluminum shoe (EDDS, Penrose, CO). has interchangeable plastic rails *(A)*. It is specially machined to pull the point of breakover *(small arrows)* back. The cushion elastomer is set back from the toe *(B)*. Sole support is provided with cushion elastomer *(C)*.

Horses with instability of the distal phalanx require a custom-made (International Podiatry Center, Versailles, KY) or commercially available (Equine Digit Support System, Penrose, CO) aluminum rail shoe (Fig. 35-10) to provide the additional required foot support. The new design of these shoes automatically pulls the breakover back, raises the heel, and provides palmar support. Ideally, the breakover should be close to the tip of the distal phalanx. A cushion elastomer (Advanced Cushion Support) is used between the palmar

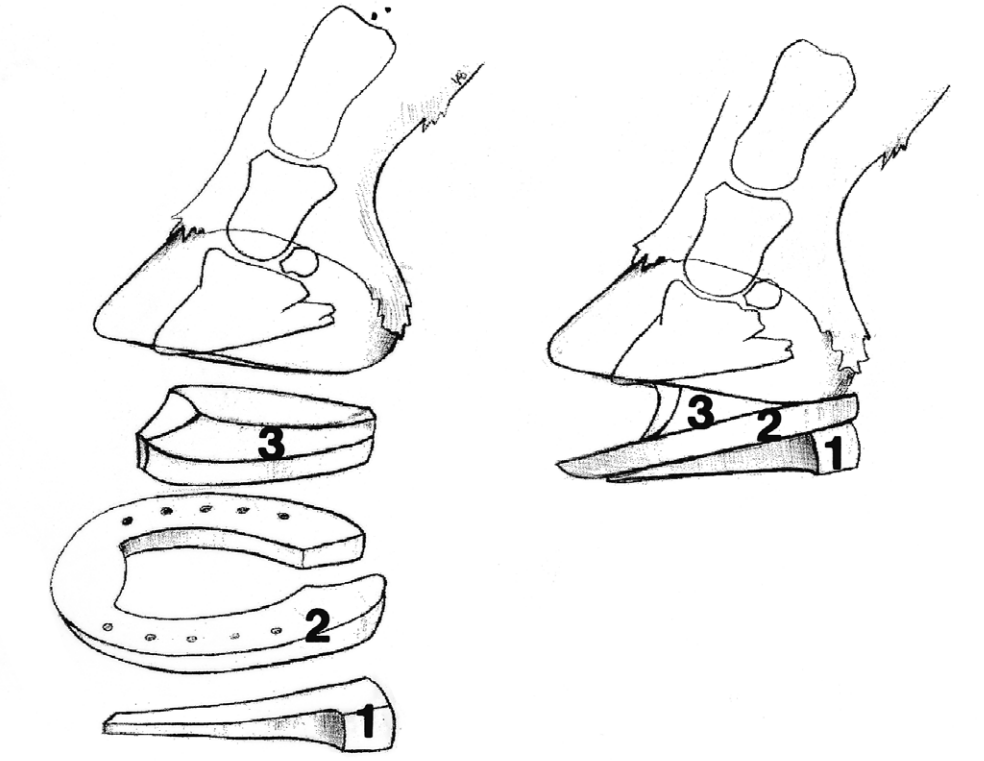

Fig. 35-11 This drawing illustrates the special shoeing technique for a horse with insufficient heel to remove for reorientating the foot and when there is penetration of the sole by the corium. The components of this technique are *(1)* plastic rails, *(2)* the EDSS shoe, and *(3)* cushion elastomer. The cushion elastomer is used as a spacer to keep the contact surface of the shoe parallel to the solar surface of the distal phalanx. The shoe is attached with a hoof acrylic and fiberglass cloth because it cannot be attached to the hoof conventionally. Tenotomy of the deep digital flexor tendon is mandatory with this technique.

structures of the sole and the shoe to provide support of the entire foot.

Horses with severe rotation, penetration of the sole, or both conditions usually have insufficient heel to re-establish the normal relationship between the solar surface of the distal phalanx and sole by removing the heel alone. A special technique is required. The cushion elastomer is used to provide sole support and act as a spacer between the weight-bearing surface of the hoof wall and the therapeutic shoe (Fig. 35-11). These shoes cannot be attached to the hoof conventionally; they are fastened to the hoof using an acrylic adhesive and fiberglass cloth (Equilox and Equilox Composite Cloth, Equilox International, Pine Island, MN). Routine clinical and radiographic evaluations provide useful information to determine the patient's progress every 5 to 6 weeks when the shoes are reset.

In horses with unstable feet exhibiting progressive rotation or penetration of the corium through the sole, a deep digital flexor tenotomy is also recommended to reduce the active forces influencing separation of the lamellae and of the distal phalanx on the sole. This procedure relieves pain, prevents or minimizes rotation, and allows reestablishment of the normal relationship between the solar surface of the distal phalanx and the sole. Severing the DDFT causes partial luxation and hyperextension of the distal interphalangeal joint, as well as overloading of the superficial digital flexor tendon. This abnormal joint position may cause palmar heel pain and usually results in osteoarthritis of the distal interphalangeal joint. Post-operative management of these horses is very important to prevent or minimize these complications. Shoeing is crucial to protect the distal interphalangeal joint and reduce the load on the tendons. The horse is shod with a slight flexion of the distal interphalangeal joint with a shoe in which the heels are raised and extend caudally approximately 1 to 1.5 cm (Fig. 35-12).

Treatment of horses with complicated laminitis may take months or years and requires perseverance and team commitment. It can be an emotional roller coaster for the owner who must be made aware of these realities.

DEEP DIGITAL FLEXOR TENOTOMY FOR MANAGING LAMINITIS

• Robert J. Hunt

Transection of the DDFT has been advocated in treatment of horses with chronic refractory laminitis.[1-4] The procedure initially appeared to have merit when used in horses with acute laminitis, but the long-term results were poor because of the severe and unstable nature of the laminitis.[2] The procedure attenuated pain, but most horses had ongoing displacement of the distal phalanx and suffered recurrent abscessation, and ultimately humane destruction was necessary.

The rationale for surgery is based on the biomechanical forces in the foot, which include the attachments of the dermal lamellae between the distal phalanx and the hoof wall, the downward vertical load through the bony column of the limb, the proximal palmar traction of the DDFT on the distal phalanx, the proximal pull of the common digital extensor

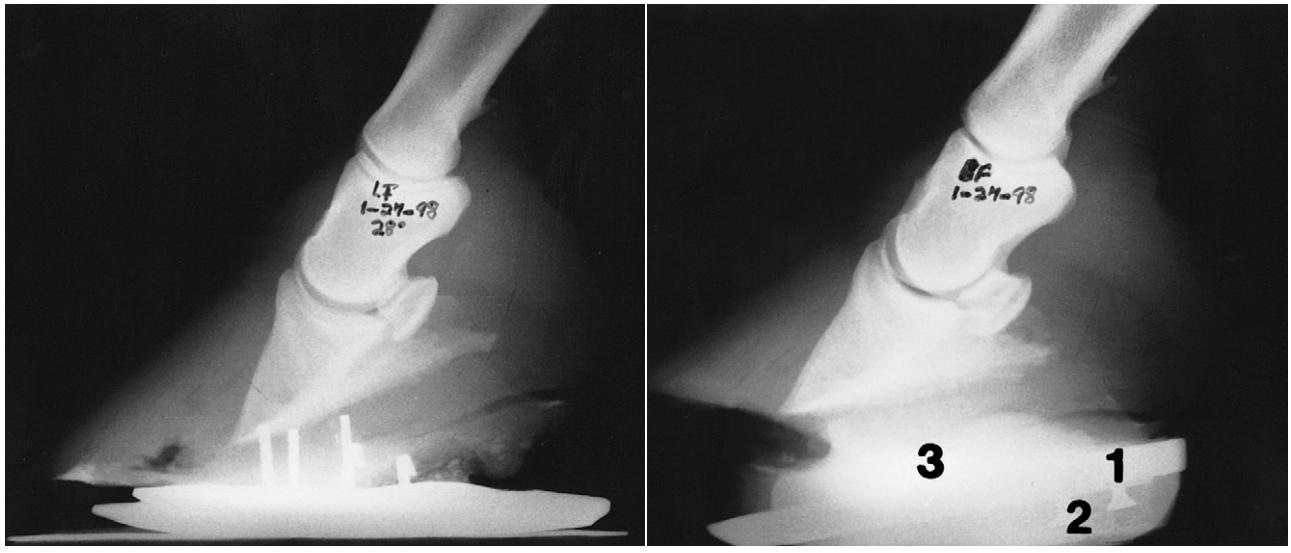

Fig. 35-12 Lateromedial radiographic views of a foot of a horse with severe rotation of the distal phalanx, which clinically had penetrated the corium of the sole. **A,** The horse was shod unsuccessfully with a reverse shoe with frog support. **B,** Note the phalangeal axis and the relationship between the solar surface of the distal phalanx and the contact surface of the shoe immediately after tenotomy of the deep digital flexor tendon had been performed and the special shoeing technique. The foot is shod with the distal interphalangeal joint in slight flexion to prevent partial luxation of the joint. *1*, The EDSS shoe; *2*, plastic rails; *3*, cushion elastomer.

tendon, and the digital cushion. The balance of these forces maintains a functional unit.

During a non–weight-bearing state, essentially no force is imposed on the digit by the DDFT. When the limb is placed under load, the DDFT serves as a tension band and places shearing forces on the dorsal lamellae of the digit from its proximal palmar pull. The predominant force on the digit is the vertical load produced by the weight of the horse. Neither of these forces is necessarily detrimental under normal conditions; however, with compromise of the dorsal lamellae during laminitis, these forces result in distraction of the distal phalanx from the hoof capsule. The type and extent of displacement of the distal phalanx is determined by the degree of laminar damage and the load placed on the foot.

The rationale for tenotomy is to reduce the proximal palmar pull of the DDFT on the distal phalanx and therefore decrease the shearing forces on the lamellae of the dorsal aspect of the foot. Transecting the tendon also permits lowering the heels if indicated to allow more normal alignment of the distal phalanx. The procedure generally is considered a salvage procedure for breeding animals or horses not intended for athletic endeavors, although some horses have returned to successful athletic careers. Generally the degree of damage associated with the laminitis, rather than the surgery, limits future soundness.

No clear-cut guidelines dictate when and if surgery should be performed. In general, surgery is reserved for horses with chronic recurring laminitis that suffer from periodic hoof abscesses and show varying degrees of distal phalangeal rotation, with minimal to no sinking, and that produce a reasonable dorsal hoof wall.

Tenotomy may be repeated with recurrence of clinical signs or with the development of a metacarpophalangeal joint flexural deformity subsequent to a mid-pastern tenotomy. Performing repeat tenotomy is easier after a mid-metacarpal tenotomy, although repeat tenotomy is also possible to perform following a mid-pastern tenotomy. I have performed tenotomy of the DDFT in the same horse five times in a 4-year period. Clinical improvement was seen after each procedure, and subjectively the effects were not as beneficial or prolonged as in the previous tenotomy. This may have been associated with progressive deterioration of the digit associated with laminitis or from adhesions of the DDFT preventing tension relief after transection. This experience is similar to that in three horses with repeat tenotomies (one to three times).

Deep digital flexor tenotomy is performed in the mid-metacarpal or mid-pastern region (Figs. 35-13 and 35-14). When performed in the mid-metacarpal region, the tenotomy may be done with the horse standing, under local analgesia, or under general anesthesia. An audible pop often occurs once transection is complete. A 1- to 2-cm gap in the transected tendon ends is immediately palpable. The stab incisions do not require closure, but a firm pressure bandage is applied.

Mid-pastern tenotomy is almost always performed with the horse recumbent, with the limb flexed to relax the DDFT (see Fig. 35-14). Performing the procedure in a standing horse is possible if general anesthesia is prohibited, such as in a late-term pregnant mare. A higher likelihood of contamination of the surgery site that involves the digital flexor tendon sheath (DFTS) is possible with the horse standing; therefore extreme caution should be taken.

It is mandatory to apply an extended and optimally elevated heel shoe in horses with mid-pastern tenotomy before or during surgery. The shoe should be worn for a minimum of 8 to 10 weeks to prevent subluxation of the distal interphalangeal joint. Although this shoe is not mandatory for all horses with mid-metacarpal tenotomy, if clinical evidence exists of distal interphalangeal joint subluxation or no improvement clinically after surgery, an extended and elevated heel shoe should be applied. After tenotomy a horse should be confined to a restricted stall-size area. Bandages should be changed every 2 to 4 days for 8 to 10 weeks to minimize swelling.

The amount of tension release is greater after mid-pastern tenotomy because of the anatomical approximation to the

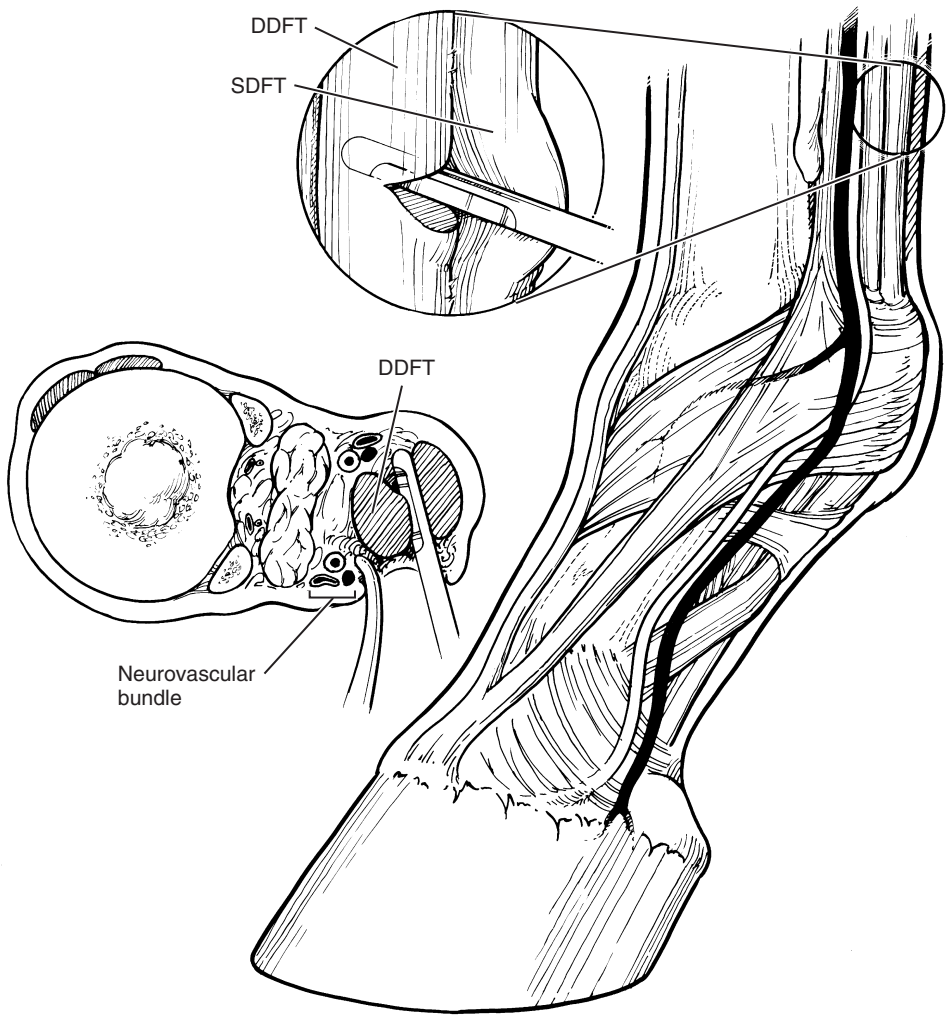

Fig. 35-13 Deep digital flexor tenotomy can be performed in the metacarpal region in a standing horse or with the horse under general anesthesia. *DDFT,* Deep digital flexor tendon; *SDFT,* superficial digital flexor tendon.

insertion of the DDFT on the distal phalanx and unrestricted separation within the DFTS. The tendon may separate 6 to 10 cm after transection in this region. In contrast, separation after mid-metacarpal tenotomy is limited by peritenon attachment to the subcutaneous tissue.

Clinical improvement is generally seen within 2 to 3 days of surgery. In general, clinical effects after tenotomy appear to be beneficial for several months. A flexural deformity of the metacarpophalangeal joint may develop from chronic pain, resulting in unweighting of the limb and contracture of scar tissue at the tenotomy site. Chronic pain may result from overloading the superficial digital flexor tendon before healing, osteoarthritis of the distal interphalangeal joint, or chronic infections of the digit. Chronic infection may be a major complication, especially if infectious osteitis of the distal phalanx develops. Systemic antibiotics, local debridement, topical anti-microbials, and bandaging are important in resolving infection. Treatment of such complicated conditions may take many months to resolve at great emotional and financial cost, and everybody involved must be aware of this.

OTHER MANAGEMENT ASPECTS OF LAMINITIS

• **Sue J. Dyson and Mike W. Ross**

Medical management of laminitis (see page 329) and some aspects of hoof care focused on a horse with progressive rotation of the distal phalanx (see page 332) are discussed elsewhere. This section discusses some additional aspects of management, routine care, monitoring of the patient, and prevention of recurrence. It must be acknowledged that in equine practice, ideal management is not always possible and compromises must sometimes be made to adapt to the prevailing circumstances.

In a horse with acute laminitis, some clinicians favor removal of the shoes, assuming that the horse can stand on soft bedding. However, in our experience removal of the shoes often results in increased discomfort, and in the acute stages of laminitis, we prefer to leave the shoes in place. Alternatively, the normal shoes may be replaced with glue-on heart bar shoes, foam pads, frog pads, or custom-made boots,[1] which seem to enhance comfort. Not all affected horses develop rotation or sinking of the distal phalanx; however, even if baseline radiographs reveal no evidence of rotation, each horse should be monitored carefully. If there is any evidence of increased discomfort, the feet should be re-examined radiographically. The client must be instructed carefully about observing the horse's stance and mobility and the amount of time spent lying down and advised that veterinary advice should be sought if there is any evidence of deterioration.

Ideally a horse with acute laminitis should be restricted to stable rest, but this is not always possible, especially for a child's pony that lives outdoors throughout the year. In these circumstances a small area of the field should be fenced off using electric fencing. This area should be tightly mown and the grass clippings should be removed. Spreading a thick layer of wood shavings over the entire surface may be beneficial.

Many horses and ponies that develop laminitis are grossly overweight, and reduction of body weight is crucial for successful management. Owners are often reluctant to admit that the horse is overweight and find it difficult to restrict the diet adequately. It is helpful to weigh the horse or make an estimate of body weight using a height-specific weigh tape[2] and then set a target for the expected weight loss with monitoring at intervals. Strict instructions concerning dietary management should be made, stipulating the amounts of food, preferably by measured weights, that should be fed. If a pony is living outdoors and cannot be stabled, then a strip grazing system should be established; each strip should be finely mown before the animal has access to it.

In horses with chronic laminitis, even if rotation of the distal phalanx occurred previously, the position of the distal phalanx may actually be stable. The heel tends to grow more quickly than the toe, and regular trimming of the heel and shortening the toe are imperative to try to re-establish correct alignment of the distal phalanx within the hoof capsule. The heart bar shoe recruits part of the frog to share load bearing and if correctly fitted, shifts weight-bearing load away from the toe, thus sparing the dorsal structures of the foot. This approach, combined with removal of the lamellar wedge, often results in improved alignment of the hoof wall and distal phalanx and improved comfort. Correct positioning of the frog support plate is critical so that even, mild pressure is applied over the length of the frog. Reverse shoes or W-shoes (open toe shoe with a heart bar) nailed on with one or two nails both medially and laterally, or glued or taped in place, may provide comfort in some horses. Often what works in one horse may not work in another and a different strategy must be used.

The term *derotation* of the distal phalanx has become popular; however, we believe that this is an inappropriate term. Although lowering the heel changes the angle of the distal phalanx with respect to the middle phalanx, it cannot acutely change the position of the distal phalanx relative to the hoof wall. The position of the distal phalanx within the hoof capsule often appears improved after removal of excessive toe.

It is critical for the farrier and veterinarian to work together closely. If the veterinarian believes that the farrier is not trimming the foot sufficiently aggressively, obtaining lateromedial radiographs may be helpful to demonstrate excess toe, heel, or both. Lateromedial radiographs are also useful for demonstrating excessive separation of the dorsal hoof wall or accumulation of fluid and when limited dorsal hoof wall resection may be indicated. If sinking of one or more of the distal phalanges is evident on radiographs, the owner must be advised that the prognosis for recovery is extremely guarded.

If pain is not adequately controlled by systemic analgesics, daily patient monitoring, preferably by a veterinarian, is crucial to identify signs of impending penetration of the sole, such as increased softening of the sole dorsal to the apex of the frog and red discoloration. The coronary bands of all feet should be assessed carefully; depression at the coronary band may herald sinking of the distal phalanx. Increased patient discomfort may be associated with a sub-solar abscess that requires establishment of drainage. A horse that has developed or is at risk of development of mechanically induced laminitis because of a painful condition in the contralateral limb must be monitored particularly vigilantly. In these horses, subtle evidence of mechanical laminitis is easily missed and usually occurs between 4 and 6 weeks after injury to the contralateral limb. However, in some horses, usually racehorses, mechanical

laminitis occurs early, even within the first few days, and is inexplicable. Often the first sign of contralateral mechanical laminitis is increased weight bearing on the injured limb, or treading. Increased weight bearing on the injured limb may be a sign of improved comfort, but the clinician should investigate the contralateral limb carefully for the development of mechanical laminitis.

Careful assessment of digital pulse amplitudes and foot temperature may be useful for detecting the development of laminitis or deterioration of pre-existing laminitis. In older horses in which laminitis cannot be stabilized, consideration should always be given to the existence of primary Cushing's disease.

It is critical that clients be kept well informed of the likely outcome and are well appraised of the long convalescent periods that often are required after substantial rotation of the distal phalanx. They must be warned that unexpected relapses may occur despite steady progress. Nonetheless, it is important to recognize that with early aggressive treatment some horses can make a complete recovery to athletic function despite marked rotation of one or more distal phalanges. The prognosis is generally more favorable in ponies than in horses. Clients must be advised that continued long-term dietary management may be crucial to prevention of recurrent laminitis.

The prognosis in heavy breeds of horse with sinking of the distal phalanges is generally hopeless. These horses seem particularly prone to the development of laminitis secondary to retention of the placenta, and although with aggressive management they can be salvaged until the foal is weaned, longer-term treatment is invariably unsuccessful.

CHAPTER • 36

The Proximal and Middle Phalanges and Proximal Interphalangeal Joint

Alan J. Ruggles

ANATOMICAL CONSIDERATIONS

The term *pastern* originated from the shackle that was secured below the metacarpophalangeal or metatarsophalangeal joints to tether a horse to the pasture.[1] The proximal interphalangeal joint or pastern joint is a diarthrodial joint, which is formed from the distal aspect of the proximal phalanx and the proximal aspect of the middle phalanx. The pastern region is bounded dorsally by the common digital extensor tendon and on the palmar/plantar border by the distal sesamoidean ligaments, digital flexor tendons, digital flexor tendon sheath (DFTS), and the proximal and distal digital annular ligaments. The superficial digital flexor tendon (SDFT) inserts on the distal palmar/plantar aspect of the proximal phalanx and the proximal palmar/plantar aspect of the middle phalanx. The straight distal sesamoidean ligament arises from the base of the proximal sesamoid bones (PSBs) and extends distally to insert on the proximal palmar/plantar aspect of the middle phalanx. The oblique (middle) distal sesamoidean ligaments arise from the base of the PSBs and attach to the triangular region on the palmar/plantar region of the middle portion of the proximal phalanx. The medial and lateral collateral ligaments of the proximal interphalangeal joint provide support in the sagittal plane and attach to the collateral tubercles of the distal proximal phalanx and proximal palmar/plantar aspect of the middle phalanx. The paired smaller abaxial and axial ligaments are located just palmar/plantar to the collateral ligaments. The neurovascular bundle of the digit runs just abaxial to the deep digital flexor tendon on the medial and lateral sides.

The palmar/plantar eminence of the middle phalanx extends proximal to the horizontal axis of the joint surface and blends proximally with a fibrocartilaginous cap at the most proximal extent of the middle phalanx. In the adult horse this is dense, and it is important to engage this portion of the bone during internal fixation of fractures or arthrodesis procedures.

The proximity of the pastern region to the ground, the paucity of soft tissue coverage over the dorsum and sides, and the important soft tissue structures on the palmar/plantar surfaces make it especially vulnerable to external trauma. Wounds in this region may involve the DFTS and warrant careful investigation. Angular deformities from growth disturbances at the pastern are uncommon. Radiographic closure of the proximal physis of the proximal and middle phalanges occurs by 6 to 9 months of age, but functional closure is earlier, usually by 8 weeks of age.[2] Radiographic closure of the distal physis of the proximal phalanx occurs by 1 month of age. Radiographic closure of the distal physis of the middle phalanx occurs by the time of birth.

LAMENESS EXAMINATION

Physical derangements usually are obvious because of minimal soft tissue coverage of the pastern. Phalangeal fractures usually are associated with soft tissue swelling and focal pain. Effusion of the DFTS is typical of penetrating wounds of the sheath, damage to the enclosed flexor tendons, or injury of the sesamoidean ligaments located dorsad. In horses with osteoarthritis, new bone formation on the dorsomedial and dorsolateral aspects of the proximal interphalangeal joint often occurs. Angular deformity of the digit often is present in horses with complete fractures of the proximal or middle phalanx. Effusion in the metacarpophalangeal or metatarsophalangeal joint is common in horses with fractures of the proximal articular surface of the proximal phalanx.

Lameness from the pastern region ranges from severe to subtle depending on the injury. Generally, disorders involving the proximal interphalangeal joint or DFTS cause obvious lameness, but lameness from early osteoarthritis of the proximal interphalangeal joint may be mild and the clinical signs and blocking pattern may be confused with foot or occasionally fetlock lameness. Pain in the pastern region is exacerbated by distal limb flexion. There is often a weight-bearing lameness that is worse if a horse is lunged or trotted with the affected limb on the inside of a circle.

Response to intra-articular analgesia varies depending on the injury, but improvement of lameness by 50% or more implicates the proximal interphalangeal joint as an important source of pain. Entry into the proximal interphalangeal joint can be difficult, especially if new bone is present as a result of osteoarthritis. Techniques for intra-articular and perineural analgesia are described in Chapter 10. Complete analgesia of the proximal interphalangeal joint is not always accomplished by perineural analgesia of the palmar nerves at the level of the PSBs, and a low four-point (palmar and palmar metacarpal nerves) block may be necessary. However, in some horses lameness improves with palmar/plantar digital analgesia. Intra-articular analgesia of the proximal interphalangeal joint should be considered in a horse with suspected metacarpophalangeal or metatarsophalangeal joint pain that has not responded to treatment. Complete analgesia of the DFTS requires intrasynovial or a low four-point block.

IMAGING CONSIDERATIONS

Standard radiographic examination for evaluation of the proximal phalanx includes lateromedial, dorsopalmar (plantar), dorsal 45° lateral-palmaromedial oblique, and dorsal 45° medial-palmarolateral oblique views. Oblique radiographs that are angled distally are helpful to identify osteochondral fragments on the proximal palmar/plantar aspect of the proximal phalanx.[3] If a sagittal plane fracture of the proximal phalanx is suspected, dorsopalmar/plantar radiographs that are 5° off the mid-sagittal plane are useful. Slight underexposure of the lateromedial projection helps to identify callus on the proximodorsal aspect of the proximal phalanx associated with chronic, short, incomplete fractures. Radiographic examination of the proximal interphalangeal joint includes lateromedial,

dorsopalmar/plantar, and oblique views. Flexed oblique views are particularly helpful for evaluation of the articular margins.[3] A well-positioned and exposed dorsopalmar/plantar projection may reveal subtle joint space narrowing and sclerosis of the subchondral bone consistent with early osteoarthritis. Comparative views of the contralateral limb may be helpful.

Contrast radiography may be used to determine the course of fistulous tracts or to identify communication between wounds and the DFTS or areas of proliferative synovium within the DFTS. Contrast radiography is performed by placement of a 50% solution of diatrizoate preglumine and diatrizoate sodium (Hypaque-76; Nyromed, Princeton, NJ) within a draining tract or directly into the synovial structure, after aseptic preparation. Standard radiographs are obtained to identify communication with draining tracts or filling defects.

Computed radiography is helpful in detecting subtle changes in trabecular bone and bone density. As computed tomography of the distal limb becomes more common, new information on development of pastern injury will become available.

Ultrasonographic evaluation of the pastern region is helpful in identifying abnormalities associated with the soft tissue structures[4] and is discussed in detail in Chapters 16 and 83.

Nuclear scintigraphy is useful in identifying incomplete fractures of the proximal phalanx. Incomplete fractures of the proximal articular margin of the proximal phalanx can occur in all breeds, but they are most commonly seen in Standardbred (STB) and Thoroughbred (TB) racehorses. Clinical signs and response to perineural analgesia varies. Nuclear scintigraphy should be considered to eliminate fracture in horses with lameness referable to the fetlock and clinical signs consistent with an incomplete fracture of the proximal phalanx. Nuclear scintigraphy can be helpful to identify bone remodeling in the early phases of osteoarthritis of the proximal interphalangeal joint. Other bone-related abnormalities in the pastern region often are evident radiographically and scintigraphy is unnecessary.

BREED PREDILECTION

Differential diagnoses of disorders of the pastern region of all breeds include osteoarthritis, osteochondrosis, fractures, and infection. The types of fractures tend to be breed or use specific. Fractures of the proximal phalanx occur most often in racing breeds, with the STB most often affected. Fractures of the middle phalanx occur most commonly in horses used for Western-type activities such as reining, but are seen in all breeds during lunging or after kicks. Osteochondrosis of the proximal aspect of the proximal phalanx is common in yearling and 2-year-old TBs and STBs. Osteochondrosis of the distal aspect of the proximal phalanx and proximal aspect of the middle phalanx is less common with no breed predilection. Osteoarthritis of the proximal interphalangeal joint occurs most often in older horses used for riding or Western-type activities. It may be seen in young horses secondary to osteochondrosis.

FRACTURES OF THE PROXIMAL PHALANX

Fractures of the proximal phalanx are important causes of lameness in all breeds. Racing breeds are particularly prone. Clinical signs vary from subtle to obvious. In horses with complete fractures, lameness is severe and limb swelling and deformity may be present. In horses with incomplete fractures, lameness may be subtle, and careful clinical and radiographic examination may be necessary to define the fracture. Serial radiographs may be needed to detect radiolucency and callus formation associated with short incomplete fractures of the proximal phalanx. Nuclear scintigraphy may be helpful.

Fractures of the proximal phalanx include the following types:

- Short and long incomplete sagittal
- Complete fractures that exit the lateral cortex
- Simple complete
- Comminuted
- Dorsal frontal
- Proximal palmar/plantar avulsion fractures associated with the collateral ligament

Incomplete fractures of the proximal phalanx occur most commonly in racing breeds. Clinical signs include mild to severe lameness. Fetlock joint effusion and mild swelling and pain over the dorsal aspect of the proximal phalanx are common. Most fractures are readily identified radiographically, but in some horses dorsopalmar/plantar projections that are slightly off the sagittal plane are useful. In addition, obtaining follow-up radiographs 7 to 10 days after the fracture allows time for osteoclastic resorption along the fracture line to occur so that the fracture line becomes more obvious. Treatment for incomplete sagittal fractures includes stall rest or internal fixation, depending on the degree of lameness, concern about catastrophic fracture of the bone, and economic factors. The advantages of surgical repair are well documented, but incomplete short fractures of the proximal aspect of the proximal phalanx can often be managed with rest alone. In some circumstances a bone screw is placed to provide compression for short fractures to reduce the risk of fracture recurrence.

Indications for internal fixation of incomplete fractures include fractures that extend more than 15 mm from the proximal articular surface, those with potential for catastrophic failure, and those that occur in horses with severe lameness. Internal fixation is accomplished by placement of 4.5- or 5.5-mm cortical bone screws in lag fashion. Although 4.5-mm screws generally are used and provide ample compression, 5.5-mm screws provide maximal fracture compression and can be used to replace a stripped 4.5-mm thread. Because these fractures are non-displaced, open reduction is not required and the screws can be placed through minimal incisions. Horses with incomplete fractures are reported to have a 67% to 89% chance to return to racing soundness after treatment. However, STBs returned to racing with slower racing times and reduced performance indices.[5-7]

Horses with complete fractures of the proximal phalanx are candidates for internal fixation to provide anatomical reduction and compression of the articular surfaces, improved comfort, reduced risk of osteoarthritis, and early return to use. In horses with acute, minimally displaced fractures, reduction may be achieved by percutaneus placement of bone reduction forceps under radiographic control. Open reduction, arthrotomy, or both are required in horses with moderately to severely displaced fractures, chronic fractures, or fractures in which fragments of bone prevent reduction of the fracture fragments. After debridement of the fracture bed and reduction of the fracture, compression of the fracture fragments is accomplished using 4.5- or 5.5-mm cortical bone screws. External coaptation with a half-limb cast may be required for recovery or the immediate post-operative period. Prognosis for horses with non-comminuted complete fractures depends on whether the proximal interphalangeal joint is involved. Horses with fractures that enter the proximal interphalangeal joint had an approximate 50% chance to return to racing. Of those with complete fractures that exited the lateral cortex, 71% returned to racing.[5,7]

Salter-Harris type II fractures of the proximal aspect of the proximal phalanx occur in foals and weanlings. Reduction of the fracture is accomplished with the horse under anesthesia. Methods of coaptation include bandaging alone, bandaging with splinting, or half-limb cast application. I prefer to use a cast for 4 weeks, but it is important that the cast be changed

at 2 weeks. Other clinicians prefer less aggressive coaptation to avoid complications of flexor laxity and osteoporosis of the PSBs.

Dorsal frontal fractures of the proximal aspect of the proximal phalanx occur in three general types: incomplete proximal dorsal articular fractures, complete proximal dorsal articular fractures, and fractures that originate in the midportion of the proximal articulation and extend distally into the proximal phalanx. These fractures usually are incomplete. Incomplete proximal dorsal frontal fractures occur most commonly in STB racehorses. The right hindlimb is most commonly affected. Proximal dorsal articular fractures can be treated with rest alone or internal fixation with a 3.5-mm cortical bone screw. The prognosis for horses with proximal fractures is good.[8] Horses with large fractures that originate in the central portion of the metacarpophalangeal or metatarsophalangeal joint need internal fixation. In my experience, osteoarthritis tends to develop despite anatomical reduction and internal fixation of the fracture, and the prognosis for athletic soundness is poorer.[9]

Horses with comminuted fractures of the proximal phalanx have acute, non–weight-bearing lameness and often limb deformity. Appropriate first aid is required to prevent further injury to the soft tissues, with or without disruption of the digital artery blood supply. A half-limb cast with a dorsally incorporated splint is appropriate to realign the bony column for transport to a surgical facility. Comminuted fractures can be divided into two categories for treatment: those with and those without an intact column of bone extending from the proximal to distal articular surfaces. This intact strut of bone allows reconstruction of many comminuted fractures of the proximal phalanx by lag screw fixation of the fracture fragments to the strut. Treatment strategies include the following:

- Complete reconstruction via bone screws, plates, or both by open reduction, partial reconstruction, and transfixation cast or external fixator
- Transfixation cast alone
- Use of external skeletal fixation (see Chapter 88)

In my opinion, the use of half-limb casts alone is not the best method of sole treatment for most horses with comminuted fractures of the proximal phalanx, although successful outcomes have been reported. Half-limb casts significantly reduce axial loading in the intact skeleton,[10,11] but the risks of fracture compression, skin injuries leading to open fractures, and contralateral limb laminitis are substantial.

Horses with comminuted fractures with an existing strut of bone are candidates for open reduction and reconstruction with bone screws. An initial study reported an unacceptably high risk of infection after open reduction and internal fixation,[12] but a more recent report described a good prognosis for pasture soundness.[13] If the strut has a transverse fracture but enough bone stock proximal and distal to the transverse fracture, I have reconstructed the bone with two 4.5-mm narrow dynamic compression plates and bone screws. With both screw fixation alone and plate and screw fixation, external coaptation with a half-limb cast is required. Partial reconstruction of the articular surfaces and placement of a transfixation cast or external fixator is elected when possible in horses with severely comminuted fractures to reduce degenerative changes, improve long-term comfort, and reduce the requirement for subsequent arthrodesis. A transfixation cast is used when comminution is severe enough to prevent anatomical reconstruction and protection of the fracture from collapse is required. Transfixation casts have been shown to significantly improve axial stability compared with standard casts in an osteotomy model.[14] External fixators are used in place of transfixation casts if the fracture is open to allow direct access to the injury site (see Chapter 88).[15] The use of transfixation casts and external fixators carries the risk of catastrophic failure of the third metacarpal (metatarsal) bone, and the overall prognosis for salvage is only fair (Fig. 36-1).

Palmar/plantar avulsion fractures of the proximal phalanx usually occur after kicks, falls, or stall injury. Lameness is variable and fetlock effusion is usually present. Differential diagnosis includes fracture and osteochondritis dissecans fragmentation. Because this region is the distal attachment for the collateral ligaments, surgical treatment is recommended to improve bony union and prevent osteoarthritis. Treatment options include lag screw fixation, with one or preferably two 3.5-mm cortical bone screws. Removal is also possible for chronic or small fractures or those that cannot be properly reduced. After removal, external coaptation for recovery from general anesthesia and then for an additional 4 weeks is recommended. The prognosis is considered good with either treatment in the absence of osteoarthritis.

DORSAL OSTEOCHONDRAL FRAGMENTS IN THE METACARPOPHALANGEAL/ METATARSOPHALANGEAL JOINT

See Chapters 37 and 38 for a discussion of dorsal osteochondral fragments in the metacarpophalangeal/metatarsophalangeal joint.

OSTEOCHONDROSIS OF THE PROXIMAL INTERPHALANGEAL JOINT

Osteochondrosis of the proximal interphalangeal joint is less common than that of the metacarpophalangeal or metatarsophalangeal joints. As with other sites, osteochondrosis involves fragmentation (osteochondritis dissecans), or osseous cyst-like lesions. Sites include the distal aspect of the proximal phalanx and proximal aspect of the middle phalanx. A radiolucent area at the distal central aspect of the proximal phalanx usually is an incidental radiographic finding. Radiolucent areas or fragmentation in the condylar regions of the distal aspect of the proximal phalanx tend to cause clinical signs. In the most severe circumstances, these subchondral lucencies in weight-bearing portions of the joint may cause significant osteoarthritis and lameness requiring arthrodesis of the proximal interphalangeal joint. Osseous cyst-like lesions are more common in the hindlimb than in the forelimb and can occur bilaterally. Osseous cyst-like lesions can communicate with the proximal interphalangeal joint, and if lameness is present, radiographic evidence of osteoarthritis can be substantial. Subtle clinical signs often are seen in horses with osseous cyst-like lesions that do not communicate with the proximal interphalangeal joint. Although unusual, sudden-onset severe lameness can occur as a result of osseous cyst-like lesions even though the radiographic abnormality was present for several months or years. Clinical relevance of osseous cyst-like lesions must be established using diagnostic analgesia, and in some horses scintigraphy is required. Management of horses with osseous cyst-like lesions may include intra-articular injections, or in some horses arthrodesis of the proximal interphalangeal joint. Arthrodesis of the proximal interphalangeal joint can yield a good prognosis for soundness in Western performance horses or other types of sport horses that are not expected to perform at advanced levels. A STB pacer that underwent arthrodesis of the left hindlimb proximal interphalangeal joint raced successfully.[16] A peri-articular drilling procedure can be used in horses with osseous cyst-like lesions that do not communicate with the proximal interphalangeal joint. A small drill bit is used under radiographic guidance to approach the cystic cavity. Either methylprednisolone acetate or liquid bone marrow can be injected. Alternatively,

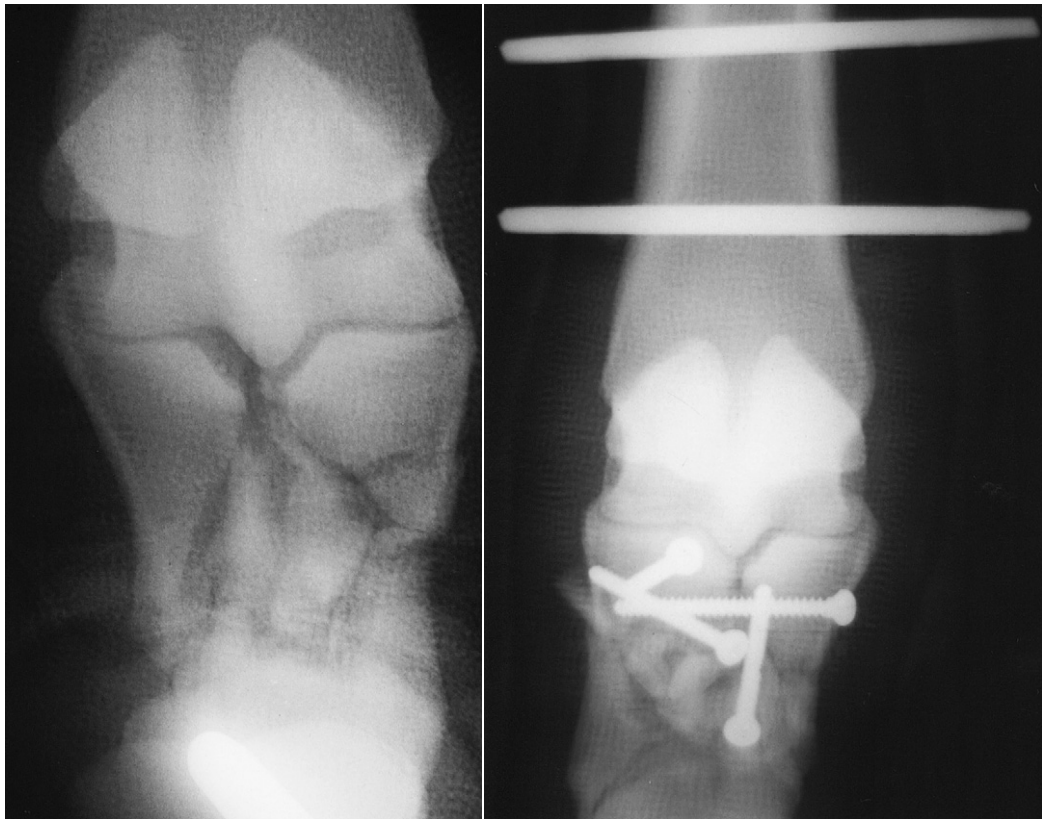

Fig. 36-1 A and B, Dorsoplantar radiographic projections of a 3-year-old Standardbred filly with a severely comminuted fracture of the proximal phalanx before **(A)** and after **(B)** treatment by partial reconstruction of the proximal articular portion of the fracture and a transfixation pin cast.

cancellous bone can be packed into the cyst cavity. Radiographic evidence of healing of the cyst cavity is variable, and in some horses residual lameness remains. Osteochondral fragments associated with osteochondrosis tend to occur at the palmar/plantar eminence of the proximal aspect of the middle phalanx and cause variable lameness. They often are incidental findings found on radiographs taken before sale, but they certainly can complicate the sales process. Prognosis is difficult to assess in yearlings that have not been trained. Osteochondrosis fragments are more common in the hindlimbs than in the forelimbs. There is often radiographic evidence of advanced osteoarthritis, even if lameness is mild. Because these fragments are difficult to remove, it is important to document the true source of lameness before surgery is considered. Arthroscopic techniques for the pastern have been described, but because of limited surgical access, I generally perform an arthrotomy to remove the fragments, which often are large.[17,18]

OSTEOARTHRITIS OF THE PROXIMAL INTERPHALANGEAL JOINT

Osteoarthritis of the proximal interphalangeal joint is also known as *high ringbone*. Horses used for jumping, dressage, and Western-type activities seem to be prone to high ringbone. It can also be a consequence of articular fracture, infection, or osteochondrosis. The clinical signs of osteoarthritis of the proximal interphalangeal joint include mild to severe lameness. Lameness is exacerbated by distal limb flexion. Obvious bony formation or angular deformity may be present in horses with advanced lameness. Diagnosis is based on clinical signs, response to perineural or intra-articular analgesia, and radiographic findings. Radiographic abnormalities commonly include new bone formation, periarticular sclerosis, and loss of joint space typically on the medial aspect of the proximal interphalangeal joint. Angular deformity is typically only present in horses with advanced osteoarthritis (Fig. 36-2). Comparative radiographs of the contralateral limb should also be obtained because the condition may be bilateral. Pain associated with the proximal interphalangeal joint may be present without any radiographic signs of osteoarthritis, and scintigraphic examination is useful in documenting active bone modeling. On the other hand, horses may develop acute severe lameness with radiographic evidence of existing osteoarthritis that predated any clinical evidence of pain. Lameness improves after perineural or intra-articular analgesia.

In horses with mild osteoarthritis of the proximal interphalangeal joint that is unrelated to fracture, conservative treatment includes therapeutic shoeing aimed at reducing the toe length, and in some horses, elevating the heel and easing breakover. Non-steroidal anti-inflammatory drugs are quite useful. The therapeutic value of administering intramuscular glycosaminoglycans and intravenous hyaluronan is questionable. Intra-articular injections are of considerable value. A combination of hyaluronan and corticosteroids or corticosteroids alone is most effective in horses with mild or moderate osteoarthritis. However, in horses with advanced osteoarthritis, particularly those with extensive periarticular proliferation and extensive loss of joint space, arthrodesis should be considered. The surgical procedure is invasive and expensive but is generally considered a better solution over the long term. Natural ankylosis of the proximal interphalangeal joint can occur, but it is a long, painful process and one

Fig. 36-2 This dorsoplantar radiographic projection demonstrates proliferative and radiolucent changes associated with advanced osteoarthritis of the proximal interphalangeal joint. There is complete loss of joint space on one side and angular deformity of the proximal interphalangeal joint.

that is not necessarily complete. Surgical arthrodesis is best. Tibial neurectomy can be helpful in horses with advanced hindlimb proximal interphalangeal osteoarthritis.[19]

ARTHRODESIS OF THE PROXIMAL INTERPHALANGEAL JOINT

Arthrodesis of the proximal interphalangeal joint is indicated in horses with advanced osteoarthritis or an articular fracture. Lag screw fixation of simple fractures can be performed, but because of difficulty in obtaining anatomical reduction of the proximal interphalangeal joint surface and resisting tension forces at the palmar/plantar eminences, lag screw fixation alone is usually unsuccessful in preventing osteoarthritis and returning horses to athletic soundness. Therefore I recommend proximal interphalangeal joint arthrodesis in horses with articular fractures.

Many methods of arthrodesis of the proximal interphalangeal joint are described, and opinions vary as to which is preferred. Current preferred methods involve the insertion of three parallel 4.5- or 5.5-mm screws or dorsally applied plate or plates with additional transarticular screws. I have used both methods and prefer the plating technique because it improves comfort in the immediate post-operative period and reduces the necessity for prolonged cast application. This method requires cast coaptation for 2 to 3 weeks to protect the incision site. The plating technique provides improved stability compared with the three 5.5-mm parallel screw technique in fatigue testing.[20] After arthrodesis of the proximal interphalangeal joint with screws alone, approximately 80% of horses with hindlimb and 46% to 67% of horses with forelimb lameness returned to athletic soundness.[21,22] Long-term follow-up data for the plating technique are currently unavailable, but in my opinion, the results are at least similar, if not superior.

Horses with comminuted middle phalanx fractures or those that involve the distal interphalangeal joint should undergo arthrodesis of the proximal interphalangeal joint with single or double plating and potentially transfixation casts or external skeletal fixation (see Chapter 88). Comminuted fractures of the middle phalanx should be repaired if possible to preserve the distal interphalangeal joint surface, and if possible, the proximal interphalangeal joint surface. Displacement of the distal articular surface considerably worsens prognosis. Single or double plating can be used depending on the configuration of the fracture. The use of additional screws placed in lag fashion is usually required to reduce large fragments and reconstruct the articular surface. Another plate technique using a Y-plate has been tested experimentally and shows similar biomechanical properties to the double-plate technique.[23] Cast coaptation is required for 6 to 8 weeks after surgery. Transfixation pins are used to prevent collapse of the fracture in horses with severely comminuted fractures. This technique may be combined with plate and screw fixation. Prognosis after double-plate fixation of 10 horses with comminuted fracture of the middle phalanx was good for pasture soundness, and 5 horses were able to be ridden or shown, but mild lameness persisted.[24]

SOFT TISSUE INJURIES

Soft tissue injuries in the pastern are discussed in Chapter 83.

SUBLUXATION OF THE PROXIMAL INTERPHALANGEAL JOINT

Subluxation of the proximal interphalangeal joint is uncommon and can occur in the palmar/plantar direction or dorsally. Palmar/plantar subluxation usually is seen after severe, traumatic soft tissue injury, such as complete tearing of the distal sesamoidean ligaments, SDFT branch injury, or a combination of soft tissue injuries (Fig. 36-3). Treatment options for palmar/plantar subluxation include both conservative and surgical management. External coaptation often is successful in adult horses managed acutely. The application of a Kimzey splint (Kimzey Leg Saver Splint; Kimzey, Inc., Woodland, CA) is an excellent method of external coaptation with this injury. Cast immobilization can be successful, but instability of the proximal interphalangeal joint may preclude successful realignment with this method. Arthrodesis of the proximal interphalangeal joint is always an option. Dorsal subluxation can occur after traumatic disruption of the suspensory apparatus and arthrodesis of the fetlock joint to manage this problem, but it most commonly occurs in horses with progressive, severe suspensory desmitis. This is particularly true in the STB or TB racehorse in which suspensory desmitis is common. Swelling along the dorsal aspect of the pastern region is the first clinical sign recognized, but progressive hyperextension (dropping) of the fetlock joint is usually present. The appearance of dorsal subluxation in any horse with chronic suspensory desmitis is a negative prognostic sign.

Dorsal subluxation of the proximal interphalangeal joint can occur without any identifiable structural abnormality of the pastern or metatarsal soft tissue structures. This occurs primarily in the hindlimbs in young horses, and lameness is usually absent or mild. Dorsal subluxation is most often dynamic in nature and resolves during full weight bearing. The presence of changes consistent with osteoarthritis worsens prognosis. Dorsal subluxation of the proximal inter-

Fig. 36-3 Lateromedial radiographic projection of the pastern in a foal with plantar subluxation from avulsion of the attachments of the superficial digital flexor tendon and subsequent loss of plantar support. This foal underwent arthrodesis of the proximal interphalangeal joint.

phalangeal joint as a result of mild flexor deformity was reported in three horses.[25] In these horses, ranging in age from 5 months to 4 years, subluxation was believed to be caused by mild contraction of the DDFT without compensatory contraction of the SDFT.[2–5] Subluxation was seen primarily during early weight bearing, but the condition resolved during full weight bearing. Tenotomy of the medial head of the DDFT in the proximal metatarsal region resolved dynamic dorsal subluxation.[25]

WOUNDS IN THE PASTERN REGION

Lacerations and puncture wounds in the pastern region have a high propensity to involve the proximal interphalangeal joint or DFTS. Careful inspection of the wound, radiography, ultrasonography, and analysis of synovial aspirates are often required to determine the extent of the wounds. Wounds that involve the proximal interphalangeal joint or DFTS require aggressive management to prevent synovial infection. Treatments include synovial lavage, wound debridement, drain placement, and antimicrobial therapy with or without tenoscopic examination. Intrasynovial, systemic, and regional perfusion of antimicrobial agents can be used. Sequelae of proximal interphalangeal joint infection include osteoarthritis. Sequelae of infection of the DFTS include intrasynovial adhesion formation and infectious osteitis of the PSBs (see Chapter 75).

CHAPTER • 37

The Metacarpophalangeal Joint

Dean W. Richardson

ANATOMICAL CONSIDERATIONS

The metacarpophalangeal (fetlock) joint is an intensely loaded, high-motion joint that is frequently injured in athletic horses. Fetlock region lameness can occur in horses of any occupation, but the joint is at particularly high risk in horses performing at maximal speed. Countering the high load experienced by the joint is the elastic suspensory apparatus that constrains the range of extension. Both the superficial and deep digital flexor muscle tendon units additionally serve to actively support the fetlock joint because of the position on the palmar aspect of the joint. Loss of this active support by the flexors may lead to overload of the suspensory apparatus support and some degree of hyperextension. Extreme extension of the metacarpophalangeal joint results in impingement of the proximal rim of the proximal phalanx against the dorsal aspect of the third metacarpal bone (McIII), high compressive forces on the distal, palmar aspect of McIII opposing the proximal sesamoid bones (PSBs), and both tensile and bending forces on the PSBs intercalated within the suspensory apparatus. Complex forces of torsion on the loaded fetlock joint result in a myriad of injuries.

The metacarpophalangeal joint is anatomically composed of the distal McIII, the proximal phalanx, and both PSBs. A single synovial space extends on its palmar aspect at least 3 cm proximal to the apex of the PSBs. Dorsally, a bilobed synovial "pad" is located on the proximal dorsal articular rim of the distal McIII; this pad presumably functions to help cushion the impingement of the McIII and proximal phalanx. The ligamentous elements of the fetlock joint are complex and important. Well-developed medial and lateral collateral metacarpophalangeal and metacarposesamoidean ligaments constrain the almost purely sagittal motion of this joint. The suspensory branches insert on the proximal, palmar abaxial margins of the PSBs and functionally continue through the distal sesamoidean ligaments to attach the distal portion of the sesamoids to the proximal phalanx (cruciate or deep and oblique or middle) and the middle phalanx (straight or superficial). The intersesamoidean ligament attaches the axial aspects of the PSBs.

The digital flexor tendon sheath and its contents are described elsewhere (see Chapter 75). The common digital extensor tendon is unsheathed as it passes over the dorsal aspect of the joint. Branches of the medial and lateral palmar and metacarpal nerves primarily supply innervation to the fetlock joint,[1] but small subcutaneous branches of the ulnar nerve supply a minor amount of dorsal sensory innervation.

DIAGNOSIS

Careful physical examination to detect heat, swelling (effusion with or without periarticular fibrosis), and pain with palpation or manipulation is critical for diagnosis of lameness of the metacarpophalangeal joint. However, physical findings may be subtle or seemingly non-existent, whereas diagnostic analgesia often pinpoints the joint or region as the source of pain. Interpretation of fetlock flexion test results should be made with caution, because many horses have false-positive responses to forced flexion of this joint, especially if the toe is used to increase leverage. Pain originating in the limb distal to the fetlock joint often is exacerbated by fetlock or lower limb flexion tests. False-negative responses to fetlock joint flexion also are quite common, especially in horses with subchondral bone injury and chip fractures. Increased fluid in the fetlock joint can also be a false localizing sign. The presence of an effusion in the absence of heat and pain may indicate some derangement in synovial function, but not necessarily point to the source of a clinically relevant lameness. Lameness characteristically occurs with weight bearing and usually, but not always, is worse with the limb on the inside of a circle. If clinical signs do not adequately localize lameness, perineural or intrasynovial analgesia can specify the region relatively easily. In the absence of localizing clinical signs the foot and pastern regions should first be eliminated as sources of pain by a mid-pastern digital nerve block with a dorsal subcutaneous ring. Ideally this is followed by intra-articular analgesia. If the lameness does not improve within 15 to 20 minutes of intra-articular analgesia, the clinician should perform a low palmar block or palmar and palmar metacarpal nerve blocks. In most horses with intra-articular chip fractures, synovitis, capsulitis, and osteoarthritis, lameness improves after intra-articular analgesia. Horses with major fractures, non-articular fractures, subchondral bone injuries, and tendon and tendon sheath lesions usually are only markedly improved with perineural analgesia. Perineural techniques are superior in abolishing the pain associated with the fetlock joint. Pain in horses that do not respond to intra-articular analgesia should not necessarily be presumed to originate elsewhere.

Several techniques are used for intrasynovial analgesia of the fetlock joint. I prefer to inject the local anesthetic solution with the horse's limb on the ground. The dorsal aspect of the fetlock is readily accessible when the horse is bearing weight. As the clinician faces forward and uses the back of his or her arm to hold the horse's carpus, a 22-gauge 2.5-cm needle

CHAPTER • 37

The Metacarpophalangeal Joint

Dean W. Richardson

ANATOMICAL CONSIDERATIONS

The metacarpophalangeal (fetlock) joint is an intensely loaded, high-motion joint that is frequently injured in athletic horses. Fetlock region lameness can occur in horses of any occupation, but the joint is at particularly high risk in horses performing at maximal speed. Countering the high load experienced by the joint is the elastic suspensory apparatus that constrains the range of extension. Both the superficial and deep digital flexor muscle tendon units additionally serve to actively support the fetlock joint because of the position on the palmar aspect of the joint. Loss of this active support by the flexors may lead to overload of the suspensory apparatus support and some degree of hyperextension. Extreme extension of the metacarpophalangeal joint results in impingement of the proximal rim of the proximal phalanx against the dorsal aspect of the third metacarpal bone (McIII), high compressive forces on the distal, palmar aspect of McIII opposing the proximal sesamoid bones (PSBs), and both tensile and bending forces on the PSBs intercalated within the suspensory apparatus. Complex forces of torsion on the loaded fetlock joint result in a myriad of injuries.

The metacarpophalangeal joint is anatomically composed of the distal McIII, the proximal phalanx, and both PSBs. A single synovial space extends on its palmar aspect at least 3 cm proximal to the apex of the PSBs. Dorsally, a bilobed synovial "pad" is located on the proximal dorsal articular rim of the distal McIII; this pad presumably functions to help cushion the impingement of the McIII and proximal phalanx. The ligamentous elements of the fetlock joint are complex and important. Well-developed medial and lateral collateral metacarpophalangeal and metacarposesamoidean ligaments constrain the almost purely sagittal motion of this joint. The suspensory branches insert on the proximal, palmar abaxial margins of the PSBs and functionally continue through the distal sesamoidean ligaments to attach the distal portion of the sesamoids to the proximal phalanx (cruciate or deep and oblique or middle) and the middle phalanx (straight or superficial). The intersesamoidean ligament attaches the axial aspects of the PSBs.

The digital flexor tendon sheath and its contents are described elsewhere (see Chapter 75). The common digital extensor tendon is unsheathed as it passes over the dorsal aspect of the joint. Branches of the medial and lateral palmar and metacarpal nerves primarily supply innervation to the fetlock joint,[1] but small subcutaneous branches of the ulnar nerve supply a minor amount of dorsal sensory innervation.

DIAGNOSIS

Careful physical examination to detect heat, swelling (effusion with or without periarticular fibrosis), and pain with palpation or manipulation is critical for diagnosis of lameness of the metacarpophalangeal joint. However, physical findings may be subtle or seemingly non-existent, whereas diagnostic analgesia often pinpoints the joint or region as the source of pain. Interpretation of fetlock flexion test results should be made with caution, because many horses have false-positive responses to forced flexion of this joint, especially if the toe is used to increase leverage. Pain originating in the limb distal to the fetlock joint often is exacerbated by fetlock or lower limb flexion tests. False-negative responses to fetlock joint flexion also are quite common, especially in horses with subchondral bone injury and chip fractures. Increased fluid in the fetlock joint can also be a false localizing sign. The presence of an effusion in the absence of heat and pain may indicate some derangement in synovial function, but not necessarily point to the source of a clinically relevant lameness. Lameness characteristically occurs with weight bearing and usually, but not always, is worse with the limb on the inside of a circle. If clinical signs do not adequately localize lameness, perineural or intrasynovial analgesia can specify the region relatively easily. In the absence of localizing clinical signs the foot and pastern regions should first be eliminated as sources of pain by a mid-pastern digital nerve block with a dorsal subcutaneous ring. Ideally this is followed by intra-articular analgesia. If the lameness does not improve within 15 to 20 minutes of intra-articular analgesia, the clinician should perform a low palmar block or palmar and palmar metacarpal nerve blocks. In most horses with intra-articular chip fractures, synovitis, capsulitis, and osteoarthritis, lameness improves after intra-articular analgesia. Horses with major fractures, non-articular fractures, subchondral bone injuries, and tendon and tendon sheath lesions usually are only markedly improved with perineural analgesia. Perineural techniques are superior in abolishing the pain associated with the fetlock joint. Pain in horses that do not respond to intra-articular analgesia should not necessarily be presumed to originate elsewhere.

Several techniques are used for intrasynovial analgesia of the fetlock joint. I prefer to inject the local anesthetic solution with the horse's limb on the ground. The dorsal aspect of the fetlock is readily accessible when the horse is bearing weight. As the clinician faces forward and uses the back of his or her arm to hold the horse's carpus, a 22-gauge 2.5-cm needle

attached to a 75-cm extension set is inserted horizontally into the dorsal joint just proximal to the margin of the proximal phalanx and deep to the common digital extensor tendon. I use 10 to 15 ml of 2% mepivacaine, but other practitioners generally use no more than 6 to 10 ml.

IMAGING CONSIDERATIONS

The fetlock joint is easy to image accurately because of the size and accessibility. Numerous flexed and oblique radiographic views to specifically silhouette or separate structures help to identify subtle lesions. The same advantages apply to scintigraphic and ultrasonographic diagnostic imaging. For example, flexed scintigraphic images can help determine whether a lesion in the palmar fetlock involves the base of a PSB or the palmar surface of McIII. A minimum set of radiographs should include dorsopalmar, lateromedial, flexed lateromedial, and both oblique views. The size of the region and absence of overlying soft tissues results in excellently detailed radiographs, even with portable x-ray machines, if suitable screen-film combinations are used. A number of specific radiographic views should be used if certain lesions are suspected. For example, if a subchondral injury involving the distal palmar McIII is suspected, the oblique views should be taken in a more proximal to distal direction than usual. If a lateral condylar fracture is identified, a partially flexed dorsopalmar view should be used to help identify comminution along the distal, palmar aspect of the fracture line. Osteochondrosis of the sagittal ridge of the McIII and incomplete sagittal fractures of the proximal phalanx are lesions that can be difficult to identify in over-exposed lateromedial views or under-exposed dorsopalmar projections.

TYPES OF FETLOCK JOINT LAMENESS

Most fetlock joint lamenesses can be categorized into one of three types:

1. Acute or repetitive overload injuries without specific fracture or fractures: capsulitis/synovitis, chronic proliferative (villonodular) synovitis, osteoarthritis, subchondral bone injury without obvious fracture, and sesamoiditis.
2. Articular fragments that can be removed (traumatic and developmental lesions) from the dorsal or palmar aspects of the proximal phalanx; apical, abaxial, and basilar sesamoid fractures; and fragments from the sagittal ridge of the McIII.
3. Major articular fractures (i.e., those that should be repaired), including sagittal and dorsal frontal fractures (mostly seen in the hindlimbs); collateral avulsion injuries (mostly foals and yearlings) of the proximal phalanx, mid-body; large abaxial or basilar fragments of the PSBs; and condylar fractures of McIII.

Conditions specific to the metatarsophalangeal joint and a detailed description of sagittal fractures of the proximal phalanx are included elsewhere (see Chapters 36 and 43).

ACUTE OR REPETITIVE OVERLOAD INJURIES

Capsulitis/Synovitis

Clinical Signs

Virtually every young racehorse has one or more episodes of metacarpophalangeal capsulitis or synovitis that is characterized by heat, effusion, and pain with flexion. Overt lameness usually is mild and often not evident after the horse warms up. Signs typically manifest as the horse increases the speed and distance of its exercise regimen. If the typical localizing signs are missed, the major indication may be a decrease in performance. In horses with chronic disease, visible thickening of the periarticular tissues usually is noticeable, with decreased range of motion of the joint.

Diagnosis

A diagnosis of primary capsulitis or synovitis usually is made by clinical observations and the absence of radiographic scintigraphic bony abnormalities. In most horses, synovitis and capsulitis accompany other causes of fetlock joint lameness, such as chip fractures. Synovial fluid analysis has not been particularly useful in diagnosis or prognosis for most fetlock joint injuries except to help identify sepsis.

Treatment

In most young horses the condition resolves with nonsteroidal anti-inflammatory drugs (NSAIDs), adjustments in training, and increased fitness. Intra-articular hyaluronan (20 mg) is helpful in horses with acute, mild to moderate synovitis, but a combination of hyaluronan with a low dose of corticosteroid (e.g., 3 to 5 mg of triamcinolone or 20 to 30 mg of methylprednisolone acetate) is more consistently effective in resolving the clinical signs of inflammation. Injection should be followed by a decrease in exercise intensity for 1 to 2 weeks if possible. Post-exercise icing of the involved fetlock joints can be helpful. Generic osteoarthritis treatments, including oral glucosamine with or without chondroitin sulfate, intramuscular polysulfated glycosaminoglycan, and intravenous hyaluronan merit consideration, but they do not usually yield the consistent response seen after intra-articular therapy.

Chronic Proliferative (Villonodular) Synovitis

Clinical Signs

Chronic capsulitis/synovitis is caused by repetitive injury of the dorsal aspect of the fetlock joint. The lesion is defined by a thickening of the normally dorsally located bilobed synovial pad that hangs down on either side of the sagittal ridge of the McIII. With extreme extension of the fetlock joint the dorsal rim of the proximal phalanx impinges on the synovial pad, and repetitive trauma results in its inflammation and subsequent fibrosis. The tissue can become so thick that the dorsal profile of the joint is visibly disfigured. The characteristic swelling is asymmetrical on the mid-proximodorsal aspect of the fetlock (Fig. 37-1) rather than simply spherical in outline as in a typical osteoarthritic fetlock joint (this is called an *osselet*). Exercise inflames the tissue further, and clinical signs of lameness or diminished performance can result.

Diagnosis

The diagnosis of proliferative synovitis is based on physical examination, radiography, ultrasonography, or a combination of these modalities. The most common radiographic sign of the lesion is a crescent-shaped, radiolucent "cut-out" on the dorsal aspect of the McIII at the level of the joint capsule attachment (Fig. 37-2). The proliferative lesion may undergo dystrophic mineralization and be radiographically visible. Radiographic contrast studies can be used, but ultrasonography is simpler and more reliable (Fig. 37-3). However, many horses have a substantial synovial pad without any concomitant discomfort. Mere identification of a slightly thicker than average structure is certainly not an indication for surgical excision. Horses with extremely severe osteoarthritis have proliferative synovitis in the palmar pouch, and a large concave outline of the distal palmar aspect of the McIII is seen proximal to the PSBs. A crescentic concavity in this region is a strong indication of severe osteoarthritis and is associated with a poor prognosis.

Treatment

Treatment for proliferative synovitis usually consists of aggressive intra-articular therapy (e.g., hyaluronan and corticosteroids), rest, and alterations in training. Many horses require frequent medication until the joint becomes stiff enough to

Fig. 37-1 An older Thoroughbred racehorse with chronic proliferative synovitis. The dorsal swelling is firm and localized in the proximodorsal aspect of the joint *(arrows)*.

prevent dorsal impingement. Horses appear to be able to work through this problem as they develop increasing strength and fitness. If the horse does not respond to medical treatment, surgical excision using an arthroscopic technique is recommended.[2,3] Surgical debridement must be followed with continued medical treatment and careful attention to the training regimen. It is important to recognize that the thickening of the proximal dorsal synovial pad may be just one part of a chronic, osteoarthritic joint. In such horses, any therapy such as surgery directed solely at this lesion probably will fail.

Subchondral Bone Injury

Clinical Signs

Subchondral bone injury is an extremely important cause of lameness involving the metacarpophalangeal joint, especially in racehorses. There are no specific localizing clinical signs in many horses other than variable lameness and an observable diminution in performance. Signs such as heat, swelling, or response to flexion can be absent or extremely subtle, even in horses with overt lameness. Although subchondral bone injury is far more common in racehorses, it appears that single-step overload injuries that focally damage a portion of the proximal phalanx can occur in non-racehorses. Such injuries may result in radiographically visible sclerosis or lysis. The severity of the lameness in such horses can be surprising and infection is often a differential diagnosis.

Diagnosis

The inconsistent response to local analgesia can make diagnosis difficult unless a reasonably high index of suspicion for these lesions is maintained. Many horses do not achieve soundness with intra-articular analgesia. Horses with full-thickness cartilage injury overlying the subchondral injury may be most likely to experience improved outcomes because of the access of the anesthetic agent to the site. Lameness in most improves dramatically with low palmar analgesia.

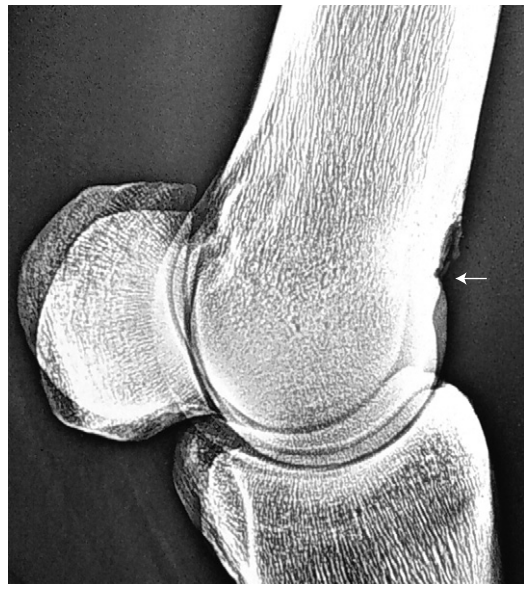

Fig. 37-2 Chronic proliferative (villonodular) synovitis of the metacarpophalangeal joint with a typical erosive lesion *(arrow)* along the proximal dorsal margin of the third metacarpal bone seen in a lateromedial radiographic view. The fibrotic tissue may have small fragments of bone and cartilage or dystrophic mineralization.

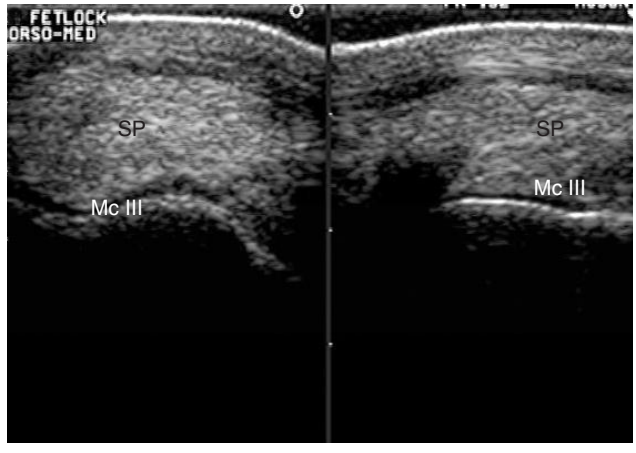

Fig. 37-3 Transverse *(left)* and longitudinal *(right)* ultrasonographic images of the distal dorsal metacarpal region. Ultrasonographic examination can confirm a thickened synovial pad, but the diagnosis usually is made on the basis of physical examination and radiographic findings. *McIII*, Third metacarpal bone; *SP*, synovial pad.

The two most common locations for subchondral injury of the fetlock are the distal palmar aspect of the McIII and proximal phalanx under the center of the weight-bearing portion of the medial or lateral articular surfaces. The palmar metacarpal lesion appears to develop as a focal overload injury where the base of the PSB impacts during maximal weight bearing.[4,5] In this location, linear or crescent-shaped lucencies are the most common indications of a major subchondral bone injury (Fig. 37-4). These often can be seen on a lateromedial projection, but special views may improve the likelihood of seeing a lesion. A slightly flexed, horizontal beam dorsopalmar projection silhouetting the distal palmar aspect of the McIII can help define an irregular subchondral outline

Fig. 37-4 Lateral radiographic view of a metacarpophalangeal joint. Subchondral crescent-shaped *(arrow)* or linear lucencies in the distal palmar third metacarpal bone are important radiographic findings. Most horses with such lesions have clinical signs of fetlock pain, especially with hard training. The cartilage overlying such lesions is damaged and often unstable.

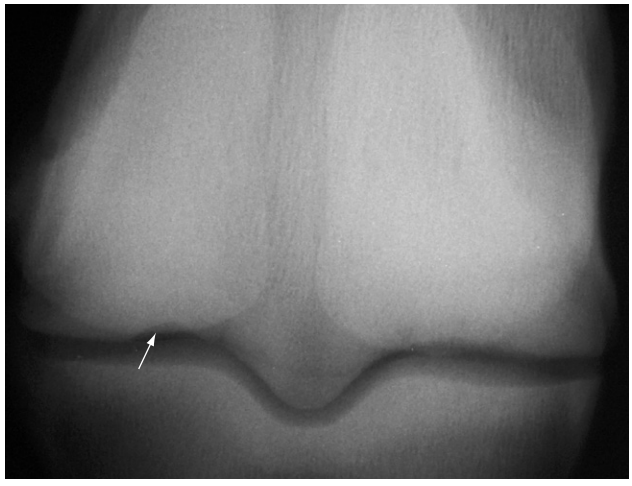

Fig. 37-5 Slightly flexed dorsopalmar radiographic view of the metacarpophalangeal joint is helpful to define *lesions (arrow)* of the distal palmar third metacarpal bone.

(Fig. 37-5).[6,7] Oblique projections obtained in a slightly (25° to 30°) proximal-distal direction also allow a better evaluation of the palmar condyle and the presence of radiolucent defects (Fig. 37-6).[8] With lesions of the proximal phalanx an increase in subchondral density may be evident before lytic lesions develop, but sclerosis in the McIII is much more difficult to recognize.

Scintigraphy is the most sensitive diagnostic tool and can identify lesions well before radiographic lesions are evident. Even arthroscopic diagnosis can be difficult in the fetlock joint, because the anatomical location of these lesions makes evaluation quite difficult. If the lesions are accessible, the overlying cartilage may be thin or discolored. The amount of cartilage fibrillation or crazing of the joint surface is variable.

Treatment

Rest is the only currently accepted treatment for subchondral bone injury, although medications such as isoxsuprine and aspirin are frequently recommended. Damaged bone can heal if the horse is rested, but prognosis depends on the amount of structural damage to the overlying cartilage and any loss in the normal architecture of this critical area.

Fig. 37-6 Oblique xeroradiographic view taken at a proximal to distal 30° angle will allow identification of the radiolucent changes of the third metacarpal bone *(arrow)* otherwise obscured by the proximal sesamoid bone.

INJURIES TO THE PROXIMAL PHALANX

Osteochondral Fragments: Dorsoproximal Aspect of the Proximal Phalanx

Clinical Signs

The most common chip fracture in Thoroughbred (TB) racehorses involves the proximal dorsal aspect of the proximal phalanx and is an important differential diagnosis in any young TB with acute swelling or heat in a metacarpophalangeal joint. Affected horses rarely are lame for more than 2 days after a fracture and may never show overt lameness. An observant groom or trainer may notice an effusion with some heat, and forced flexion usually causes a painful response. Common historical findings include diminished performance, refusal to change leads, and bearing in or out, especially in the stretch.

Dorsal chip fractures can also be seen in yearlings and nonracehorses as an incidental finding. Most presumably occur as a traumatic event during early development and simply go unrecognized until presale radiographs are obtained. Such fragments occur equally in the forelimbs and hindlimbs, whereas traumatic injuries in active racehorses are most commonly seen in the forelimbs.

Diagnosis

Chip fractures of the proximodorsal aspect of the proximal phalanx of any size are not difficult to diagnose if they are displaced, but non-displaced fragments may require nearly perfect radiographs. Most chips occur on the prominence just medial to the median sagittal groove of the proximal phalanx. The left forelimb is slightly more commonly affected than the right forelimb in North American TBs. Bilateral chips are fairly common, and thus both fetlocks should be radiographed before surgery is considered. The fragments generally are seen best on a dorsolateral-palmaromedial oblique (Fig. 37-7) or lateromedial projection, depending on the obliquity of the fracture line and projection. Correct radiographic technique is especially important for small chips, because over-exposure burns out the lesion on a lateromedial view and under-exposed oblique views do not have enough penetration. Although most radiographically diagnosed fractures are dorsomedial, it is

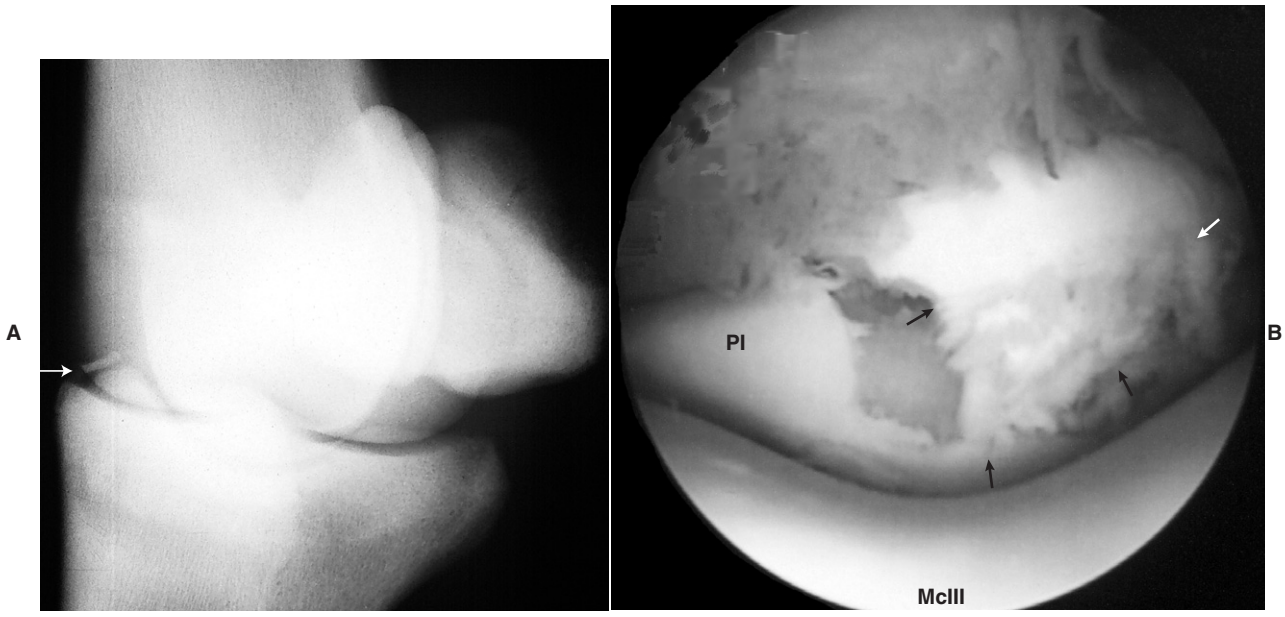

Fig. 37-7 **A,** Proximal dorsomedial osteochondral fragments (chip fractures; *arrow)* of the proximal phalanx are the most common chip fracture in Thoroughbred racehorses and can be seen on this dorsolateral-palmaromedial oblique view. **B,** Ideal treatment is early arthroscopic removal that allows a rapid return to training. The fragment *(arrows)* can be seen in this intraoperative view. *McIII*, Third metacarpal bone condyle; *PI*, proximal phalanx

important to evaluate arthroscopically the entire dorsal rim of the proximal phalanx, because small chondral fractures are common. Horses in which a dorsolateral fragment is seen radiographically usually also have a lesion on the dorsomedial side.

Treatment
